$$C_{x(\text{unk})} = C_{x(\text{std})} \frac{m_{\text{std}}}{wm_{\text{unk}}} \frac{(A_{0(\text{unk})})}{(A_{0(\text{std})})} R_{\theta} R_{\phi} R_{\sigma} R_{\epsilon} \quad (30.35)$$

where $C_{x(\text{unk})}$ is the element content in the unknown sample (in $\mu\text{g/g}$), $C_{x(\text{std})}$ is the element content in the primary assay standard (in $\mu\text{g/g}$), m_{std} is the mass of the primary assay standard used (in g), m_{unk} is the mass of the sample used (in g), w is the dry mass correction factor, $A_{0,\text{unk}}$ is the decay-corrected counting rate for indicator gamma-ray of the unknown, $A_{0,\text{std}}$ is the decay-corrected counting rate for indicator gamma-ray of the standard. A_0 , for a measured nuclide is calculated as:

$$A_0 = \frac{N_x \lambda e^{\lambda t_D}}{1 - e^{-\lambda t_C}} \quad (30.36)$$

where N_x is the number of counts in the indicator gamma-ray peak, λ is the decay constant for the indicator nuclide, t_D is the time elapsed between the end of activation and the start of counting, and t_C is the live time of counting.

The ratio factors R in Eq. (30.35) are ideally unity, but small deviations and their uncertainties must be considered. R_{θ} is the ratio of isotopic abundances for the unknown and standard, R_{ϕ} is the ratio of neutron fluences (including fluence drop off, self-shielding, and scattering), R_{σ} is the ratio of effective cross sections if the shape of neutron spectrum differs from the unknown sample to standard, R_{ϵ} is the ratio of counting efficiencies (differences due to geometry, γ -ray self-shielding, and dead-time effects).

Standards for comparison have been prepared in all conceivable forms, using solids or liquids containing a single element of interest or complex multielement mixtures. Solid standards are commonly made from high purity metals and compounds, certified reference materials, or other materials with known content of the element(s) of interest. Frequently solutions of high purity elements or compounds are prepared as single- or multielement standards, or commercial products such as liquid standards for spectrometry techniques are used for INAA. Care is usually taken that specifically prepared (multielement) standards minimize interferences and allow approaching the unity condition for comparison of the unknown with the standard.

An example for the continuous use of a certified reference material (NIST SRM 1633 Fly Ash) as standard in the multielement comparator INAA is reported by Blackman and Bishop (2007). They have analyzed 32,000 samples in 1,750 irradiations over 29 years, looking for 35 elements. A standard clay co-analyzed as a control sample 311 times showed a 1% coefficient of variance for several elements.

The comparator method has been shown to deliver highest accuracy with standards prepared from chemicals of known purity. A combined uncertainty of $<0.2\%$ was achieved in the determination of implanted As in Si (Greenberg et al. 2000). Other examples of high

quality INAA measurements achieving uncertainties of $\ll 0.5\%$ based on the comparator method were reported by Lindstrom et al. (1978), Fleming and Lindstrom (1987), and Zeisler et al. (2005). Similar small uncertainties have become routine quality features of the results reported by the INAA comparator method in recent CCQM key comparison exercises, e.g., CCQM-K49 Key Comparison Essential and Toxic Elements in Bovine Liver (CCQM 2008).

30.4.4.2 The k_0 Method and Other Parametric Methods

The possibility of using a single element as a comparator for multielement INAA is very attractive since every radioisotope observed in the gamma-ray spectrum can be related to a quantity of the parent element in the sample. A number of schemes have been devised to accomplish this; the one that is most widely accepted is called the k_0 method. This method is discussed in more detail below.

Even before 1970, several researchers had devised standardization techniques for various projects, where calibration factors, sometimes called k -factors, were measured for the gamma rays of the desired elements for specific irradiation and counting conditions. It was very convenient to continue using these k -factors as long as the conditions did not change. These simpler but less robust procedures have been used in many applications where one or several element standards provided an experimental calibration function for an irradiation facility and counting efficiencies for multielement analysis. Usually counting rates of elements were measured and tabulated in spreadsheets as ratios to the counting rate of the monitor element(s). Examples can be found in air particulate monitoring with several elements evaluated against a cobalt monitor (Ondov et al. 1990), and in PGAA analysis where elements in biological materials are assayed against a titanium monitor (Mackey et al. 1998).

Development of the k_0 Method

The development of the k_0 method was motivated by the need for a standardization method that was more convenient than the classical relative method, where a standard of each element had to be prepared to match the specific conditions of every analysis.

In the early 1970s, Simonits proposed the development of a standardization method using universal k -factors. In this method, the essential information for a gamma ray emitted by any nuclide produced by neutron activation would be contained in a universal constant, the k_0 factor, and all factors depending on the specific irradiation and counting conditions would be calculated by models. The inventors of the k_0 method envisioned that for each sample analyzed at least one neutron flux monitor would be co-irradiated and counted, and all other parameters of the models would be measured once and only remeasured when irradiation conditions changed. Thus, multielement analysis could be performed with the same amount of work needed for single-element analysis.

After the k_0 method was introduced (Simonits et al. 1975), the development of the method required many years of hard work. The k_0 values were accurately measured for the gamma rays of 112 nuclides (Simonits et al. 1980; Moens et al. 1984; De Corte et al. 1989a) produced by neutron irradiation, as were other activation and decay properties (De Corte et al. 1989a; De Corte and Simonits 1989; De Corte et al. 1989b). The model for the activation process needed to take into account the complex neutron spectrum of any research reactor. Initially, the k_0 method was seen mainly as a method for modeling the activation process. Of course, the gamma-ray detection process is equally important and the models for it are much more

complex. The gamma ray emission–transmission–detection process was originally modeled by Moens et al. (1981).

A detailed description of the k_0 method can be found in the habilitation thesis of Frans De Corte (1987).

Details of the k_0 method

To understand the k_0 method, it is useful to compare the formula used for calculating the mass fraction or concentration of an element with the one used in the classical relative method:

$$C_{x(\text{unk})} = C_{x(\text{std})} \frac{\left(\frac{N_x/t_c}{\text{SDCW}}\right)_{\text{unk}} \Phi_{\text{std}} \varepsilon_{\text{std}}}{\left(\frac{N_x/t_c}{\text{SDCW}}\right)_{\text{std}} \Phi_{\text{unk}} \varepsilon_{\text{unk}}} \quad (30.37)$$

In the relative method, the mass fraction of the analyte element in the unknown sample is obtained using the mass fraction of the same element in the standard. The equation takes into account the peak areas obtained in the unknown and in the standard; the sample weight (mass), W ; the decay factors S , D , and C (see ► Eq. (30.26)); differences in neutron flux; and differences in detection efficiency due to slightly different counting geometries.

With the k_0 method, the mass fraction of an element is calculated by the formula:

$$C_{x(\text{unk})} = C_m \frac{\left(\frac{N_x/t_c}{\text{SDCW}}\right)_{\text{unk}} k_{0,m} \Phi_m \frac{1 + Q_{0,m}(\alpha)/f}{1 + Q_{0,x}(\alpha)/f} \varepsilon_m}{\left(\frac{N_m/t_c}{\text{SDCW}}\right)_m k_{0,x} \Phi_{\text{unk}} \varepsilon_{\text{unk}}} \quad (30.38)$$

This equation, first written by Simonits et al. (1980), has the same structure as the equation used with the classical relative method, but contains additional correction factors because the analyte nuclide is different from the monitor nuclide. The subscript “m” refers to the monitor, f is the ratio of thermal flux to epithermal flux, and Q_0 is the ratio of the resonance integral to the thermal neutron cross section (see ► Eq. (30.9)).

This equation calculates the mass fraction by comparing the peak area, N_x , measured for a given gamma ray in the unknown sample to the peak area measured in the monitor. The decay correction factors for irradiation (S), decay (D), and counting (C) are simple for the more common exponential decay, but they have been formalized in the k_0 method for more complicated cases (De Corte et al. 1989a), including daughter activity growth and activation and decay schemes with several delayed branches.

In the equation, it is assumed that the peak areas have been corrected for count-rate-dependent random counting losses, whether they are caused by pulse pile-up or by analog-to-digital converter (ADC) dead time. Since modern spectrometers have very accurate live-time clocks, this correction is usually achieved simply by using the spectrometer live-time in the factor N_x/t_c . In the case of a highly varying count rate and significant decay of the analyte nuclide during the counting period, it may be more accurately achieved by a real-time correction method, such as loss-free counting.

All the nuclear factors are contained in the compound nuclear constant, k_0 . For a given gamma ray, γ_x , of a given product nuclide, the k_0 factor is proportional to the isotopic abundance of the target nuclide, the thermal neutron activation cross section, and gamma ray emission probability, and inversely proportional to the atomic mass:

$$k_{0,m}(x) = \frac{(\theta \sigma P_\gamma / M)_x}{(\theta \sigma P_\gamma / M)_m} \quad (30.39)$$

In practice, the k_0 factor is not determined using [Eq. \(30.39\)](#), because the thermal neutron activation cross-section, σ , and the gamma ray abundance, P_γ , are often not known with sufficient accuracy; instead the k_0 factor is measured experimentally. It is expressed relative to a monitor element, “m,” which is usually gold; the k_0 value for the ^{198}Au 411.8 keV gamma ray is defined as unity. The Au activation cross section is 98.7 barns and the 411.8 keV gamma-ray abundance is 95.5%. All other published k_0 values have been measured relative to ^{198}Au . Over the years, accurate k_0 values have been measured for more than 500 gamma rays emitted by more than 144 nuclides, which are essentially all the gamma rays used in NAA. As an aid to understanding the concept, a k_0 value can be thought of as the number of gamma rays emitted per unit mass of the element and unit thermal neutron fluence.

The factor, Φ_m/Φ_{unk} , in [Eq. \(30.38\)](#) corrects for thermal neutron flux differences due to the flux gradient at the positions of the monitor and the unknown sample. In cases where the monitor is irradiated before or after the unknown sample, which is often the case with short irradiations, Φ_m/Φ_{unk} corrects for the possible change in flux between the two irradiations. With the exception of this correction factor, the thermal neutron flux does not directly appear in [Eq. \(30.38\)](#); however, the quantity calculated with the flux monitor (the product of all the factors containing “m”) is proportional to the thermal flux. Thus, when using this equation, it is commonly understood that the quantity measured with the unknown sample is divided by the thermal neutron flux measured with the monitor.

In [Eq. \(30.38\)](#), the term $Q_0(\alpha)/f$ in the factor $(1 + Q_0(\alpha)/f)$ corrects for activation by epithermal neutrons. This factor is the heart of the k_0 method and was the key innovation that made the method possible. It was necessary to predict, with high accuracy, the relative reaction rates for two different (n,γ) reactions in any reactor neutron spectrum. For each reaction, the Q_0 value, the ratio of the resonance integral to the thermal neutron activation cross section, and f , the ratio of thermal flux to epithermal flux for the irradiation channel used, is needed.⁶

This simple method for calculating reaction rates in a mixed thermal–epithermal spectrum is called the Hogdahl convention (Hogdahl, 1965). It assumes that in the thermal neutron region the activation cross section varies with neutron energy as $E^{-1/2}$, the $1/v$ law. This is important because the neutron temperature varies from reactor to reactor, and, as a result, the mean energy of the thermal neutrons varies. However, since the reaction rates for all (n,γ) reactions vary by the same amount, any reaction rate relative to an ^{197}Au monitor remains constant. The Hogdahl convention also assumes that the neutron spectrum varies with energy as $1/E$ in the epithermal neutron region. A small variation from $1/E$ is accommodated by assuming the spectrum varies as $1/E^{1+\alpha}$. The shape parameter, α , is usually measured at the same time as the thermal to epithermal flux ratio, f . The resonance integral, and thus the Q_0 value, varies with α . It varies most for reactions that have resonances at high neutron energies. In the Hogdahl convention, the calculation of $Q_0(\alpha)$ is simplified by using the concept of mean resonance energy, where the contribution to the resonance integral of all the resonances is approximated by one resonance situated at the effective mean resonance energy E_r . Once α is known, $Q_0(\alpha)$ can be calculated using a simple formula:

$$Q_0(\alpha) = (Q_0(0) - 0.429)(E_r/\text{MeV})^{-\alpha} + \frac{0.429}{(2\alpha + 1)0.55^\alpha} \quad (30.40)$$

The mean resonance energies were calculated by Jovanovic et al. (1987) by integrating over all the resonances for all the (n,γ) reactions used in neutron activation analysis.

The assumption that the activation cross section varies with neutron energy as $1/\nu$ in the thermal neutron region is valid for most (n,γ) reactions. The two reactions that deviate the most from the $1/\nu$ assumption are $^{176}\text{Lu}(n,\gamma)^{177}\text{Lu}$ (typically $+0.4\%/K$) and $^{151}\text{Eu}(n,\gamma)^{152}\text{Eu}$ (typically $-0.1\%/K$). The reaction rates for these two reactions, relative to a monitor reaction like $^{197}\text{Au}(n,\gamma)^{198}\text{Au}$, will depend on the thermal neutron temperature in the irradiation channel used. A new set of equations, the Westcott formalism (Westcott 1955), was developed to account for these cases and used the Westcott $g(T_n)$ factor, which is a measure of the variation of the effective thermal neutron activation cross-section relative to that of a $1/\nu$ reaction. In the modified Westcott formalism, the following differences are also included: the $Q_0(\alpha)$ value of the Hogdahl formalism is replaced by the $s_0(\alpha)$ value, and the thermal to epithermal flux ratio, f , is replaced by the modified spectral index, $r(\alpha)(T_n/T_0)^{1/2}$. To use this formalism with the k_0 method (De Corte et al. 1994), it is necessary to measure the neutron temperature, T_n , for each irradiation and a Lu temperature monitor should be irradiated. The Westcott formalism needs to be implemented only when analyzing for Lu and Eu. There are several other non- $1/\nu$ nuclides: ^{103}Rh , ^{115}In , ^{164}Dy , ^{168}Yb , ^{191}Ir , and ^{193}Ir , but for these the error that results from using the simpler Hogdahl formalism will always be less than 1%, except for neutron temperatures far from those normally found in research reactor irradiation channels. One can question the usefulness of the Westcott formalism; when it is used, Lu is measured relative to the Lu monitor, i.e., not by the k_0 method, and the Westcott formalism gives significantly more accurate results for only one element, Eu. A more user-friendly correction method for Lu and Eu has been proposed by St-Pierre and Kennedy (2007), thus eliminating the need for the Westcott formalism.

De Corte et al. (1989a) emphasized the need to take into account neutron self-shielding in the k_0 method for both thermal and epithermal neutrons. With the self-shielding correction factors, the basic equation becomes:

$$C_{x(\text{unk})} = C_m \frac{\left(\frac{N_s/t_c}{\text{SDCW}}\right)_{\text{unk}}}{\left(\frac{N_m/t_c}{\text{SDCW}}\right)_m} \frac{k_{0,m} \Phi_m}{k_{0,x} \Phi_{\text{unk}}} \frac{G_{\text{th},m} + G_{\text{ep},m} Q_{0,m}(\alpha)/f}{G_{\text{th},x(\text{unk})} + G_{\text{ep},x(\text{unk})} Q_{0,x(\text{unk})}(\alpha)/f} \frac{\epsilon_m}{\epsilon_{\text{unk}}} \quad (30.41)$$

The thermal and epithermal self-shielding factors, G_{th} and G_{ep} , are very close to unity for activation reactions in most samples, such as biological materials, and can be ignored. However, the self-shielding effect is important for samples containing large amounts of nuclides with high neutron absorption cross sections. It is also important for many of the neutron spectrum monitors used, such as wires, foils, and pellets. Historically, G_{th} and G_{ep} were extremely difficult to calculate and required Monte Carlo calculations in the case of resonance neutrons; moreover it was recommended to dilute the samples to avoid self-shielding. Now, G_{th} and G_{ep} can be calculated easily and accurately with analytical formulae (Chilian et al. 2008).

Practical Considerations

Users of the k_0 method must determine the thermal neutron flux, the ratio of thermal flux to epithermal flux for the irradiation channel used (f), the shape parameter (α), and detection efficiencies for all counting geometries used. Since the calculations for the derivation and the use of these parameters are extensive, a software package is needed. Some new users begin a collaboration with one of the many laboratories using the k_0 method and adopt their methods of calculation and their software. Two complete software packages are now readily available to all potential users. The KAYZERO/SOLCOI Software (Van Sluijs et al. 1997), now called KayWin, performs the calculations in the well-understood classical manner. It is widely used

and has been well tested over many years. The k_0 -IAEA Software (Rossbach et al. 2007) uses a holistic approach, making use of all available information, and benefits from the support of the International Atomic Energy Agency (IAEA). The maintainers of both packages also provide training.

The instructions with the software packages indicate how to determine f and α , how to measure the parameters of the efficiency calibration of the detector and convert it to specific counting geometries, and how to convert the peak areas into the mass fractions of the elements. The software packages have libraries of k_0 values, Q_0 values, mean resonance energies, half-lives, decay types, and the details of the decay schemes needed for true coincidence summing calculations.

Measuring f and α

Many methods have been developed to measure f and α . They all involve the activation and counting of a number of nuclides having a range of Q_0 values and mean resonance energies. The most accurate measurements of α use irradiations under cadmium cover to activate only with epithermal neutrons. However, many laboratories may not require such high accuracy or may not be permitted to irradiate under cadmium cover. Bare irradiations have been shown to give sufficient accuracy if carefully done. Since the parameters are determined by subtraction of the thermal neutron-produced activity from the total activity – two possibly similar quantities – accurate element masses, peak areas, and detection efficiencies are needed. The minimum number of monitors that need to be irradiated for the simultaneous determination of the thermal neutron flux, the factor f , and α is three.

One of the most convenient trios of monitor elements is Cr, Au, and Mo (Koster-Ammerlaan et al. 2008). The $^{50}\text{Cr}(n,\gamma)^{51}\text{Cr}$ reaction has a low Q_0 value and is primarily produced by thermal neutrons. The $^{197}\text{Au}(n,\gamma)^{198}\text{Au}$ reaction is produced by thermal and low-energy epithermal neutrons, and the $^{98}\text{Mo}(n,\gamma)^{99}\text{Mo}$ reaction is produced by thermal and high-energy epithermal neutrons. Along with samples to be analyzed, the irradiation of a pellet containing well-known quantities of Cr, Au, and Mo, typically 500, 4, and 1,000 μg , respectively, gives the thermal neutron flux, f and α after a simple calculation.

► Figure 30.4 illustrates a Cr, Au, and Mo pellet ready for irradiation next to a sample of ceramic material. They are irradiated in a polyethylene irradiation vial using a pneumatic transport system and 5 days after irradiation, the Cr, Au, Mo pellet is counted to measure the

■ Fig. 30.4

Next to an open polyethylene irradiation vial is an assembly consisting of a 150 mg sample of ceramic material to the left and a smaller diameter neutron-spectrum monitor (in the form of a Cr, Au, Mo pellet) ready for irradiation

thermal neutron flux, f , and α . The sample is counted after 5 and 15 days and the mass fractions of up to 50 elements are determined by the k_0 method. To achieve the same results using the relative method would require irradiating the ceramic material along with the standards of 50 elements. This would be a daunting task even if suitable multielement standards were available.

Detection Efficiency ϵ

Detection efficiencies appear to occupy only a minor part of [Eq. \(30.38\)](#), but in fact their accurate determination is by far the most difficult aspect of the k_0 method. With the relative method, the counting geometry for the unknown sample is maintained almost identical to that of the standard, and only a small correction factor needs to be calculated. With the k_0 method, the counting geometry for the unknown sample may be completely different from that of the monitor and the comparison is between two different nuclides. The fact that monitor and samples may be counted with any geometry is a major advantage of the k_0 method.

It may be straightforward to determine a relative efficiency curve of efficiency versus gamma-ray energy for a point source far from the germanium detector, but what is needed are efficiencies for small or large samples, which may be counted very close to the detector. The efficiency calculation routine, a major part of any k_0 software package, may use a physical or parametric model that considers the gamma ray detection probability as a function of the position of the emitting atom relative to the center of the face of the detector. The calculation includes integration over the volume of the sample and takes into account attenuation in the sample and its support. Using calibrated and uncalibrated sources for absolute and relative efficiencies, respectively, the user will perform the measurements necessary to determine the parameters of the model; the measured dimensions of the detector may also be used. Finally, the parameters of the model are fine-tuned using further measurements in typical counting geometries.

A huge complication is coincidence summing of gamma rays. This is negligible with the relative method because the standard and the unknown contain the same nuclide, they are at the same distance from the detector, and the effect is the same for both. With the k_0 method, the software must have the decay schemes of all the nuclides used, to determine the probability of each decay path involving the gamma ray of interest. Then, for each gamma ray of interest and each counting geometry, the software calculates the probability of summing with the gamma rays emitted simultaneously along each decay path. Many routines have been developed to perform coincidence summing calculations. Three of the routines used with the k_0 method were compared for the case of a small sample counted close to the detector (Van Sluijs et al. 2000). The reduction in detection efficiency due to summing-out was as high as 30% for some nuclides. Discrepancies between the three routines were usually less than 1%, but as high as 10% in some cases. When the reasons for the discrepancies, programming bugs, outdated decay schemes, and neglect of summing with X-rays, were understood they were corrected in all the routines.

Not all routines accurately correct for coincidence summing with X-rays. This may be important, especially for heavy nuclides, but it is difficult to accurately correct because it varies greatly with detector window thickness and sample thickness. For this reason, detectors with thin beryllium windows should not be used with k_0 -NAA unless samples are counted at distances of 10 cm or more. None of the routines correct for coincidence summing with beta rays. This may be important for some short-lived light nuclides that emit high-energy betas in coincidence with gamma rays. In these cases, a 4 mm thick plastic absorber should be placed between sample and detector.

Accuracy

In 1987, it was estimated that the uncertainty of analytical results using the k_0 method was typically 3.8% (De Corte et al. 1987), and included 1% from k_0 values, 1% from Q_0 values, 2.5% from f and α , and 2.5% from detection efficiencies, all combined in quadrature. Since then, several expert laboratories have made a considerable effort to completely understand the method and to determine and eliminate the causes of uncertainty. These laboratories now routinely achieve 2% accuracy under favorable conditions, such as counting the samples far from the detector and using an irradiation channel with high f value. However, for new laboratories adopting the method, a large number of papers comparing results with the accurately known mass fractions in certified reference materials show many deviations between 5% and 10%. These papers did not identify the likely causes of these deviations, and they were not able to resolve them. Thus, it may be concluded that new laboratories adopting the method should expect accuracies between 2% and 5%, depending on the resources available to fully develop the method.

An important step toward improved quality assurance is the development of the synthetic multielement standards (SMELS) material (Vermaercke et al. 2006). There are three types of material, SMELS I, SMELS II, and SMELS III, that produce nuclides with short, medium, and long half-lives when activated. In each of the three spectra, many clear gamma-ray peaks, emitted by at least a dozen nuclides that are produced by (n,γ) reactions with low and high Q_0 values, over the entire energy range are obtained. These stable, homogeneous materials with well-known mass fractions of all the elements are very useful in verifying the method. In spite of their popularity, the three materials are still available from the developer. SMELS I and SMELS II can be recycled after the decay of the activated nuclides. The intended use of this material is to verify that the k_0 method is being correctly used. If discrepancies with the expected mass fractions are observed, the user determines the reason and makes corrections.

There is a continuing effort to improve the nuclear database (De Corte and Simonits 2003) that contains the recommended k_0 values, Q_0 values, mean resonance energies, and half-lives for 144 nuclides. This will make a difference for a few nuclides for which the currently used k_0 and Q_0 values may be in error by as much as 10% (St-Pierre and Kennedy 2006 and references therein). The international committee updating the database hopes to identify all the nuclides for which the current k_0 values may be in error by more than 2% and to publish new recommended values.

30.5 Radiochemical Activation Analysis (RAA)

In radiochemical activation analysis (RAA), the various techniques of activation analysis (AA), i.e., neutron activation analysis (NAA), photon activation analysis (PAA), and charged particle activation analysis (CPAA) are combined with radiochemical separation procedures with the intention of extending the capabilities offered by the purely instrumental methods.

The primary objective of RAA is to increase the sensitivity and/or the accuracy of the analysis, while preserving the main advantage of the instrumental techniques, their multi-element character. The instrumental modes of activation analysis are widely used analytical techniques for the nondestructive and simultaneous determination of trace element mass fractions or concentrations. As a result of chemical separation, interferences caused by other elements/radionuclides are removed; thus additional elements of low concentration become detectable and/or the accuracy of the determination is improved. In this sense, RAA complements instrumental AA methods.

Radiochemical methods can be successfully applied to separate elements and/or radionuclides that cannot be directly analyzed in the radioactive matrix by instrumental methods, e.g., pure beta emitters, short-lived nuclides in the presence of long-lived matrix components. In this case, there is no instrumental alternative to RAA.

A recently defined and new objective has been trace element speciation, which provides information about the physical/chemical state of the trace elements. Species separated by chemical methods are subsequently determined by instrumental or radiochemical activation analysis.

30.5.1 Major Types of RAA

The term RAA is used for the conventional form of radiochemical activation analysis with post-irradiation chemical processing, as well as – in a broad sense – for all types of AA involving chemical and radiochemical operations.

In conventional RAA, chemical separations are carried out *after* the irradiation of samples. The well-known advantages of this technique over other types of trace element analysis where chemical treatment is involved are the reduction of contamination risks and uncontrolled losses of trace elements during processing. These are the beneficial consequences of postirradiation treatment of radioactive samples and the addition of carriers after the irradiation.

Pre-irradiation chemical treatment of samples cannot be always avoided. Samples of large volume or mass have to be concentrated before being analyzed. In the literature this technique is referred to as pre-concentration activation analysis (PCAA). This treatment considerably increases the concentration of the elements to be determined. It may provide a tool for chemical separation of the interfering elements/isotopes at once, thus greatly increasing the sensitivity of AA.

In some extremely demanding cases, pre-irradiation chemical concentrations are carried out together with postirradiation separations, combining the advantages and the drawbacks of both techniques. This method, referred to as PC-RAA, can provide the highest possible sensitivity of trace element analysis among the AA techniques.

Pre-irradiation chemical separations followed by activation analysis are also performed for speciation studies. Speciation cannot be done after irradiation, since the chemical form can be changed due to recoil effects under the drastic conditions of nuclear reactions. This type of analysis is called chemical or molecular activation analysis (CAA).

The most common form of RAA is its use with neutron activation and is called RNAA.

30.5.2 Main Features of RAA

Radiochemical separations involved in conventional postirradiation RAA have some special characteristics that distinguish them from separation procedures used in classical trace element analysis.⁷

Chemical processing usually contains the following steps: Irradiated samples, after the addition of tracers and/or carriers, are dissolved by one of the following destruction/dissolution methods: dry ashing in open or closed systems, wet ashing with mineral acids in open or closed systems, or alkaline fusion. Thermal and microwave ovens or hot plates are often used as heat

sources. The main methods for separation involve precipitation, ion exchange, solvent extraction, and distillation. Chromatographic techniques in the form of ion exchange, extraction chromatography, or thermochromatography are often applied for the separation of single elements as well as groups of elements or for the removal of the matrix interference. Separated sources are usually counted by high-resolution gamma spectrometers and, in some cases, by beta detectors or liquid scintillation counters (LSC).

The major pitfall of chemical separations is the varying and unavoidable loss of material. Nonetheless, there are several ways of controlling the losses by calculating the chemical recoveries for the whole procedure. The amount of carrier can be determined in the measurement source at the end of separation and compared with the initial value. Recovery should be corrected for the presence of the element in the original sample. The amount of carrier can be determined by classical analytical methods, such as gravimetry or by nuclear techniques. In the case of short-lived nuclides, reactivation is an appropriate technique.

Recovery measurements are often performed with the addition of radiotracers, which are most likely analyzed together with the analyte in the measurement source. Since the tracers should not be produced in the sample during irradiation, cyclotron-produced tracers are preferred in NAA, e.g., Co analysis by NAA in the presence of cyclotron-produced ^{56}Co yield tracer. High accuracy in the analysis can only be assured if recovery for each analyte in each sample is determined.

There are several other advantageous features of RAA techniques, such as:

1. The reduction or elimination of contamination hazards of the sample during processing unless the laboratory is contaminated by radionuclides.
2. Chemical losses of the analytes due to formation of radiocolloids and adsorption on the vessels' surfaces are minimized by the addition of carriers to the samples after irradiation and before chemical processing. Using stable isotopes of the analyte of interest increases the overall concentration of the analyte and the carrier beyond the trace level, hence better separation yields can be achieved. Similarly, the addition of stable interfering matrix elements aids the separation efficiency.
3. The multielement character of AA implies that trace elements do not have to be individually separated; it is sufficient to separate them into several groups or just remove the interfering components. Thus, chemical separation schemes are relatively simple and extremely high decontamination factors are not attained. When the recoveries are well controlled, separations need not necessarily be quantitative, although high yields are always desirable. For the determination of short-lived nuclides, fast separation procedures are of major concern.⁸
4. Matrix components generally do not interfere with trace element determination, e.g., C, H, O, and N contained in organic materials do not affect the detection of trace metals in NAA. On the other hand, minor or trace elements that are easily activated, e.g., ^{24}Na , may significantly influence the detection limits for trace elements. Matrix activities are frequently eliminated by selective chemical removal, thus increasing the sensitivity for many trace elements.
5. Since RNAA is applied as a complementary method to INAA, it is most frequently used to analyze single elements that are difficult to determine, e.g., I, Th, and U in biological materials. In this case, chemical separations are designed for the removal of the analyte as a single element or a group of elements that behave chemically similarly, e.g., rare earth elements; thus, separation chemistry can be relatively simple.

An obvious disadvantage of RAA separations is that samples often have to be treated in shielded facilities or in hot cells because of the radioactivity.

General RAA trends have been discussed by various authors (de Bruin 1998; de Goeij 1999; Guinn 1999; Heydorn 1999; Parr 1999) and several excellent reviews on RAA of geological, biological, and environmental samples have been published (Alfassi 1994a, b; Balla et al. 1998; Zeisler and Guinn 1990). Examples from the last 10–20 years are given in the following sections.

30.5.3 Application of RNAA in Materials Science

Neutron activation analysis, including nondestructive as well as radiochemical techniques, has been successfully used for the determination of trace elements in metals, especially high purity metals. In the past, radiochemical separations were extensively used for the removal of matrix interferences. Later this procedure was extended to the group separation of trace elements. Radiochemical methods are also applied to the accurate and sensitive determination of single “difficult-to-determine” elements.

30.5.3.1 Removal of the Main Activity and Separation of Element Groups

The demand for high purity metals has tremendously increased due to needs in the information technology and telecommunications industries. High purity Al is used in various micro-electronic devices and semiconductor detectors are made of hyperpure Ge and Si, etc. Impurity levels depend upon both the raw material and the purification method and may influence the function of the device. For example, in semiconductor materials, alpha particle emission creates damage causing the so-called soft error effect. For this reason, U and Th levels are strictly limited in these applications.

The main activity induced by neutrons in an aluminum matrix is ^{28}Al , which is a short-lived radionuclide ($T_{1/2} = 2.25$ min) that decays within an hour. However, fast neutrons, also present in a nuclear reactor spectrum, react with Al yielding ^{24}Na via the $^{27}\text{Al}(n,\alpha)^{24}\text{Na}$ reaction. Because of the relatively long half-life ($T_{1/2} = 15$ h) and the high-energy photons that cause significant increase of the background due to Compton interaction, ^{24}Na becomes a major interference in the determination of trace elements in Al.

One method (Egger and Krivan 1986) was developed to separate ^{24}Na from irradiated Al using hydrated antimony pentoxide (HAP) in hydrochloric/hydrofluoric acid (HCl/HF) solution. Eighteen trace elements with mass fraction levels of 0.1 ng/g were determined, and another 20 elements could be determined above the 1 ng/g mass fraction level. As shown by Girardi and Sabbioni (1968), HAP retains Na almost quantitatively from concentrated HCl and HF helps elute some slightly adsorbed elements from the column (Ta, As, Se).

Discarding simplicity, the sensitivity of the method was further improved by integrating chromatographic group separation steps into the procedure using ion-exchange columns (Egger and Krivan 1988). Ten groups of elements were formed allowing the determination of 43 trace elements below the 10 ng/g level. After the removal of Na by HAP, the elements were separated into five groups by elution chromatography using an anion-exchange column. U and Th were determined by separating the indicator radionuclides (^{239}Np and ^{233}Pa) using another anion exchange resin; and finally, a cation-exchange resin was used to divide the rest of the elements into four groups.

A sequential group separation method was developed also by Zaidi et al. (1999a) to determine 32 trace elements in high purity Al. The sample was digested, then dissolved in 10 mol/l HCl and passed through an anion-exchange resin column. Non-retained elements were divided into two groups by co-precipitating some of them with calcium oxalate, while others remained in the filtrate. A third group was formed by stripping the retained anions with dilute nitric acid. Low mass fractions of U and Th were determined by retaining the indicator radionuclides, ^{239}Np and ^{233}Pa , from the HCl solution on an additional anion-exchange resin column and preparing a co-precipitated source with LaF_3 .

Comparing the three methods for the determination of trace elements in high purity Al, it can be said that the more complicated the separation, the greater is the number of elements that can be analyzed.

Zaidi et al. (1999b) have successfully adopted the same chemical procedure for the analysis of nickel-based alloys. Nickel was concentrated from the effluent of the anion-exchange resin column by precipitating it with dimethylglyoxime followed by an oxalate precipitation in the same manner as the Al analysis and 40 elements could then be determined. Besides nickel, the other major components were Fe, Cr, Ca, Mg, Ce, Mn, Na, and V, while the rest of the elements were present in minor and trace quantities. Nickel-based alloys are extensively used in the electronics and telecommunications industries as well as in the chemical industry and aircraft production.

Zaidi et al. (2002) adopted the same radiochemical procedure for the determination of minor and trace elements in high purity Ti and W. (Later the procedure was also successfully applied to the analysis of milk samples (Gill et al. 2003).) After acid destruction, Ti and W are precipitated as H_2TiO_3 and H_2WO_4 , respectively. Next, a separation procedure based on anion exchange and precipitation of the rare earth oxalates is applied. Thirty-six elements were determined with high chemical yields and improved sensitivity compared to that of INAA. Due to its light weight, high strength, chemical resistance, and biocompatibility, titanium is used in air- and spacecraft industry and in medical structures such as implants. High purity tungsten has also many applications, e.g., in light bulbs as filament; in electronic equipment as seals, contacts, electrodes; and, more recently (in alloyed form), in sporting equipment.

A simple postirradiation radiochemical procedure has recently been developed at the Jozef Stefan Institute in Slovenia for the selective removal of iron from iron minerals and iron-based reference materials (Makreski et al. 2008, Jacimovic et al. 2008). Iron chlorocomplexes were extracted with di-*i*-propyl ether (DIPE) or *i*-amyl acetate (IAA). After Fe elimination, the distribution of 35–39 elements in the extraction systems was determined. Twelve to fourteen elements, particularly the lanthanides, could be detected with increased sensitivity, while Sb, Mo, Au, Se and Te were co-extracted with Fe, which prevented the determination of these elements.

Single-step separation procedures for the removal of major interferences are scarcely applied, but removal of the matrix activity is often combined with a relatively simple group separation scheme. Chromatographic techniques offer this convenience by eluting or stripping the retained elements sequentially according to the different distribution ratios. Ion-exchange chromatography was very often used. Because of its high capacity, it can be applied to the removal of the matrix as well as to trace element separations. Recently, extraction chromatography has been favored, especially in combination with other separation procedures.

Several procedures have been developed for the determination of trace elements in molybdenum and tungsten that take advantage of the anionic character of both elements. Park et al. (1988) studied the mass fraction of 13 trace elements in Mo by separating them from Mo

and W, which were responsible for the matrix activities. Sequentially eluted cation- and anion-exchange resin columns were used to obtain three groups of elements. Mo and W passed through the cation column and were eluted from the anion column with 7 mol/l nitric acid. The anion exchange served to separate Np and Pa selectively allowing the determination of U and Th traces. In the modified procedures of Theimer and Krivan (1990), 20 elements were determined in high-purity molybdenum using anion-exchange separations from HF media. One of the procedures has the advantage of high sensitivity for Th determination. Caletka et al. (1988) developed a procedure for the determination of 19 trace elements in tungsten. Tungsten was retained by anion-exchange resin and trace elements were eluted into two groups. In order to analyze Ta and Sb, they were selectively extracted as diantipyrimethane (DAM) complexes with an organic solvent before the ion-exchange separation took place. The pure beta emitter, ^{32}P , was also determined after sub-stoichiometric extraction, a method described by Suzuki (1990).

Caletka et al. (1982) analyzed 26 trace elements in niobium by irradiating and processing two sample aliquots. The first aliquot was for the determination of medium-lived nuclides and the second one was for the analysis of long-lived indicator isotopes. In both procedures, solvent extractions were followed by column chromatographic separations. Niobium was removed by extracting its diantipyrimethane (DAM) complexes with dichloroethane. The procedures involve solvent extraction, anion-exchange chromatography, and in the first case sorption on HAP, and in the second case, extraction chromatography on an HDEHP column.⁹

Fifteen trace elements were determined at ng/g mass fraction levels in high purity Sn by Kolotov et al. (1996) using extraction chromatography on Teflon-supported tributylphosphate (TBP). Tin, together with Sb and In radionuclides, which are formed in secondary nuclear reactions of Sn during irradiation, were retained from 6 M HCl on the column. The ^{24}Na was removed from the eluted trace element fraction by sorption on hydrated antimony pentoxide (HAP). Gas phase impurities of N, C, and O were also analyzed in the same material by radiochemical photon activation analysis via ^{13}N , ^{11}C , and ^{15}O detection.

The major disadvantage of group separation procedures is the lack of a chemical recovery determination for each element in each sample.

30.5.3.2 Separation of a Single Element

A few important examples were selected for discussion, i.e., analysis of silicon in high purity metals, phosphorus, and sulfur in steel, molybdenum, and tungsten in geo- and cosmochemical samples.

Silicon. The difficulty with the determination of Si by NAA lies in the fact that the $^{30}\text{Si}(n,\gamma)^{31}\text{Si}$ reaction has a small cross section, the isotope abundance of ^{30}Si , as well as the gamma-ray emission probability of ^{31}Si are small, and the half-life of the latter is short ($T_{1/2} = 2.62$ h). To increase the sensitivity, detection of the emitted β^- radiation is preferred to traditional gamma-ray spectrometry. In this case, ^{31}Si has to be separated from other radionuclides in the sample.

Rouchaud et al. (1977) determined Si in Mo by concentrating it from dilute acid on an anion-exchange resin column and separating it by elution. Silicon was further purified and concentrated using an aluminum oxide column. Silicon was determined by the same author (Rouchaud et al. 1980) in iron and aluminum, but used cation-exchange resins since they offered better separation by retaining the matrix elements than the anion-exchange resins.

Schmid and Krivan (1986) separated Si based on the volatility of SiF_4 by distillation from an $\text{HF} + \text{HCl}$ solution. Silicon was determined in vanadium and niobium using this method.

Phosphorous. The presence of trace amounts of phosphorus in metals and semiconductors is known to affect material properties. The ^{32}P produced in the (n,γ) reaction is a pure β^- emitter and has to be separated and rigorously purified. Paul (1998, 2000) developed a method for P determination in steels and other high-temperature refractory alloys of interest to the aircraft industry. Irradiated samples were dissolved; passed through cation-exchange columns to remove Co, Ni, and Cr; followed by repeated precipitations of magnesium ammonium phosphate and ammonium phosphomolybdate. One of the major advantages of this technique is the determination of the chemical yield by gravimetry. Phosphorus was determined by INAA in matrices other than metals, e.g., polymers. In this case, the beta spectrum was corrected for interferences and self-absorption (St-Pierre and Kennedy 1998). A modified version of this procedure has been used to certify implanted phosphorus in silicon (Paul et al. 2003).

Sulfur. Sulfur is determined by measurement of ^{35}S produced via the $^{34}\text{S}(n,\gamma)^{35}\text{S}$ reaction. It is a pure beta-emitting isotope that can be detected with high counting efficiency by liquid scintillation (LS) counting, but a highly selective separation is required to remove other radionuclides that could interfere with ^{35}S . The chemical separation is often based on the ion exchange of sulfates. According to Paul (2008), sulfate is reduced to sulfide and collected as H_2S in a basic solution that is mixed with LS cocktail. Since the reaction is specific for sulfate, a clean separation of ^{35}S is obtained. The chemical yield of the postirradiation procedure is determined by iodometric titration for the individual samples. To achieve high accuracy, the Cl content of the sample is also determined by RNAA by separating chlorine as AgCl precipitate and correcting the result for the ^{35}S content produced via the $^{35}\text{Cl}(n,p)^{35}\text{S}$ reaction.

Molybdenum and tungsten. Oura et al. (2007) applied postirradiation RNAA to determine trace amounts of Mo and W in geo- and cosmochemical samples. Samples were fused and Mo and W were separated from other elements by an anion resin. Chemical recoveries were determined by ICP-OES for both elements in each sample. To correct the Mo results for fissiogenic ^{99}Mo resulting from fission of ^{235}U , another fission product, i.e., ^{133}I in each sample solution was determined by RNAA. Iodine was separated as PdI_2 precipitate. Under the given experimental conditions, detection limits of about 100 ppb for Mo and W were achieved.

Several other valuable publications have recently appeared on the use of RNAA for trace elements in metals, e.g., the analysis of Na and K in W-Ti alloys by Kim et al. (1998) and trace elements in ancient gold objects by Olariu et al. (1999). Postirradiation RNAA methods separating a single element have the advantages that low detection limits as well as high analytical accuracy can be achieved when results are corrected for chemical losses and all possible interferences are taken into consideration.

30.5.4 RNAA of Biological, Environmental, and Geological Samples

30.5.4.1 Removal of the Main Interfering Activities

The main activities of irradiated biological samples are ^{24}Na ($T_{1/2} = 15$ h), ^{42}K ($T_{1/2} = 12$ h), ^{32}P ($T_{1/2} = 14$ d), and occasionally ^{82}Br ($T_{1/2} = 35$ h). They are produced by neutron capture reactions in Na, K, P, and Br, respectively. When analyzing short-lived radionuclides, ^{38}Cl ($T_{1/2} = 37$ min) contributes significantly to the total activity. In geological and environmental samples, the same nuclides are usually responsible for the matrix activities.

There were many semi-successful attempts to remove these radionuclides by selective chemical separations. A historically important development was the discovery of the high-retention properties of hydrated antimony pentoxide (HAP) by Girardi and Sabbioni (1968). The removal of Na by HAP is quantitative and fast. This discovery contributed to the widespread application of the NAA technique by allowing trace element determinations even before the appearance of semiconductor detectors when NaI(Tl) scintillation detectors were used to register gamma-ray spectra. Investigations were initiated all around the world to find inorganic sorbents that had high selectivity for other elements like that of HAP for Na (Amphlett 1964; Clearfield 1982): removal of phosphate by acidic aluminum oxide or zirconium phosphate, retention of K on titanium dioxide, distillation or extraction of Br and Cl as acid vapors and elemental halogens, respectively, etc. Most of these methods failed to some extent or did not have a long-lasting career because the required high selectivity was not attained. In contrast, many papers were published about the application of HAP for Na removal, either as single-step procedures or as part of sophisticated separation schemes (Schuhmacher et al. 1977; Samsahl 1966).

30.5.4.2 Separation of a Single Element and Groups of Chemically Similar Elements

Single-element separation usually allows the determination of very small amounts, thus providing a highly sensitive analytical method. The activity of the separated radionuclide can be measured by an efficient but less-selective nuclear measuring technique, such as scintillation counting. This technique was used in the past before semiconductor detectors were available and its application is justified at present by the demands of high sensitivity and accuracy in trace analysis in bioassay and other fields studying the role of trace elements. In the following section, examples of the large number of procedures will be given based on recent research revealing new tendencies in RNAA. Other valuable procedures will be cited occasionally to indicate the wealth of this field. A detailed literature review and summary on RNAA until 1994 was prepared by Alfassi (1994a).

Determination of Essential Elements by RNAA

Selenium. It has been recognized that Se plays a seemingly contradictory role in biology as an essential micronutrient for several organisms and a toxic element. It can be determined via the short-lived ^{77m}Se ($T_{1/2} = 17.4$ s) as well as the long-lived ^{75}Se by RNAA (as well as by INAA). Elemental Se can be precipitated after reduction using ascorbic acid (Damsgaard et al. 1973; Alamin et al. 2006), 1-amido-2-thiourea (Itawi and Turrel 1973), or cysteine (Czauderna 1985, Czauderna 1996) as reducing agents. The latter procedure is based on the counting of the precipitated Se without further purification. This was the preferential procedure by many authors in the past when complexes of Se (2-mercaptobenzothiazole, *o*-phenylenediamine, ammonium pyrrolidine dithiocarbamate) were formed followed by solvent extraction or precipitation.

Iodine. Iodine is an essential trace element, which forms an indispensable part of thyroid hormones. Hence, the constant supply of I via the food chain is necessary. Iodine is determined via the $^{127}\text{I}(n,\gamma)^{128}\text{I}$ reaction. A comparative evaluation of INAA and two different methods of RNAA was given by Kucera et al. (2001). In the radiochemical procedures, irradiated samples were digested by alkaline-oxidative fusion to avoid losses of volatile I. According to the first

RNAA procedure, elemental I_2 was extracted with chloroform; in the second procedure, it was precipitated as AgI. The lowest I detection limit of 1 ng/g was achieved by the first procedure. AgI contained some traces of impurities increasing the detection limit, while the detection limit of INAA was two orders of magnitude higher. The chemical yield of the procedure was determined using a ^{131}I radiotracer. The procedure was used by Kucera et al. (2004, 2007) for the determination of I in Asian diets. The iodine extraction procedure was applied with slight modifications by several others (Dermelj and Byrne 1997). I_2 was also separated by distillation from the sample and retention on MnO_2 followed by purification via distillation according to Pietra et al. (1986).

Iodine and bromine. Trace amounts of halogens were determined in silicate rock samples by Ozaki and Ebihara 2007. Activated samples were fused with NaOH and dissolved in water. Metal impurities were removed with hydroxide precipitate. Iodine was separated as PdI_2 , and then a mixed AgCl–AgBr precipitate was formed. Chemical yields determined by the reactivation method varied between 70% and 80%.

Determination of Toxic Elements by RNAA

Mercury. Mercury is an important toxic element of health concern in many materials including coal stack gases and food products. Mercury can be determined by NAA via the 77 keV gamma line of the 2.7 days ^{197}Hg , but in RNAA it is typically analyzed through the longer-lived 47 days ^{203}Hg isotope. INAA data proved to be unsuitable for the determination of low Hg content in the environment. RNAA can be performed by the combustion method that was introduced by Kosta (1969) and applied by several laboratories, e.g., Norman and Becker 1999. The sample was ignited with an oxygen-natural gas torch and the condensed and dissolved Hg was directly counted. The procedure was effective in producing analytical data at the ng/g mass fraction level in biological and coal matrices. An RNAA method based on pyrolysis was developed by Blanchard and Robertson (1997); Hg was collected by double gold amalgamation. The detection limit for Hg in coal was 5 ng/g. Lindstrom (2005) introduced a modification to the combustion method in order to separate selenium from mercury to avoid the interference of ^{75}Se with the 279 keV gamma-ray of ^{203}Hg . Mercury was separated from Se by precipitating mercuric periodate, $Hg_5(IO_6)_2$. Chemical recovery was determined by gravimetry. The method of high accuracy and sensitivity was applied for the certification of Hg content in standard reference materials. Jacimovic and Horvat (2004) determined Hg in environmental and biological samples via the ^{197}Hg isotope where there was no Se interference. Fast combustion separation was performed and ^{197}Hg was detected with a high-efficiency NaI detector.

Hg was often separated by wet chemical procedures containing solvent extraction and precipitation steps in the form of HgI_2 , $Hg(SCN)_2$, HgS , or elementary Hg (Grimanis and Kanas 1982; Biso et al. 1983; Pietra et al. 1986).

According to Goncalves et al. (1998, 2000), irradiated samples were leached with aqua regia in a microwave oven with subsequent selective Hg extraction with bismuth diethyldithiocarbamate. In the organic phase, ^{203}Hg and ^{197}Hg were counted. Mercury mass fractions in soil and sediment samples taken around a gold mine in Brazil were determined above the detection limit of 10–50 $\mu g/kg$. Kucera (2007) described a procedure where Hg was extracted with nickel diethyldithiocarbamate, $Ni(DDC)_3$, into chloroform followed by its stripping with HCl/H_2O_2 solution. Mercury was determined via ^{203}Hg and parallel to Hg. Se was analyzed by INAA and RNAA. Alamin et al. (2006) applied the combined method for the determination of trace amounts of Hg and Se in Libyan food items.

Cadmium. Cadmium is a toxic heavy metal and a main elemental pollutant in the environment originating from metallurgical industry; the production of batteries; anticorrosive coatings of metals, pigments, burning of coal; etc. It is detected via ^{115}Cd in secular equilibrium with its daughter $^{115\text{m}}\text{In}$ by gamma-spectrometry. Bedregal and Montoya (2002) performed postirradiation RNAA of Cd after separation of the chlorocomplexes on an anion-exchange resin column. Ions retained on the resin, i.e., phosphates, iron, zinc, and cadmium were sequentially eluted with 6 mol/l HCl, 0.25 mol/l HCl, 0.024 mol/l HCl, and $\text{NH}_3\text{-NH}_4\text{Cl}$ buffer (pH 10), respectively. The detection limit was about 0.04 mg/kg. Samczynski and Dybczynski (2002) developed a pre- and postirradiation radiochemical procedure for the determination of Cd and Zn that was based on the retention of the analytes on the amphoteric ion-exchange resin Retardion 11A8. Samples are loaded from 2 mol/l HCl on the column. In the pre-concentration step, Cd and Zn are eluted together, during the postirradiation procedure Zn is stripped with an NH_4Cl buffer first, and finally Cd is stripped with 9 mol/l HNO_3 –1 mol/l NH_4Cl . The detection limit of the method was 37 mg/kg and 25 mg/kg for Cd and Zn, respectively.

Arsenic. Arsenic is a well-known toxic element with toxicity depending on the chemical species. On the other hand, sublethal doses of arsenic trioxide can be administered to patients for cancer treatment. INAA is often used to determine As in biological samples. A postirradiation RNAA method of increased sensitivity has been developed at the Jozef Stefan Institute, Slovenia by Byrne and Vakselj (1974). The separation procedure is based on acid destruction of the organic matrix followed by the extraction of AsI_3 into chloroform. The method was used successfully for the determination of the total As content of blood fractions of cancer patients (Slejkovec et al. 2008) with As mass fractions of blood samples in the ng/g range. Speciation studies were performed using HPLC. RNAA was applied for the determination of As in total diet samples from various Iranian provinces (Gharib et al. 2001).

Determination of Elements of Radiological Importance

Strontium. There is a growing interest for the determination of trace elements, which have radiologically important radioactive isotopes in the environment. Biokinetic data about Sr will help predict the behavior of ^{90}Sr in the environment and in human beings. Complementing data provided by INAA, Sr was analyzed by RNAA in total diet samples (Dang et al. 2000, 2001). After acid digestion, Sr was simply co-precipitated with calcium oxalate, thus obtaining a detection limit of 50 ng for Sr in the samples. The dietary intake of Sr by adult Indian population was determined. For Sr RNAA, after the anion-exchange separation of rare earth elements, a sulfate precipitation was performed (Tian et al. 2001).

Thorium and uranium. To study the behavior of alpha-emitting thorium and uranium isotopes in bioassay samples, ultra-sensitive measuring methods are required.

Dang et al. (2000) increased the sensitivity of NAA for Th by separating the indicator radionuclide, ^{233}Pa , using co-precipitations with manganese dioxide and barium sulfate and determined Th in total diet samples. A similar postirradiation procedure was coupled to the following pre-irradiation separation and concentration of Th (PC-RNAA) by Höllriegel et al. (2005) to increase the sensitivity of the method for the determination of urinary Th excretions. The pre-concentration procedure consisted of phosphate and calcium oxalate co-precipitations. The detection limit of Th in the urine sample was about 10 pg (0.04 μBq).

Glover et al. (1998, 2001) developed an ultra-sensitive method for the analysis of ^{232}Th in bioassay and environmental samples and pre-concentration radiochemical neutron activation analysis (PC-RNAA) was applied. In the pre-irradiation procedure, Th was concentrated using

an ion-exchange resin. In the course of the postirradiation chemistry, ^{233}Pa was separated either by ion exchange or by extraction chromatography. For the latter purposes, a TEVA/TRU tandem column containing organic amine (TEVA) and phosphate and phosphine oxide derivatives (TRU) was used (TEVA and TRU are the trade names of the products of Eichrom Co.). (Note: Certain commercial equipment and materials are identified in this work for the purpose of adequately describing experimental procedures. Such mention does not imply endorsement by the National Institute of Standards and Technology.) Finally, the electrodeposited source of Pa was counted. Chemical recoveries were determined both in the pre-concentration and postirradiation processes using the radiotracers ^{229}Th and ^{231}Pa , respectively. The detection limit of 3.5×10^{-7} Bq for ^{232}Th was almost three orders of magnitude lower than for alpha spectrometry.

An ultra-sensitive method was developed for U and Th as well as for ^{40}K determination in liquid scintillators used for neutrino and dark matter experiments. In the RNAA procedure, 250 ml of irradiated cocktail was chemically processed and indicator nuclides of U and Th, namely, ^{239}Np and ^{233}Pa were extracted with tributylphosphate (TBP). Using coincidence techniques, a sensitivity for U down to 10^{-16} g/g was realized (Goldbrunner et al. 1998).

A fast postirradiation separation procedure for the simultaneous determination of V and U in biological (total diet) samples was reported by Repinc and Benedik (2005). Samples were destroyed with mineral acids, V was extracted with BPHA (see above), and U was extracted with TBP. The chemical yield for U was determined by γ spectrometry of the added natural U carrier.

Single-element separations for RNAA purposes have recently been carried out more frequently than before. A detailed bibliography is given in the book by Alfassi (1994a) about the separations of V, Cr, Mn, Cu, As, Zn, Ag, Cd, and Cs. RNAA methods for single element determination and separation are occasionally used for intercomparison purposes. Such procedures of intended high accuracy have been developed, e.g., by Dubczinskij (1996) for the analysis of Cu, Co, Mo, Cd, and Ni in biological materials.

Determination of Other Elements

The role of many trace elements, e.g., V, Sn, Si, Ag, etc. in the environment and biology is not well understood and is often due to the lack of high accuracy analytical data. Recently, several RNAA procedures have been developed/applied for the determination of such elements. Some examples are discussed below.

Vanadium. Vanadium is released to the environment by emission from coal- and oil-fired power plants. Little information is available on natural levels and the role of V on human health. Vanadium can be determined via the short-lived (3.75 min) ^{52}V isotope produced via the $^{51}\text{V}(\text{n},\gamma)$ reaction. Analytical sensitivity has been increased by a rapid postirradiation chemical separation (Repinc et al. 2005). In the separation, biological or environmental samples are destroyed in a Kjeldahl flask; V is oxidized to pentavalent state and extracted with *N*-benzoyl-*N*-phenylhydroxylamine (BPHA). Chemical recovery is determined by detecting the violet complex by spectrophotometry. Nanogram levels of V were determined in selected food and total diet samples from Slovenia (Repinc et al. 2005) and Iran (Gharib et al. 2001).

Silver. Silver has a variety of applications, e.g., in photographic industry, electronics, and jewelry. It can be released to the environment where it can accumulate in biological organisms, including human beings. A postirradiation RNAA procedure has been developed for the determination of Ag in biological reference materials in ng/g mass fractions at the Nuclear Physics Institute, Rez, Czech Republic (Mizera et al. 2008). Samples were irradiated in a Cd

shield to obtain ^{110m}Ag via the nuclear reaction with epithermal neutrons of ^{109}Ag . The simple separation is based on fast fusion of the biological matrix using NaOH and Na_2O_2 followed by the precipitation of Ag as a hydroxide and AgCl . Chemical yields were determined by gravimetry or tracers studies using ^{106m}Ag or ^{105}Ag .

Silicon. It is assumed that Si is an essential element for humans. A postirradiation RNAA method of sufficiently high sensitivity for biological studies has been reported by Kucera and Zeisler (2005). The postirradiation separation consists of fusion, followed by sequential evaporation of Cl , Br , and the distillation of Si as SiF_4 that is absorbed in a boric acid and ammonium molybdate-containing solution. The beta radiation emitted by ^{31}Si produced with thermal neutrons via the $^{30}\text{Si}(\text{n},\gamma)^{31}\text{Si}$ reaction was measured by liquid scintillation counting (LSC). Detection limits as low as $0.5\text{ }\mu\text{g/g}$ could be achieved.

Tin. Tin is used not only as metal alone or alloying component of bronze, but also as a heat and light stabilizer for PVC, pesticides, and fungicides. Radiochemical NAA methods have been reported for the determination of Sn in aquatic biota (Armer and Shawky 2002) and in daily diet samples (Gharib et al. 2001).

There are two groups of chemically similar elements that attract much attention especially in geological and environmental samples, although interest has been raised for presence in bioassays as well: the platinum group elements and the rare earth elements.

Platinum group elements (PGE). PGEs consist of Ru , Rh , Pd , Os , Ir , and Pt . They represent a coherent group of siderophil elements (PGEs extended by Re and Au) from which conclusions can be drawn on the history of rocks. The release of PGEs to the environment has increased because of their applications in the catalysts of cars and pharmaceutical products.

Two methods have been developed for the sensitive determination of PGEs and gold in geological materials by Garuti et al. (2000): an RNAA procedure and pre-concentration NAA. In the RNAA procedure, irradiated samples were subjected to acid destruction in a microwave bomb; Os and Ru were separated by extraction of the tetraoxide compounds into CCl_4 , the remaining noble metals were retained as chlorocomplexes on an anion-exchange column, and divided into two groups by means of elution. In the PC-NAA method, concentration of PGEs and Au in a nickel sulfide bead by a fire assay technique was followed by INAA determination. Detection limits in the range of $0.001\text{--}0.015\text{ ng}$ were derived for both methods. Separation procedures for PGEs based on fire assays have previously been reported (Hillard 1987; Parry et al. 1988).

For the determination of Ir in aerosol particulate samples, Heller-Zeisler et al. (2000) compared three methods, INAA, RNAA, and thermal-ionization mass spectrometry. In the RNAA procedure, Ir was separated from the digested sample on an anion-exchange resin as a chlorocomplex. The sensitivities of INAA and RNAA were comparable, i.e., $60\text{--}100\text{ fg}$ and both of them were superior to mass spectroscopy.

When Au or Pt are determined by RNAA, the ^{198}Au and ^{199}Au indicator radionuclides have to be separated, e.g., by retention as a chlorocomplex on an anion-exchange resin, by precipitation as a reduced metal, by electroplating, or by solvent extraction. For samples containing both Au and Pt , it has to be kept in mind that ^{199}Au is formed from both elements (Zeisler and Greenberg 1982).

Other methods for PGE and noble metal separations have also been published. Chai reviewed the RNAA of PGEs (Chai 1988) and Alfassi prepared a summary (Alfassi 1994a). For group separation purposes, chelating ion-exchange resins (Nadkarni and Morrison 1977; Chai et al. 1987), solvent extraction with long-chain primary amines (Chai et al. 1987), and the combinations of different separation procedures obtaining complicated separation schemes

have been applied. Kucera et al. (2006) has recently published two radiochemical methods for the sensitive and accurate determination of the siderophil element, Re, by RNAA. Rhenium is separated either by extraction with tetraphenylarsonium chloride or by extraction chromatography with trioctylmethylammonium chloride (Aliquat 336, trademark of Cognis Corp.).

Rare Earth Elements (REE). Several radiochemical procedures are based on the chemical similarities of the rare earth elements, especially those of lanthanides.

A simple and accurate chemical separation procedure was applied to the determination of seven REEs in fossil shells by Ohde (1998). REEs were co-precipitated with ferric hydroxide and chemical yields were determined by reactivation of Gd and Yb. Detection limits in the range of 0.1–10 ng/g were attained. Lanthanides were co-precipitated as mixed hydroxides and carbonates followed by their co-precipitation as oxalates in the postirradiation RNAA procedure of Kucera et al. (2006). Chemical yields typically around 80–90% were determined individually for each sample by reactivation of the Pr, Er, and Lu carriers. Detection limits for most lanthanides in agricultural crops were at the level of ng/g. One of the most sensitive analytical procedures for the determination of REEs in geological and cosmochemical samples (1–10 pg) was developed by Minowa and Ebihara (2003), Minowa et al. (2007). After irradiation, REEs were concentrated by co-precipitation as hydroxides and fluorides, then anion-exchange resin was used to remove chloride complexes, e.g., Fe, Co, Cr. Extraction chromatography using TRU resin, an organic phosphorous extractant was applied to separate Sc from the REEs. Thus, the most seriously interfering isotope, ^{46}Sc was removed ($<0.005\%$ ^{46}Sc). Chemical yields determined for 11 REEs by ICP-OES varied between 20% and 60%.

Separations of REEs using anion or cation exchangers, anhydrous manganese dioxide, organic complexes (ammonium pyrrolidone dithiocarbamate), precipitations with hydroxides, fluorides, and the development of combined separation schemes based on these procedures have also been reported and a short review was given by Alfassi (1994a).

Recently, Takeda et al. (2007) and Minowa et al. (2007) introduced a complex RNAA procedure for the determination of trace siderophil elements and REEs in rock and meteorite samples. After irradiation, samples were subjected to alkaline oxidative fusion. Osmium and Ru were removed sequentially by evaporation and the remaining siderophil elements were retained on the chelating resin SRAFION NMRR. REEs, Au, and Pt, and finally, Re and Ir were sequentially stripped from the column with 0.05 mol/l HCl, 5% thiourea, and 7 mol/l NH_4OH , respectively. Although chemical yields determined by the reactivation method widely varied, the method seems to be promising for the sensitive determination of several PGEs (Ru, Os), Re, and lanthanides.

30.5.4.3 Separation of Several Elements and Various Groups of Elements

The literature in this field has grown tremendously during the last 50 years, but most of the publications appeared before the end of the 1980s. When semiconductor detectors became available, INAA almost entirely replaced radiochemical applications. The latest generation of high-purity Ge detectors has not only high resolution, but also high efficiency. At present, the general trend in RNAA is the application of simple and fast separation procedures that allow for the analysis of short-lived nuclides and the exploitation of the inherent multielement nature of the method. The procedures, including chemistry as well as nuclear measurement techniques, should be under total quality control. Fardy (1990) summarized the studies from 1980 to 1988 in table form. The review by Alfassi (1994a) covers the literature to 1994. To illustrate

the major tendencies that determined the research in RNAA to the end of the 1980s, some examples are given below.

Samples were often divided into many groups to enable detection with NaI(Tl) scintillators that had relatively low resolution but high efficiency. The separation scheme was based on the application of a set of columns filled with selective or semi-selective sorption materials that retained certain groups of elements. In the ideal case, the same load solution was passed through consecutively joined columns, thus offering a chance for automation of the procedure.

Pietra et al. (1986) developed several procedures for the separation of as many elements as possible. The most extended procedure is applicable to the analysis of 50 elements in biological materials. In this method, volatile components (Cl, Br, I) are removed by distillation, followed by the chromatographic separation of the condensate using anion exchange (AG1 \times 8: Sb, Sn, Hg, Au) and titanium dioxide: As, Se, Ge columns; Re and Ru are found in the effluent. Nonvolatile components are passed through the following sets of columns: hydrated antimony pentoxide (HAP: Rb, K, Na, Ta), anion-exchange resin (AG1 \times 8: Ga, Fe, Zn, Cd, Pd, Bi, Mo, Au), copper sulfide (CUS), tin dioxide (TDO: Hf, Pa, W, Zr, I), acidic aluminum oxide (AAO: P, Ir), and cation-exchange resin (AG50: Co, Cr, Cs, Mn, Ca, Ba, Sr, Sc, REE). Neptunium and Ag appear in the final effluent. In another procedure for geological and biological samples, 39 elements were separated into five groups using five consecutive columns in the following order: AAO, TDO, CUS, CDO (cadmium oxide) and HAP. Pietra and his coworkers (Pietra et al. 1986) developed altogether 22 RNAA procedures for environmental and biological samples. Several of those, intended for the separation of only a limited number of elements, are less complicated.

Several studies were devoted to the construction of automated equipment for rapid and remote-controlled operation. In 1966, Samsahl (1966) published a paper about the development of an automated system that was based on ion-exchange column separation.

Although automation has not been successfully applied in many laboratories, chromatographic separations using a limited number of columns form the basis of the present investigations and are routinely used in many laboratories. Ion exchange and extraction chromatographic (EC) procedures are available for more and more applications. EC materials were prepared and applied for group separation purposes at the Nuclear Physics Institute, Rez, Czech Republic. Supported CYANEX 301 extractant was applied for the separation of Cu, Cd, As(III), Sb(III), while supported Zn-DDC₂ extractant retained Mo as well as Cu, Cd, As, and Sb (Lucanikova et al. 2006). The general tendency of using selective organic compounds of standard quality, instead of the irreproducible inorganic sorbents of high selectivity, can be recognized.

The general tendency to apply RNAA for the determination of trace elements when high sensitivity and precision are required can be confirmed. Methods have also been developed for multielement determinations by RNAA. These methods are generally based on complicated separation schemes and usually combine several individual procedures. Randa et al. (2003) reported a method for the determination of REEs, Cs, and Rb combining the REE separation based on oxalate precipitation with the Cs–Rb separation using ammonium molybdophosphate (AMP). Tian et al. (2001) published an RNAA method for the determination of REEs, U, and Ba consisting of a fluoride precipitation of REE and U, and a Ba sulfate precipitation. According to another RNAA method, U and Th determination was based on fluoride precipitation of the analyte nuclides (Np and Pa), while Sr was precipitated as sulfate. Combined procedures of Zaidi were briefly reviewed in [Sect. 30.5.3.1](#) (see also Zaidi et al. 2001).

30.5.5 Application of RNAA for the Determination of Radionuclides

Because of its high sensitivity, RNAA has been used to study the behavior of some long-lived radionuclides present in the environment. Strictly speaking, the analysis of uranium and thorium belongs in this field because neither of these elements have stable isotopes, but due to the billion-year long half-lives they are commonly treated like stable elements. There are some isotopes of anthropogenic origin that have some orders of magnitude shorter half-lives (“only” in the range of millions of years) and thus have higher specific activities and are found in nature in ultra-trace levels. Some of these radionuclides were released to the environment during the atmospheric bomb tests of the 1950s and 1960s, as well as during normal and accidental emissions from the nuclear energy industry. These radionuclides represent a potential hazard for the population due to possible leaks in nuclear facilities and waste-disposal sites, not only in the near-term but far into the future as well. ^{129}I ($T_{1/2} = 1.6 \times 10^7$ a) is one of the major representatives of this group, but ^{99}Tc ($T_{1/2} = 2.1 \times 10^5$ a), ^{237}Np ($T_{1/2} = 2.1 \times 10^6$ a) and ^{135}Cs ($T_{1/2} = 2.1 \times 10^6$ a) can also be mentioned.

An excellent review paper was recently written and published by Hou (2008). To express and quantify the advantage of activation analysis with respect to direct radiometric detection of radionuclides, an advantage factor AF was defined by Byrne and Benedik (1999):

$$AF = \frac{A_2}{A_1} = ((\Phi)_{\text{th}}\sigma_{\text{th}} + \Phi_{\text{epi}}I_0) \frac{(1 - e^{-\lambda_2 t_i})}{\lambda_1} \quad (30.42)$$

where $A_1 = N\lambda_1$ is the original activity of the target nuclide, and A_2 is the activity of the new radionuclide produced by irradiation over the period t_i .

Advantage factors of NAA for some long-lived radionuclides under selected irradiation conditions ($\Phi_{\text{th}} = 10^{13} \text{ n cm}^{-2} \text{ s}^{-1}$, $\Phi_{\text{epi}} = 5 \times 10^{11} \text{ n cm}^{-2} \text{ s}^{-1}$, $t_i = 15 \text{ h}$) have been calculated and are given in the paper by Hou (2008). The AF for ^{129}I , ^{99}Tc , ^{237}Np , and ^{135}Cs are 1.3×10^6 , 2.1×10^4 , 3.6×10^5 , and 3.9×10^3 , respectively.

30.5.5.1 Determination of ^{129}I by PC-RNAA

Excellent examples of the determination of ultra-trace levels are provided by the analysis of ^{129}I in environmental and biological samples. The short-lived ^{130}I is produced in the (n, γ) reaction and is easily detected by gamma-ray spectrometry, while the stable ^{127}I undergoes the $(n, 2n)$ reaction-forming ^{126}I that can be used to monitor the chemical recovery. Recovery can also be monitored with radiotracers, e.g., ^{125}I and ^{131}I . To achieve the highest sensitivity, postirradiation radiochemical separation and pre-irradiation chemical concentration are also applied.

For the analysis of ^{129}I and the determination of the $^{129}\text{I}/^{127}\text{I}$ ratio, various separation procedures have been developed. Parry et al. (1995, 2001) used anion-exchange resin for pre-concentration of iodine from milk, vegetation, and atmospheric samples. After irradiation, iodine was eluted and precipitated as AgI . Detection limits below 10 mBq/kg (or mBq/l) for the ^{129}I activity concentration and 10^{-7} for the $^{129}\text{I}/^{127}\text{I}$ ratio were achieved.

Aumann and Güner (1999) used PC-RNAA to determine ^{129}I in soil. The combustion technique was used to pre-concentrate iodine that was collected on charcoal, then removed by heat and finally trapped in a quartz vial. Postirradiation purification consisted of solvent extraction and distillation. Szidat et al. (2000) used the same pre-concentration technique

followed by postirradiation chemistry and precipitation of AgI. Iodine could be separated from solid samples by alkaline fusion and oxidative I_2 extraction and by reductive back-extraction. Frechou et al. (2001) applied PC-RNAA for the measurement of ^{129}I including pre-irradiation separation leading to lead iodate and final evaluation according to the k_0 method. For pre-concentration of large-volume water samples, an anion-exchange resin was used by Szidat et al. (2000) and AgCl co-precipitation technique was applied by Kabai and Vajda (2002). Hou et al. (2002, 2003) determined ^{129}I in various environmental samples collected from the Baltic Sea and from Chernobyl. The PC-RNAA analytical procedure consisted of pre-concentration, extraction of elemental iodine, and conversion to MgI_2 or LiI . During postirradiation separation, iodine was extracted again and finally precipitated as PdI_2 . Osterc and Stibilj (2008) used a similar radiochemical procedure for the determination of ^{129}I and the $^{129}I/^{127}I$ ratio in marine algae from the North Adriatic Sea.

RNAA for ^{129}I is an old technique, used in 1962 by Studier (1962), but its capabilities have significantly been improved. Among the competitive techniques regarding the sensitivity for the $^{129}I/^{127}I$ ratio, accelerator mass spectrometry (AMS) appears to be superior to RNAA. AMS is sensitive enough to determine pre-nuclear environmental ratios in the range of 10^{-10} (Szidat et al. 2000). ICP-MS may also provide results of high sensitivity (Farmer et al. 1998).

RNAA can also be successful for the determination of other long-lived radionuclides, although ICP-MS and AMS are often possible better alternatives.

30.5.5.2 Determination of ^{237}Np by PC-RNAA

In the irradiation of ^{237}Np with thermal neutrons, the 2.1-day ^{238}Np isotope is produced and can be detected by γ spectrometry. Because ^{237}Np is produced both from ^{238}U by (n,2n) reaction and from ^{235}U by consecutive neutron capture, uranium has to be separated from the samples in a PC procedure before irradiation. Three techniques are used to separate Np from the matrix and interfering elements: hydroxide precipitation, solvent extraction, and ion exchange. Postirradiation chemical separation is performed by solvent extraction, ion exchange, or extraction chromatography. In the procedure of Chen et al. (2001), soil samples are destroyed by evaporation with aqua regia, Np is preconcentrated by repeated co-precipitations as hydroxide, extracted with tert-octylamine (TOA) from HCl solution, and purified on an anion-exchanger column. Postirradiation separation is necessary to remove activated impurities. Byrne (1986) used TTA extraction, Germain and Pinte (1990) applied anion-exchange chromatography, and Kalmykov et al. (2004) used UTEVA extraction chromatography. UTEVA is the trade name of the resin produced by Eichrom Co. that contains dipentylpentyl phosphonate on an inert support material. Typically, ^{239}Np is used as a tracer for chemical yield determination.

Neptunium-237 has also been determined by alpha spectrometry, RIMS, AMS, and ICP-MS. RNAA can be regarded as the most sensitive analytical technique for ^{237}Np .

30.5.5.3 Determination of ^{99}Tc by PC-RNAA

In the irradiation of ^{99}Tc with thermal neutrons, the short-lived (15.8 s) ^{100}Tc isotope is produced and can be detected by either gamma spectrometry or a low-background beta counter. Analysis can be performed only with a fast sample transfer system. Both pre- and

postirradiation separations are required to get sufficient purity. Many procedures have been developed for the pre-concentration and separation of Tc. It can be co-precipitated with tetraphenylarsonium perrhenate, retained on an anion exchanger as TcO_4^- anion, separated as a metal cation on a cation exchanger, extracted with cyclohexanone, tert-butyl phosphate, or separated as pertechnetate using TEVA extraction chromatographic material. Chen et al. (1990) used a hydroxide scavenger to remove metals and then retained Tc on an anion-exchange resin. Technetium eluted from the resin was purified by extraction chromatography on TEVA resin. Cyclic activation is preferred if postirradiation separation is not possible. Foti et al. (1972) developed a fast RNAA procedure based on the removal of metal impurities with hydroxide precipitation and precipitation of Tc with tetraphenylarsonium perrhenate. The best detection limit by PC-RNAA (2.5 mBq) is similar to that of the radiometric method (Chen et al. 1990). Lower detection limits can be achieved by ICP-MS.

30.5.5.4 Determination of ^{135}Cs by PC-RNAA

In the neutron capture reaction of ^{135}Cs , the 13-day isotope, ^{136}Cs , is produced and emits a gamma ray of relatively low abundance. The sensitivity of the gamma spectrometric determination is further reduced by the presence of other γ -emitting Cs isotopes, i.e., ^{137}Cs , ^{136}Cs , and ^{134}Cs . There have been a few attempts to determine ^{135}Cs by PC-RNAA. In the procedure by Chao et al. (1996), Cs is pre-concentrated with ammonium molybdophosphate (AMP) and purified by cation-exchange chromatography. In the postirradiation procedure, Cs is removed from the cation exchanger and co-precipitated with AMP or purified with cation-exchange chromatography. A detection limit of 10^{-4} Bq has been reported. Because of the spectral interferences, mass spectrometric techniques seem to be more promising for the determination of ^{135}Cs .

30.5.6 Application of NAA for Speciation Studies

Speciation studies about the chemical nature of trace elements have recently attracted much attention. Chemically separated fractions can be analyzed by NAA (both INAA and RNAA). Out of the increasing number of publications, two examples are mentioned here, one for biological investigations and the other for environmental investigations.

Shoop et al. (1998) studied the behavior of aluminum in urine to understand the role of Al in diseases, such as dialysis, dementia, and osteomalacia, which are of major concern to patients with end-stage renal failure. Non-protein- and protein-bound Al species were separated using a cation-exchange resin followed by NAA of Al. The total Al content was determined by RNAA. It was concluded that the majority of Al is bound to protein.

Pre-separation neutron activation analysis was used to determine the contribution of iodide and iodate to the total iodine content of seawater (Hou et al. 2000). Iodine species were separated by means of an anion-exchange resin that preferentially retained the iodide. Iodate in the effluent was reduced to iodide and passed through another anion exchange column. Both fractions were analyzed by NAA. Urine and milk samples were also analyzed.

30.6 Quality Assurance and Control in NAA

Nuclear analytical techniques have been demonstrated many times to be reliable and under complete statistical control. Nevertheless, a continuous effort by the practitioners is necessary to maintain the accuracy and precision of the analytical results and make these results acceptable in the modern quality environment of a testing laboratory.

This section highlights the common sources of uncertainties in NAA, the resulting uncertainty budgets, and the means of validation. Similar principles are applicable to all forms of activation analysis having in common many of the fundamental considerations regarding the uncertainty of nuclear measurements.

30.6.1 Sources of Uncertainty

As in all analytical determinations, the potential for uncertainties affecting results of a testing laboratory from sources outside the laboratory and outside the applied method must be understood and may not be underestimated (Iyengar 1981; Zeisler 1986). According to the ISO terminology, the uncertainties can be divided into Type A (uncertainties evaluated by statistical methods) and Type B (all other). The Type A terms are dependent mostly on the amount and the reaction cross section of the analyte. In the context of this chapter, only the method-specific sources of uncertainty will be treated, with the main emphasis on NAA.

30.6.1.1 Nuclear Reaction Rate and Sample Integrity

The rate of the nuclear reaction is not constant within a bulk sample. With neutrons, and more predominantly with charged particles, the energy distribution will change within the sample as will the overall density of the activating particles due to the interaction with the sample. In NAA, matrix or sample size and shape effects have been observed with PGAA procedures in an external neutron beam (Mackey et al. 1991), but cannot be studied easily in the isotropic neutron fields of internal irradiation sites. However, the flux in a sample can be significantly affected by the absorption of neutrons. Components of the sample with high neutron absorption cross sections and/or high neutron scattering cross sections, combined with high material density, will result in considerable self-absorption effects, even in rather small samples.

The exact calculation of neutron self-absorption and scattering requires complex numerical calculations. Nevertheless, a set of analytical approximations has been established and proven to be very useful to correct for these effects. These solutions are accurate for spherical samples, infinite and defined length cylinders, and infinite slabs or foils. (As an example, expressions for the self-shielding for a foil in collimated and isotropic neutron fields are given by [Eqs. \(30.18\)](#) and [\(30.19\)](#), respectively.) Many sample shapes approach one of these models and spreadsheets have been made available that calculate an absorption factor, i.e., an average fraction of the sample that has been activated (Fleming 1982, Blaauw 1996). The spreadsheets include tables of all known cross-section values to calculate a macroscopic cross section depending on the composition of the sample that is entered by the analyst. The spreadsheets then resolve the shape function to provide the absorption factor according to the selected shape model. For high-accuracy analysis the selection and exact definition of a sample shape will limit the uncertainty of these corrections. Prudent analysis strategies will limit these absorption corrections to a few percent.

The integrity of sensitive samples with somewhat volatile components cannot be assumed for most irradiation procedures. Thermal mobilization and/or radiative mobilization, recoil effect, and radiolysis can cause the volatile components to leave the sample during irradiation. Containment in quartz vials will prevent loss of the elemental species, but the analyte may be distributed over the whole volume of the container instead of the sample only. Therefore it is required that Hg is determined with the samples sealed in quartz and that provisions are taken to correctly assay the content regardless where the radioactive species are located in the container.

30.6.1.2 Geometry Uncertainties in Irradiation and Counting

A basic requirement for accurate NAA is the correct characterization of the irradiation facility (Becker 1987). Local and temporal neutron flux density gradients as well as gradients in the neutron energy spectrum of the irradiation position must be well understood and known for each irradiation. [Figure 30.5](#) illustrates the gradients in an irradiation capsule as measured by flux monitor foils. A difference of 1 mm in sample positioning will result in a 0.6% relative difference in the measured concentration.

It must be noted that this example presents a rather ideal situation since axial rotation of the irradiation capsule during the irradiation eliminates lateral gradients and the central linear gradient allows for elimination of the gradient through 180° inversion of the capsule at the midpoint of irradiation. Other mechanical devices for minimizing flux gradients in sample irradiation positions include rotators (Abugassa et al. 1999) positioned next to the reactor core for large numbers of samples or larger-size samples (Bode et al. 1997; Lin and Henkelmann 2002). An effective means for quality control of the irradiation are flux monitor foils. It is highly recommended to use these with each irradiation of samples and standards to verify the assumptions about the accurate irradiation geometry. Foils or wires of metals such as titanium, cobalt, zinc, copper, etc., or Al–Au alloy wires can be used for this purpose.

■ Fig. 30.5

Flux gradient within an irradiation capsule in the NIST CNR reactor RT-4 pneumatic tube irradiation facility (mean flux: $3.4 \times 10^{13} \text{ cm}^{-2} \text{ s}^{-1}$). The vertical axis was determined using Zn foils as monitors, where values are percent Zn found when compared to a foil in position 0 cm. The essentially linear drop-off in neutron flux between positions 20 mm and 60 mm provides a roughly even effective flux (see upper curve) when the capsule is turned halfway around its vertical axis (i.e., by 180°) at the midpoint $t_A/2$ of the irradiation

Uncertainties due to counting geometry can be controlled much more reliably, since in principle only geometry factors must be considered. Extensive references can be found regarding gamma-ray spectrometry of various source shapes (Debertin and Helmer 1988) and software is available for appropriate calculations (e.g., KAYZERO/SOLCOI 1996).

Other uncertainties in the gamma-ray detection yield, unrelated to counting geometry, are matrix effects that can suppress some gamma rays by self-absorption. These effects are gamma-ray energy dependent, and can be mathematically or experimentally corrected.

For narrow collimation, the self-absorption correction factor for a slab of thickness d is obtained by integrating the exponential attenuation function:

$$f_T = \frac{1 - e^{-\mu d}}{\mu d}. \quad (30.43)$$

Calculations according to [Eq. \(30.43\)](#) require the knowledge of the photon attenuation coefficients μ of the sample matrix (see [Sect. 11.5.1 in the Appendix of Vol. 1](#)). Experimental calibrations are readily conducted by placing an unirradiated sample between the activated sample and the detector, thus determining the attenuation coefficients for an unknown or unlisted matrix. By using an irradiated standard identical to the sample, as is possible in the comparator method, the need for geometry, self-shielding, and self-absorption corrections is eliminated, and thus the potential errors are reduced.

30.6.1.3 Timing Uncertainties

An accurate time base is essential for the accurate calculation of decay factors for different counting and decay times during the measurement. For the determination of indicator nuclides with less than 300 s half-life, an order of 0.1 s or even 0.01 s timing resolution may become crucial. The recording of real time and live time of a count with this precision is standard in many modern MCA systems. Unfortunately, some “advances” in computer operating systems, e.g., the user-friendly Windows surfaces, do not guarantee the immediate implementation of a MCA command. The range of differences in reading time tags and implementing, e.g., the start of acquisition, has caused manufacturers of PC-based MCAs to report only full seconds for the start of acquisition, a significant source of uncertainty when measuring fluorine using ^{19}Ne with $T_{1/2} = 17.22$ s.

More important to consider are uncertainties in the published half-life of the indicator nuclides. Determinations that rely on experiments with significantly different irradiation and counting times, as well as decay times, are too susceptible to uncertainties in the published values and may require a re-evaluation of the indicator nuclide’s half-life to assure accuracy (Greenberg et al. 2000; Lindstrom et al. 2007). Other methods of minimizing this type of uncertainty are of course irradiation and counting procedures that are exactly the same throughout a measurement cycle.

30.6.1.4 Uncertainties in Signal Detection and Processing

Relevant mechanisms that cause loss of counts from the photopeak include partial conversions of the incident energy event with part of the energy escaping the detector, true coincidence summing, random summing of pulses, also known as pile-up, and dead time. While the first two effects are part of the detector’s efficiency and are the same for all sample and standard counts, random summing and dead time are dependent on a sample’s activity.¹⁰

Dead time is the time required in each of the measurement components to process a single event; additional events arriving during this time cannot be processed. All MCAs exhibit counting losses due to the dead time required to process pulses from any given source of radioactivity. Many algorithms, both electronic and computational, are available to determine the amount of time during which those losses occur. When count rates of the sample being measured are practically constant over the counting period, then the standard method for calculating this time is the use of live-time clocks (LTC). The well-proven Gedcke–Hale live-time extension method (Jenkins et al. 1981) is employed in most nuclear spectroscopy systems. The fundamental problem with this method is that changing dead times during the counting will result in measurements during extended live-time periods when the measured activity can be significantly different from the one at the beginning of the counting period. This results in an underestimation of the activity by the LTC method.

The *loss-free counting* (LFC) method of correcting for dead time losses, as introduced by Harms (1967) and improved by Westphal (1981) gives much better results than LTC techniques in cases where the counting rate changes significantly during the measurement. The LFC method estimates the number of counts lost during a dead time interval and adds this number to the channel of the just processed pulse. This dynamic add-on process is capable of presenting a loss-corrected spectrum, but because of this process, the data no longer obey Poisson statistics. Consequently, the calculation of the resulting activity uncertainty is not easy, or not thought to be possible (Pomme et al. 1999).

A different method of loss-free counting has been implemented in the zero dead time method (ZDT) of a commercial digital signal processor. The ZDT correction is dynamically calculated by the processor to produce both the corrected data spectrum and the channel-by-channel variance spectrum. Upp et al. (2001) have shown that this digital method allows correct estimates of the uncertainty.

Recently Westphal and Lemmel (2008) summarized the correction methods and gave a recommended method for calculating the uncertainty.

The *pile-up losses* are corrected by electronic or computational means. Most spectroscopy amplifiers employ a pile-up detection and rejection circuit, which simply blocks further processing of the event and adds the dead time. The aforementioned dead-time correction principles apply. If pile-up events are not rejected, a calibration of the spectrometer for the losses in dependence of the dead time can be used. For more accurate results injection of events from a highly stable pulser provide a measure with the spectral data with the assumption that these events are subject to the same degree of pile-up as the photopeak events.

Summing of events, either a result of coincident emission of gamma rays in the decay chain of the nuclide of interest or of random coincident emissions, can lead to significant losses or potential additions to an otherwise “clean” peak (De Bruin and Blaauw 1992; Becker et al. 1994). While coincidence losses are not an issue for comparator NAA, calibration, and/or computational correction must be applied (Debertin and Helmer 1988; Blaauw and Gelsema 1999) to arrive at “true” peak areas for other methods of calibration.

30.6.1.5 Gamma-Ray Spectrum Evaluation and Software

The tendency toward fully automated gamma-ray spectrum evaluation can introduce errors. The degree of the potential for error varies among the software packages, nevertheless, there are some common risk factors that must be checked and evaluated by the user. These factors lie in

the peak-shape and peak-background functions used and the quality of the calibration of the functions' parameters as well as the quality of the spectrometry system performing within certain bounds of these calibrations. Since these factors are controlled by the user and the working spectroscopy system, it is suggested here that the analyst should evaluate the bounds of uncertainty introduced in this step. The analyst may resort to forms of interactive peak evaluations, including simple summing routines between visually established peak area boundaries (Lindstrom 1994), or apply different software packages to the evaluation of the collected gamma-ray spectra for quality assurance. The IAEA regularly conducts intercomparisons of software packages with respect to statistical performance (Blaauw et al. 1997). Depending on the individual spectrum, the analyst may find no additional uncertainty discernible from the counting statistics to tenths of percent differences for statistically well-defined peaks.

30.6.1.6 Interferences

There are potential interferences in activation analysis that must be considered and corrected for; these include interfering activation reactions and gamma-ray spectral interferences. Several well-known cases for NAA will be discussed; other forms of AA will need an assessment according to each experiment.

A given radionuclide can often be produced in more than one way. If the indicator nuclide used in the analysis is produced from an element other than the analyte, then a *primary interfering reaction* occurs. The magnitude of many of the primary interferences in NAA depends on the fast-to-thermal flux ratios in a reactor. The analytical reaction $^{50}\text{Cr}(n,\gamma)^{51}\text{Cr}$ with thermal neutrons is subject to the interfering reaction $^{54}\text{Fe}(n,\alpha)^{51}\text{Cr}$ with fast neutrons. For this reason, the determination of Cr in the presence of high Fe content can lead to erroneous results without corrective action. In some cases, corrections can be experimentally determined; in other cases the presence of the interfering reaction may preclude the determination of the analyte. The determination of Cr in whole blood suffers from the above interference, where the apparent Cr content can exceed the natural levels. This interference can be minimized by irradiation in a well-thermalized neutron flux (Zeisler and Young 1987). Recently the RNAA determination of silicon via $^{30}\text{Si}(n,\gamma)^{31}\text{Si}$ in biological materials has been successful through the use of a well-thermalized flux in a thermal column to minimize the primary interference from phosphorus (Kucera and Zeisler 2005). A rather ubiquitous primary interference occurs from uranium fission products in geological, environmental, and, sometimes, biological materials. Again, calibration and correction may be possible, but the apparent mass fraction of the interfering elements (^{99}Mo , ^{131}Ba , ^{140}La) is typically equal to or larger than the common levels of the trace elements when uranium is present at those levels.

A *secondary interfering reaction* is the result of interaction of an activation product with the activating particles. An example of this type of reaction is the activation of ^{198}Au produced from gold in a sample. In this case the reaction $^{198}\text{Au}(n,\gamma)^{199}\text{Au}$ directly interferes with the NAA of Pt via ^{199}Au . This interference can prohibit the determination of platinum in the presence of gold (Zeisler and Greenberg 1982; Rietz and Heydorn 1993). Another possibility is that the product particles interact with the element of interest. Activating particles are preferentially produced in higher-energy activation reactions. For example, in the determination of nitrogen by 14 MeV FNAA via $^{14}\text{N}(n,2n)^{13}\text{N}$ in an organic matrix, the fast neutrons scattering on hydrogen induce a flux of protons that results in the interfering reaction

$^{13}\text{C}(\text{p},\text{n})^{13}\text{N}$. In most instances the latter type of interference is not a serious problem since the secondary particle fluxes are relatively low.

Gamma-ray spectral interference means that two radionuclides emit gamma rays with the same or nearly the same energy. For instance, ^{51}Ti and ^{51}Cr formed in thermal neutron activation decay to the same final nuclide ^{51}V , emitting a single 320.08 keV gamma ray. For these two nuclides, however, a separation via the half-life is in all practical instances possible. In some instances a spectral separation is difficult even with the best-resolution detectors when the count rates are high and the peaks get broadened. An illustrative example is interference between the 846.77 keV line of ^{56}Mn ($T_{1/2} = 2.56$ h) and the 843.74 keV line of ^{27}Mg ($T_{1/2} = 9.45$ min). This interference can be resolved through the use of other gamma-ray lines of ^{27}Mg , or by utilizing the different half-lives. In other situations the difference in half-lives may not be very significant or the nuclide of interest has even a somewhat shorter half-life than the interfering nuclide. One well-known case is the interference for the determination of mercury via the 279.19 keV line of ^{203}Hg ($T_{1/2} = 46.6$ days), which is overlapped by the 279.54 keV line of the selenium indicator nuclide ^{75}Se ($T_{1/2} = 119.77$ days). This case can be resolved because ^{75}Se emits several gamma rays and the interference is corrected by measuring the ratio of the interfering photopeak to a “clean” peak. In this instance, the ratio of the 279.54 to 264.66 keV line of ^{75}Se is typically 0.46 and a corresponding number of counts is calculated based on the “clean” peak and subtracted from the combined peak to arrive at the ^{203}Hg peak. It should be mentioned that in complex matrices care must be taken not to have the “clean” peak interfered by another nuclide, in this instance, e.g., by ^{182}Ta . It can be stated that essentially all spectrometric interferences can be resolved by one of the discussed means. Improvement of detector resolution may help in some cases, or anti-coincidence or coincidence counting can either reduce the interfering photopeaks or allows selection of a nuclide’s gamma rays.

When the interference cannot be resolved by the aforementioned means, the option of selecting a different indicator nuclide may lead to a solution, but sometimes a radiochemical separation may become necessary. Radiochemical separations are discussed in [Sect. 30.5](#). (It should be noted that additional uncertainties are encountered with RNAA.) More examples of interferences can be found in the review by Alfassi (2001).

30.6.2 Uncertainty Budget

An uncertainty budget for NAA can be developed on the basis of [Eq. \(30.35\)](#), or for k_0 -INAA by using [Eq. \(30.37\)](#). All parameters are essentially independent, therefore the combined standard uncertainty in C_x can be obtained from the well-known differential expression for the combination of individual uncertainties.¹¹

$$u_{C_{x(\text{unk})}}^2 = \sum_i \left(\frac{\partial C_{x(\text{unk})}}{\partial p_i} \right)^2 u_{p_i}^2 \quad (30.44)$$

where p_i is the i th parameter on the right-hand side of [Eq. \(30.35\)](#) or [Eq. \(30.37\)](#) (some of which are listed in the first column of [Table 30.2](#)) and u is the uncertainty associated with the parameters.

The following example of a high-accuracy INAA determination of Cr in SRM 1152a Stainless Steel illustrates the use of an uncertainty budget and the resulting observation of a satisfactory measurement outcome (Zeisler et al. 2005). The experiment had been designed to

Table 30.2

Uncertainty analysis for SRM 1152a stainless steel

Uncertainty budget					
Parameter (p_i)	Typical value	Standard uncertainty	Type A/B	n	Description
C_s (g/g)	1.0	0.00022	B		Analyte mass fraction contained in primary assay standard
m_x (g)	0.8?	0.00002	A	8	Mass of sample used
m_s (g)	0.8?	0.00002	A	5	Mass of primary standard used
N_x	1.2×10^7	2,710	A	8	Number of counts in indicator gamma-ray peak for sample
N_s	2×10^7	5,859	A	5	Number of counts in indicator gamma-ray peak for standard
λ (d^{-1})	0.0250211	0.0000022	B		Decay constant
$t_{D,x}$ (d)	10	0.00006	B		Decay time until start of measurement for sample
$t_{D,s}$ (d)	10	0.00006	B		Decay time until start of measurement for standard
$t_{C,x}$ (d)	0.16667	1.16×10^{-7}	B		Elapsed time of measurement for sample
$t_{C,s}$ (d)	0.16667	1.16×10^{-7}	B		Elapsed time of measurement for standard
R_θ	1	0 ^a	B		Ratio of isotopic abundances for sample and standard
R_φ	1	0.0087	B		Ratio of neutron fluences (including fluence gradient, neutron self-shielding and scattering)
R_σ	1	0.001	B		Ratio of effective cross sections if neutron spectrum shape differs for sample and standard
R_ϵ	0.9975	0.0025	B		Ratio of counting efficiencies (including geometry, gamma-ray self-shielding and counting effects)
Results					
C_x (g/g)	0.17776				Analyte mass fraction contained in the sample
u_C (g/g)	0.00175				Combined uncertainty
$U(=ku_C)$	0.0035				Expanded uncertainty ($k = 2$)

^aSet to zero because no natural variations have been reported by the IUPAC Commission of Atomic Weights and Isotopic Abundances (Rosman and Taylor 1998); measurement based on ⁵¹Cr decay.

illustrate that uncertainties comparable to those of other methods can be obtained by INAA. As shown in Table 30.2, the certified value for Cr in the SRM is given as 17.76% with an uncertainty of 0.04% (0.23% relative); the measurement resulted in an expanded uncertainty of 0.17% relative. Examination of the budget shows that the largest relative component of

uncertainty was in the ratio of neutron fluxes between sample and standard because the sample could not be cut to a foil with very uniform thickness. The resulting uncertainty in the fluence gradient corrections determined this component of uncertainty. Obviously, more uniform and correctly measurable foil thickness would minimize this problem, and other uncertainty components, such as weighing, may become the more significant and limiting sources of uncertainty.

The ability to formulate uncertainty budgets directly relating to all components of the measurement equation is a tremendous bonus offered by the AA procedures. Analysts can easily obtain estimates for each of the components of uncertainty for each individual sample measurement. This detailed knowledge not only provides realistic estimates of the overall combined uncertainty, but also provides the information needed for a reduction of these uncertainties for a particular measurement problem.

30.6.3 Validation

Practitioners of AA have paid explicit attention to the quality of their analytical output, not only since the new quality culture has become a common staple of an analytical laboratory but practically since the inception of the procedures. The tools for validating the performance of an AA procedure have been and still are determinations in an interlaboratory comparison exercise, comparisons of the procedures' results with those obtained from a different analytical method, and determinations in certified reference materials (CRM) as well as determinations traceable to an accepted standard (e.g., a CRM).

Interlaboratory comparison exercises, by voluntary participation or by mandate from a quality system requirement, will usually give the analyst a sense of the procedures' performance relative to some average or even all results of a measurement. Recent examples range from NAA-only round-robin analyses (Becker 1993) to multi-method comparisons among national metrological laboratories (CCQM 2008).¹² Sometimes z-scores are given to highlight the degree of agreement or disagreement with the defined reference value, e.g., the mean of the data population. Preferentially, this reference value is established by an authoritative measurement laboratory, such as those participating in the CCQM efforts.

The ability to conduct direct comparisons with another analytical method may be limited because of existing capacities within or outside a laboratory, and frequently the special nature of the AA determination in terms of sensitivity or selectivity for the analyte of interest does not allow determinations with another technique. In these instances as well as a general substitute for a comparison on the investigated sample, the AA of a CRM will provide the desired information. Due to the advantages of being relatively matrix- and amount-independent, it is normally not difficult to demonstrate the accurate performance of nuclear analytical techniques. Of course, it must be noted that the user's result will always have a larger uncertainty than the uncertainty stated for the CRM.

Based on the discussed advantages, it is also relatively easy for the users of AA to include the concept of "traceability" in the quality statements on results from the users' laboratory. Traceability is defined in the international vocabulary on metrology (VIM 2007) as "*The property of a result of a measurement or standard whereby it can be related to a stated reference, usually national or international standards, through an unbroken chain of comparisons all having stated uncertainties.*" AA procedures have generally little problem to demonstrate the unbroken chain of comparison (see ► Eq. (30.35)) and can provide a complete uncertainty budget (see ► Sect. 30.6.2).

30.7 Location Sensitive Analysis

Neutron depth profiling (NDP) is a method of near surface analysis for nuclides that undergo neutron-induced charged particle reactions, e.g., (n,α) , (n,p) , with a positive Q -value. NDP combines nuclear physics with atomic physics to provide information about near-surface concentrations of certain light elements. The technique was originally applied in 1972 by Ziegler et al. (1972) and independently by Biersack and Fink (1973). Fink has produced an excellent report giving many explicit details of the method (Fink 1996). NDP is based on measuring the energy loss of the charged particles as they exit the specimen. Depending on the material under study, depths of up to 10 μm can be profiled and depth resolutions of the order of 10 nm can be obtained. The most studied analytes have been boron, lithium, and nitrogen in a variety of matrices, but several other analytes can also be measured. Because the incoming energy of the neutron is negligible and the interaction rate is small, NDP is considered a nondestructive technique. This allows the same volume of sample to receive further treatment for repeated analysis, or be subsequently analyzed using a different technique that might alter or destroy the sample.

30.7.1 Fundamentals of the Technique

Lithium, boron, nitrogen, and a number of other elements have an isotope that upon absorbing a neutron, undergoes an exoergic charged particle emission. In the low energy region, the cross sections are inversely proportional to the speed, i.e., to the square root of the neutron energy. That is, the lower the neutron energy, the greater the reaction rate. The charged particles produced are protons or alpha particles and an associated recoil nucleus. The energy of the particles is determined by the conservation of mass-energy and is predetermined for each reaction (for thermal neutrons, the added energy brought in by the neutron is negligible). As the charged particle exits the material, its interaction with the matrix causes it to lose energy and this energy loss can be measured and used to determine the depth of the originating reaction. Because only a few neutrons undergo interactions as they penetrate the sample, the neutron fluence rate is essentially the same at all depths. The depth corresponding to the measured energy loss is determined by using the characteristic stopping power of the material. The chemical or electrical state of the target atoms has an inconsequential effect on the measured profile in the NDP technique. Only the mass fraction of the major elements in the material is needed to establish the depth scale through the relationship of stopping power.

Mathematically, the relationship between the depth and residual energy can be expressed as

$$x = \int_{E(x)}^{E_0} \frac{dE}{S(E)} \quad (30.45)$$

where x is the path length traveled by the particle through the matrix, E_0 is the initial energy of the particle, $E(x)$ is the energy of the detected particle, and $S(E)$ is the stopping power of the matrix. This expression is equivalent to [Eq. \(30.14\)](#) defining the range r (usually denoted by R) of the particles, i.e., the distance traveled until they are fully stopped in the medium. Examples of the relationship between $S = -dE/dx$ and E are displayed in [Fig. 30.6](#) for $^{10}\text{B}(n,\alpha)$ in silicon and $^{14}\text{N}(n,p)$ in ScN.

For the boron reaction, $^{10}\text{B}(n,\alpha)^7\text{Li}$, there are two outgoing alphas with energies of 1.472 MeV (93% branch) and 1.776 MeV (7% branch), and two corresponding recoil ^7Li

■ Fig. 30.6

Stopping power in units of keV/ μm for alpha particles in silicon and ScN¹³

nuclei with energies of 0.840 and 1.014 MeV. For the nitrogen reaction, $^{14}\text{N}(\text{n,p})^{14}\text{C}$, there is a 584 keV proton and a 42 keV ^{14}C recoil. Particles escaping from the surface of the sample are detected by a silicon surface barrier detector. The charge deposited in the detector is directly proportional to the energy of the incoming particle.

30.7.2 Elemental Detection Limits

The elemental detection limit is directly related to the reaction cross section of the isotope of interest. Only a limited number of elements can be determined by NDP and as a result very few interfering reactions are encountered. Furthermore, since the critical parameters in the technique are nuclear in origin, there is no dependence upon the chemical or optical characteristics of the sample. Consequently, measurements are possible at the outer few atomic layers of a sample or through a rapidly changing composition such as at the interface between insulating and conducting layers, and across chemically distinct interfaces. In contrast, measurement artifacts occur with surface techniques such as secondary ion mass spectrometry (SIMS) and Auger electron spectrometry (AES) when the sample surface becomes charged and the ion yields vary unpredictably. ▶ Table 30.3 lists the major reactions of the NDP method, important parameters and typical detection limits based on a neutron intensity of $6 \times 10^9 \text{ s}^{-1}$ and a 24 h counting interval.

30.7.3 Concentration Determination

To compare concentration profiles among samples, both the charged particle spectrum and the neutron fluence that passes through each sample is monitored and recorded. The area analyzed on a sample is defined by placing an aperture securely against the sample surface. This aperture prevents the charged particle from reaching the detector and can therefore be very thin. Neutron collimation is used to reduce unwanted background, but it does not need to be precise. The

Table 30.3

NDP parameters

Reaction	Abundance (%)	Energy of emitted particles (keV)		Useful range in silicon (μm)	Cross section (b)	Detection limit* (at./cm ²)
³ He(n,p) ³ H	0.00014	572	191	5.7	5,333	1.5 × 10 ¹²
⁶ Li(n,α) ³ H	7.5	2,055	2,727	40	940	9.0 × 10 ¹²
¹⁰ B(n,α) ⁷ Li	19.9	1,472	840	3.8	3,837	2.1 × 10 ¹²
¹⁴ N(n,p) ¹⁴ C	99.6	584	42	5.0	1.83	4.5 × 10 ¹⁵
¹⁷ O(n,α) ¹⁴ C	0.038	1,413	404	3.6	0.24	3.5 × 10 ¹⁶
³³ S(n,α) ³⁰ Si	0.75	3,081	411	11	0.19	6.0 × 10 ¹⁶
³⁵ Cl(n,p) ³⁵ S	75.8	598	17	5.2	0.49	1.7 × 10 ¹⁶

*Detection limit based on 0.1 c/s, 0.1% detector solid angle, and a neutron intensity of 6 × 10⁹ s⁻¹

absolute area defined by the aperture need not be accurately known as long as the counting geometry is constant between samples. The neutron fluence recorded with each analysis is used to normalize data from different samples. In practice, a run-to-run monitor that has a response proportional to the total neutron fluence rate is sufficient to normalize data taken at differing neutron intensities and time intervals. If one of the spectra was obtained using a sample of known isotopic concentration, the true concentration for all the samples can be determined.

30.7.4 Depth Determination

The total sample depth that can be probed using NDP is fixed by both the stopping power of the host material and the energy and charge of the emitted particle. The rate of energy loss for a charged particle is a function of the atomic number of the elements of the matrix, the instantaneous energy of the particle, and its charge.¹⁴ As the charged particle travels through the sample it interacts with the electronic structure of the matrix, which results in incremental losses in the charged particle energy. Ziegler (1977) discusses the physics of stopping power and its calculation in detail. Once the particle emerges from the sample, it is traveling through a vacuum and therefore no longer loses energy until reaching the detector. The detector is typically a surface-barrier detector or other high-resolution charged-particle detector.

The difference between the initial energy of the particle (determined by the neutron reaction kinematics) and its measured energy is equal to the energy loss and, according to ▶ Eq. (30.45), yields the depth of origin. The depth resolution varies from a few nanometers to a few hundred nanometers. ▶ Table 30.3 lists the useful probing depth in a silicon substrate for the tabulated nuclides. For substrates other than silicon the maximum range of analysis will differ. Information from deeper in the sample can sometimes be obtained by carefully etching off a portion of the surface and measuring the area again using NDP. Under optimum conditions the depth resolution for boron in silicon is approximately 8 nm.

Stopping powers for individual elements are given in compilations like that of Ziegler (1977). For compounds such as LiNbO₃, stopping powers are closely approximated by using Bragg's law of addition of the stopping power of individual elements. Because the analytical results are obtained in units of areal number density (atoms/cm²), a linear depth scale can be assigned only if the volume number density (atoms/cm³) of the material remains constant and

is known. Consequently, the conversion of an energy loss scale to a linear depth axis is only as accurate as the knowledge of the volume number density. By supplying a few physical parameters, customized computer programs are used to convert the charged particle spectrum to a depth profile in units of concentration and depth. A Monte Carlo program, SRIM (Ziegler et al. 2008), can also be used to provide stopping power and range information. Even if the density is not well known, mass percent concentration profiles can be accurately determined even through layered materials of different density. In many cases, it is the mass percent composition that is the information desired from the analysis.

30.7.5 Sources of Uncertainty

As is the case in all measurements, the uncertainties from NDP can be divided into Type A (statistical) and Type B (all other). The Type A terms are dependent mostly on the concentration and the neutron cross section of the analyte. While the statistical precision can always be improved by increasing the irradiation time, there are some practical limits. Beam time is in high demand and rarely more than a day can be devoted to a single sample, with 1 h being more typical. There is always some background present and the background subtraction increases the statistical uncertainty. For typical samples of boron in semiconductor materials, the Type A uncertainty is usually about 1% at 1 σ confidence level.

Type B uncertainties are more sample dependent and therefore more difficult to generalize. All samples will have an uncertainty due to the uncertainties of the stopping power of the matrix elements. If the exact composition of the matrix is unknown, this will amplify the uncertainty. Stopping powers are most accurately described in terms of energy loss per atom/cm² of stopping material.¹⁵ To convert to energy loss per linear depth the density of the matrix must be known. The linear depth uncertainty will be proportional to the uncertainty of the density. At all depths, the energy of the outgoing particles will have dispersion due to the energy straggling and this dispersion will be greater as the depth increases. Additional smaller uncertainties derive from such details as the reproducibility of the sample and counter geometry, inscatter and outscatter of the outgoing particle, and accuracy of the energy calibration of the detector. Type B uncertainties are typically of the order of 2% (1 σ). The quadratic sum of Type A and Type B uncertainties yields therefore a resultant uncertainty of the order of 2.5% (1 σ) and in more optimum cases of the order of 2% (1 σ). Interpretation of NDP charged-particle spectra is not always single valued. It is important to obtain as much knowledge about the sample as practical to simplify the analysis and reduce ambiguity. This includes information about lateral variations in surface roughness, which would be averaged within the beam spot of an NDP analysis.

When determining an NDP profile, it should be remembered that only the isotopic concentration is actually determined and that the elemental profile is inferred. While natural isotopic abundances are usually present, anthropogenic activities can severely distort isotopic ratios, especially for boron and lithium. Natural processes can also perturb isotopic proportion, however this is both rare and small in magnitude. Materials prepared by ion implantation will be isotopically different from natural materials. ¹¹B is more abundant (80.1%) and consequently more economical to implant than ¹⁰B. As a result, boron-implanted samples must be especially prepared for NDP analysis. ⁶Li is less abundant in nature and historically has been separated from natural lithium for nuclear applications. This provided a relatively inexpensive source of ⁶Li-depleted, i.e., purified, lithium available for chemical applications.

This not only invalidated simple assumptions for calculating total lithium abundance but also significantly changed the atomic weight of lithium for gravimetric chemical procedures.

30.8 Editors' Notes

1. See [Fig. 3.10 \(left diagram\)](#) in [Chap. 3](#), Vol. 1, on “Nuclear Reactions.” The diagram also shows the “ $1/\nu$ ” law mentioned that appears as a sloping line in the log–log presentation (p. 1557).
2. See [Eq. \(50.33\)](#) as well as [Chap. 50](#), Vol. 5, on “Particle Accelerators” (p. 1558).
3. See more about stopping power in [Chap. 8](#), Vol. 1, on “Interaction of Radiation with Matter,” starting with [Eq. \(8.1\)](#) (p. 1558).
4. The range is normally denoted by R ; however, it has been changed to r , which cannot be confused with the reaction rate (p. 1558).
5. The “macroscopic cross section” is an analogous quantity to the “linear attenuation coefficient” that is used in the exponent of the “Beer–Lambert law” describing the attenuation of γ radiation (p. 1559).
6. The Q value often mentioned in this chapter is a dimensionless number. It is not to be mixed with the Q value of nuclear reactions, which has energy dimension (p. 1579).
7. See more about radiochemical separations in [Chaps. 52](#) and [53](#), Vol. 5, on “Solvent Extraction and Ion Exchange in Radiochemistry” and “Radiochemical Separations by Thermochromatography,” respectively (p. 1584).
8. The separation techniques described in [Chaps. 52](#) and [53](#) of Vol. 5 are really fast. Fast separation is also a crucial requirement for the identification of transuranic/transactinide and superheavy elements as discussed in [Chaps. 18–21](#) of Vol. 2 (p. 1585).
9. HDEHP is di(2-ethylhexyl)orthophosphoric acid. It is used in SISAK equipment, e.g., for the identification of ^{243}Np and ^{244}Np . See [Fig. 18.10](#) in [Chap. 18](#), Vol. 2, on “Production and Chemistry of Transuranium Elements” (p. 1588).
10. The term “photopeak” means the same as the “full-energy peak” used in [Chap. 48](#), Vol. 5, on “Radiation Detection.” The reason for the longer expression is that in a voluminous detector the photopeak is not necessarily connected with a single photoelectric effect. It can also be the result of a sequence of Compton scatterings etc. within the sensitive volume (p. 1602).
11. See [Eq. \(9.58\)](#) in [Chap. 9](#), Vol. 1, on “Stochastics and Nuclear Measurements” (p. 1605).
12. For the benefit of those who are not familiar with American idioms it should be mentioned that the adjective “round-robin” means here that the analysis is done on samples taken from the same material sent to different NAA labs (p. 1607).
13. Although the dimensions are different, the peculiar shapes of the curves can be traced back to that of the Bragg curve shown in [Fig. 8.5](#) of [Chap. 8](#), Vol. 1, on “Interaction of Radiation with Matter” (p. 1609).
14. As regards the rate of energy loss of charged particles and its dependence on different parameters see, e.g., [Eqs. \(8.1\)](#) and [\(8.3\)](#) in [Chap. 8](#), Vol. 1, on “Interaction of Radiation with Matter” (p. 1610).
15. Regular (mass) surface density (in g cm^{-2}) gives essentially the same accuracy as a real number density (in atoms/cm^2). This is why the stopping power expressions in [Chap. 8](#), Vol. 1, contain x as a measure of sample thickness in surface density units (e.g., in g/cm^2) rather than a linear distance (in cm) (p. 1611).

Acknowledgments

The authors wish to thank Donna O'Kelly, NIST Analytical Chemistry Division, and David F. R. Mildner, NIST Center for Neutron Research, for their critical reading of the manuscript and valuable suggestions.

31 Neutron-Induced Prompt Gamma Activation Analysis (PGAA)

Z. Révay¹ · R. M. Lindstrom² · E. A. Mackey² · T. Belgya¹

¹Hungarian Academy of Sciences, Budapest, Hungary

²National Institute of Standards and Technology, Gaithersburg, MD, USA

31.1	<i>Introduction</i>	1621
31.2	<i>Fundamentals of Prompt Gamma Activation Analysis</i>	1622
31.2.1	Fundamental Processes	1622
31.2.2	Activation Equations	1623
31.2.2.1	Thin Sample Approximation	1623
31.2.2.2	“Black” Sample Approximation	1624
31.3	<i>Characteristics of PGAA</i>	1625
31.3.1	Analytical Properties	1625
31.3.2	Characterization of Prompt Gamma Spectra	1626
31.3.3	Dynamic Range and Detection Limit	1627
31.4	<i>Neutron Beams and PGAA Facilities</i>	1628
31.4.1	Neutron Beams	1628
31.4.2	Neutron Sources	1628
31.4.3	Shaping and Tailoring Neutron Beams	1631
31.4.4	Neutron Absorbers and Shielding Materials	1632
31.4.5	Neutron Shutter, Beam Tube, Sample Holder, and Beam Stop	1633
31.4.6	Characterization and Monitoring the Neutron Beam	1634
31.4.7	PGAA Facilities	1635
31.5	<i>Samples and Standards</i>	1635
31.5.1	Sample Size and Shape	1635
31.5.2	Standardization	1636
31.6	<i>High-Energy Gamma-Ray Spectroscopy</i>	1637
31.6.1	Fundamental Processes	1637
31.6.2	Instrumentation	1638
31.6.2.1	Detector Selection	1638
31.6.2.2	Electronics and Its Characteristics	1639
31.6.2.3	Response Function of Germanium Detectors	1640
31.6.3	Calibration Procedures	1642
31.6.3.1	Energy Resolution	1642

31.6.3.2	System Nonlinearity	1643
31.6.3.3	Detector Efficiency	1644
31.6.3.4	Determination of Spectral Background	1647
31.6.4	Compton-Suppressed Spectrometers	1648
31.6.5	Other Sophisticated Detection Solutions	1649
31.6.5.1	Composite Germanium Detectors	1649
31.6.5.2	Coincidence Techniques	1650
31.6.5.3	Chopped-Beam PGAA	1650
31.7	<i>Spectrum Evaluation</i>	1650

Abstract: This section presents the principles, the practical aspects, and the applications of neutron-induced prompt gamma activation analysis (PGAA). The fundamentals of the method, the characteristics of the analytical technique, and the instrumentation are introduced. The measurements of samples and standards together with the procedures of the quantitative analysis are described. High-energy gamma-ray spectroscopy, enabling reliable chemical analyses, is discussed in detail. A comprehensive section of the most recent applications of the PGAA method is also given.

31.1 Introduction

While investigating the capture reaction of neutrons in hydrogenous materials, the emission of a highly penetrating gamma radiation had already been observed in 1934 (Lea 1934). This was the first prompt gamma radiation ever detected. Now it is known as the prompt gamma ray of 2,223.2487 keV energy from the reaction $H(n,\gamma)^2H$.

Whenever a nucleus absorbs a neutron, its binding energy is released in the form of the so-called prompt gamma radiation. If the product nuclide is stable, the process ends here. If it is radioactive, then it decays away while emitting typically a beta particle, mostly followed by gamma rays, too. Both types of gamma radiation are characteristic of the capturing nucleus, and thus are suitable for elemental analysis. Neutron activation analysis is based on the detection of the decay-gamma radiation (see [Chap. 30 in this Volume](#)), while prompt gamma activation analysis (PGAA) utilizes both, but mainly the prompt radiation.

Both activation analytical techniques require powerful neutron sources. The first reactor-based PGAA measurement was performed by Isenhour and Morrison in 1966 (1966a, b) using a chopped neutron beam from a reactor and detecting the gamma rays with a NaI(Tl) detector. In the late 1960s, a major breakthrough was the introduction of semiconductor detectors, whose energy resolution was more than an order of magnitude better than that of the best scintillators. The performance of the PGAA technique has further increased thanks to the new Ge(Li)–NaI(Tl) Compton-suppressed systems (Orphan and Rasmussen 1967). Neutron guides at research reactors were also introduced to this analytical method: first at the Saclay reactor in 1969 (Comar et al. 1969a, b), and then at the high-flux reactor in Grenoble (Henkelmann and Born 1973), while several facilities have been established at collimated reactor beams (Molnár 2004). The application of the PGAA method has increased thanks to the availability of high-flux thermal and cold beams during the 1990s at National Institute of Standards and Technology (NIST), USA (Lindstrom et al. 1993), at Jülich Research Center, Germany (Rossbach 1991), at Japanese Atomic Energy Research Center (JAERI), Japan (Yonezawa et al. 1993) and at the Budapest Neutron Center, Hungary (Molnár et al. 1997). Several other systems have been put into operation since then.

One of the reasons that PGAA was held back from common use was the lack of a proper analytical database. The first systematic series of measurements of capture-gamma spectra for 75 elements was performed by a group at Massachusetts Institute of Technology (MIT) at the end of the 1960s (Orphan et al. 1970; Rasmussen et al. 1969). The best-known compilation of these data was published by Lone et al. (1981). The “Lone table” and its electronic version have been the only source of spectroscopic data for scientists working in the field of PGAA for more than 20 years. The first complete catalog of prompt gamma lines appeared only in 2004 based on the measurements at the Budapest Research Reactor by Révay et al. (Molnár 2004).

31.2 Fundamentals of Prompt Gamma Activation Analysis

31.2.1 Fundamental Processes

Neutrons are elastically or inelastically scattered, or absorbed when they interact with matter. The most essential reaction induced by neutrons in matter is *radiative neutron capture*, or the **(n,γ) reaction** (see [▶ Chap. 30 in this Volume](#)). Prompt gamma radiation is emitted by the excited nuclei after the capture, releasing the binding energy of the neutron (typically 6–9 MeV) within 10^{-14} s. If radioactive isotopes are produced, delayed gamma radiation can also be detected with energies up to 2–3 MeV. Decay gamma radiation from short-lived nuclides can also be observed in prompt gamma measurements.

Other important competing reactions that can occur in samples, are the neutron-induced emission of charged particles, specifically (n,p), (n,α) reactions, and fission, noted as (n,f) reaction (Molnár 2004). The most important cases are the following:

- (n,p) reactions on: ^3He and ^{14}N
- (n,α) reactions on: ^6Li and ^{10}B
- (n,f) reaction on: ^{235}U

Light nuclides have weak (n,γ) branching, while their charged-particle emission branch is much stronger. In the case of ^{10}B , the emission of the alpha particle is followed by the emission of a gamma ray from the residual ^7Li nucleus with the energy of 478 keV. Because of the recoil of the nucleus, the spectrum peak is characteristically broadened over an energy range of about 15 keV. This strong peak makes possible the unambiguous identification of *boron*.

In the case of fissile nuclides, fission can be the dominant reaction. From among the naturally occurring nuclides, it is ^{235}U whose fission cross section is significant— 583 barn— while the capture cross section is 98 barn. During fission, energy of about 15 MeV is released in the form of gamma radiation, which is more than in the case of neutron capture, for which the binding energy is 6.395 MeV. This action results in a characteristic shape of the spectrum with a much steeper low-energy trend, compared to a spectrum from (n,γ) reactions only.

For bulk samples, elastic scattering of the neutrons before the capture reaction may also play an important role, lengthening the path of the neutrons inside the target. The energy distribution of the neutrons may also be modified by elastic scattering especially in the case of hydrogenous materials.

The neutron-capture cross section of the (n,γ), (n,p), and (n,α) reactions typically follow the **1/v law** for low neutron energy. For these *regular nuclides*, the cross section can be described using the following expressions:

$$\sigma(v) = \sigma_0 \frac{v_0}{v} \quad \sigma(E) = \sigma_0 \sqrt{\frac{E_0}{E}} \quad \sigma(\lambda) = \sigma_0 \frac{\lambda}{\lambda_0} \quad (31.1)$$

where σ_0 is the thermal cross section, $v_0 = 2,200 \text{ m s}^{-1}$, $E_0 = 25.26 \text{ meV}$, $\lambda_0 = 1.80 \text{ Å}$. In the cold energy range (below 10 meV) all nuclides are regular. The 1/v dependence continues until the first resonance (if any). Most resonances appear in the eV – keV neutron kinetic energy range. In some cases, the lowest energy resonances partly overlap with the thermal region (^{113}Cd , ^{149}Sm , etc.), resulting in an increase of the capture cross section. These *irregular nuclides* will have an increased reaction rate in thermal beams relative to the regular ones. This discrepancy can be corrected with the so-called Westcott g factor (Westcott 1955).

31.2.2 Activation Equations

In PGAA, one is interested in the correlation of the characteristic spectral peak areas and the masses of the emitting components. The calculation here is simpler, for many reasons, than in neutron activation analysis (NAA):

- In PGAA, the activation takes place in an almost parallel beam instead of an isotropic neutron field. Thus, the attenuation of neutrons can be calculated in a simpler way.
- The spectrum peaks from prompt gamma radiation are acquired only during the activation; hence, peak areas do not need to be corrected for decay.
- Many neutron beams contain only a small amount of epithermal and fast neutrons, and thus any reaction induced by them can normally be neglected.

The simplest equation for the reaction rate produced by a parallel beam of monochromatic neutrons in an ideally thin and homogeneous sample can be written as follows:

$$R = n \sigma \Phi \quad (31.2)$$

where R is the reaction rate (s^{-1}), n is the number of atoms of the examined nuclide in the neutron beam, σ is the cross section for neutron capture at the given energy (cm^2), and Φ is the neutron flux ($\text{cm}^{-2} \text{s}^{-1}$). For the characterization of a given gamma ray, the so-called partial gamma-ray production cross section is used:

$$\sigma_\gamma = \theta \sigma P_\gamma \quad (31.3)$$

where θ is the natural abundance of the given isotope in the element of interest, σ is the isotopic capture cross section, and P_γ is the emission probability of the gamma ray with the given energy and gives the fraction of the emitted gamma photons per capture. The count rate of a peak at a given energy in the gamma spectrum can be written as

$$\rho_\gamma = \varepsilon(E_\gamma) n \sigma_\gamma \Phi = \varepsilon(E_\gamma) \frac{m}{M} N_A \sigma_\gamma \Phi \quad (31.4)$$

where ρ_γ is the count rate, i.e., the net peak area divided by the measuring time (live time of the counting system) and $\varepsilon(E_\gamma)$ is the counting efficiency of the detector (see later), m is the mass of the element, M is its atomic weight, and N_A is the Avogadro constant.

In many practical cases, the neutrons follow an energy distribution, the cross section is energy-dependent, the sample may not be regarded as ideally thin, and thus the modification of the neutron field and the attenuation of gamma rays within the sample must also be taken into account. Instead of considering all these effects, simplifying assumptions may be introduced. Let us examine two limiting cases in more detail, which can be approximated in reality quite well (Molnár 2004).

31.2.2.1 Thin Sample Approximation

When irradiating a homogeneous and thin sample, the gamma-ray self-absorption, neutron self-shielding, as well as other effects, modifying the counting efficiency and the variation of the internal flux inside the sample can be neglected. Thus the reaction rate, as shown in

► Chap. 30 in Vol. 3, depends on the integral of the product of the partial cross section and the neutron flux. For a regular nuclide (i.e., whose cross section follows the $1/v$ law), this integral can be replaced with the product of two average quantities:

$$\int_0^{\infty} \sigma_{\gamma}(E_n) \Phi(E_n) dE_n = \sigma_{\gamma 0} \Phi_0 \quad (31.5)$$

where $\sigma_{\gamma 0}$ is the partial gamma-ray production cross section measured with monochromatic neutrons having the speed of $v_0 = 2,200 \text{ m s}^{-1}$, which equals the cross section determined in a neutron beam having a thermal distribution with the temperature of 293 K, and Φ_0 (sometimes written as Φ_{th}) is the *thermal equivalent neutron flux*:

$$\Phi_0 = \frac{v_0}{\langle v \rangle} \Phi_r \quad (31.6)$$

where Φ_r is the real flux, i.e., the actual number of neutrons reaching a unit surface of the sample in a second. When activating in a cold neutron beam, the reaction rate becomes higher due to the increase of the cross section, which is inversely proportional to the average speed. In PGAA, however, the use of thermal cross sections is preferred for their conceptual simplicity. The speed dependence is taken into account by using the thermal equivalent flux, which is inversely proportional to the average speed. (As can be seen from ► Eq. (31.1), it is also inversely proportional to the square root of the average energy and is proportional to the average wavelength.) Using Φ_0 , the reaction rate expressions become similar to ► Eqs. (31.2) and ► (31.4):

$$R^0 = n \sigma_0 \Phi_0 \quad \rho_{\gamma}^0 = \frac{m}{M} N_A \sigma_{\gamma 0} \Phi_0 \varepsilon(E_{\gamma}) \quad (31.7)$$

It should be mentioned that in this approximation, the count rate depends only on the mass of the component in the beam, and it does not depend on the sample shape, or even the surface area facing the beam (Molnár 2004).

31.2.2.2 “Black” Sample Approximation

In the other limiting case, one of the major components has an extremely large capture cross section, so all the neutrons are absorbed close to the surface in the sample, and every neutron generates gamma photons according to the emission probabilities of the capturing nuclide. The observed count rate does not depend on the cross section any more, but it is directly proportional to the number of neutrons, i.e., the real flux multiplied by the emission probability:

$$\rho_{\gamma}^{\infty} = S P_{\gamma} \Phi_r \varepsilon(E_{\gamma}) \quad (31.8)$$

where S is the surface area of the sample facing the beam, P_{γ} is the emission probability, and Φ_r is the real flux. If the real flux of two different beams is the same, the count rate for black samples will be the same, too. Using black samples, the real flux becomes a directly measurable quantity. Comparing it with the thermal equivalent flux based on ► Eqs. (31.6) and ► (31.7) the average speed or wavelength of the beam can be determined (Molnár 2004; Révay 2005).

31.3 Characteristics of PGAA

31.3.1 Analytical Properties

The most important characteristic of PGAA is based on the fact that both the neutrons and the emitted gamma radiation are highly penetrating. For example, an iron plate with a thickness of 1 cm transmits 80% of incident thermal neutrons, and about the same percentage of high-energy prompt gamma radiation. For gamma lines above 100 keV self-absorption is typically of minor significance. PGAA can be regarded as a matrix-independent analytical tool for samples up to a few grams. As the neutrons illuminate the samples throughout their whole thickness, the analysis provides the *average composition* of the illuminated *bulk sample*.

There are a few cases, when a special care has to be taken:

- When the sample contains a nuclide with a high neutron-capture cross section in a high concentration, neutron self-shielding may become important. However, in spectra of homogeneous samples all peak areas will be lowered uniformly by the neutron absorption, leaving the peak-area ratios the same.
- When the irradiated material contains mainly high-*Z* elements, gamma self-absorption may become significant, especially for the low-energy gamma rays. However, above the energy of 2 MeV the attenuation of the gamma rays is almost independent of energy, which again means an approximately uniform decrease of the absolute intensities, i.e., area ratios of high-energy peaks can be used for chemical analysis without correcting for self-absorption.

The analytical result is independent of the chemical state of the elements because the analytical signal originates from the excitation of the nuclei, not the electron shells. Hence, PGAA can be used for multi-elemental *panorama analysis* without any prior information on the sample.

Since neutron and gamma fields cannot be separated, as is done in NAA, a more complex shielding is needed in this technique. This requires more construction material in the vicinity of the detector, thus increasing the spectral background induced by the scattered neutrons in these materials. (See later.)

PGAA is *nondestructive* in several ways:

- No sample preparation is necessary.
- The irradiation does not change the elemental composition of the sample. (The converted nuclei are mostly stable isotopes of the same element, and their number is at least ten orders of magnitude less than for the atoms in the sample.)

The radiation damage in the sample caused by the neutrons and gamma rays is normally negligible. If, however, charged-particle emission is induced by the neutrons, the material may undergo minor radiation damage, resulting in modifications in the chemical or crystal structure followed by discolorations. This effect may be remarkable when irradiating lithium-, boron- or nitrogen-containing samples.

Usually, the only problem requiring attention is the formation of *radioactive isotopes*. In the worst case, samples must be cooled for a few weeks until their radiation reaches the background level.

Special care must be taken, when *fissile material* is analyzed. From the gamma radiation of the original material its previous irradiation history can be determined, and this may be distorted by exposure to neutrons.

Every chemical element (except ^4He) can be analyzed with PGAA. However the neutron capture cross sections vary by eight orders of magnitude (from O: 0.00019 barn to Gd: 48,800 barn). Thanks to this fact that high-cross section elements can be determined in low-cross section matrices with high sensitivity.

The main power of the method is the analysis of *light elements* (i.e., Ca and below). Their capture cross sections are characteristically a few tenths of a barn, which allows their assay even in weak neutron beams (e.g., the industrial analysis of raw materials using neutron generators). The most important of them is hydrogen, which can be analyzed with a fairly good sensitivity in almost any kind of matrix. PGAA is a unique tool for the determination of hydrogen or water content even in trace amounts.

In NAA, the samples are irradiated in an isotropic neutron field, and the induced decay gamma radiation can be detected even in contact geometry. In PGAA, neutron beams are used for activation (10^{-4} to 10^{-5} times weaker than the activation in reactor cores), and the detector cannot be placed too close to the sample (10^{-2} to 10^{-3} maximum efficiency). On the other hand, only a fraction of the total number of decay events takes place during the counting in NAA, decreasing the sensitivity of the method by a factor of 10^{-1} to 10^{-3} (Isenhour and Morrison 1966b), while in PGAA all prompt gamma photons can be detected with the above mentioned efficiency. All these effects result in analytical sensitivities of PGAA being lower by a factor of usually 10^{-4} to 10^{-6} compared to NAA. This deficiency can partly be overcome by using longer irradiations and larger samples. This fact, however, predestines PGAA to be primarily a major-component analytical technique (Molnár 2004).

31.3.2 Characterization of Prompt Gamma Spectra

The highest-energy prompt gamma lines are close to 12 MeV, unlike decay lines, which are mostly below 3 MeV. Thus, the energy range of prompt gamma spectra is much wider than that used in NAA. Prompt gamma spectra usually contain several hundred peaks. The largest fraction of the counts appears in the spectral background, not in characteristic peaks.

The complexity of prompt gamma spectra depends on the nuclear level structure of the emitting nuclide. There are two major types of spectra:

1. The lightest nuclides have no energy levels below their capture states; thus, only one prompt gamma peak appears in their spectra corresponding to the transition from the capture state to the ground state (^2H , ^3H , and ^4He product nuclides). The other light nuclides have a couple of levels below their capture states, so besides the direct transitions only a few others appear in the spectra (^7Li , ^8Li , ^{13}C , ^{17}O). These spectra consist of strong prompt gamma lines (the emission probabilities are greater than 10%). The lower energy lines always sit on the Compton plateau caused by the higher-energy lines resulting in an increasing baseline toward low energies.
2. For the heavy elements another spectrum shape is typical because of the large number of possible transitions in the nuclei. The large number of overlapping peaks forms an almost smooth continuum in the mid-energy range and continuously rising with the decreasing energy (the most typical examples are Eu, Tb, and Ir). Identifiable prompt gamma peaks appear only at the low- and high-energy ends of the spectra originating from the primary and the ground-state transitions. The emission probabilities for these lines are typically a few percent only. The basic types of prompt gamma spectra are illustrated schematically in [Fig. 31.1](#).

■ Fig. 31.1

Typical shapes of prompt gamma spectra for the lightest (type 1) and the heaviest nuclides (type 2)

The density of the prompt gamma peaks at the high-energy end is much lower than the density at low gamma energies. Thus, high-energy peaks can be used much more reliably for qualitative analysis. When analyzing multielement samples, one can observe that the upper half of the energy range (6–12 MeV) typically contains peaks from light elements due to the energy dependence of the binding energy (Molnár 2004).

31.3.3 Dynamic Range and Detection Limit

Characteristic peaks always stand on a spectral background originating mainly from the Compton scattering of the higher-energy gamma photons. This Compton continuum usually contains counts that are less by two to three orders of magnitude in each channel than the area of the full-energy peak (FEP) from the gamma ray that generates it. In the case of spectra acquired with high count rates for several hours one can expect a few strong peaks with up to a few million counts, which are standing on a baseline with the height of thousands of counts per channel. In a spectrum like that a peak with the minimum area of a few hundred counts can be detected. In the everyday routine analyses, such high counts are rarely collected, so the area ratio of the strongest and the weakest peaks is typically closer to a thousand. This means that the dynamic range of the prompt gamma spectra, over which the peak areas are detectable, is three to four orders of magnitude.

From these considerations, the detectability of the elements can be estimated. In the case of a sample containing two elements only, the strongest peaks of the minor component can be at least three to four orders of magnitude smaller than those of the dominant component. This is true for the opposite case, too, so the mass ratio of any two elements can vary between six and eight orders of magnitude. For example, 0.1 mg of chlorine can be easily detected in 1 g of water (approximately 0.1 g H), and 0.1 mg of hydrogen (or 1 mg of water) can be analyzed in 0.1 g of carbon tetrachloride (containing 90% chlorine).

In spectra taken on a mixture of elements, the detection limits for components can be estimated efficiently using a few rules of thumb. The efficiency of the detector between 100 keV and 10 MeV drops by two orders of magnitude. Similarly, the minimum detectable peak area varies from a few hundreds of counts at low energies to a few counts at the highest energies. These peak areas corrected with the counting efficiency can be approximated as being constant

all over the spectrum, and that equals the minimum detectable peak area at the maximum of the detector efficiency. For the case of a high-purity germanium (HPGe) detector, the efficiency function has its maximum around 100 keV, and its value equals the geometric efficiency (see later). Based on ► Eq. (31.4), the *detection limit* is the following:

$$DL/g = \frac{A_{\min} M / g \text{ mol}^{-1}}{0.6 \sigma_{\gamma 0} \Phi_0 \varepsilon_{\text{geom}} t_{\max} / \text{mol}^{-1}} \quad (31.9)$$

where A_{\min} is the minimum detectable peak area at 100 keV, M is the atomic weight of the element, 0.6 is the rounded Avogadro constant times 10^{24} (its unit is mol^{-1}), $\sigma_{\gamma 0}$ is the partial gamma-ray production cross section in barns (10^{-24} cm^2), Φ_0 is the thermal equivalent flux ($\text{cm}^{-2} \text{ s}^{-1}$), $\varepsilon_{\text{geom}}$ is the geometric efficiency (the fraction of detected solid angle), and t_{\max} is the maximum possible measurement time (s). For instance, if the minimum detectable peak area is 600 (a typical value) and the collimated detector is at a distance of about 25 cm away from the sample, then the geometric efficiency will be approximately 0.001. If the maximum measurement time is taken 100,000 s (a little longer than 1 day) and the flux $10^8 \text{ cm}^{-2} \text{ s}^{-1}$, then using the above values and a constant with the proper unit, the estimated detection limit in micrograms can be estimated as follows (► Table 31.1; Molnár 2004):

$$DL/\mu\text{g} = \frac{M / g \text{ mol}^{-1}}{10 \sigma_{\gamma 0} / \text{b}} \quad (31.10)$$

31.4 Neutron Beams and PGAA Facilities

31.4.1 Neutron Beams

A PGAA instrument consists of a source of neutrons, a collimating beam tube to shape and direct a beam of neutrons onto a sample, a shutter to turn the beam on and off, a target assembly to position the sample reproducibly in the neutron beam, a gamma-ray detector, a beam stop to absorb the neutrons that are not absorbed by the sample, and shielding to protect the detector and personnel from neutron and gamma radiation. Each of these components will be considered in turn. The construction of a recent system illustrates clearly many of the choices involved (Robinson et al. 2009). More detailed information on the issues can be obtained in the PGAA Handbook (Molnár 2004).

To make the best analytical measurements, the PGAA beam should be both bright and clean. The neutron flux at the sample position should be high enough to obtain good counting statistics for the elements of interest in a reasonable time. Moreover, the beam should be temporally stable, spatially uniform, and contain few epithermal and fast neutrons and gamma rays so as to minimize interfering reactions and background. There should be a permanent scientist in charge of the instrument, which should be accessible to users from outside the host institution. These desiderata follow from the fundamental considerations in the previous sections.

31.4.2 Neutron Sources

The dominant neutron sources in laboratory PGAA are beams extracted from *research reactors*. Other neutron sources, based on radioactive nuclides or neutron generators, commonly used

in industrial applications are discussed in detail elsewhere (Alfassi and Chung 1995). Reactor neutrons originate in fission reactions at high energy, and are slowed to thermal energies by scattering from light atoms in a moderator, typically water or heavy water, surrounding the fuel. The beam is a mixture of three components: a high-energy ($\sim\text{MeV}$) fission source distribution, a near-Maxwellian ($\sim\text{meV}$) thermal spectrum at the moderator temperature, and an epithermal ($\sim\text{eV}$) slowing-down region with a spectrum being approximately inversely proportional to the neutron energy. Because most neutron cross sections are inversely proportional to the neutron speed, the thermal portion is the most effective in producing (n,γ) neutron capture reactions used in PGAA. *Cold neutrons* from a cryogenic moderator are especially desirable, not only because the reaction rate per neutron is several times that of a room-temperature spectrum but also because cold neutrons can be efficiently transported by neutron guides, as will be discussed below.

The flux of neutrons normally is proportional to the inverse square of the distance from the source, so for the greatest analytical sensitivity, the sample irradiation position should be near the reactor. This is also where the gamma-ray and neutron backgrounds are highest, so care in optimizing the shielding is needed for good results. Published fluxes of reactor beams that have been used for PGAA range from $10^5 \text{ cm}^{-2} \text{ s}^{-1}$ to over $10^{10} \text{ cm}^{-2} \text{ s}^{-1}$, although $10^7\text{--}10^8 \text{ cm}^{-2} \text{ s}^{-1}$ is most common.

31.4.3 Shaping and Tailoring Neutron Beams

Thermal neutron beams are produced by geometrical collimation, with absorbing apertures at each end of a long flight path. A collimator does not affect the neutron energy, so the beam at the sample often contains more fast neutrons and gamma rays than desired. To improve this, the beam may pass through a filter that preferentially removes the fast neutron component and also absorbs gamma radiation. For example, 5.3 cm of sapphire in the thermal PGAA beam at NIST reduced the epithermal neutron background fivefold and the low-energy gamma ray background by an order of magnitude (Mackey et al. 2004). A number of different filter materials used in PGAA systems are listed in the PGAA Handbook (Molnár 2004).

Epithermal and fast neutrons can be eliminated entirely by using diffraction to extract a narrow range of wavelengths from the beam (Byun et al. 2002). Several orders of diffraction can be summed to increase the flux. The best beams are those from *neutron guides*, which operate by total internal reflection in a narrow channel. Neutrons incident on a surface at

angles below a characteristic critical angle are totally reflected, removing the $1/r^2$ loss with distance from the source. The critical angle depends on the material comprising the surface, and is inversely proportional to the neutron wavelength; for this reason, the guide acts as a low-pass filter. The critical angle for natural nickel is 0.7° at 6.8 \AA (the most probable wavelength at the normal boiling point of hydrogen, 20 K) and 0.2° at 1.8 \AA (the most probable wavelength at 300 K). Larger critical angles increase by severalfold, and hence greater transmission efficiency (which is proportional to the square of the critical angle) can be obtained with multilayer *supermirror* reflectors. Curved guides are used to avoid direct sight of the neutron source that emits also fast neutrons and gamma radiation. Reflective optical elements can increase the flux by concentrating the beam into a smaller area (Copley and Majkrzak 1989), at the expense of increased divergence. Capillary optics has been used to create a high-flux submillimeter analytical probe (Mildner et al. 2002).

31.4.4 Neutron Absorbers and Shielding Materials

The perfect neutron shielding material does not exist. Ideally, a shield should absorb all neutrons of all energies in a short distance without generating secondary radiation or producing residual radioactivity (Table 31.2). In practice, the most important absorbers are ^6Li , ^{10}B , and ^{113}Cd , via the (n,α) and (n,γ) reactions. Only ^6Li (and ^3He) absorb neutrons efficiently without producing gamma rays. Although metallic Cd is easily shaped and an excellent absorber, neutron irradiation produces substantial residual radioactivity in addition to the strong prompt 559-keV capture gamma rays, so B and Li are preferred for high-flux tasks such as shutters and beam stops.

Boron has a high cross section and most of the 2.8-MeV reaction energy from neutron capture is carried by an alpha particle and ^7Li recoil nucleus. However, 94% of absorbed neutrons produce a gamma ray of 478 keV. This energy is readily shielded, requiring only 4 mm of lead to reduce the radiation by half. With lithium, there is no gamma ray from the $^6\text{Li}(n,t)^4\text{He}$ reaction, but the high-energy tritons produce about 10^{-4} energetic secondary neutrons per incident neutron from light elements by (t,n) reactions (Lone et al. 1980). If the

Table 31.2

Characteristics of neutron-absorbing materials

Nuclide	Isotopic abundance, %	Cross section, b	Reaction	Product half-life and decay	Chemical forms
^3He	0.00014	5,330	$(n,p)^3\text{H}$	12 years, β^-	Gas
^6Li	7.5	941	$(n,\alpha)^3\text{H}$	12 years, β^-	LiF , Li_2CO_3 , metal, glass
^{10}B	19.9	3,838	$(n,\alpha)^7\text{Li}$	Stable	B_4C , H_3BO_3 , $\text{Na}_2\text{B}_4\text{O}_7$
^{113}Cd	12.22	20,600	$(n,\gamma)^{114}\text{Cd}$	Stable	Metal
^{114}Cd	28.73	0.23	$(n,\gamma)^{115}\text{Cd}$	53 h, β^-,γ	
^{155}Gd	14.8	60,900	$(n,\gamma)^{156}\text{Gd}$	Stable	Metal
^{157}Gd	15.6	255,000	$(n,\gamma)^{158}\text{Gd}$	Stable	
^{160}Gd	21.7	1.51	$(n,\gamma)^{161}\text{Gd}$	3.7 min, β^-,γ	

flux is high, the tritium produced may be hazardous. Isotopically enriched ^6Li and ^{10}B are sometimes used; 100% enrichment improves the stopping power over natural Li and B by a factor of 13 or 5, respectively.

Lithium carbonate and fluoride are inert and can be shaped into machinable forms. A ^6Li silicate glass (Stone et al. 1994) has been used with success for collimators, beam stops, and shielding. Both carbonate and the fluoride have been mixed with polymers or paraffin to make castable (Anderson et al. 1981) or flexible neutron absorbers, but hydrogen capture gamma rays from the organic matrix can be excessive for use in the field of view of the gamma detector. The collimating aperture near the neutron source is commonly fabricated from Boral, a mixture of boron carbide and aluminum powder rolled into sheets and clad with aluminum. Where secondary radiation is of no concern (for instance shielding a detector from the last few neutrons), sheets of cadmium or boron-loaded polymer are often used. For large parts of the apparatus and for personnel protection, massive concrete in either poured or block form is cost-effective for both gamma-ray shielding and neutron shielding.

31.4.5 Neutron Shutter, Beam Tube, Sample Holder, and Beam Stop

It is necessary to shut the neutron beam off in order to change samples. Like the first collimating aperture, the shutter is best located close to the neutron source and surrounded by shielding, so as to minimize stray radiation at the sample position. Thermal neutron shutters are commonly made of thick boron- or lithium-containing materials, supplemented by thermalizing material or epithermal absorbers.

Neutrons are lost from the beam by scattering in air in the flight path: in passing through 1 m of air, about 5% of the neutrons are scattered into the surroundings. For this reason, it is desirable to evacuate the beam tube or fill it with helium, especially the portion outside the biological shield of the reactor. Alternatively, the beam tube can be made large in diameter and lined with ^6Li absorber (Mackey et al. 2004).

Ideally, for PGAA the sample should be held in position by a material that neither absorbs nor scatters neutrons. Fluorocarbons such as **Teflon**[™] Tetrafluoroethylene (TFE) or Fluorinated ethylene propylene (FEP) (both with empirical formula CF_2), or Teflon[™] PFA (approximately $\text{C}_4\text{F}_7\text{O}$), are commonly used; in most cases, only fluorine is an important contributor to the blank spectrum. Heat-sealable FEP is available in monofilament fiber or thin film. Thin polyolefin and polyester films are readily heat sealed, but their hydrogen content can be troublesome. Low-mass samples can be suspended in the beam with fluorocarbon strings, which for most purposes add negligible background (Anderson et al. 1981). For more massive samples, a sample holder can be made of any material that does not absorb neutrons strongly or contain the elements of interest. Aluminum, magnesium, vanadium, graphite, quartz, and silicon have been used. The target chamber should be lined with a neutron absorber, preferably ^6Li , to stop the neutrons scattered by the target.

Only a small fraction of the neutrons striking a typical sample are absorbed. The unused neutrons must be disposed of so that they will not endanger the experiment or the experimenters. Like the shutter, an absorber must stop the entire beam for long periods of time. A common configuration contains boron, surrounded by lead or concrete to absorb the 478-keV capture gamma ray and located out of view of the gamma-ray detector. In an unfiltered beam, the gamma rays from the neutron source must be accounted for: this component may be as important as capture in the beam stop itself.

31.4.6 Characterization and Monitoring the Neutron Beam

For reliable analysis, it is necessary to understand the characteristics of the neutron beam, namely its intensity (flux), spectrum, and spatial and temporal uniformity. These issues are discussed at length in the PGAA Handbook (Molnár 2004). *Foil activation* is the simplest, and perhaps the most accurate, method of measuring flux (ASTM 1998; Beckurts and Wirtz 1964). A known mass of a monitor element is irradiated for a known time, and its induced radioactivity measured with a detector of known efficiency. If the reaction rate per atom $R = \Phi\sigma$ is determined, then with the thermal cross section $\sigma = \sigma_0$ measured at $2,200 \text{ m s}^{-1}$ the thermal equivalent flux Φ_0 is obtained. Gold-198 ($T_{1/2} = 2.7$ days) is a convenient indicator nuclide, with the cross section $\sigma_0 = 98.65 \text{ b}$ for the reaction $^{197}\text{Au}(n,\gamma)^{198}\text{Au}$. The epithermal flux is measured by irradiating a monitor bare and another specimen of the same monitor element under a shield of cadmium to absorb the thermal neutrons. Fast-neutron (MeV) monitoring is similar, using threshold reactions that cannot be induced by slow neutrons, such as $^{54}\text{Fe}(n,p)^{54}\text{Mn}$. Spatial mapping can be done quickly by transfer autoradiography. A foil of In, Gd, or other readily activated material is exposed at the sample position and the induced activity detected with an X-ray film or phosphor plate. *Neutron radiography* cameras can also be used for this purpose (Hilger et al. 2006). One of two methods is generally used to measure the time stability of the neutron beam. If the reactor power is known to be stable during an analysis, the capture rate in a known standard (e.g., the 1,381.7 keV peak in a particular specimen of titanium foil) can be measured before and after each sample in order to normalize to separately irradiated standards. If the neutron source is not constant during the irradiation period, the neutron flux must be measured continuously with a neutron monitor during the time the sample is irradiated. This can be done either by measuring scattered neutrons from the beam or with a low-efficiency transmission neutron monitor.

Excellent beam quality and detector shielding can more than compensate for low neutron flux (Maier-Leibnitz 1969; Kobayashi and Kanda 1983; Matsumoto et al. 1984; Molnár et al. 1997). With careful attention to background, the sample-detector distance can be small and thus the gamma efficiency high. As a result, microgram quantities of boron have been determined in tissue with a neutron flux of only $2 \times 10^6 \text{ cm}^{-2} \text{ s}^{-1}$.

Design criteria for the shielding of the gamma-ray detector in PGAA are similar to that for any gamma-ray spectrometer, with some differences due to the presence of neutrons. *Lead* is the most common shielding material for gamma rays, but it is translucent to neutrons. Even though the capture cross section is small, neutrons striking a massive shield will produce the characteristic 7,368 keV lead capture line and its Compton continuum. Reducing thermal neutron background in the detector requires an absorber outside the lead shield. Enriched ^6Li is best in the line of sight between the sample and the detector because it does not produce extra gamma rays, and does not greatly attenuate gamma rays.

The Ge detector itself is the most convenient tool to measure both fast and thermal neutron background rates at the detector (Chung and Chen 1991). The spectrum may show a composite of the sharp 595.9 keV line from capture of slow neutrons in ^{73}Ge and a broad triangular peak from $(n,n'\gamma)$ fast-neutron excitation of the same level of ^{74}Ge . In addition to increasing background, fast neutrons can lead to *detector damage* at a fluence as low as 10^7 cm^{-2} (Chung 1995); n-type germanium is an order of magnitude less sensitive than p-type.

In addition to the quasi-constant background characteristic of the apparatus, a variable background comes from the presence of a sample in the neutron beam. Capture gamma rays from other elements increase the continuum background under the analytical capture peak,

and may also contribute an interfering peak. Neutrons scattered by the sample itself into the apparatus may affect H, B, C, N, F, Al, Fe, Ge, and other elements (Anderson and Mackey 1993).

31.4.7 PGAA Facilities

PGAA has been performed at dozens of research reactors, with varying degrees of success and permanence. Since a comprehensive list was published in 2004 (Molnár 2004), new PGAA instruments have been established in Beijing (Zhang et al. 2005), Forschungreaktor München Research Reactor at Munich (FRM-II) Munich (Kudejova et al. 2008), and Oregon State (Robinson et al. 2009). Systems at Korea Atomic Energy Research Institute (KAERI) Daejeon, (Cho et al. 2005a) Texas (Révay et al. 2007), and Bhabha Atomic Research Center (BARC) Trombay (Acharya 2009) have been upgraded, and a system is under construction in Lisbon (Beasley et al. 2009).

31.5 Samples and Standards

For a given sample material and experimental arrangement, there is an optimum sample size and shape. Samples must be large enough to give a high capture rate for good counting statistics in a reasonable measurement time but small enough to avoid inaccuracies that creep in with high counting rates. In addition, the sample should be small enough that bias from neutron absorption or scattering will be acceptably small. These considerations usually lead preferentially to small samples and long irradiation times. The composition, the experimental conditions, and the required accuracy determine what “small” means in practice.

31.5.1 Sample Size and Shape

Neutron self-shielding (De Soete et al. 1972; Fleming 1982; Martinho et al. 2003) and gamma-ray self-absorption (Debertin and Helmer 1988; Gilmore and Hemingway 1995) are well understood in conventional instrumental neutron activation analysis (INAA) and apply in PGAA as well. As a rule of thumb, if the thickness of the sample multiplied by the macroscopic absorption cross section (the product of element cross section and concentration summed over all components, with dimension cm^{-1}) is less than 0.01, then *self-shielding* will give less than 1% bias in the analytical result. Similarly, if the product of the gamma attenuation coefficient (in $\text{cm}^2 \text{g}^{-1}$) and the mass thickness (in g cm^{-2}) is less than 0.01 then gamma *self-absorption* may be unimportant. Both self-shadowing effects are best avoided by using small samples, usually less than 1 g. However, PGAA can be performed on massive specimens, even larger than the neutron beam. Normalizing to an internal standard such as a matrix element sacrifices one degree of freedom, but need not compromise the measurement when an element ratio or mass fraction is in fact the quantity of interest. The difficult general case of large samples of unknown composition is approachable through a combination of modeling and experiment (Sueki et al. 1996; Degenaar et al. 2004).

The shape of the sample may be important, especially for hydrogenous materials such as polymers and tissues. When a sample is irradiated in a nearly parallel collimated beam of neutrons, the effects of *neutron scattering* in the sample are much greater than in the nearly

isotropic neutron field generally used for irradiations in INAA (Copley and Stone 1989; Mackey and Copley 1993). Scattering by hydrogen affects the path length of the neutrons in the sample, and therefore the probability of absorption. As a result, reaction rate is no longer proportional to the mass of analyte. The greater the scattering power of the sample (the greater the hydrogen content), the greater the bias; for instance, it is as much as 15% for 0.1 g pellets of cellulose (Mackey et al. 1991). For the most accurate work, standards are made to match the shape and hydrogen content. The shape dependence can be reduced or eliminated by making the sample spherical, or nearly so (Mackey and Copley 1993). Scattering of neutrons from the sample also increases the background from capture in the materials of the apparatus (Anderson and Mackey 1993).

31.5.2 Standardization

The simplest situation is a point sample, smaller than the neutron beam and with negligible mass of material to scatter or absorb neutrons or gamma rays. Most applications of reactor-based PGAA approach this ideal. The analytical sensitivity is defined as the counting rate at a certain gamma-ray energy per unit quantity of element under specified standard conditions. If the neutron flux is constant, the geometry of the system is unchanging, and the counting system is stable, the sensitivity is a constant. Two methods are in use to determine the sensitivity: using elemental standards for each element, and using fundamental parameters.

The elemental standard approach is the most straightforward, and the most tedious. A known quantity of the element of interest is irradiated under standard conditions. Standards are best prepared from pure elements or simple compounds known to be stoichiometric (Moody et al. 1988). Usually selected high-purity metals or analytical reagent grade chemicals are adequate, but a useful check is to compare multiple standards from different sources. If a suitable mass of an element cannot be accurately weighed, it may be dissolved in a suitable solvent and evaporated on filter paper. Solid standards can be diluted with an inert material such as high-purity graphite and pressed into pellets. Prepared PGAA standards may be used repeatedly for many years without change. A few exceptions have been noted: e.g., boric acid volatilizes slowly from filter paper although borax does not.

A drawback of this approach is that each element to be determined requires a separate standard. Moreover, if the experimental conditions change, for instance, a new gamma detector is installed, then each standard must be remeasured. A more robust approach is the k_0 standardization method (Molnár et al. 1998), which does not require standard samples.

If element X irradiated simultaneously with a monitor element M, then the flux cancels and the ratio of counting rates per unit mass can be written according to ► Eqs. (31.4) and ◀ (31.5):

$$\frac{\rho_X/m_X}{\rho_M/m_M} = \frac{\sigma_{\gamma,X}/M_X}{\sigma_{\gamma,M}/M_M} \cdot \frac{\varepsilon(E_X)}{\varepsilon(E_M)} = k_0 \frac{\varepsilon(E_X)}{\varepsilon(E_M)} \quad (31.11)$$

where ρ again is the counting rate, m is the mass of the component, M is the atomic weight, and ε is the counting efficiency at the characteristic energies of elements X and M, while k_0 is a constant. Values of k_0 and their uncertainties, relative to the hydrogen capture gamma ray at 2,223 keV, have been tabulated for more than 30,000 capture lines, (Molnár 2004; Choi et al. 2007), and are available at <http://www-nds.iaea.org/pgaa>. For any experimental conditions, to measure any element relative to any other element only the relative detector efficiency needs to

be calibrated. If epithermal capture is important then the equations contain other terms, but the principle is the same. A list of partial gamma-ray production cross sections (σ_γ) can be found in the Appendix of this volume.

Certified reference materials (CRMs), described in the Appendix such as those available from NIST (<http://ts.nist.gov/>), IAEA (<http://www.iaea.org>), BCR (<http://www.irmm.jrc.be>), or other national or international standards bodies, are occasionally used as multielement calibration standards. The chief drawbacks of these materials are the difficulty of selecting an appropriate material for all the elements of interest and the inferior accuracy of certified element content compared with in-house preparations. The most important use of CRMs is to validate the results of a measurement: if the certified value is obtained when a sample is analyzed in the same manner as the unknown, then the measurement is less likely to be in serious error.

As with most nuclear methods of analysis, backgrounds (peaks present in the absence of a sample) are generally small for most elements. A major goal in the design of a PGAA spectrometer is to minimize the spectral background. As with gamma spectrometry in INAA, detection limits and accuracy are impaired by a high baseline under the analyte peak. Unlike INAA, however, capture-gamma spectra contain so many transitions that the baseline can never be certain to be free of interfering peaks. A first-order background correction can be made by subtracting the signal from an empty sample container irradiated in the same manner as the sample.

However, much of the gamma-ray background counting rate is due to neutrons scattered into the apparatus by the sample. Thus, the background depends on the scattering power of the sample. Since hydrogen usually dominates the scattering, the gamma-ray background of components other than H can be estimated from the counts of the H peak. Conversely, the H background in hydrogenous samples can be estimated from the counting rate of other background components such as Al and Pb. A comprehensive listing of background lines and their origins has been published (Belgya et al. 2005).

31.6 High-Energy Gamma-Ray Spectroscopy

31.6.1 Fundamental Processes

The most important part of the PGAA facility is the gamma-ray spectrometer. The main component is the detector, which converts the energy of the gamma ray to an electronic signal. This signal is amplified, shaped, digitized, and stored in a histogram that makes up a spectrum of gamma peaks.

There are three major interactions a gamma photon may undergo in the detector (Knoll 2000):

- In the *photoelectric absorption* process, the gamma photon gives all of its energy to an electron in the detector material. The released high-energy electron creates electron-hole pairs in semiconductors or excited atoms in scintillators.
- In a *Compton scattering*, only a part of the photon energy is transferred to an electron, which then ionizes the material as it slows down, similar to a photoelectron. The Compton-scattered photon left from the scattering may interact again in the detector or may leave it.

- In *pair production*, a high-energy photon creates an electron–positron pair. Both the electron and the positron ionize the atoms of the material. After the positron slows down to thermal energy, it annihilates with an electron, creating most likely two so-called annihilation photons. The two photons have equal energies of 511 keV and fly off in exactly opposite directions. They may have further interactions.

The photoelectric interaction is the most probable process up to a few hundred keV and that is the only interaction that results in a complete absorption of the photon. Compton scattering may occur at all energies, but is the most important between a few hundred keV and a few MeV, while at high energies pair production becomes the most important interaction (see [Fig. 31.4](#)).

Gamma rays deposit their full energy only when the photoelectric absorption is the final step in the sequence of interactions inside the active volume of the detector, thus resulting in the full-energy peak (FEP). In Compton scattering, gamma photons having almost any energy below the initial energy can escape from the detector, causing a continuum (Compton plateau) below the FEP. Compton-scattered or escape events, however, can be identified using a guard detector annulus around the semiconductor detector. In Compton suppression mode of this guarded system the signal of gamma rays, which leave the germanium crystal (see later), are rejected. The most commonly used materials for the guard detector are sodium iodide (NaI) and bismuth germanate (BGO).

31.6.2 Instrumentation

31.6.2.1 Detector Selection

The energy range of prompt gamma radiation extends from a few tens of keV up to 12 MeV. There are two detector types in practice that are able to detect gamma rays over this wide energy range: the solid *scintillation* detector and the germanium semiconductor detector:

- Industrial applications require durable, shock-and vibration-resistant, easy-to-use equipment, which may be operated in a wide range of temperature, humidity, and pressure environments (Johansen and Jackson 2004). These criteria can be better satisfied by scintillation detectors, and such detectors may also be satisfactory for monitoring the composition of nearly identical objects.
- The superior energy resolution of the *high-purity germanium (HPGe) detectors* makes them ideal for high sensitivity analysis of samples having a large variety of compositions (Knoll 2000; Leo 1987).

In this chapter, focus is put on the spectroscopic work with HPGe detectors. There are two types of HPGe crystals; they differ in the donor or acceptor concentration. In the case of n-type detectors, the outer surface is doped with acceptor atoms, typically boron, with a thickness of a few micrometers. They have been shown to have much better resistance against neutron damage than p-type detectors, doped with a thicker layer of acceptor atoms (Knoll 2000). For the measurements of low-energy gamma radiation planar detectors are used, while in PGAA the larger-volume (at least 100 cm³) closed-ended coaxial detectors are preferred (Knoll 2000; Leo 1987) (see [Fig. 31.2](#)). The germanium crystal has to be cooled to liquid nitrogen temperature (77 K) when operated.

■ Fig. 31.2

Schematic shapes of planar and closed-ended types of high-purity germanium (HPGe) detectors. Thick lines show electrode connections

To increase the ratio of the full-energy signal relative to the Compton continuum, the simplest way is to increase the volume of the germanium detector. The suppression, however, is not proportional to the volume as often thought. The peak-to-background ratio improves approximately with the square root of the volume (Heath et al. 1999). There is another serious limitation, too: the width of the active, depleted volume can extend only for about 2–3 cm. The longest crystals commercially available these days are about 9-cm long, which are the best choice for the detection of high-energy gamma rays at present. The efficiency of charge collection of larger detectors is worse than for the smaller ones. Therefore, smaller detectors have better resolutions at low energy; however, at about 1.3 MeV, the difference practically disappears.

31.6.2.2 Electronics and Its Characteristics

Analog electronics. The number of electron–hole pairs produced in the absorption of gamma photons is in the order of hundred thousands. The induced extremely low current has to be amplified before further signal processing. There are two types of *preamplifiers*:

- The Resistive-capacitive feedback (RC-feedback) type produces exponentially decaying signals with decay times of around 50 μs .
- The transistor-reset preamplifiers (TRPs) generate continuously increasing step-like signals, which have to be reset before reaching an upper limiting voltage level. TRPs are supposed to handle high count rates better.

The signal, whose amplitude is carefully maintained to be proportional to the energy of the impinging radiation, is digitized by an analog-to-digital converter (ADC) and the digitized result is sorted in a multichannel analyzer (MCA), then stored in a computer for further analysis. This is the traditional scheme of signal handling.

Digital signal processing (DSP). Digital spectrometers have been available in the market for more than 10 years (Jordanov et al. 1994). The simplest device replaces the spectroscopy amplifier and the ADC. The preamplifier signal enters and digitized data leave the module, which can be directly fed to an MCA. The desktop models integrate the functionality of the high-voltage supply, spectroscopy amplifier, the ADC, and the MCA. The common factor in all of these digital signal processors is that the preamplifier signal is conditioned and a fast sampling ADC digitizes the signal flow in real time. The stream of numbers passes through digital filters, which determines the amplitude and detection time of the signal pulse and the processor generates the corresponding channel numbers for energy or time.

There are two types of digital filters continuously processing the data stream coming from the preamplifier. The filtering process involves the calculation of sums of the digitized data using different weighting factors.

- A fast filter with the total duration of a few hundred nanoseconds is used for the detection of the events, for monitoring pileup, and yields the detection times.
- A slow filter is used to determine the step height of the preamplifier signal, which carries the energy information.

Among other advantages, the DSP manufacturers provide evidence that the temperature and long-term gain stability is much better for the DSP systems than for analog systems. Due to the shorter shaping process, the DSP systems show better high-count rate properties than the analog systems. The throughput and energy resolution also show better characteristics. However, Szentmiklosi et al. (2005) found that in wide energy range applications such as PGAA, there are still problems to be solved.

Dead time and pileup. All detector systems have a certain characteristic time period required to process an event. The detector system may or may not remain sensitive during this period. In the second case, events arriving during this characteristic resolution time will be lost, while in the first case, they may pile up and change the measured value, so generating a count in a different channel, and thus both events will effectively be lost. The time period during which incoming events are lost is called the dead time. To avoid a significant distortion of the number of events occurring, the count rate must be kept sufficiently low. A maximum of a few ten thousand counts per second can be handled by systems available at present. The dead time is influenced by all components of the detector system (Gilmore and Hemingway 1995).

Taking into account the dead time of a detector system is very important when an absolute intensity experiment is performed. All ADCs estimate the dead time, however their accuracy is sometimes questionable. Digital spectrometers are supposed to estimate the dead time accurately, since the time of the signal processing is exactly prescribed.

The simplest way to determine the overall dead time is to measure it using a pulser. The pulser signals should be connected to the preamplifier of the detector, using a pulse amplitude greater than that from any expected capture photon. From the known rate of the pulser and the recorded number of pulser counts, the number lost due to the dead time can be determined. The best performance is obtained with counting a radioactive source or a random time pulser together with the sample (Knoll 2000).

The *pileup* of events occurs when a second signal arrives at the amplifier within its resolution time, i.e., within the shaping width of a single pulse (typically 2–3 times the peaking time for RC-feedback preamplifiers). The piledup pulses then produce one count with an amplitude somewhere between that of the smaller event and the sum of the two event amplitudes (Gilmore and Hemingway 1995) depending on the response of the ADC to the distorted signal. When using an analog amplifier, this effect can be reduced if the *pileup rejection* mode is switched on. When a second event is detected by a fast discriminator during an adjustable inspection interval, a gating pulse is generated to inhibit the storing of the original pulse. This feature can effectively reduce the level of the continuum in the spectrum. DSPs also handle pileups: signals processed by the slow filter are rejected, if the fast filter registers additional events.

31.6.2.3 Response Function of Germanium Detectors

In PGAA, the energy spectrum is collected by a multichannel analyzer (MCA). The spectral shape for a single gamma ray of a given energy is called the response function. Its shape depends on the size of the germanium detector, the spectrometer electronics, the gamma-ray energy

■ Fig. 31.3

The normal and Compton-suppressed spectra of ^{24}Na with the gamma energies of 1,369 keV and 2,754 keV, as measured in Budapest. The features marked with numbers are listed in the text

itself, and the surrounding materials. Figure 31.3 shows the response function in the case of counting ^{24}Na with a 25% HPGe detector in normal and in Compton-suppressed modes.

The following components could be identified in the spectrum. (Some of the events can be more easily identified in a Compton-suppressed spectrum.)

- FE Full-energy peak (FEP), when the photon loses all its energy (E) within the active volume of the detector.
- S Step below the full-energy peak, when the photons lose a small amount of energy in a small-angle Compton scattering in the collimator or in the dead region of the detector followed by full absorption of the scattered photon.
- MC Multiple Compton scattering region below the full energy peak and above the Compton edge.
- CE Compton edge about 220–250 keV below the full energy peak. It is a result of a single Compton-event and corresponds to the highest energy left in the detector in a single scattering. The Compton edge is below the FEP with an energy of $E/(1 + E/255.5 \text{ keV})$, as calculated for free electrons.
- CP Compton plateau is formed, when the Compton photon leaves the detector.
- SE, DE Single and double escape peaks are 511 and 1,022 keV below the full energy peak of high-energy photons that can produce an electron–positron pair. These peaks are produced when one or both annihilation photons leave the detector.
- CF Between the single escape peak and the Compton edge there are events from single escape processes. The escaping 511 keV photons may produce a Compton scattering before leaving the sensitive volume. Even a peak due to back scattering of the annihilation photon from the cold finger can be identified at the energy of $E - 341 \text{ keV}$ (i.e., below the FEP). This component is stronger for high-energy photons.
- AE Between the single escape and double escape peaks there are events from Compton scattering of both escaping 511 keV photons, which leave the sensitive volume. Their

Compton edge is 170 keV below the single escape peak. Sometimes a back-scattered peak of one of the escaping 511 keV photons can be identified at 341 keV below the single escape peak (too weak to see in ► Fig. 31.3).

- A Annihilation peak at 511 keV, when an annihilation radiation produced in the surrounding structural material or the sample is detected.
- BS Back scattering peak at 220–250 keV is produced when back-scattered Compton-photons from the sample chamber and other structural materials in front of the detector are observed. [The exact energy is $E/(1 + E/255.5 \text{ keV})$.] In the special case plotted in ► Fig. 31.3 there are two back scattering peaks according to the two gamma energies, while in the typical prompt gamma spectra it covers a wider region.
- B The strongly increasing background intensity toward low energies comes from the *bremstrahlung* from photo- and Compton-electrons and also from the beta particles emitted by radioactive nuclides. A large amount of shielding material placed next to the detector may also increase the baseline at low energies due to gammas from the multiple Compton scattering in the shield (called buildup). The slope of this region can be especially steep, when the spectrum contains intense high-energy components.
- X Characteristic X-ray peaks also show up below 100 keV from the shielding and other structural materials.

In case of strong pileup or random coincidences, any combinations of the above events can happen, which produce double or higher-order Compton edges or peaks at summed energies of full energy peaks. These random coincidences and peak summing must be distinguished from the true coincidence summing of gamma rays from cascades (Molnár 2004).

31.6.3 Calibration Procedures

The gamma spectrum is a set of counts sorted into channels, which correspond to gamma energies absorbed in the detector. This histogram must be converted into a gamma activity versus energy relationship for the determination of the reaction rate. The activities can be derived from peak areas using the *counting efficiency*. The transformation of channel numbers into energy values is called energy calibration. In the simplest linear energy calibration, one determines the channel positions of two gamma-ray peaks with accurately known energies. To obtain accurate energy data over the whole PGAA spectrum, one usually needs a correction for *nonlinearity* of the counting system. The energy *resolution* is an important quantity giving the peak width as a function of energy. It must be well known to determine the peak areas with high reliability.

31.6.3.1 Energy Resolution

The energy resolution of HPGe detectors is a very important quantity. Its deterioration warns the user of the onset of various problems in the spectrometer system. The peak resolution of a HPGe-based spectrometer depends on three factors (Owens 1989):

- W_d : the statistical fluctuation in the number of electron–hole pairs created by gamma radiation of a given energy. It is a property of the HPGe crystal. Its standard deviation is proportional to the square root of the gamma-ray energy (Knoll 2000).

- W_x : there is a statistical fluctuation in the charge collection, which depends linearly on the gamma-ray energy and is also a property of the HPGe crystal. This term is neglected in most calculations, though experiments with various detectors clearly show that the term is significant, especially at high energies.
- W_e : the electronics has a constant noise, which does not depend on the energy. Part of the electronic noise is superposed on the signals after the amplification and thus, when using a low-gain setting, this component becomes significant (Szentmiklosi et al. 2005).

The total width W_t has the following form:

$$W_t = \sqrt{W_d^2 + W_x^2 + W_e^2} = \sqrt{aE + bE^2 + c} \quad (31.12)$$

For characterization of the width of gamma peaks, the so-called full width at half maximum (FWHM) is used. For a Gaussian peak shape, the FWHM = 2.3548σ , where σ is the standard deviation. Another quantity can be derived in a similar way, the full width at tenth of maximum (FWTM), FWTM = 4.2919σ for Gaussian shapes. Thus, the FWTM/FWHM ratio equals 1.8226 for a pure Gaussian peak. The so-called Gaussian ratio implemented in certain data acquisition programs equals $0.5487 \cdot \text{FWTM}/\text{FWHM}$, which is greater than unity, when the peak has a tailing.

31.6.3.2 System Nonlinearity

The components of the spectrometer have a more-or-less linear response to the energy, which enables the use of a simple two-point energy calibration in most applications. However, there are small deviations from linearity of the order of 10^{-3} , which can be of great importance in PGAA because of the very wide energy range covered. Most data acquisition softwares offer the possibility of a parabolic energy calibration based on three data points; but for precise spectroscopic work over a large energy span, this may not be accurate enough.

The major source of the nonlinearity is the ADC. In fact, it has been observed that the shape of the nonlinearity depends only slightly on the gain settings. The most accurate way of determining the nonlinearity of the spectrometer is based on the measurement of calibration sources with well-known energies (Helmer et al. 1971). The nonlinearity of the spectrometer can be quantified as the difference of the measured peak position, ΔP_p , from a linear function, which is determined by a two-point calibration based on two distinct peaks of the calibration source:

$$\Delta P_i = P_i - P_{\text{low}} - \frac{E_i - E_{\text{low}}}{s} \quad s = \frac{E_{\text{high}} - E_{\text{low}}}{P_{\text{high}} - P_{\text{low}}} \quad (31.13)$$

where E_i is the energy of the i th peak taken from the literature, P_i is the measured channel number for the same peak, and s is the slope of the two-point energy calibration line. The nonlinearity is thus a channel-dependent function, which is zero at the two calibration points by definition. Two nonlinearity functions are regarded as equivalent when they differ only in their constant and linear terms. The same nonlinearity curve can be used for slightly different gains. This is a large advantage compared to the nonlinear energy-dependent functions, (as done with the parabolic energy calibration).

The typical nonlinearities cause only a small energy difference when the amplifier gain is high, which can be neglected in low-energy gamma spectroscopy (e.g., NAA). However,

a typical nonlinearity of one-two channels may cause an energy difference of more than 1 keV at the low gains used in PGAA, which makes the peak identification impossible, and thus the application of the nonlinearity correction is vital.

Radioactive and (n, γ) sources with accurately known energies should be used for the determination of the nonlinearity, e.g., ^{152}Eu , ^{133}Ba , and $^{110\text{m}}\text{Ag}$. The $^{35}\text{Cl}(n,\gamma)$ capture lines extend the energy range up to 8.9 MeV (Krusche et al. 1982). Above this energy, there are no better data than those of $^{14}\text{N}(n,\gamma)$ (Jurney et al. 1997); however, the identification of prompt gamma peaks are not problematic in this energy range. A method has been developed by Fazekas et al. (1999) to fit an overall nonlinearity function with polynomials to separately measured data sets.

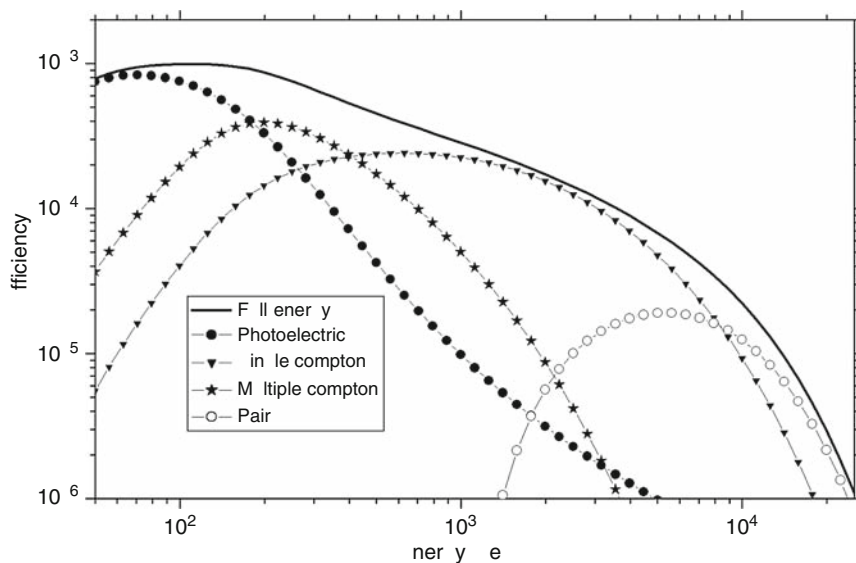

31.6.3.3 Detector Efficiency

To determine reaction rates from the gamma spectrum, the analyst has to know the counting efficiency of the detector, i.e., the ratio of the number of recorded pulses to the number of gamma rays emitted by the source. For germanium detectors, this depends on several factors, the most important of which are the geometry and the gamma-ray energy.

There have been many attempts to determine the absolute detector efficiency ε from various calculations. For instance, a *semiempirical formula* has been derived by Freeman and Jenkins (1966) and has been successfully applied by Owens et al. to HPGe detectors (Owens et al. 1991). This function was successfully fitted to the measured full-energy efficiency data (Molnár et al. 2002b), see Fig. 31.4.

■ Fig. 31.4

The plot of the semiempirical efficiency functions for the Budapest spectrometer. The lines represent the individual effects, which build up the full-energy efficiency

The model has a large number of parameters, so its use in the routine analysis is inconvenient. However, it emphasizes some important characteristics of the efficiency function, e.g., the slight efficiency decrease around 500–600 keV, which explains why the linear approximation on a log–log plot cannot be used in an accurate spectroscopic work.

It is preferable to measure the efficiency using gamma-ray sources with known disintegration rates [activity or reaction rate for (n,γ)-sources]. The corresponding formula is

$$\varepsilon(E_\gamma) = \frac{C_\gamma}{NP_\gamma} K = \frac{R_\gamma}{AP_\gamma} K \quad (31.14)$$

where C_γ is the measured net peak area (counts), R_γ is the count rate, N is the number of disintegrations, A is the activity, P_γ is the emission probability of the corresponding gamma ray, and K contains all the correction factors for losses during the acquisition of gamma-ray events, such as dead time and coincidence summing (Molnár et al. 2002b).

In PGAA, the sample-to-detector distance is usually large, which makes the summing of true and random coincidences negligible.

When determining mass ratios in PGAA, it is sufficient to use only the relative efficiency. During its determination, it is not important to know the accurate source activity, and it is also insensitive to the uncertainty in the source positioning. Thus, the *relative efficiency* can be determined with a higher accuracy.

In [Eq. \(31.14\)](#), ε will depend on the attenuation of gamma rays in the layers between the sample and the detector (e.g., neutron shielding). Therefore, it is important to calibrate the detector system efficiency with the same arrangement that is used for the measurements on unknowns.

Just as in the determination of the nonlinearity, the best way to perform an accurate efficiency calibration is to measure the sources separately. To cover the whole energy range used in PGAA, it is necessary to combine data from several measurements involving both *isotopic multi-gamma sources and capture reactions* (Molnár et al. 2002b). The data sets from different sources must be normalized together at overlapping energy regions. The efficiency at any energy can be interpolated using either nonlinear or linear functions on a log–log scale or polynomials (Kis et al. 1998; Molnár et al. 2002b):

$$\ln \varepsilon(E) = \sum_{i=0}^n a_i (\ln E)^i \quad (31.15)$$

The form of [Eq. \(31.15\)](#) is flexible enough to follow the curvature of the efficiency over a wide energy range (Molnár et al. 2002b). The parameters of the polynomial can be determined from a least-squares fit to the count rates versus energy.

In many cases, the full detector efficiency can be factorized into intrinsic and geometric efficiencies. The *intrinsic efficiency* is the ratio of the number of recorded pulses to the number of gamma rays incident on the detector surface, which depends on the interactions between the gamma photons and the material of the detector, as discussed above, while the *geometric efficiency* equals the fraction of the gamma rays reaching the detector relative to the emitted ones.

Collimated detectors. In contrast to unshielded detectors, collimated detectors show a strong dependence of the counting efficiency on the position of the sample (Debertin and Helmer 1988). The gamma rays can reach a shielded detector only by passing through a *collimator* channel. The range of sample positions over which the detector can be seen from the sample is determined by the dimensions of the collimator a , b , and r (see [Fig. 31.5](#)). The normal viewing solid angle is determined by the radius of the rear collimator hole and the distance $a +$

■ Fig. 31.5

Layout of the collimated detector, and the transmission geometry of the collimator (0 – the geometric center, a – sample-to-shielding distance, b – thickness of the collimator, r – radius of the collimator, e – end of the partial illumination region, d – the distance of the inner aperture to the sample). In the middle, the thick line shows the geometry factor, increasing from 0 to 1 in the transitional regions. The hatched circle represents the view of the front collimator aperture as seen by the source point. The empty circle is the source point view of the rear aperture (drawing is not to scale)

b of this hole from the sample. This result remains valid for any sample position for which the rear aperture is not obscured by the front wall of the shielding, i.e., at sample positions 0 to r . High-energy radiation may also be partially transmitted through the shielding around the apertures, increasing the effective solid angle and thus the geometric efficiency.

If a point source is moved along the line in front of the detector, its detected activity will follow the bold curve (the so-called geometry factor) in the middle of the figure. In the geometrical center ("0"), the point source illuminates the detector with the highest possible intensity (dotted lines in ▶ Fig. 31.5). The source can be moved slightly in the vicinity of the center without changing the illumination of the detector. The observed intensity is constant within the interval from $-r$ to $+r$ (thin lines in ▶ Fig. 31.5). Starting from the position r , the collimator partly shades the detector, and fully covers it at position e (thick dashed line in ▶ Fig. 31.5). The length of the partial illumination zone depends mainly on the ratio of a to b :

$$e = r + 2r \frac{a}{b} \quad (31.16)$$

The geometry factor is unity in the center, and decreases to zero in the interval from r to e . The decrease can be well approximated with a straight line (see the right side of ▶ Fig. 31.5). If the source is further away from the shielding than the thickness of the collimator, the *partial illumination zone* is longer than the constant region in the middle (Molnár 2004).

Active and effective volume of the sample. When measuring bulk (finite size) samples, one detects the different points of the sample with different geometry factors, which may affect the observed intensity. In the case of homogeneous samples, it is useful to introduce two quantities, the active and the effective volumes. The first one is the actual volume of the sample from where photons are emitted and may reach the detector, while the latter one is the integral of the geometry factor over the whole radiating (active) volume of the sample. Because of the

partial illumination zone, these volumes can be significantly different and may be much greater than the volume simply estimated from the projection of the collimator (Molnár 2004).

31.6.3.4 Determination of Spectral Background

The background means any gamma rays that do not arise from the sample under investigation. The lower the background, the lower are the detection limits. That is why it is important to fight for lower background, though it is usually a tedious process.

The origins of the background can be divided into two components. One of them is the *room-background*, which is always present. The other component is present only when the neutron beam is on (the so-called beam-background).

The room-background data discussed here are based on a week-long measurement performed using the Compton-suppressed HPGe detector in Budapest (Belgya et al. 2003; Belgya et al. 1997; Révay et al. 2004). The majority of the peaks originate from the *natural radioactive decay* chains, i.e., the ^{232}Th , ^{238}U , ^{235}U , ^{237}Np series, and ^{40}K . These nuclides are in the construction materials of the building.

The other peaks come from the continuous activation and excitation by the different-energy neutrons induced by the *cosmic rays* of the surrounding shielding and structural materials, like aluminum, fluorine from Teflon and ^6LiF -containing shielding, and even excitation and activation of the germanium in the detector and in the BGO. The evidence for inelastic scattering of fast neutrons in the PGAA detector comes from the presence of the so-called germanium triangles in the room-background spectra. *X-rays* are also observed from the lead shielding and bismuth of the BGO anti-Compton shield surrounding the detector, which are results of the interaction between them and cosmic muons (Nunez-Lagos and Virto 1996).

Some other radiations observed have special explanations for their origin. One part of these radiations is the gamma radiation coming from long-lived ^{207}Bi in the BGO that is an isotopic impurity in the elemental bismuth used in the manufacturing process (Lindstrom 1990). The ^{60}Co gamma rays may originate from activation of ^{59}Co in the iron structure by slow neutrons. Again, the long lifetime makes it a persistent background component.

The total room-background rate for a well-shielded PGAA detector system may be below 1 cps, similar to the performance of a well-shielded low-background experimental set-up (Lindstrom et al. 1990), while the rate is about 100 cps for the unshielded detector.

The *beam-background* can be investigated using a high-purity heavy water (D_2O) sample, as a dummy target. This background spectrum contains peaks from radiation emitted by the nearby structural materials after excitation by the scattered neutrons, as well as the gamma rays from the constituents of the sample holder. The nitrogen capture lines also appear if the sample chamber is not evacuated. The Li and C peaks probably originate from the plastic neutron shielding (which contains ^6Li), while the Al, Pb, Fe, and Sb peaks probably come from the structural materials.

When the germanium detector is not shielded well enough against slow neutrons, the material of the crystal can also be activated. As a result, prompt and decay gamma peaks of germanium isotopes appear in the spectrum. The relative intensities of germanium peaks in this case will be completely different from those of a germanium sample because of the almost complete true coincidence summing of gamma-ray cascades inside the detector. The prompt gamma peak at 596 keV is a clear sign of the prompt activation of the germanium detector by neutrons leaking through the detector shielding (Belgya et al. 2005).

Besides gamma peaks, the β^- spectra from the decays of ^{75}Ge with the maximum energy of 1.2 MeV and with a half-life of 83 min, and of ^{77}Ge ($E_{\beta\text{max}} = 2.2$ MeV, $T_{1/2} = 11.3$ h) can be seen. The β^- particles are in coincidence with the detected decay gammas from the daughter isotopes, partly shifting the **β^- spectrum**. Under steady-state operational conditions one count in the 139.7 keV peak from $^{75\text{m}}\text{Ge}$ indicates about two counts of β^- decay from the 83 min half-life isotope, and similarly one count in the 159.7 keV peak from $^{77\text{m}}\text{Ge}$ accompanies about two counts from the 11.3 h half-life isotope. The conclusion is that one has to wait several days to make low-background measurements with detectors exposed previously to slow neutrons.

Gamma peaks identified as arising from inelastic scattering of fast neutrons on various materials are coming from fast neutrons generated after slow-neutron capture on light elements (Li, B in slow-neutron shielding materials) (Lone et al. 1980). Thus their relative yields depend strongly on the shielding materials. The lowering of this component is the most difficult part of the construction of the shielding, due to the large penetration power of fast neutrons and the diffuse nature of their sources. The most important signals from the (n,n') reaction on the germanium detector (the germanium “triangles”) appear at 596 and 692 keV, and less significant triangles at 834, 563, and 1,039 keV.

31.6.4 Compton-Suppressed Spectrometers

Compton-suppressed spectrometers, as mentioned earlier, are used to decrease the Compton plateau associated with all peaks in the spectrum. The Compton shielding also suppresses the single- and double-escape peaks. The most frequently used setup consists of a main germanium detector, which is surrounded by one or more scintillators, with the exception of an aperture where the radiation enters. (There is also another hole at the back or at the side for the insertion of the germanium detector into the suppressor.) The annulus detects gamma rays scattered out from the germanium detector. To minimize the rate from the external radiation, the detector system should be placed into a thick lead shielding. When, due to a Compton event, the photon transfers only a portion of its energy to the germanium detector, and the resulting Compton photon is caught by the *scintillator*, the registration of the detector signal can be prohibited by an anti-coincidence gating. The most efficient Compton suppressor systems can reduce the Compton plateau by more than an order of magnitude.

The annulus serves both as an active and a passive shielding for the germanium detector. The annular guard detector is often made of sodium iodide [NaI(Tl)] or *bismuth germanate* ($\text{Bi}_4\text{Ge}_3\text{O}_{12}$ or BGO). The BGO has higher gamma-ray detection efficiency than the cheaper NaI(Tl) , and so is frequently used in PGAA.

There are two basic layouts of Compton-suppressed detector systems.

- In the simpler *coaxial arrangement*, the cylindrical surface of the germanium detector is fully covered by the scintillator. More sophisticated layouts partly cover the flat surfaces in the front and in the back, as well. In the latter geometry, only a small solid angle of the forward and of the backward scattering directions is not shielded (see [Fig. 31.6](#)).
- In the *perpendicular geometry*, the scintillator is placed coaxially with the direction of the detection, while the germanium detector is placed at right angles to it. Thus the detector observes the photons from the side, through the hole in the scintillator facing the source, and the forward scattered photons are caught behind the germanium detector by the scintillator.

■ Fig. 31.6

Coaxial and perpendicular Compton-suppressed detector systems

■ Fig. 31.7

Normal and Compton-suppressed spectra of a nitrogen-containing compound (deuterated urea)

The perpendicular arrangement preserves more from the shape of the normal spectrum, which may be disadvantageous. The response function of the coaxially arranged HPGe–BGO detector system is simpler by being effective at suppressing the smooth continuum and in many cases the suppression is also better.

Typical normal and Compton-suppressed spectra are shown in ▶ Fig. 31.7.

31.6.5 Other Sophisticated Detection Solutions

31.6.5.1 Composite Germanium Detectors

Composite detectors are relatively new developments in gamma-ray spectroscopy. They make possible the tracking of gamma rays inside the detector. The clover detector has four closely placed germanium crystals arranged like the leaves of a four-leaf clover. The cluster detector has

seven segments; one of them is in the center (Wilhelm et al. 1996). Both of these detector types can also be surrounded by a BGO guard detector. The advantage of this arrangement is that a part of the Compton photons leaving one detector may be detected in a neighboring one. These scattered signals can be used for Compton suppression, but it is better to add them up for the purpose of getting back the original peak energy (Elekes et al. 2003).

31.6.5.2 Coincidence Techniques

The usefulness of γ - γ coincidences in elemental analysis was pointed out by Ehmann and Vance (1991). The simplest coincidence setup consists of two germanium detectors (Ember et al. 2002). In coincidence mode, the two detectors detect two gamma rays that are emitted in fast consecutive decays of an excited nucleus. By doing this, the spectrum can be greatly simplified at the expense of a low coincidence count rate. Single-step (non-cascading) gamma rays can be greatly suppressed together with their Compton continua.

Another way to improve the coincidence detection efficiency is the utilization of gamma-ray detector arrays. This has been proposed and used by the Material Science Group at JAERI (Hatsukawa et al. 2002).

31.6.5.3 Chopped-Beam PGAA

The purpose of a beam chopper is to turn the beam on and off periodically. The separation in time of prompt and decay gamma transitions by means of a beam chopper was suggested in the pioneering work of Isenhour and Morrison (1966a, b), and more recently by Zeisler et al. (2001), with the aim to identify spectral interferences in the prompt spectrum from the decay gammas.

One of the simplest beam choppers is a rotating disk partially covered with neutron-absorbing material. ^6Li -loaded plastic is ideal for prompt gamma measurements because it produces no background gammas resulting in a *pulsed neutron beam*. When a neutron pulse hits the target, it activates the sample just like the continuous beam. The gamma spectra are detected in both the prompt and the pure decay phases. As a result, one can consider the chopped-beam measurement as a combination of PGAA and cyclic NAA (Szentmiklosi et al. 2006a). The decay peaks of certain short-lived nuclides can be measured in a chopped neutron beam with detection limits of about an order of magnitude better than normal PGAA (Szentmiklosi et al. 2005).

31.7 Spectrum Evaluation

Accurate and reproducible evaluation of prompt gamma spectra is of great importance, as the sample composition is determined from the evaluated peak areas. At different energies in a typical prompt gamma spectrum, the height of the baseline and the peak areas may differ by several orders of magnitude. The peaks are asymmetric, their shapes, especially their widths, depend on the energy, and may also depend on the count rate, and the peaks sometimes appear in complex multiplets. It is not infrequent that more than 1,000 peaks can be identified in

a prompt gamma spectrum. The minimum requirement an evaluation software must meet to be applicable in PGAA is the ability to fit at least ten peaks in one region of interest (ROI), and to have the asymmetric built-in function that describes HPGe peaks under extreme conditions. It must be able to evaluate most of the peaks automatically, but it should allow manual fitting whenever needed in difficult cases. Only a few of the evaluation software available on the market can handle this extraordinary task.

Many softwares are capable of fitting only a few peaks in each region. *Peak shapes* are often fit with only the symmetric Gaussian curve, or in some cases with a curve combined from a Gaussian and an exponential decay at the low-energy side, joining smoothly to each other. But many of the features, appearing in typical PGAA spectra cannot be handled using these simple algorithms. One of the most successful approaches is the Hypermet algorithm developed at the Naval Research Laboratory in the 1970s (Phillips and Marlow 1976a, b), which was further developed into PC-based and later into Windows-based, user-friendly programs, and now also involve the calibration routines (energy, efficiency, and nonlinearity correction) (Fazekas et al. 1997).

Peaks are fit in regions wherever the counts exceed the average level of the baseline significantly. The counts in the regions are described as the sum of peaks, peak-dependent background terms, and a parabolic baseline. A peak consists of a symmetric and an asymmetric part, usually a low-energy tailing:

- The symmetric part of the peak is described by a Gaussian. Its width W depends on the energy: $W = (a + bE)^{1/2}$.
- The asymmetric part of the peak, called the *skew term*, is intended to describe the effects of the improper charge collection. It is an exponentially modified Gaussian (EMG) function, i.e., an exponential term with a constant decay parameter convoluted with a Gaussian function having a width of W . The amplitude of the skew term is proportional to the whole peak area (Révay et al. 2001b).

The sum of these two components makes up a peak, while the sum of their integrals equals the peak area.

Peak-dependent background is a step-like shape below the peak, which consists of a rounded step due to small-angle Compton scattering and a tailing component:

- The step is described by the convolution of a Heaviside function (i.e., a unit step function) shifted to the peak and a Gaussian function (with the same width as the peak). This rounded step is thus described with an erf function, whose inflection point is at the peak energy. Full-energy peaks have reverse steps, their height is in the order of a few thousandths of the peak area (Révay et al. 2001b), while the steps below the escape peaks increase toward the high energies. The step height of a single escape peak is almost negligible, and for a double escape peak it is similar to that of the full-energy peak.
- A longer tail is due to surface effects for high-intensity peaks. It is also described by an EMG function, but with a longer decay.

The peaks sit on a baseline described by a second-order parabola. A *right skew* may also appear, especially in the case of strong peaks in the low-energy region. In many cases, this component can be eliminated by adjusting the pole/zero setting of the amplifier (in the case of RC-feedback preamplifiers), at the cost of slightly increasing the easily treatable left skew.

The positions of the peaks can be calculated as the centers of gravity

$$\langle E \rangle = \frac{\int_{-\infty}^{\infty} E(j)P(j) \, dj}{\int_{-\infty}^{\infty} P(j) \, dj} \tag{31.17}$$

where j is the serial number of the channel, $E(j)$ is the energy, while $P(j)$ is the count number in the channel. The above peak shape and its fit to measured data points for two very different single isolated peaks are shown in [Fig. 31.8](#).

The peaks are more asymmetric at high energies, i.e., a substantial fraction of their areas come from the skew. The Gaussian ratio, as defined earlier, is usually about 1.1–1.6 depending on the energy. Low-energy, strong peaks may show further asymmetries compared to the ideal Gaussian shape: e.g., the skew term may increase with increasing count rate.

Fig. 31.8
Prompt gamma peaks of nitrogen at 1,885 and 10,830 keV

The increase in the peak width as well as the amplitude and slope of the skew term over time is a natural consequence of detector *aging*, and can be tracked by the periodic calibration of these parameters. The appearance of a long left skew and a significant, irremovable right skew can be signs of the damage to the semiconductor crystal, which can temporarily be fixed by adjusting the pole/zero in the RC-feedback preamplifier.

In the case of single peaks with shapes that cannot be described using the model built into the evaluation software, the simple *peak summing* method can be used for the determination of their areas. Peak summing (as described in Gilmore and Hemingway 1995) must be performed carefully especially in the case of asymmetric peaks. The region of the summing must be defined symmetrically around the peak maximum, so the background value subtracted using a linear interpolation will not be significantly different from the one using a step function. In the case of peaks with extremely good statistics, peak summing can also be more helpful than fitting, since the minor deviations from the model function may become significant. The uncertainty of peak area determined this way can be simply calculated from the Poisson statistics of the channels involved, i.e., $A \pm \sqrt{A + B}$, where A is the net peak area after background subtraction, B is the background, so $A + B$ equals the total counts in the examined region. This method can be used for single peaks only.

The most important non-electronic process that results in distorted peaks is the *Doppler broadening* of gamma lines due to the recoil of the emitting nucleus (see Sect. 31.2.1). This broadening usually can be corrected with a slightly increased width parameter during the fit; however, in some cases the evaluation programs fit complicated multiplets. The two most prominent representatives of this effect in prompt gamma spectra are the annihilation peak, and the *boron peak* from the $^{10}\text{B}(n,\alpha\gamma)^7\text{Li}$ reaction. While the first one is not used for analysis, the second one is one of the most frequently analyzed peaks in PGAA. Its shape highly depends on the composition of the matrix through the degradation constant (Szentmiklosi et al. 2007a).

31.8 Quantitative Analysis

During quantitative analysis, the masses of certain components and the composition of the sample are determined using peak areas and spectroscopic data. There are two approaches for quantitative analysis: absolute and relative.

31.8.1 Absolute Approach

In the absolute method, the masses of certain components are determined. Assuming thin samples, peak areas are directly proportional to the masses, so the mass can be determined from nuclear constants and the conditions of the measurement based on Eq. (31.4) as follows:

$$m = \frac{M}{N_A} \frac{A}{\varepsilon(E_\gamma) t \sigma_{\gamma 0} \Phi_0} \quad (31.18)$$

where M is the atomic weight, N_A is the Avogadro constant, A is the net peak area, $\varepsilon(E_\gamma)$ is the counting efficiency at a characteristic gamma-ray energy of the given nuclide, t is the measurement time (live time), $\sigma_{\gamma 0}$ is the partial gamma-ray production cross section, and Φ_0 is the thermal equivalent neutron flux. The flux can be determined as described in Sect. 31.4.6, or by measuring a known amount of any element with a known partial cross section.

The analytical sensitivities (count rate per unit mass) can also be determined for any PGAA facility using standards with known masses of components. According to the most frequently used procedure a flux monitor is irradiated first, and the peak area is corrected with the ratio of the monitor values as measured during the analysis and the determination of the sensitivity.

In the case of the absolute method of PGAA the sample has to be weighed, and the concentrations of the detected components can be determined as the ratios of their masses compared to that of the sample. So the accuracy of the final result depends on two measurements, the mass determination with PGAA and the weighing of the sample.

The absolute method can be used with high accuracy, if the following criteria are met:

- The mass of the sample is known accurately. (The sample is chemically stable, and it does not contain unknown amount of absorbed water, etc.)
- The sample has to be close to the ideally thin case, i.e., no significant self-absorption or self-shielding corrections are necessary, and neutron scattering does not affect the result either.
- The flux profile is uniform across the neutron beam and the flux is stable in time.
- The dead-time correction of the spectrometer is accurate in the given count rate range. This is necessary to obtain the accurate live time.
- Samples are measured always in the same geometry using the same detector (i.e., the efficiency does not change).

31.8.2 Relative Approach

In the relative method, the components are determined from a single measurement on one sample. Instead of the masses, the mass ratios of the components are determined to avoid the mentioned corrections and other possible sources of error, whether or not the above criteria are fulfilled. Following the idea of the k_0 standardization (see [Eq. \(31.11\)](#)) the mass ratio can be expressed as

$$\frac{m_1}{m_2} = \frac{A_1 \varepsilon(E_2) \sigma_{\gamma 2} M_1}{A_2 \varepsilon(E_1) \sigma_{\gamma 1} M_2} \quad (31.19)$$

where A is the net peak area, M is the atomic weight, $\varepsilon(E)$ is the counting efficiency, σ_{γ} is the partial gamma-ray production cross section, and subscripts 1 and 2 represent two different chemical elements and their characteristic energies. The equation needs the determination of the peak areas, the counting efficiency, and then the mass ratio can be determined using the partial cross sections from a spectroscopic database (Révay 2009).

The determination of mass ratios is not sensitive to the variation of the neutron flux or the improper dead-time correction. For homogeneous samples, the inhomogeneous flux profile and the neutron self-shielding do not affect the result either. Gamma-ray self-absorption can be neglected in many cases, though it can distort the results when irradiating thick samples and if peak areas at both low and high energies are used in the calculation. When using peaks with the energies above 2 MeV, as mentioned in [Sect. 31.3.1](#) this effect can also be neglected even in the case of bulk samples.

Relative and absolute methods can be used simultaneously, but the analyst has to keep in mind that mass ratios have lower uncertainties than the mass values. The uncertainty calculation is described in detail by Révay (2006).

In many cases, all major and minor components of the sample can be detected using PGAA with a reasonable accuracy. (The total amount of trace elements has to be negligible compared to the uncertainties of the concentration values.) In this case, the concentrations of the constituents can be determined as the ratios of the masses and their sum. The sum of the calculated masses is biased with the same systematic errors as the individual masses; thus, their ratios will be unbiased like the mass ratios (Révay 2009).

Even when it is the dominant component of the sample, oxygen can only be determined with a low accuracy. In the case of minerals, concrete or glasses and many natural inorganic materials the amount of oxygen can be best determined from stoichiometry (Révay 2009).

31.9 Applications

Since the establishment of PGAA in the 1970s as a nuclear method for multielement quantitative analysis, there have been several reviews of PGAA applications; see, e.g., (Deconninck et al. 1981) or more recently (Paul and Lindstrom 2000) and (Yonezawa 2002). In addition, there is a PGAA handbook that includes an excellent application review section by Anderson (Molnár 2004). The last of these is quite thorough and covers reactor-based PGAA applications from 1980 through 2004. Other reviews have focused on measurements of specific elements for which PGAA is highly applicable and widely used such as the review of PGAA hydrogen measurements by Paul (1997), PGAA for boron by Sah and Brown (1997) and Paul (2005), and for cadmium by Grazman and Schweikert (1991). There are also several overviews of applications and developments at specific PGAA facilities. Révay et al. (2008a) has recently published a review of PGAA activities at the Institute of Isotopes, Park et al. (2005) a review of activities at the Korea Atomic Energy Research Institute, Rios-Martinez et al. (1998) and Wehring et al. (1997) reviews of PGAA at the University of Texas, US, Yonezawa (1999) of PGAA at Japan Atomic Energy Research Institute, and Unlu and Rios-Martinez (2005) a review of PGAA at university reactors. To avoid redundancy with or duplication of these very thorough reviews that have preceded this work, this section focuses on PGAA applications developed or implemented during the past decade, focusing primarily on those of the last 5 years and refers the reader to the aforementioned reviews for historical and additional information.

There continues to be development of neutron generator-based PGAA (see, e.g., Park et al. 2009; Reijonen et al. 2004), neutron source-based PGAA (Turhan et al. 2004; Park et al. 2004), and more recently, accelerator-based PGAA (Naqvi and Nagadi 2004; O'Meara et al. 2001; Postma et al. 2007; Postma and Schillebeeckx 2005) in which resonance neutron capture is exploited for quantitative analysis. Applications of PGAA based on the use of these nonreactor neutron sources include: analysis of archeological artifacts (Postma and Schillebeeckx 2005); online bulk analysis of carbon, oxygen, and other elements (see, e.g., Lim and Sowerby 2005); portable-source PGAA detection of explosives or other prohibited materials (Dokhale et al. 2001) and detection of land mines (Miri-Hakimabad et al. 2008). Uses of portable sources include those for borehole logging for coal and ore analysis (e.g., Borsaru et al. 2004; Charbucinski et al. 2004). There has also been recent work using *in vivo* PGAA for determination of nitrogen as it relates to protein status (Ahlgren et al. 1999; Kasviki et al. 2007a, b; O'Meara et al. 2001). See (Morgan 2000) for a review of *in vivo* PGAA applications. The scope of this review has been restricted to PGAA applications using neutron beams extracted from nuclear reactors.

An analysis of recent reactor-based PGAA applications reveals that there have been a number of new developments during the past decade, and that some of the applications that helped to establish the utility of PGAA as a quantitative method continue to be implemented in both traditional and innovative ways. As has been observed for many years, there is a great deal of PGAA work performed in the fields of archeometry and geological sciences, and in the areas of hydrogen and boron analysis. During the past 5 years, innovations have included uses of PGAA in combination with other modes of analysis such as neutron imaging, improvements in instrumentation, innovations based on modifications of the neutron beams, and the development of dynamic in situ PGAA. There has also been an expansion of PGAA applications into the fields of advanced materials analysis, and fissile and explosive materials analysis. This section will begin with a description of new applications and innovations in implementation of PGAA methods, followed by uses of PGAA in fundamental nuclear chemistry, PGAA of advanced materials, element-specific applications, field-specific applications, and finally PGAA for quality assurance and reference material certification.

31.9.1 Innovations and Advances in PGAA Methodologies

31.9.1.1 In Situ PGAA

Perhaps the most noteworthy achievement of the last decade was the work by Révay et al. (2008b) in which the first in situ PGAA measurements of dynamic processes were reported. The challenges presented by dynamic, in situ PGAA measurements are not trivial and include difficulties arising from neutron capture background signals, achieving timing resolution that is consistent with the process, and limitations in amount of signal for a given time window. In this work, uptake of hydrogen by palladium catalysts was observed dynamically by using PGAA to monitor the hydrogen to palladium element ratios. The significance of the new PGAA method has been described as it relates to the process of hydrogenation in catalysts in a recent paper by Teschner et al. (2008).

31.9.1.2 Neutron Focusing

Some of the recent innovations in PGAA involve the use of neutron optics to increase the intensity of the beams used to interrogate the sample. Over the past 2 decades, focused beams of neutrons have been used to provide greater neutron flux density on the sample, thereby enhancing neutron absorption reaction rates (Chen-Mayer et al. 1999; Mildner and Chen-Mayer 1999). Applications of focused beams in PGAA continue to appear in the literature, though are typically limited to analyses of high absorption cross section materials or major element components of a material. Chen-Mayer et al. (2000) achieved threefold PGAA sensitivity gains using multi-capillary lenses. These focused beams combined with prompt gamma-ray spectrometry were used to detect and quantify the amount of a number of elements in a variety of materials, including boron in Standard Reference Material (SRM) 611 Trace Elements in Glass, and iron and chromium in SRM 160b Stainless Steel. For this work, the samples were larger than the focal spot, so the reaction rate gains were not commensurate with the gain in neutron current density. Neutron current density gains of a factor of 40 were

achieved at this same facility using a monolithic lens and the sensitivity for a gadolinium beam enhanced by a factor of 34 (Chen-Mayer et al. 2001). Focused-beam PGAA was used to determine the radial distribution of residual chlorine in high-purity quartz cylinders formed from flame hydrolysis of silicon tetrachloride (Chen-Mayer et al. 2003). This information in combination with NAA results for total chlorine content was used as the basis for comparison with XRF results. Neutron focusing systems at the same facility were used by Swider and Walters (2004) to evaluate the utility of this approach in analysis of paint pigments and metals. Hils et al. (2004) used parabolic guide tube to increase neutron intensity, achieving a sixfold gain in neutron intensity; the authors predicted that gains of several orders of magnitude could be achieved by multiplexing. More recently, Segawa et al. (2008) achieved two-dimensional compositional mapping of cadmium wire figures with spatial resolutions on the order of a millimeter with a focused and collimated neutron beam.

31.9.1.3 PGAA and Neutron Diffraction and Imaging Methods

Additional innovative developments in PGAA, pioneered by scientists from the Institute of Isotopes, Budapest have been achieved through hybridization of PGAA with other neutron-based analytical methods such as neutron imaging and diffraction. Kasztovszky et al. (2007) developed the combination of time-of-flight neutron diffraction and PGAA to provide compositional and structural information on ceramic and metal samples. Pulsed neutrons from a spallation source were used to investigate the utility of performing PGAA to provide compositional information in combination with neutron diffraction studies (Kasztovszky et al. 2008d). This was further developed in a very elaborate combination of neutron and X-ray tomography to locate samples in thick, opaque containers (Kasztovszky et al. 2008c). Belgya et al. (2008) constructed an instrument, which combined PGAA and neutron tomography to provide both compositional information and imaging results.

31.9.1.4 Chopped Beams

Chopped or pulsed neutron beams have been used to improve signal-to-noise ratios in PGAA spectra and to extend the breadth of analytical capabilities by combining PGAA with short-lived NAA, allowing detection and quantification of a larger number of elements from the same experiment. Zeisler et al. (2001) demonstrated the use of coincidence counting with a chopped neutron beam to eliminate the 472-keV gamma-ray interference arising from neutron capture by sodium from the Doppler-broadened gamma ray accompanying neutron capture by ^{10}B , improving the ability to determine boron in biological systems.

More recent work implementing chopped neutron beams includes a number of applications performed at Budapest. Chopped neutron beams were used in conjunction with measurements designed to determine gamma-ray production cross sections (essentially, the neutron absorption cross section multiplied by and gamma yield) and k_0 values for short-lived nuclides used for conventional (delayed) neutron activation analysis (Révay et al. 2003, 2005; Szentmiklosi et al. 2006a). This work was developed further with improvements in the chopper controller to improve the precision and provide simultaneous acquisition of prompt and delayed activation analysis spectra (Szentmiklosi et al. 2007b). The combined PGAA/INAA system was applied to analysis of relatively large samples (several grams) of sodium iodide in

which PGAA and the delayed spectra were used for determination of sodium, iodine, scandium, thorium, and thallium (Szentmiklosi et al. 2008).

31.9.1.5 PGAA in Highly Absorbing Samples or Containers

There has long been utility in performing PGAA for quantitative analysis of materials that cannot be subjected to conventional INAA. A subset of these is strongly absorbing materials. Such materials are typically prohibited from the in-reactor irradiations used for conventional INAA, but not prohibited from neutron beam irradiations. Although, PGAA has very good sensitivities for strong absorbers, these materials present other challenges due to neutron attenuation within the sample. There are two basic approaches to provide accurate results in the PGAA of strong absorbers, one uses experimental data in the form of calibration curves or internal standards contained in the matrices of interest, and the other, calculations to determine correction factors. In recent work by (Acharya 2009), valid results in determination of element content of strongly absorbing samples were obtained by use of a combination of an internal standard and calibration/validation over a large range of mass fraction values of the absorber of interest, boron. A similar approach was used by Harrison and Landsberger (2009) to account for absorption by boron.

When the sample cannot be removed from the container and the container is strongly absorbing, the analysis may be even more complicated as there may be both gamma-ray attenuation and neutron absorption to consider. Révay (2008) described determination of element content of samples in thick containers, specifically the determination of noble gases in aluminum cylinders and uranium compounds in thick lead containers. Two different approaches were applied, one for which gamma-ray attenuation and neutron absorption by the container is minimal, and the other for which attenuation is significant.

31.9.1.6 PGAA of Large Samples

PGAA is an attractive method for determining the average bulk element content of large samples, particularly when the size of the subsamples typically used by other more conventional analytical methods would not be indicative of the bulk composition due to material heterogeneity. However, bulk PGAA measurements present a challenge because both neutron attenuation and gamma-ray attenuation may be significant. A recent approach described by Blaauw and Belgia (2005), to account for neutron attenuation within large samples used a Monte Carlo approach to calculate correction factors for a standard sample geometry based on the absorbing and scattering power of the sample. The results from the Monte Carlo calculations were compared with experimental results for three materials and agreed favorably for correction factors on the order of 5% and 24% but were not in agreement for more strongly absorbing materials.

31.9.1.7 Improvements in signal-to-noise ratio

As with all methods for quantitative analysis, improvements in signal-to-noise ratios are desirable as a means of increasing sensitivities and decreasing limits of detection. Developments

in this area include the use of digital spectrometry, coincidence and anti-coincidence counting, and sophisticated mathematical data manipulation. Improvements in signal-to-noise using Compton suppression were implemented at the PGAA facility at Korean Atomic Energy Research Institute by Cho et al. (2005a) as part of work to optimize the instrument for boron determinations. Coincidence counting was used to improve signal-to-noise in PGAA measurements of liquids containing hydrogen and boron (Ember et al. 2002) and of gadolinium tracers in borosilicate glass samples (Ember et al. 2004). Toh et al. (2008) used coincidence of two or more gamma rays as a means of improving signal-to-noise in analysis of foods and polymer materials. A very innovative approach to improving signal-to-noise was reported by Im et al. (2007), who used principle component analysis to identify and then exclude the noise component of a PGAA spectrum.

31.9.1.8 Advances and Applications in k_0 PGAA

The use of the k_0 method, originally developed for INAA, has come into prominence for use with PGAA during the past decade. This method was originally developed for INAA as a means of standardization for quantitative analysis based on the use of a single comparator, efficiency curves for the detection system, and experimentally determined constants to account for characteristics of the reactor neutron spectrum for a given facility. As applied to PGAA, the k_0 method essentially looks at element sensitivities for a given neutron beam and detection system (efficiency curve) combination. Lindstrom (2003) recently published an overview of k_0 PGAA. Research performed during the past decade has included the work by Sun et al. (2003) at the Korean Atomic Energy Research Institute for determination of k_0 factors for non- $1/\nu$ nuclides (^{113}Cd , ^{149}Sm , ^{151}Eu and ^{155}Gd , ^{157}Gd), and by Sun et al. (2005) for determination of k_0 factors and partial gamma-ray production cross sections for several elements (boron, nitrogen, silicon, phosphorous, sulfur, and chlorine) commonly determined using PGAA.

Applications of the k_0 method in quantitative PGAA are widespread. Some specific examples include the multielement characterization of a National Institute for Environmental Studies (Ibariki, Japan) typical diet reference material (Matsue and Yonezawa 2001) and a collaboration in which scientists used INAA and PGAA for determination of element composition of environmental and food samples (Freitas et al. 2008). In the latter work, k_0 PGAA was performed using the method described by Révay (2006), which includes a very thorough and detailed evaluation of uncertainty. PGAA facilities, particularly those equipped with neutron beam choppers, have also been used for determination of k_0 factors for short-lived products of neutron activation for use in k_0 NAA; see, e.g., (Révay et al. 2003) and (Szentmiklosi et al. 2006a).

31.9.2 Measurements of Cross sections, Gamma-Ray Energies, and Emission Probabilities

The very basis of PGAA, neutron capture followed by de-excitation of the compound nucleus through emission of characteristic gamma rays, provides information on the nuclear properties of the absorbing nuclide. Careful measurements permit determination of the prompt gamma-ray production cross section, which may be decoupled into the gamma yield, and neutron capture cross section. Quantitative PGAA may be based on comparison with element standards

of known composition, or may be based on calculations involving values for the number of neutrons interacting with the sample and values for these cross sections. For this reason, there have been many experiments designed to measure these values. For example, Park et al. (2006) performed high accuracy PGAA to determine the value of the neutron absorption cross section of ^6Li , and Borella et al. (2005) to determine the value for ^{209}Bi .

A great deal of high accuracy, high precision prompt gamma-ray spectroscopy was performed at Budapest to provide values for the partial prompt gamma-ray neutron capture cross sections, as well as gamma-ray energies and intensities (Molnár et al. 2000; Révay et al. 2000, 2001a; Molnár 2004). Their compilation of results represents the most up-to-date and accurate PGAA data available. There are many examples of determinations of partial gamma-ray production cross sections for specific isotopes. For example, thermal neutron capture cross section values were published for ^{99}Tc (Molnár et al. 2002a). In that work, it was also noted that PGAA provided order of magnitude better sensitivity than passive counting for quantitative analysis of this isotope. Extremely careful PGAA measurements to determine the intensities of the prompt gamma rays emitted from neutron capture by chromium were performed to provide more precise values than were available in the literature (Belgya and Molnár 2004). Determinations of the intensities of 36 gamma rays from ^{35}Cl were published in order to enable energy and efficiency calibrations of germanium detection systems over the wide range of energies commonly encountered in PGAA work, i.e., from about 100 keV to 11 MeV (Molnár et al. 2004). Similar work by Belgya (2008) involved determination of the intensities of prompt gamma rays from nitrogen for which the highest energy prompt gamma ray is above 10 MeV, to permit calibration of PGAA detection systems to these energy ranges.

PGAA facilities have also been used to assist in the elucidation of nuclear structure, as de-excitation gamma rays provide information on the level structure of the absorbing nucleus. Swider et al. (1994) used PGAA spectroscopy to observe gamma-ray cascades induced by neutron capture in ^{128}Te , indicating level structure of the ^{129}Te product nucleus. More recent work by Walters (2009) has involved the use of a PGAA gamma-ray spectrometer to provide information on the level structures of several germanium isotopes. Investigations of nuclear parameters involving higher energy, resonant capture phenomenon have been published recently (Pallone and Demaree 2009).

31.9.3 Identification of Explosives and Fissile Materials

Another area in which the number of PGAA applications has grown is that of detection and identification of fissile materials. Neutron-based analytical techniques have the sensitivity and selectivity needed for the investigation of many nuclear materials. Molnár et al. (2004) described the use of chopped beam PGAA to provide both the prompt gamma neutron capture and short-lived decay spectra from uranium isotopes and the use of these values in the determination of uranium and the degree of ^{235}U enrichment. English et al. (2004) described the use of gamma spectrometry and PGAA to characterize *legacy radioactive materials* and subsequently extended the work to include short-lived NAA as well as PGAA (English et al. 2008).

For many years, PGAA has been exploited for use in detection and identification of explosive materials, often based on the use of portable neutron sources and detection of nitrogen. Very recently, Im et al. (2009b) have applied principle components analysis to evaluation of PGAA spectra for identification and classification of explosives. Im and Song (2009a) recently published a review of PGAA applications in the detection of illicit materials.

31.9.4 Measurements of Advanced Materials

Measurement of advanced materials is another area in which the number of PGAA applications has been increasing steadily. The utility of PGAA has kept pace with the needs of the materials science community in the characterization of materials such as the new generations of metal catalysts, ceramics, and biopolymers. In addition, many of the recent PGAA applications have been associated with the study of hydrogen storage materials such as metal hydrides, components of hydrogen fuel cells, hydrogen-selective membranes, and other emerging energy-efficient technologies. Measurements of advanced materials that deal exclusively with determination of hydrogen or boron are covered in the subsequent sections; other recent applications in advanced materials are reviewed here.

PGAA determinations of carbon, nitrogen, and silicon were used to help ascertain the amounts of silicon nitride and silicon carbide formed by high-temperature and high-pressure processes (Balazsi et al. 2004, 2005). Results from PGAA for carbon and hydrogen in fiber epoxy composite samples were used to estimate fiber volumes based on the carbon to hydrogen ratios and comparison with samples of known fiber volume (Dorsey et al. 2004). Kasztovszky et al. (1999) determined impurities in aluminum oxides and Szentmiklosi et al. (2006b) in materials containing calcium-sulfate, as some impurities are known to affect thermoluminescence in materials used for radiation dosimetry. PGAA (together with Fourier-transform infrared spectrometry) was used in the study of another ceramic, barium titanium oxide, to distinguish residual free hydrogen from hydroxyl groups associated with moisture (Atakan et al. 2008). Contaminants also affect magnetic or electrical properties of many metal oxyanion materials; PGAA was used to evaluate levels of both dopant and impurity elements in a variety of these materials (Perry et al. 2008). Similar studies using PGAA to determine rare-earth contaminant elements were carried out on a variety of rare-earth oxides (Perry et al. 2005). In the field of biopolymers, Balazsi et al. (2009) recently used PGAA to determine element composition of biopolymer-apatite structures derived from eggshells with biodegradable coatings. And PGAA was used extensively to determine the chemical composition and water content of synthetic polymer membranes (Young et al. 2003).

Analysis of fullerenes for impurities, especially residual hydrogen has been an important component in the study of the structure and properties of these materials. Révay et al. (2006) determined the amounts of carbon and impurity elements (hydrogen, boron, and nitrogen) in C_{60} and C_{70} fullerenes. In a similar vein, recent work by Paul et al. (2009) involved characterization of carbon nanotube materials to determine levels of residual catalyst metals and hydrogen impurities present in commercially available materials. Other recent applications of advanced materials include the study of proton uptake in un-doped and yttrium-doped $BaPrO_3$ and compared with that in Gd-doped $BaCeO_3$ (Jones et al. 2005).

31.9.5 Analysis of Hydrogen

PGAA is uniquely suited for quantitative analysis of hydrogen due to the large dynamic range of the method and due to the nondestructive nature of the analysis as compared with other analytical methods, which typically rely on combustion of the sample. PGAA has been used to determine hydrogen levels ranging from a few micrograms per gram to several percent. Limits of detection for hydrogen for some representative matrices and facilities include 70 μg for coal and botanical materials at the Oregon State University PGAA facility (Robinson et al. 2009);

15 μg for geological materials at the Japan Atomic Energy Research Institute PGAA facility (Yamazaki et al. 2007); 15 μg for biological materials at the National Institute of Standards and Technology thermal neutron PGAA facility (Mackey et al. 2004); and 5 μg in palladium catalysts in Budapest (Révay et al. 2008b).

Relatively small amounts of hydrogen may affect the properties of metals, ceramic oxides, minerals, and other materials. For example, hydrogen causes embrittlement of metals, alters proton conductivity of ceramics and the physicochemical structures and melting points of minerals. There has been an enormous expansion of PGAA applications for determination of hydrogen in the materials sciences, especially those involving hydrogen storage materials, fuel cells, and other emerging energy-efficient technologies. Recent applications are presented here; for earlier work in hydrogen PGAA applications, see the review by Paul (1997).

PGAA has been used to study a number of materials, particularly light metals, to determine hydrogen storage capacity. Cao et al. (2009) reported using of PGAA to measure hydrogen in thin films that were fabricated to evaluate the H storage capacity of metal and metal alloy hydrides. Materials studied included a series of magnesium hydride thin films that had been exposed to hydrogen for different times and PGAA results were used to evaluate the optimum exposure conditions for maximum hydrogen uptake. To help determine the optimum magnesium-to-titanium ratio for hydrogen uptake, a series of thin films consisting of magnesium–titanium metal alloys with continuously varying composition were exposed to hydrogen to form metal hydrides. PGAA results indicated that the molar fraction of hydrogen increased with increasing magnesium mole fraction. Tompa et al. (2003) used PGAA to determine hydrogen in amorphous alloys containing varying amounts of nickel, copper, and zirconium. Results of PGAA in combination with those from NMR were used to evaluate hydrogen diffusion in alloys of differing compositions and to evaluate residual hydrogen in these materials. Results of PGAA were used together with those obtained from gas chromatography to determine residual hydrogen in aluminum foils and single crystals; gas chromatography was needed to supplement PGAA results due to the presence of hydroxyl–aluminum surface coating (Buckley and Birnbaum 2002).

Other studies have focused on ceramics and other materials that preferentially filter hydrogen, and on engineered catalysts for potential use in hydrogen fuel cells. Some recent PGAA measurements with direct or indirect implications for hydrogen fuel uses include the following examples. PGAA was used to determine hydrogen in platinum catalysts before and after drying to evaluate free hydrogen content, water content, and the hydroxyl component of the support structure (Kasztovszky et al. 2002). Results from quantitative PGAA of hydrogen, combined with qualitative results from other techniques including infrared spectroscopy, neutron vibrational spectroscopy, and small angle X-ray scattering were used to study hydrogen in crystalline and amorphous alumina (Paglia et al. 2004). And similarly, Atakan et al. (2008) used PGAA in combination with Fourier-transform infrared spectroscopy and thermogravimetric analysis to study effects of heat treatments on residual water in ceramic oxides and to help distinguish free hydrogen from hydroxyl groups. PGAA was used to determine amount of hydrogen sequestered by the cage compounds of microporous silicate, clathrasil decadodecasil, finding that results were consistent with those from NMR analyses, which indicated that H was released upon cage decomposition (van den Berg et al. 2007). PGAA has been used extensively by researchers at the University of Texas (US) to study proton exchange in lithium ion batteries (Aghara et al. 2005; Alvarez et al. 2007). At the same facility, Arunkumar et al. (2008) used PGAA for investigations into the structure and proton transfer properties of lithium–manganese–nickel compounds studied for potential use in lithium-type batteries.

A great deal of PGAA work on hydrogen determinations focused on facility characterization and method improvements. Chung et al. (2007) described a very thorough characterization of the PGAA instrument at the Korean Atomic Energy Research Institute, including characterization of the background spectrum and validation of the PGAA method for hydrogen quantification. Validation was accomplished, in part, using SRM 1632c Trace Elements in Coal (Bituminous), SRM 173c Titanium Alloy, and SRM 2453 Hydrogen in Titanium Alloy, demonstrating the large dynamic range for hydrogen measurements. Yamazaki et al. (2007) described a method developed for determination of low levels of hydrogen in geological standards in which samples were measured under helium gas to prevent moisture uptake. This work also involved a very careful hydrogen sensitivity calibration and characterization of hydrogen background count rates for that facility.

31.9.6 Analysis of Boron

PGAA is also uniquely suitable for determination of boron, in this case due to the high neutron capture cross section of ^{10}B , and correspondingly high PGAA sensitivity. Limits of detection for boron using this technique are nearly always submicrogram and often of the order of a few nanograms, depending on the characteristics of facility (Molnár 2004). Robinson et al. (2009b) reported limits of detection of $\leq 0.6 \mu\text{g}$ for botanical materials using a thermal neutron PGAA instrument with a neutron flux of $2.8 \times 10^7 \text{ cm}^{-2} \text{ s}^{-1}$ at Oregon State University, USA. Mackey et al. (2004b) report detection limits of 70 ng for biological materials using a thermal neutron PGAA facility with a neutron flux of $3 \times 10^8 \text{ cm}^{-2} \text{ s}^{-1}$. Byun et al. (2004) report detection limits of 67 ng at the Korean Atomic Energy Research Institute PGAA facility with a flux of $7.9 \times 10^7 \text{ cm}^{-2} \text{ s}^{-1}$ based on evaluation of background and sample container blanks. Detection limits may be even lower for facilities with higher neutron fluxes or more efficient detection systems. Determination of boron is nearly always included in multielement PGAA work; recent work focusing exclusively on PGAA determination of B is described here.

Some recent work determining boron by PGAA has focused on the analytical difficulty, caused by neutron attenuation, of measuring high-content boron materials (Acharya 2009; Harrison and Landsberger 2009). Others have dealt with the difficulty presented by high count rates from highly absorbing, boron-containing materials, such as the work described by Ember et al. (2001) in determining Gd in borated glasses and subsequent work using coincidence counting to improve signal-to-noise in highly absorbing material (Ember et al. 2002). Other PGAA scientists have presented methods for determining the peak area that address the difficulties associated with modeling the shape of the Doppler-broadened peak resulting from the emission of the 472-keV gamma ray from ^7Li following the $^{10}\text{B}(n,\alpha\gamma)^7\text{Li}$ reaction (Sun et al. 2008) or the difficulty encountered when subtracting Gaussian-shaped interfering gamma-ray peaks from the Doppler-broadened boron peak (Szentmiklosi et al. 2007a; Zeisler et al. 2001). Both Sakai et al. (2005) and Yamauchi et al. (2005) interrogated the shape of the broadened boron peak to obtain information on the chemical environment of the capturing nucleus.

PGAA has been employed for quantitative analysis of boron in boron-containing tumor drugs used for boron neutron-capture therapy. To study the distribution of such drugs in the mouse model, Cho et al. (2007) determined boron in tumors and other tissues of mice that had been injected with boronophenylalanine. Accuracy of the boron determinations at this facility had been established by previous work describing the facility, element standards, and the analysis of several certified reference materials (Cho et al. 2005b). Byun et al. (2004)

determined boron in a variety of reference materials as part of work to fully characterize the diffracted polychromatic neutron beam used at the Korean Atomic Energy Research Institute.

31.9.7 Biological and Environmental Applications

PGAA has been used in combination with INAA (or other methods) in biological and environmental studies in which a complete (or nearly complete) compositional characterization is desired. Anderson and coworkers have used both PGAA and INAA for determination of element content of foods for the past 2 decades. Highlights have been described in a 2001 overview of that program (Anderson et al. 2001). A more recent description of quantitative PGAA of 22 elements in a variety of foods, food and dietary supplements was presented by Anderson and Mackey (2005). Similarly, Freitas et al. (2008) used INAA and PGAA for determination of element content of nutritional and environmental samples, and Oura et al. (2007) for the determination of element content of atmospheric particulate matter. Multiple methods were also used to characterize the element content of cosmetics, in which PGAA was used to determine samarium and gadolinium (Furuta et al. 2008). PGAA was used extensively to determine the nutritive elements, carbon, nitrogen, and phosphorus in cattails (Zhao et al. 2008). As part of that research Zhao and Robinson (2009) presented a comparison of results obtained using cold and thermal neutron beams, noting the differences in the effects of hydrogen and sample thickness on element sensitivities.

31.9.8 Archeometry

PGAA has been used extensively over the years, alone or in combination with INAA or other methods, for multielement analysis of archeological specimens or artifacts. In many cases, the artifact or specimen may be unique and, therefore, not expendable. Even when destruction of a portion of the artifact is acceptable, the sample or specimen may be difficult to analyze using methods that require sample dissolution. For either INAA or PGAA, multielement analysis can be achieved without sample dissolution, fusion or other destructive methods used to introduce the sample into the detection device and PGAA has the added advantage of inducing little residual radioactivity. PGAA is often used to provide scientists with information on the element composition without lasting harm to the specimen. And, if necessary, artifacts analyzed by PGAA may be subsequently subjected to further analyses by other methods. Biro (2005) published an overview of PGAA applications in this field; and Lehmann et al. (2007) presented a discussion of neutron-based analytical and imaging techniques for investigation of cultural and archeological artifacts. Selected recent applications of PGAA in archeometry are described here.

In archeometry, element compositional data are often used to determine provenance and to assess artifact age. Results from multielement k_0 PGAA of a variety of artifacts ranging from ceramics to bronzes were used to ascertain provenance and assist in determining specimen ages (Sueki et al. 1998; Oura et al. 1999). PGAA was used to determine metal contents of several bronze and silver artifacts (Kasztovszky et al. 2000) and ancient silver coins (Kasztovszky et al. 2005). The provenance of Iron-Age bronze artifacts was evaluated based on PGAA determinations of major element and selected trace element content (Rogante et al. 2007). Copper-to-zinc ratios and the lead content of organ reed pipes determined by PGAA, combined with historical information concerning the use of these metals in the components of reed

pipes, allowed researchers to estimate the dates of the artifacts (Manescu et al. 2008). Ceramic figurines created by Amerindian peoples in the Los Roques Archipelago prior to the arrival of Europeans were investigated by PGAA; major and minor element contents were used to assist researchers in determining provenance (Kasztovszky et al. 2004). Results from a similar study of Amerindian pottery artifacts from Venezuela were used to ascertain provenance and support the hypothesis that seasonal migration established relationships among communities from different locations (Sajo-Bohus et al. 2005, 2006). A large number of samples from stone tools and associated source materials were analyzed to determine geological classifications of the materials and assess provenance of the tool artifacts (Kasztovszky et al. 2008a, b). Major element and selected trace element contents determined by PGAA of prehistoric stone tools were used to distinguish tools made of green schist from those of blue schist (Szakmany and Kasztovszky 2004).

PGAA has been an integral part of European “ANCIENT CHARM” project (Analysis by Neutron resonant Capture Imaging and other Emerging Neutron techniques: new Cultural Heritage and Archeological Research Methods; <http://ancient-charm.neutron-eu.net/ach>) since its inception in 2006. The research associated with this project has contributed innovations in the method, and the information provided by PGAA measurements has contributed to the knowledge of the art and archeological artifacts studied. Two PGAA instruments, one at the Budapest Research Reactor (Hungary) and the other at the FRM-II Reactor in Garching (Germany), have been used for element determinations in a variety of cultural and archeological objects. Results from PGAA have been used alone or in combination with neutron diffraction for two-dimensional structural information or with neutron tomography for three-dimensional material characterization. The characteristics of the Prompt Gamma Activation Imaging (PGAI), or prompt gamma activation imaging facility at FRM-II reactor were described by Kudejova et al. (2008a). The characteristics of the Budapest PGAA instrument were described by Révay et al. (2004, 2008a). In development of a method to combine PGAA with time-of-flight neutron diffractometry, test samples were fabricated and analyzed as described by Kasztovszky et al. (2008c). Applications of PGAA in the Ancient Charm project have included the analysis of metal-based artifacts such as brass plates, bronze sculpture, tin-lead implements (Kasztovszky et al. 2007), and investigations of copper, limestone, bronze, and glass artifacts (Kasztovszky et al. 2008d).

31.9.9 Characterization of Geological Materials

PGAA has been used extensively over the years for multielement analysis of geological materials, in part, because geological materials may be difficult to analyze using methods that require sample dissolution and because PGAA has very good sensitivity for some elements of interest in these materials such as rare-earth elements, which are often used to distinguish the source or origin of geological materials. For example, (Perry et al. 2002) used PGAA to determine mass fraction values for 25 elements in metal sulfides and silicate rocks formed by processes at oceanic geothermal vents. The rare-earth elements were used to infer the relationship of the materials to specific geothermal field locations. More recently, Cristache et al. (2009) used PGAA and epithermal NAA to determine mass fractions of nine elements in Black Sea sediments, results of which were used to confirm the geological origins of the sediment.

Ebihara and Oura (2001) assessed the use of PGAA at the Japan Atomic Energy Research Institute for element analysis of extraterrestrial materials obtained from space missions; of

particular interest was evaluation of any residual activity and the potential perturbation of isotopic ratios that would interfere with subsequent analysis by other techniques. Evaluation indicated that PGAA was suitable in light of all considerations. More recently, Kudejova et al. (2009) reported on the feasibility of using PGAA for multielement determinations in Allende meteorite specimens.

The presence and amount content of boron in volcanic materials has been determined using PGAA in several studies conducted by Gmeling et al. (2005) and used to infer degree of fluid enrichment in magmatic materials. These researchers investigated both boron and chlorine but found boron to be most suitable as a predictor for fluid enrichment. They followed this work with PGAA studies of volcanic materials from several locations around the globe (Gmeling et al. 2007a) and from the East Carpathian Volcanic Field (Gmeling et al. 2007b). Similarly, Marschall et al. (2005) reported determination of element content of high-pressure metamorphic rocks, finding that results from PGAA compared well with those from other methods. Marschall et al. (2009) also evaluated boron and chlorine as predictors of dehydration in geological materials. Miyoshi et al. (2008) used PGAA for multielement determination of volcanic specimens (basalts) and found that ratios of boron to rare-earth element help to establish geological source information.

31.9.10 Quality Assurance and Analysis of Reference Materials

PGAA data obtained from experiments conducted at well-established facilities have been used routinely as benchmarks against which results from other techniques or newer facilities are evaluated. In the development of newer facilities and instruments in which PGAA is combined with other methods, analytical results were benchmarked against results obtained from the Budapest PGAA facility Kudejova et al. (2005). Sandor et al. (2002) have described a study for determination of major element composition of ancient coins, in which PGAA results were used as the benchmark to evaluate results from a newly developed Energy Dispersive X-Ray Fluorescence (EDXRF) method. In addition, in similar work involving PGAA and EDXRF of Roman silver coins, PGAA results were used as the benchmark (Kasztovszky et al. 2005). Results from PGAA were used by Kvardakov et al. (1998) as a benchmark against which to compare results from neutron incoherent scattering for H determinations. Similarly, hydrogen concentrations in a titanium alloy were determined by neutron incoherent scattering and compared against results obtained from cold neutron PGAA (Perego and Blaauw 2005).

Another of the traditional uses of PGAA has been that of a complementary technique to INAA and other analytical methods in certification of reference materials (Lindstrom 1998; Ihnat 2000). Use of PGAA allows certification of light elements such as hydrogen, boron, nitrogen, and some rare-earth elements such as Gd and Sm that are not easily accessible by other analytical techniques. Depending on levels present, PGAA may contribute results for many more elements in certification campaigns. Some recent applications of PGAA as applied to certification of reference materials are presented here. The materials and elements determined are presented to provide a sense of the breadth and depth of PGAA capabilities. There are no doubt additional instances in which PGAA results were used in the certification of reference materials. However, due to the routine nature of many of these analyses, results of certification analyses are included only in the certificates of analysis, and may not be found in the peer-reviewed literature.

In the analysis of biological materials, PGAA is often used to determine light elements. For example, Anderson (2000) reported use of PGAA to determine mass fractions of H, B, C, N, Na, Cl, K, and S for certification of these elements in SRM 1946 Meat Homogenate. Matsue and Yonezawa (2001) reported use of PGAA to determine H, B, C, N, Na, S, Cl, and K in a National Institute of Environmental Studies (NIES) typical diet reference material. Zeisler et al. (2008) reported on the certification of SRM 1577c Bovine Liver in which PGAA contributed values for H, N, K, and S. Other measurements of certified reference materials include determination of N in a variety of NIST biological and geological Standard Reference Materials (Paul 2001). Both INAA and PGAA data accumulated over more than 10 years were used to assess stability of two biological reference materials, SRM 1566a Oyster Tissue and SRM 1547 Peach Leaves (Mackey and Spatz 2009).

For analyses of geological and environmental reference materials, PGAA may be used to measure both major element constituents (as well as light elements) and trace amounts of boron, cadmium, and rare-earth elements. Dyar et al. (2001) used PGAA to determine boron in a variety of reference minerals. Mackey et al. (2007) reported certification of SRM 695 Multi-Nutrient Fertilizer in which PGAA was one of several techniques used to certify mass fractions for 17 elements and provide reference or information values for another seven elements. PGAA contributed to certified or reference values for B, Cd, Fe, K, Mn, and N in this material. More recently PGAA was used in certification measurements for three soil SRMs (2709a, 2710a, 2711a) contributing results for B, Cd, Fe, Gd, K, Mn, Si, Sm, and Ti in these materials. Paul et al. 2009, Mackey and Spatz 2009, Sieber et al. 2007 reported certification of major and minor element constituents of SRM 57b Silicon Metal for which PGAA was used to provide results for B, Al, Ti, Mn, and Fe. Miura et al. (2008) employed PGAA for determination of boron in National Measurement Institute of Japan ceramic certified reference materials using chlorine and silicon as internal standards in developing calibration curves for boron in this matrix.

Abstract: Miscellaneous applications of low-voltage neutron generators providing 3 and 14 MeV neutrons via the D-D and D-T reactions, respectively, are reviewed. New experimental methods are reported, and emerging applications in the areas of prompt and delayed neutron activation analysis, fast neutron imaging and profiling, irradiation effects, fast neutron radiobiology, and shielding design are highlighted.

32.1 Introduction

In this chapter some applications of low voltage (~ 150 – 200 kV) neutron generators using 3 and 14 MeV neutrons, produced via the $^2\text{H}(\text{d},\text{n})^3\text{He}$ (D-D) and $^3\text{H}(\text{d},\text{n})^4\text{He}$ (D-T) reactions, respectively, are discussed. Principles of operation and output characteristics of neutron generators have been described elsewhere (Csikai 1987, 1989; IAEA 1996, 2000). The nuclear methods based on small neutron generators have a great importance in the development of such new technologies as process and quality-control systems, exploration of natural resources, detection of illicit traffic materials, transmutation of nuclear waste, fusion reactor neutronics, irradiation effects on biological and industrial samples, which can be directly utilized in other sciences, in the economy and society.

32.2 Activation Analysis with 14 and 3 MeV Neutrons

Recently, neutron activation analysis (NAA) has been improved by application of separated isotopes as targets, quick radiochemical separations, corrections for flux perturbation in the case of bulky samples, high-resolution detectors (Ge(Li), HPGe, LEGe, Si(Li), Si-avalanche, etc. – for a summary of the properties of LEGe and other types of Ge detectors see [Fig. 48.9 in Chap. 48, Vol. 5](#), on “Radiation Detection”) and better data acquisition as well as processing systems, in addition to the use of high-efficiency detectors ($\text{Bi}_4\text{Ge}_3\text{O}_{12}$, GSO, CsI, PbWO_4 , BaF_2 , CdTe, etc.) (Proctor et al. 1999; Dokhale et al. 2001; Hlavác 2001). A typical example of the advantages of high-resolution gamma spectrometry in elemental analysis is the determination of Si in Al alloys. (The problems of trace element determination by INNA in aluminum matrix are touched upon in various parts of [Chap. 30 in this Volume](#), on “Activation Analysis”.) The intensity ratio of the 1.73 and 1.78 MeV gamma-lines produced in $^{27}\text{Al}(\text{n},\alpha)^{24}\text{Na}$ and $^{27}\text{Al}(\text{n},\gamma)^{28}\text{Al}$, $^{28}\text{Si}(\text{n},\text{p})^{28}\text{Al}$ reactions, respectively, depends strongly on the Si content in the Al matrix (see [Fig. 32.1](#)). Another example showing the importance of high-efficiency gamma detectors is related to the detection of illicit traffic materials (drugs, explosives) via the determination of carbon and oxygen, using the respective 4.44 and 6.13 MeV gamma rays from the $(\text{n},\text{n}'\gamma)$ reactions.

There are two important new fields of application of fast neutrons in elemental analysis: determination of chemical compounds by measuring the atomic ratios of the composite elements and the correlations between them, and studies of the interaction of secondary energetic charged particles (p, α , t, d) with their chemical environment (hot atom chemistry) and the role of secondary reactions in activation analysis of light elements such as Li, Be, B, and C. Considerable progress has been made in the knowledge of decay data for radioactive products (IAEA 2002) and the possible interfering reactions and gamma-lines from fast neutron reactions, as presented in [Sect. 36.3 of the Appendix of this Volume](#).

The activation expression related to the decay of a single state should be extended to a more general case in which ground and isomeric states are produced and the ground state activity is used for the analysis. Such a typical case is the $^{58}\text{Ni}(\text{n},\text{p})$ reaction in which the $^{58\text{m}+\text{g}}\text{Co}$ isomeric

■ Fig. 32.1

Gamma-ray spectrum of Al and Al + Si mixture. Note that on adding just 1% of Si to Al, the peak ratio $^{24}\text{Na}/^{28}\text{Al}$ changes from about 2/1 to about 1/4

pair is produced and the activation analysis is based on the decay of ^{58}gCo . Some decay modes of the radioactive atoms are demonstrated in ► Fig. 32.2.

If the final nucleus has an isomeric state, which can also populate the ground state via an isomeric transition IT with a branching ratio β , then the differential equations for the two states are as follows:

$$\frac{dN_m}{dt} = \Phi\sigma_m n - \lambda_m N_m \quad \text{and} \quad \frac{dN_g}{dt} = \Phi\sigma_g n - \lambda_g N_g + \beta\lambda_m N_m \quad (32.1)$$

where Φ , n , λ_g , λ_m , σ_g , and σ_m are the neutron flux density, the number of atoms to be determined in the sample, decay constants of the nuclei produced in ground and metastable states, and the corresponding cross sections, respectively.

If the activity is measured via the decay of ground state atoms as a function of cooling time, t_c the $N_g(t_c)$ function is given by

$$N_g(t_c) = \Phi n \left\{ \left(\frac{(\sigma_m \beta + \sigma_g)}{\lambda_g} + \frac{\sigma_m \beta}{\lambda_m - \lambda_g} \right) \times (1 - e^{-\lambda_g t_i}) e^{-\lambda_g t_c} - \frac{\sigma_m \beta}{\lambda_m - \lambda_g} \times (1 - e^{-\lambda_m t_i}) e^{-\lambda_m t_c} \right\} \quad (32.2)$$

where t_c and t_i are the cooling time and the irradiation time, respectively.

For example, in the case of ^{58}mCo $\beta = 1$ and the ground state decays by an 810 keV gamma-line. By measuring the peak area of this line as a function of cooling time, the σ_m/σ_g ratio can be

■ Fig. 32.2

Typical decay modes involving metastable (m) and ground (g) states

deduced. It follows from (32.2) that the intensity function $I_g(t_c)$ is given by the following expression:

$$I_g(t_c) = \Phi n (Ae^{-\lambda_g t_c} + Be^{-\lambda_m t_c}) \quad (32.3)$$

that is, the measured intensity is approximated by the sum of two exponential functions. The pre-exponential constants, A and B , contain the σ_m and σ_g values as unknown parameters. In the knowledge of the isomeric cross sections, the decay parameters, the irradiation, and measuring conditions, the number of atoms of a given element n can be determined. In some cases, if $\lambda_g \ll \lambda_m$ and t_c is high, then $I_g(t_c)$ is given by a single exponential function, that is, by the first term in (32.3).

Investigations on the sensitivity, accuracy, interfering reactions, and gamma-lines lead to the conclusion that neutron activation analysis based on small accelerators requires the use of thermal, resonance, and fast neutrons depending on the element to be determined in different matrices. In this case, the D-D and D-T targets are surrounded with hydrogenous moderators. Thermal (TNAA) and epithermal (ENAA) or resonance neutron activation analysis as well as the capture of gamma-ray techniques are favored over the fast neutron (FNAA) method for the following elements: Dy, Eu, In, Mn, Lu, Au, V; U, Th, Rb, Sr, Mo, Sb, Cs, Ba, Ta, Tb; and H, Be, B, N, O, S, Ni, Cd, Gd, Eu. It should be noted, however, that the method to be chosen for NAA depends also on the type of the detector. The RNAA is favored over TNAA, for example, for Ni, Zn, Rb, Sr, Sb, Cs, Tb, Ta, Th, and Mo, Ba, Gd, Tm, Yb, Hf, U if a GeLi, HPGe and a low energy photon (LEP) detector is used, respectively.

Though there are less interfering reactions and gamma-lines for the reactions induced by the 3 MeV D-D neutrons as compared to the 14 MeV D-T neutron reactions, the latter is recommended for NAA because of the much higher neutron yield and the availability of the multi-elemental analysis via the many open reaction channels. The specific activity expected from the principal reactions at $E_n = 14.5$ MeV was calculated using the recommended nuclear data (Bódy and Csikai 1987). The specific activity in Bq/g was calculated for the reactions of maximum yield of each element, assuming a reasonable flux $\Phi = 10^9 \text{ cm}^{-2} \text{ s}^{-1}$ and irradiation time $t_i = 1 \text{ h}$. Nuclear processes proposed for the determination of each element together with the possible interfering reactions are summarized in Sect. 36.3 of the Appendix of this Volume.

Recently, large efforts have been carried out for the determination of the thermal neutron flux perturbation factor in the case of bulky samples of unknown composition (Csikai et al. 2002b). The flux perturbation factor, F is defined by the following relation $F = \langle \Phi \rangle / \langle \Phi_0 \rangle$, where $\langle \Phi \rangle$ and $\langle \Phi_0 \rangle$ denote the average thermal neutron fluxes in the sample and in a moderator material of similar volume, respectively. It was found that the flux distribution $\Phi(x)$ both in thin (Buczkó and Borbély 1978) and bulk (Csikai et al. 2002b) absorbing samples can be described by the following expression:

$$\Phi(x) = (ax^2 + bx + c)^{-1} \quad (32.4)$$

where x is the distance from the surface of the sample while a , b , and c are fitting parameters. According to (32.4) for the determination of the $\Phi(x)$ function, it is sufficient to measure the flux value only in three positions, for example, at $x = 0$, $x = d/2$, and $x = d$ for a sample of thickness d . In the knowledge of the $\Phi(x)$ function the average neutron flux is given by

$$\langle \Phi \rangle = \frac{1}{d} \int_0^d \Phi(x) dx. \quad (32.5)$$

The unperturbed flux density $\langle \Phi_0 \rangle$ must be measured in the same positions using activation detector foils and replacing the sample with the moderator material. The spatial distribution of the thermal neutron flux around a point source changes significantly for hydrogenous moderators which prevents the use of TNAA for bulky samples. In the case of graphite moderator, the thermal neutron flux distribution changes only slightly, assuring an almost constant flux density for irradiation of bulky samples whose size is on the order of $10 \times 10 \times 10 \text{ cm}^3$.

The semi-log plot of F as a function of thickness d is linear both for graphite and for hydrogenous moderators, that is, the following simple equation

$$F = \frac{\langle \Phi \rangle}{\langle \Phi_0 \rangle} = F_0 e^{-Kd} \quad (32.6)$$

can be used for the determination of the flux perturbation factor, for both thin and bulky absorbing samples of unknown compositions if K is determined by experiment.

After determining F , the corrected activity $\langle A_0 \rangle$ at the end of irradiation time t_i is given by

$$\langle A_0 \rangle = \frac{\langle A \rangle}{F} = \langle \Phi_0 \rangle \sigma n (1 - e^{-\lambda t_i}) \quad (32.7)$$

where $\langle A \rangle$ is the activity of the sample produced by the average activating flux, $\langle \Phi \rangle$. It should be noted that the correction for the flux perturbation can be neglected neither for bulky nor for thin samples if they contain absorbing elements. For the elemental analysis of thin absorbing samples, hydrogenous moderators are recommended. For bulky samples, however, the graphite moderator is better. The attenuation of 3 and 14 MeV neutrons in different samples is discussed in (32.3) of the Appendix of this Volume.

In practice, the $\Phi(E)$ function in a given point inside the sample is determined by the unfolding method using a set of activation threshold detector foils. The most commonly used dosimetry reactions are also summarized in (32.3) of the Appendix of this Volume. With the knowledge of the $\Phi(E)$ and $\sigma(E)$ functions, the differential and spectrum-averaged reaction

rates, $R(E) = \Phi(E)\sigma(E)$ for any element can be determined. A method based on the combination of physical integration and activation threshold detectors was developed by Csikai et al. (1988) to determine the volume-averaged activity produced by neutron-induced reactions.

32.3 Prompt Radiation Analysis

In addition to NAA, neutrons are widely used in prompt radiation analysis for the determination of concentration and spatial distribution of elements in different matrices. For example, a track-etched detector (LR-115, Makrofol KG, CR 39, mica) placed on the polished surface of a sample is irradiated with fast or thermal neutrons then etched with a suitable chemical to deduce the concentration profiles from the track distributions. This method can also be used for the detection of suspended and dissolved U, Th, and Pu in water by (n,f) reactions; N in polymers by the $^{14}\text{N}(\text{n,p})^{14}\text{C}$ reaction; B and Li in semiconductors or glasses by the $^{10}\text{B}(\text{n},\alpha)^7\text{Li}$ and $^6\text{Li}(\text{n},\alpha)^3\text{H}$ reactions, respectively. For the detection of fission fragments the use of mica is recommended.

32.3.1 Neutron Methods

Neutron absorption, moderation, and reflection methods are also widely used in elemental analysis of bulk samples, especially for the determination of hydrogen and moisture content. A systematic study had shown that the relative number of excess neutrons $\eta = (I - I_0)/I_0$, measured with (I) and without (I_0) a reflector (see [Fig. 32.3](#)), depends linearly on the hydrogen content of liquid, powder, and solid samples up to about 1 cm thickness, that is,

$$\eta = sH + \eta(T) \quad (32.8)$$

where H is the hydrogen content in wt%, s is the slope of the η - H calibration function, and $\eta(T)$ is the matrix effect (Buczko et al. 1975). For the determination of the relation expressed by [\(32.8\)](#) and for the given source-sample-detector geometry, a combination of reflector with thin polyethylene (PE, composition: $\text{C}_n\text{H}_{2n+2}$) layers was recommended (Csikai et al. 2002a).

The concept of the reflection cross section of thermal neutrons σ_β as a microscopic parameter for the characterization of the reflection property of substances has been introduced (Csikai and Buczko 1999). The relation between η , σ_β , and the surface density of atoms is given by

$$\eta = Nd\sigma_\beta = \frac{n\sigma_\beta}{S} \quad (32.9)$$

where n is the total number of atoms in the sample, N the number of atoms per cm^3 , S the surface of the sample in cm^2 , and d is the thickness of the sample in cm. The quantity $Nd = mN_A/(MS)$ is obtained from the mass of the sample (m) and the molar mass of the element (M), where N_A is the Avogadro constant (see [Sect. 11.2 in the Appendix of Vol. 1](#)). If the reflector consists of molecules, the following formula can be used:

$$\eta = \frac{n_{\text{molec}}\sigma_{\beta \text{ molec}}}{S} = \frac{n_{\text{molec}} \sum_i v_i \sigma_{\beta i}}{S} \quad (32.10)$$

■ Fig. 32.3

Neutron reflection arrangement

where n_{molec} is the total number of molecules in the sample and v_i is the number of atoms of type i with cross section $\sigma_{\beta i}$ in the molecule. The cross-correlation between the σ_{β} values deduced from the $\sigma_{\beta \text{ molec}}$ data obtained for different compounds has proved that the reflection cross sections are additive. For a mixture of elements, the averaged molar mass of the elements should be used, that is,

$$\langle M \rangle = \frac{\sum_i m_i}{\sum_i \frac{m_i}{M_i}} \quad (32.11)$$

where m_i and M_i are the mass and molar mass, respectively, of the element of type i in the target. The values of cross sections for elements, organic and inorganic compounds, as well as for different combinations of metal layers are given by Csikai and Buczkó (1999), Király and Csikai (2000), and Csikai et al. (2002a). These data are useful for different applications of neutrons, like quality control of organic and inorganic compounds; bulk hydrogen analysis; atomic H/C ratio for the detection of illicit drugs, explosives, and qualification of fossil fuels; assay of nuclear materials in solutions (Mohapatra and Reddy 2001); and validation of neutron data libraries (NEA 1994). For example, it follows from the relation that the measured cross sections for hydrogenous materials, such as crude oil, coal, illicit drugs, normalized to the number of carbon atoms present in the molecule as a function of the H/C atomic ratio exhibit a straight line (Jonah 2001). The calibration equation can also be determined from the excess counts $\eta = s(n_{\text{H}}/n_{\text{C}}) + \eta_0$ measured for different hydrocarbons.

It is worth noting that the determination of hydrogen in bulk materials has great importance in many areas (NEA 2001), for example, hydrogen in metals and alloys causes structural weakness in the components of heavy-duty systems (aircraft, engines, missiles, pipelines of nuclear and chemical plants). Metal hydrides are applied in various fields of science and technology (electricity, propulsion, battery, food, nuclear fusion, etc.).

Both pulsed-neutron backscattering combined with time-of-flight (TOF; see later) measurements and the elastic scattering of neutrons can be used for the detection of light elements. Scattering signatures measured for multi-element samples were analyzed to determine atom fractions for H, C, N, O, and other elements in different objects by using a combination of TOF and pulse height measurement (Buffler et al. 2001). Simple backscattering spectrometry is based on the fact that the broad spectra of neutrons from Pu-Be, ^{252}Cf , and $^9\text{Be(d,n)}$ sources can cover a large energy interval (1.5–10 MeV) of the elastic scattering cross sections (σ_{EL}) of light elements like C, N, and O as the major constituents of a number of organic and inorganic compounds. Therefore, the spectral yields of backscattered neutrons are affected by the structures present in the $\sigma_{\text{EL}}(E_n)$ functions. The measured spectral yields and the calculated energy dependence of the reaction rate, $R(E_n)$ indicate the different structures in the $\sigma_{\text{EL}}(E_n)$ functions for C, N, and O (Csikai and ElAgib 1999). An improved neutron backscattering technique based on the combination of a ~ 1.5 ns wide-pulsed beam of 550 keV and the TOF technique at 150° scattering angle was applied for the detection of C, N, and O from different samples (Aoki et al. 2000).

32.3.2 Gamma-Ray Methods

Recently, the neutron induced prompt gamma emission method (also called prompt gamma neutron activation analysis or PGNA) is widely used in online bulk elemental analysis, especially for the identification of explosives and illicit drugs. This method is not restricted to the use of prompt gammas emitted in radiative capture or (n,γ) reaction of slowed-down neutrons, but is extended to the fast-neutron $(n,x\gamma)$ reactions with $x = (n, p, \alpha)$, in which characteristic gamma rays are also produced. Among the $(n,x\gamma)$ type reactions, the inelastic neutron scattering $(n,n'\gamma)$ is the most common in elemental analysis. The (n,γ) and $(n,x\gamma)$ reactions are quite complementary to each other. For example, the (n,γ) cross section is low for Li, Be, B, C, N, O, and also for Na, Mg, Al, and Si, while the $(n,x\gamma)$ reaction yields are very high and the produced gamma rays specific to these elements. Therefore, prompt gamma rays produced in thermal, epithermal, and fast neutron interactions are all used for the elemental analysis of bulk media (Watterson et al. 1995). A typical example is the inspection of waste containers by irradiation with low-energy neutrons. The prompt gamma rays emitted in the de-excitation of fission fragments of actinide materials are measured with an array of HPGe detectors. The actinide isotopes are identified by observing selected gamma rays emitted from the fragments in pair-wise coincidence (Smith and Micklich 2000).

Pulsed 14 MeV neutron generators with neutron pulse width in the μs and ns regions have also been developed for analysis of bulk media and for borehole logging (Clayton and Wormald 1983; Schweitzer et al. 1988). The high penetrability of fast neutrons and energetic gamma rays renders the multi-elemental analysis of bulk ($m \gg 1$ kg, $V \gg 1$ dm³) samples possible. In addition to the identification of explosives and illicit drugs by the detection of the 4.44 and 6.13 MeV gamma rays emitted in the $^{12}\text{C}(n,n'\gamma)$ and $^{16}\text{O}(n,n'\gamma)$ reactions, respectively (Gozani 1994; Vourvopoulos 1994; Viesti et al. 1999), the online analysis is applied, for

■ Fig. 32.4

Combination of the sealed tube accelerator and the associated alpha-particle method (APM)

example, at coal mines, coal preparation plants, and coal-fired power plants. Concentrations of H, C, O, and N give information on caloric value, S on environmental pollution, Cl on corrosion of boiler, Al, Si, Ca, and Fe on ash content.

The combination of the sealed tube accelerator with the associated alpha-particle method (APM), illustrated in [Fig. 32.4](#), has great importance in the analysis of bulk samples, verification of chemical and nuclear weapons, in vivo analysis of human body element contents, and three-dimensional elemental analysis in solids. The time spectrum measured by the APM suggests that about 90% of the gamma rays of interest for prompt gamma-ray analysis are emitted from the 12 cm thick surface layer of solids in less than 10 ns after the neutrons hit the sample. Considering the attenuation of neutrons and gammas in the sample, the PGNA technique can give representative information on a few 10 kg of the samples. Some recommended reactions for bulk-media assay by prompt gamma-ray analysis using thermal and fast neutrons are summarized in [Sect. 36.3 of the Appendix of this Volume](#).

Among the gamma-ray methods, pulsed fast-thermal neutron analysis (PFTNA) plays an important role. The PFTNA method (Gozani 1994; Vourvopoulos 1994) is based on 14 MeV neutrons with 10 μ s pulse duration and 10 kHz frequency produced by a sealed tube D-T generator. The gated signals from the gamma rays, emitted during and between the neutron bursts are routed separately into two channel regions of an MCA. The 4.44 and 6.13 MeV gamma rays are recorded in the prompt region while the 2.23 MeV gamma rays from the $H(n,\gamma)$ reaction induced by the neutrons thermalized in the sample volume are measured between the pulses. Two devices based on this method, namely, PELAN (Pulsed Elemental Analysis with Neutrons) for the detection of explosives and NELIS (pallet inspection system) for the observation of illicit drugs are promising. Advantages and limitations of this technique are discussed in detail in a recent publication (Dokhale et al. 2001).

32.3.3 Specific Applications

The prompt and delayed gamma rays produced in 14 MeV neutron bombardment of rocks were published by Przewlocki et al. (1984). In the case of such complex samples, a number of interfering reactions and gamma-lines are produced. Separation between different elements can be improved by the combination of the D-D and D-T reactions. For example, the $(n, n'\gamma)$ reaction cannot be performed by the 3 MeV D-D neutrons on ^{12}C and ^{16}O . The use of associated particle timing based on the D-D reaction has been demonstrated for elemental analysis of bulk samples such as the human body (Evans et al. 1997). The nanosecond timing of an HPGe detector rendered it possible to identify the spatial origin of the measured gamma rays. The major elements in most rock types are Si, O, Al, Fe, Mg, Ca, Na, K, Ti, and P. Concentrations of these elements in the well-known terrestrial rocks vary from one to four orders of magnitude, therefore, careful investigations are needed to develop the most suitable methods for the elemental analysis of minerals, standard geological materials, lunar soil samples, processing solutions or slurries, and ocean bottom cores (Csikai 1992).

The conventional neutron methods are the neutron-epithermal neutron, neutron-thermal neutron, and the neutron-gamma procedures. In all three cases, rocks are bombarded by fast neutrons and either epithermal or thermal neutrons or gamma rays from radiative capture are registered. Both pulsed and stationary neutron sources are applied to these measurements (Berg and Jacobs 1983; Morris et al. 1983; Tittle et al. 1985; Demény et al. 1988; Mills et al. 1991). The pulsed TOF prompt gamma-ray analysis has been successfully applied by a number of authors, especially to the measurements of light elements (Sawa 1993; Brown et al. 1994; Gozani 1994; Vilaithong et al. 2000).

Nuclear techniques based on neutrons from radionuclides (^{252}Cf , Pu-Be, Am-Be) or small accelerator sources are successfully used in elemental analysis of bulk samples including the detection of illicit traffic materials in airline luggage (suitcases, briefcases, small boxes) by identifying H, C, N, O, Cl as major elements of these objects (Dokhale and Hussein 1997; Evans et al. 1999; Csikai et al. 2001). The atom fractions of these elements, in particular the C/O, C/H, and C/N ratios are quite different for drugs (cocaine $\text{C}_{17}\text{H}_{21}\text{NO}_4$, morphine $\text{C}_{17}\text{H}_{19}\text{NO}_3$, heroine $\text{C}_{21}\text{H}_{23}\text{NO}_5$) and explosives (nitroglycerin $\text{C}_3\text{H}_5\text{N}_3\text{O}_9$, TNT $\text{C}_7\text{H}_5\text{N}_3\text{O}_6$, RDX $\text{C}_3\text{H}_6\text{N}_6\text{O}_6$) as compared to other materials (sugar $\text{C}_{12}\text{H}_{22}\text{O}_{11}$, alcohol $\text{C}_2\text{H}_6\text{O}$, melamine $\text{C}_3\text{H}_6\text{N}_6$). Recently, a comprehensive review on the possible use of neutron methods for the detection and identification of explosives and drugs has been published (Cinausero and Viesti 2000).

There are many more new fields in the utilization of neutrons produced mainly by small D-D and D-T accelerators (IAEA 2000). Some typical fields of activation and prompt radiation analysis are summarized in [Table 32.1](#).

32.4 Neutron Imaging and Profiling Systems

The various applications of neutron radiography (reactor technology; rocket and missile technology; medical and biological investigations; inspection of plastic coating, gaskets, and turbines) have been extended for many new fields during the last 3 decades. The main advantages of neutron radiography (NR) are the ability of revealing many low-density media (water, oil, plastic) inside dense materials such as steel, Pb, Zr, U; high penetrability; high sensitivity for certain elements (H, B); discrimination between elements of similar atomic

■ Table 32.1

Typical applications of neutrons in elemental analysis

Field	Elements (matrices)
Metallurgy	N, O, F (alloys); O (refractory and nonferrous metals); Al, Si, P, Mg (cast iron, Al, Si-compounds); Al, Si, K (tungsten)
Chemistry	N, O, P, Al, Cl (explosives and propellants); N, O, Na, P (organic compounds and polymers); Cl, I (emulsions); N, P, K (fertilizers)
Electronics	N, O, Si, Al, Ti, P, Zn, Cr, Fe, Y, Zr, Eu, Ba, Dy (oxides, circuit boards, thin films)
Biology	N, Na, P, Cl, Ca (whole body); N (proteins, fossil bones); N, O, P, Ca (mixed feeds); N, O, K, Cl, Ca, Fe (plants); F, Na, Si, S, Ca, Fe, Ti, Sr, Ba, Hg, Pb (air-dust, fly ash)
Geology/mining/space sciences	O, Al, Si, Fe (lunar rocks); H, O, Na, S, Cl, V, Mn, Ni (crude oils); U, Th (rocks); O, Mg, Al, Si, Fe (sea cores); H, O, Al, Si (zeolites); H, C, O, Al, Si, Fe (coals)

weight and physical density; discrimination between different isotopes of the same element (^{10}B , ^{11}B , ^{113}Cd , ^{114}Cd); and applicability for highly radioactive objects, for example, fuel elements (Csikai 1987). It is impossible to cover all the new applications in a short review, therefore some results on the neutron depth profiling and imaging systems are intended to be discussed.

The nanosecond pulsed beam with time gating at the detector and the associated particle method (APM) render the three-dimensional (3D) elemental analysis of solids possible (Overley 1987; Rynes et al. 1999). The APM is based mainly on the D-D and D-T reactions by the detection of ^3He and ^4He particles, respectively, emitted at $\sim 180^\circ$ to the neutron direction. The 4–5 cm/ns travel time of the neutrons allows the imaging of the interrogated volume along the direction of the ns pulsed neutrons with a spatial resolution of ~ 5 cm. Some 2D-3D fast neutron imaging principles and techniques are summarized by Gozani (1994), Mikerov et al. (1998, 2001), and Chen and Lanza (2001), while typical thermal neutron radiography systems are demonstrated by Balaskó et al. 1998, 2001) and Shaikh et al. (1998, 2001).

Fast neutron resonance radiography (NRR) used by Chen and Lanza (2001) for elemental mapping is based on a hydrogen-rich plastic scintillator to detect the transmitted neutrons of 2–6 MeV energy. Different energies of neutrons were obtained by rotating the object detector assembly around a D-D source based on a 5 MV Van de Graaff accelerator. Monoenergetic neutrons in the 1.5 and 2.5 MeV ranges could also be obtained from the $^7\text{Li}(p,n)^7\text{Be}$ reaction

with a 10 μm thin Li target. Light from the scintillator is recorded by a charge coupled device (CCD) camera to form a radiographic image.¹ The structures in the energy dependence of the total cross sections, $\sigma_T(E_n)$, below 6 MeV render the distinction between light elements possible. The 2D images were formed using a 1 cm thick BC-430 plastic scintillator lens-coupled system with a cooled CCD camera which used a $1,242 \times 1,152$ pixel CCD.

Recently, investigations on the realization and prospects of real-time fast neutron radiography with a portable sealed tube D-T neutron generator with a yield up to 10^{10} s^{-1} and a luminescent CCD detector were published (Mikarov et al. 2001). The major components of the detector are shown in [Fig. 32.5](#): fast neutron screen prepared from hydrogenous polymer mixed with powder luminophor ($\text{Gd}_2\text{O}_2\text{S:Tb}$), image intensifier, CCD matrix, and fast lens system. Efficiency of disperse fast neutron screens and the effects of X-ray emission, scattered neutrons, and geometry of measurements on the quality of the image are also described.

Dynamic neutron radiography (DNR) measurements were performed (Balaskó et al. 2001) at the thermal channel of the 10 MW Budapest Research Reactor with a collimator ratio $L/D = 170$. The $10^8 \text{ cm}^{-2} \text{ s}^{-1}$ thermal neutron flux at the sample position of a beam with diameter of 150 mm and the 40 ms imaging cycle rendered the medium speed movements up to about 2.4 m/s possible. The light from an NE 426 converter screen was detected by a high sensitivity video camera. The neutron images of $\sim 200 \mu\text{m}$ resolution were displayed on a monitor and stored by an S-VHS recorder. This neutron imaging system provides a unique possibility to visualize various hydrogen-containing materials inside closed objects. A similar electronic imaging system based on a commercially available image intensifier tube and a low-cost CCD camera has been used (Shaikh et al. 2001) for visualization and analysis of water/air, water/vapor two-phase flow inside metallic pipes under high temperature and pressure conditions. Most of the cladding metals such as aluminum or steel are transparent to neutrons while hydrogenous materials such as water are relatively opaque which makes neutrons a unique tool

■ Fig. 32.5

Fast neutron luminescent CCD-detector on the basis. 1 – CCD-matrix, 2 – lens system, 3 – mirror, 4 – luminescent screen, 5 – sample, 6 – image intensifier

for visualizing the flow pattern. The fully automated neutron radiography system (DIANE) based on a sealed tube neutron generator is commercially available (Cluzeau et al. 1994). The necessary exposure fluence is about $10^{12}/\text{m}^2$ which can be produced at a 3 m source-object distance within 1 min by an intense neutron generator of $5 \times 10^{12}/\text{s}$ output rate.

Associated particle timing based on D-D neutrons was applied successfully (Evans and Mutamba 2002) for imaging an aluminum box. A combination of a Si detector for charged particles and an NaI(Tl) scintillator for induced gamma rays yielded a time resolution of 0.4 ns assuring a spatial resolution of better than 1 cm.

Knowledge of the concentration and spatial distribution of hydrogen in solids is required in many fields of science and technology. Therefore the development of such a hydrogen depth profiling method by which over 100 μm depth can be analyzed is indispensable. The drawback of elastic recoil detection and resonant nuclear reaction methods is that the depth is limited to several micrometers and serious radiation damage may occur. However, a fast neutron beam as a probe via the $\text{H}(n,p)$ reaction is nondestructive and can extend the depth to be analyzed beyond 100 μm . The energy distribution of recoiled protons is related to the depth profile of hydrogen. A fast neutron profiling method is based on the combination of an imaging plate (IP) and a polyethylene film as a converter. An experimental setup for the depth profiling is shown in Fig. 32.6. Using an appropriate neutron energy in the 5–15 MeV interval and a converter thickness close to the proton range, fairly clear images could be obtained (Miura et al. 2000; Sanami et al. 2000).

Fig. 32.6

Schematic view of the experimental setup and principle of NERD used for depth profiling

32.5 Fast Neutron Irradiation Effects in Solids

Recently, both steady-state and pulsed fast neutron generators have been applied to the investigation of radiation damage of metals, alloys, semiconductors, and high T_c ceramics and to nuclear heating of superconductors by prompt reaction products and long-lived radioisotopes. Of the wide range of applications a few typical examples are discussed in this review (Csikai 1995).

The irradiation of solids with fast neutrons results in the displacement of atoms from their lattice sites; the resultant interstitials and vacancies can cause various radiation damage phenomena. In addition, the determination of H and He gas production as well as the neutron multiplication by 14 MeV-neutron-induced (n,p), (n, α) and (n,2n) reactions, respectively, in the construction materials of fusion reactors is very important. Studies on the tritium breeding and outgassing efficiency for different blanket materials are also important tasks.

Some physical parameters related to the radiation effects which can be studied with small neutron generators are as follows:

Determination of the average range of recoil atoms by measuring the activities (A) of catcher foils placed on the surface of a sample of thickness d . (Note that r is used for the range of recoil atoms instead of the usual notation of R . The reason for this is that the latter could be confused with the reaction rate which is also denoted by R .) The mean projected range $\langle r \rangle$ of recoil atoms in forward and backward directions are given by the ratios of the released to the produced radioactive atoms, that is, $\langle r_f \rangle = (A_f/A_t)d$ and $\langle r_b \rangle = (A_b/A_t)d$, where $A_t = A_{\text{sample}} + A_{\text{catcher}}$ while the mean range $\langle r \rangle$ is obtained from $\langle r \rangle = [(A_f + A_b)/A_t]d$. The mean range of recoil atoms is between 10 and 1,000 nm in 14 MeV-neutron-induced reactions. Both the mean range and the value of d are customarily given in mg/cm². These data are also important for the elemental analysis of thin layers at which the released atoms should be taken into account. Therefore, for the elemental analysis of thin layers by neutron-induced reactions the knowledge of the $\langle r \rangle$ versus d function is required.

For the investigations on the release of foreign and lattice atoms by diffusion or evaporation from metals and alloys, the activated sample is placed into a vacuum chamber and the released radioactive atoms are collected by catcher foils. The activity of these foils is measured as a function of time at different sample temperatures. Data on the release of alloying elements from metallic compounds and alloys are required not only by solid state physics but also by high-tech industry and fusion technology.

The diffusion coefficients of tracers and the displacement of lattice atoms and their activation energies can also be measured (Sudár et al. 1977). Using fast neutrons, radioactive tracers can be produced homogeneously in extended samples. For example, the measurement of the diffusion coefficient of the ^{24}Na produced in $^{27}\text{Al}(n,\alpha)$ reaction for different alloys has a great practical importance, because a number of alloys used in reactor technology contain aluminum (e.g., the reactor fuel can).

Production rates of total hydrogen and total helium are important parameters in the evolution of the microstructure during the irradiation of solids, especially for fission and fusion reactor construction materials. These data can be measured by using a vacuum furnace equipment connected to a mass spectrometer for the detection of H and He gases produced in an irradiated bulk sample.

The production rate and the outgassing efficiency of tritium for different Li, Be, B compounds, and alloys used as blanket or structural materials (e.g., lithium–vanadium, lead–lithium and ceramic breeder, TiBe_{12}) can be determined for fusion neutrons by using

small neutron generators, even for the EURATOM fusion project (Gasparotto 2002). Data for the outgassing efficiency as a function of heating time and temperature for different samples are required. In addition, the behavior of hydrogen in metals can also be investigated by using deuterium and tritium as tracers. Studies on deuterium and tritium as substitutes for hydrogen in solids are of considerable interest to a better understanding of the depth profile, trapping, reflection, and diffusion of hydrogen implanted into different samples like metals, semiconductors, metallic glasses, or high T_c ceramics. For deuterium the retention kinetics, concentration profile, and the saturation yield can be determined via the $^2\text{H}(\text{d},\text{p})$ and $^2\text{H}(\text{d},\text{n})$ reactions (Csikai et al. 1997).

Studies of the effect of 14 MeV neutron irradiation on semiconductor electronic components have an essential role, because many electronic instruments are used in intense fast neutron fields. Radiation effects can be observed at a fast neutron fluence in the order of $10^{10}/\text{cm}^2$ at 20°C . Changes in the main characteristics of electronic circuits depend strongly on the type of semiconductor components. For example, definite changes were observed in the operating characteristics of Si(Li) detectors, diodes, transistors, and integrated circuits after the irradiation with 14 MeV neutrons up to $\sim 10^{13}/\text{cm}^2$ fluence. Further investigations are needed to study the effect of self-recovery of the irradiated Si(Li) detectors and integrated circuits.

Irradiations of optical components (laser glasses, fiber optics) to measure any effects of 14 MeV neutrons on light transmission or the index of refraction was carried out in the last decades (Heikkinen 1989). Studies on the effect of fast neutrons on electro-optical components are also required.

Online and off-line investigations are in progress to study the effects of fast neutrons in solids using fluences in the range $\sim 10^{18}$ – $10^{15}/\text{cm}^2$. Samples and physical properties to be studied are as follows: metals and alloys (mechanical, microstructure, electrical resistivity), superconductors (critical current, temperature and field), and insulators (electrical and mechanical properties).

In recent years various types of high T_c superconducting ceramics have been developed. Studies of the effects of fast neutrons on the physical parameters of high T_c superconductors are of interest both for basic research and applications. In the case of multiphase $\text{YBa}_2\text{Cu}_3\text{O}_7$ and $\text{Tl}_2\text{CaBa}_2\text{Cu}_2\text{O}_8$ ceramics a fluence of about $10^{14}/\text{cm}^2$ can cause a definite change in the physical parameters (Bódi et al. 1994), for example, both the specific resistance R/R_{293} and the microwave absorption of the sample decrease significantly. A systematic investigation on the oxygen content of high T_c ceramics is also required. This can be measured with high accuracy by the detection of the 6.13 MeV gamma-line produced in the $^{16}\text{O}(\text{n},\text{p})^{16}\text{N}$ reaction.

32.6 Radiobiology with Fast Neutrons

Neutrons are of interest for cancer therapy because they produce protons and other densely ionizing particles (alphas, recoil nuclei) in tissue. The use of fast neutrons in cancer radiotherapy was stimulated by three radiobiological findings: the oxygen enhancement ratio (OER), the sensitivity of cells at different phases of the cell cycle, and the contribution of sublethal damage to cell reproductive death. Neutrons have advantages to treat those types of tumors which contain anoxic cells. The variation in radio sensitivity of cells in different phases is less for neutrons than for X-rays. The relative biological effectiveness (RBE) of neutrons is generally higher in tumors than in normal tissues. Taking into account the cross sections at 14 MeV and abundances of H, C, N, and O in tissues, about 65% of the absorbed dose is due to

neutron–proton elastic scattering. Therefore, the absorbed dose is proportional to the H content of the organs, that is, it is about 15% higher in fat tissue than in muscle ones, while it is much lower in bones.

The radiation therapy in practice requires from the neutron source a high dose rate, good depth dose, well-defined horizontal and vertical beams movable around the patient, and a variable beam size up to about $20 \times 20 \text{ cm}^2$. In addition, an average neutron yield of $4 \times 10^{12}/\text{s}$, as well as 125 cm specified source–screen distance (SSD), and 2 cm maximum source diameter are needed for cancer therapy. A typical treatment schedule for malignant diseases involves two fractions per week, modal tumor doses of 1.2–1.3 Gy per fraction, and total doses in the range of 14–21 Gy.

In order to estimate the induced activity, the neutron dose value and the effect of interfering reactions, the distributions of thermal, epithermal, and fast neutron flux densities should be determined in a bulk media or a phantom. The most commonly used dosimetry reactions are given in [Sect. 36.3 of the Appendix of this Volume](#). In the case of a phantom, the combination of the activation detectors and the physical integration methods is recommended for the determination of the volume averaged dose equivalent rates and through it the total dose absorbed by a given organ (Csikai et al. 1988).

32.7 Neutron Attenuation and Shielding

Neutron moderators, filters, absorbers, and shielding are used in many devices and facilities of experimental nuclear and high-energy particle physics and in nuclear technology as well. Extended neutron transporting media are considered in some large-scale projects like online analysis of bulky geological samples, such as coal and minerals (Watterson 2000), bulk hydrogen analysis using neutrons (IAEA 1998, 2001), design of blankets of fusion reactors, development of accelerator-driven transmutation of nuclear waste (NEA 2002; Reimer 2002), checking of neutron transport calculations for shielding, effects of nuclear weapons, etc.

The characterization of the transport and the estimation of the radiation-induced damage and activation inside the medium require the knowledge of the expected neutron spectrum at each point of interest or of the average value over a large volume of the materials to be investigated. The above bulky units are typically planned on the basis of detailed Monte Carlo transport calculations using cross sections taken from different libraries. The consistency of the data used in the calculations can be checked experimentally by leakage spectrum measurements using simple geometries and known spectra of primary neutrons.

The leakage spectra of neutrons depend on the integrated density of the elements present between the neutron source and the detector, and on the interaction cross sections. A pulse height response spectrometer (PHRS) based on a relatively small volume of NE213 liquid scintillator with neutron–gamma discrimination can be used to measure the spectral yield of leakage neutrons in the 1.2–15 MeV range (Oláh et al. 1998), in addition to the multiple foil activation method. The latter has advantages in the determination of the spectral yield especially in the $E_{\text{th}} \leq E_n \leq 3 \text{ MeV}$ interval. Slabs and spheres of the most important shielding, construction, biological, and geological materials are used in these studies. The use of quasi-monoenergetic $^2\text{H}(\text{d},\text{n})$, $^3\text{H}(\text{d},\text{n})$ neutrons, and broad spectra of $^9\text{Be}(\text{d},\text{n})$, ^{252}Cf , Pu–Be source neutrons can assure the integral tests of the differential data. Recently, the backscattering spectrometry as a tool for elemental analysis of bulky samples based on the broad spectrum of Pu–Be neutrons has been investigated (Csikai and ElAgib 1999). The broad spectrum of

Pu-Be neutrons can cover a large energy interval (1.5–8 MeV) of the elastic scattering cross sections (σ_{EL}) of C, N, and O. Therefore, the spectral yields of backscattered neutrons are affected by the structures present in the $\sigma_{\text{EL}}(E_n)$ functions and so the reaction rate versus incident neutron energy is given by $R(E_n) = Y_0(E_n) \sigma_{\text{EL}}(E_n)$, where $Y_0(E_n)$ is the relative yield of the source neutrons while the $\sigma_{\text{EL}}(E_n)$ data are taken from different libraries. The geometrical arrangements used for a neutron leakage and backscattering spectrometries are shown in ► Fig. 32.7. Some typical spectra compared with the calculated values are shown in ► Fig. 32.8.

► Fig. 32.7

Setup geometries for leakage spectra measurements ($1.2 \leq E_n \leq 15 \text{ MeV}$)

■ Fig. 32.8

Measured and calculated leakage spectra of $^2\text{H}(\text{d},\text{n})$ source neutrons for Al slabs at $E_d = 9.4$ MeV

Among the neutron sources, the low voltage (100–200 kV) D-T 14 MeV generators play a special role in many applications (standard cross sections, activation and prompt radiation analysis, irradiation effects, radiography, well logging, shielding). Therefore, the flux density distributions of thermal and primary 14 MeV neutrons have been measured in different source-sample-detector geometries and calculated for different configurations of bulk samples (Ali et al. 1995). On the basis of these results, the differential and integrated reaction rates as a function of sample thickness could be determined.

The removal cross section is a useful parameter for the characterization of the attenuation property of shielding materials. The flux of neutrons of energy E from a point source is given by

$$\Phi(x, d, E) = Y \frac{e^{-\Sigma(E)x}}{4d^2\pi} \quad (32.12)$$

where d , Y , x , and Σ are the distance from the source (cm), the source strength (s^{-1}), the shield thickness (cm), and the macroscopic removal cross section (cm^{-1}), respectively. Using either the activation or the PHRS methods, the value of $\ln(\Phi d^2)$ plotted against x results in a straight line from the slope of which Σ can be determined for different geometries and energies. The samples, in general, are slabs with dimensions of $30 \times 30 \text{ cm}^2$ and disks of 30 cm diameter. The thickness is changed in the range $0 \leq x \leq 25$ cm. The values of macroscopic removal cross sections of fission, 14 and 3 MeV neutrons for elements and some compounds are given in the literature (Nargolwalla and Przybyłowicz 1973; Csikai 1987, 1995). A comparison of the Σ values measured by TOF technique indicates the effect of sample-detector geometry on the removal cross section.

In general the three-dimensional Monte Carlo transport codes MCNP-4A, -4B, -4C are used to predict the measured spectra. Point-wise cross sections from FENDL/E-1 are used mainly in

■ Fig. 32.9

Neutron flux fraction and reaction rate versus neutron energy for a $^2\text{H}(\text{d},\text{n})$ source

the calculations. These data were derived by MacFarlane from ENDF/B-VI, JENDL-3.1, and BROND-2 evaluations using the NJOY code system for different elements. The ENDF/B-IV and ENDF/B-V libraries are also used in continuous energy calculations (Jordanova et al. 1999).

As shown in ► Fig. 32.9 the spectrum-averaged integrated reaction rates and through them the possible use of the prompt gamma method for the detection of C, O, and Si depends strongly on the type of the neutron source. The integrated reaction rates, R , can be determined as a function of sample thickness x using the leakage spectra of different source neutrons. The $R(x)$ function is given by

$$R(x) = \int_{E_{thr}}^{\infty} \Phi(E_n, x) \sigma(E_n) dE. \quad (32.13)$$

Recent investigations have shown that the rate function $R(d)$ depends exponentially on the sample thickness, that is,

$$R(d) = \int_0^d R(x) dx = R_0 e^{-bd} \quad (32.14)$$

where the attenuation parameter b is related to the spectrum of the source neutrons and the shielding materials.

32.8 Editors' Notes

1. Charge coupled devices are silicon chips containing a matrix of potential wells that can trap electrons released by radiation. Since the size of the potential wells is only a few micrometers, they have good spatial resolution, a useful feature for electronic imaging (p. 1684).

Abstract: This chapter discusses the basic principles of analytical methods based on positive ion beams from particle accelerators. The methods, namely, particle-induced X-ray emission (PIXE), Rutherford backscattering spectroscopy (RBS), and nuclear reaction analysis (NRA) are described in detail. Besides the underlying physical processes, methodical questions, analytical capabilities, and typical fields of application are also discussed.

33.1 Detection of Particle-Induced X-Ray

33.1.1 Characteristics of the Method

Particle-induced X-ray emission (PIXE) is a combined process, in which continuum and characteristic X-rays are generated through the recombination of electrons and electron vacancies produced in ion–atom collision events during the slowing down of a beam of charged particles in an object. The unique correspondence between the energies of characteristic X-ray lines and the atomic numbers of the excited atoms makes PIXE a useful method in instrumental analytics. The characteristic features of PIXE as an analytical tool are as follows:

1. Applicability to the determination of absolute concentration of elemental constituents in a wide range of atomic number.
2. Easy sample preparation; practically nondestructive direct analysis of the surface of the original objects.
3. High sensitivity in trace element determination on small-volume samples.
4. High speed in the preparations and measurements.
5. Possibility of obtaining analytical information from microscopic sample areas combined with linear or two-dimensional automatic scanning over the sample surface.
6. Possibility of measuring depth distribution curves for selected elemental constituents below the sample surface.
7. Easy ways for the automation of the measurements and evaluation at an acceptable level of accuracy and precision.

The physical background and the basic processes underlying the PIXE method were first described, in pioneering papers, in the middle of the 1970s (F. Folkmann 1975; Johansson and Johansson 1976).

With the development of methodology, PIXE elemental analysis has become a versatile analytical tool in a continuously broadening field of applications. Detailed introduction to the technique and overviews on its interdisciplinary applications can be found in monographs and review papers (Johansson and Campbell 1988; Koltay 1988; Johansson et al. 1995) as well as in proceedings volumes of the international series of PIXE conferences 1–11 (Johansson 1977; Johansson 1981; Martin 1984; Van Rinveld et al. 1987; Vis 1990; Uda 1993; Moschini and Valkovic 1996; Malmqvist 1999; Campbell 2002. Budnar and Campbell 2005; Miranda and Ruvalcaba-Sil 2008) as well as in proceedings volumes of the International Conferences on Nuclear Microprobe Technology and Applications (Demortier 1982; Grime and Watt 1988; Legge and Jamieson 1991; Lindh 1993; Yang et al. 1995; Doyle et al. 1997; Prozesky et al. 1999; Moretto and Bonin Mosbah 2001; Takai and Kamiya 2003; Jaksic and Bogdanovic Radovic 2005; Osipovicz et al. 2007; Rajta et al. 2009).

33.1.2 Physical Background of PIXE

The PIXE process underlying the present analytical technique can be described in the following way.

The sample to be analyzed is composed of elements $k = 1, \dots, n$ with atomic numbers Z_k present in relative concentrations by weight $C(Z_k)$. It is bombarded by a particle beam of energy E_0 in the range of 10^5 – 10^6 eV delivered by a nuclear particle accelerator. Depending on the purpose of experiment, the bombarding beam is either formed with a diffuser foil and sets of collimator slits to get uniform distribution of current density over a spot of required diameter or focused down to μm size or smaller in an ion-optical particle microbeam channel. Either the sample may be irradiated in the evacuated beam transport channel or the beam can be transported through a thin window to an external irradiation site in the atmosphere. The total number of particles incident during the bombarding time is determined as the time integral of the beam current divided by the electron charge. As the bombarding particles gradually slow down in the subsequent layers of the sample they reach the layer between x and $x + dx$ with energy E , where a set of characteristic X-ray lines with energy $E_X = E_{j,Z_k}^X$ will be induced with the respective cross sections $\sigma_{j,Z_k}(E)$, where j denotes a selected X-ray line emitted by element Z_k . X-ray quanta are detected with an X-ray spectrometer of detection solid angle $\Omega/4\pi$, and the X-ray spectrum is generated by an electronic signal processor. Absorption terms $\exp(-\mu_i x_i)$ representing X-ray absorption between sample and detector as an effect of upper sample layers, energy filter foil, windows of the vacuum chamber and of the X-ray detector, and detector efficiency depending on the X-ray energy should be taken into account in deducing elemental concentrations from the intensities of X-ray lines. The characteristic X-ray lines of intensities Y_{j,Z_k} , which contain the analytical information, are superimposed on an X-ray continuum in the spectrum. This background is partly generated by intrinsic effects during bombardment. A further considerable component is caused by the charging up of the sample by the bombarding beam. Special experimental arrangements can be used for eliminating this effect. Minimum detection limits for the different elements in the sample are mainly determined by the intensity ratio of the characteristic lines to the respective value in background continuum.

The characteristic features of the processes involved are shown in panels (1) to (5) plotted in [Fig. 33.1](#).

1. From the values of the X-ray energies/lines the atomic number of the emitter atom can be uniquely determined. The K_α and K_β lines cover the energy range 0.1–110 keV for elements from lithium to uranium, while for L_α , L_β , and L_γ lines the energy range for elements from zinc to uranium is between 1 and 21.5 keV (Leroux and Think 1977; Sevier 1979). A schematic plot of the X-ray energies is given in panel (1) of [Fig. 33.1](#). A proper selection of K and L lines can result in optimum conditions for elemental analysis in a broad range of atomic numbers.
2. The detector efficiency for a conventional Si(Li) X-ray spectrometer is close to 1 in the energy interval between 1.3 and 20 keV indicated with vertical dotted lines. The low-energy cutoff can be assigned to X-ray absorption in the entrance window of the detector. The actual curves are plotted for two typical thicknesses of the window. Data for calculating the energy-dependent X-ray absorption coefficient can be found in (Berger and Hubbel 1987). At the high-energy side, the silicon detector becomes partly transparent for the X radiation, and the shape of the cutoff depends on the detector thickness. As shown by the crossing of horizontal and vertical dotted lines in panel (2) of [Fig. 33.1](#), elements with atomic

numbers $11 \leq Z \leq 92$ can be detected with high detection efficiency if K and L lines are used for the detection of elements with atomic numbers $Z \leq 47$ and $Z > 47$, respectively. It should be mentioned, however, that the low Z limit can be shifted to $Z \approx 6$ with the application of extra thin windows or even of windowless detectors (Uzonyi et al. 2001).

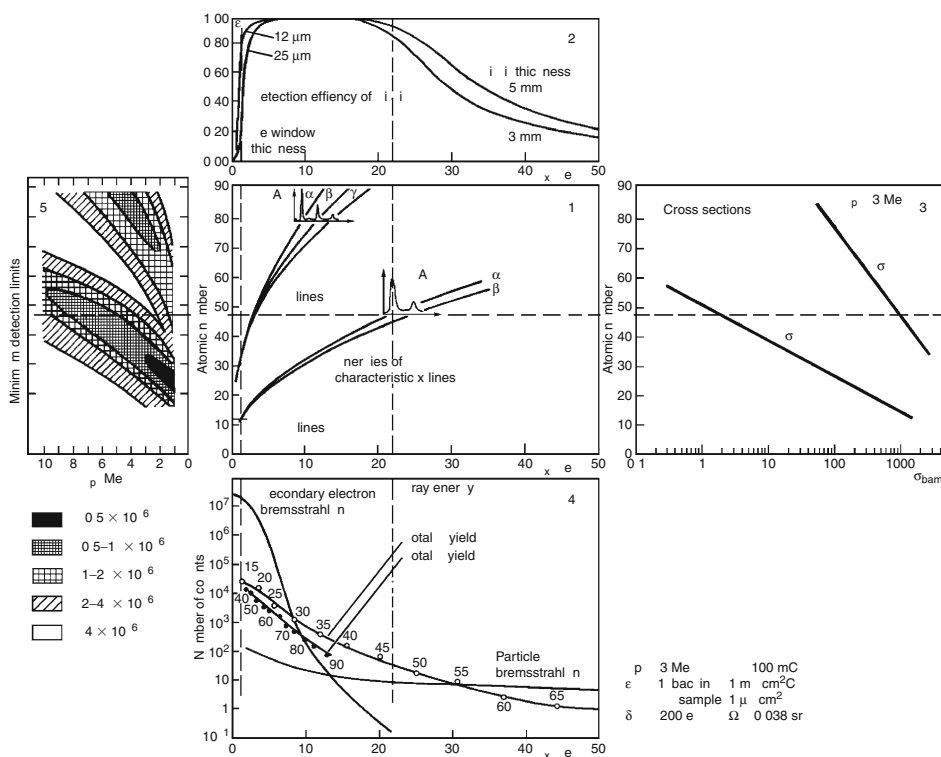

3. The cross sections of the excitation of X-ray lines exhibit a strong decrease with the bombarding energy. The dependence of total cross sections σ_K and σ_L on atomic number is shown for 3 MeV proton bombarding energy (Gardner and Gray 1978; Cohen and Harrigan 1985) in panel (3) of [Fig. 33.1](#). The overall high cross-section values of the excitation process clearly indicate that PIXE can generally be used as a fast, high yield analytical procedure. The strong decrease of σ_K for high Z elements calls again for the application of L lines in the high Z region, in full correspondence with the conclusion drawn in point (2) from the trend of decreasing detector efficiency for high-energy K lines.
4. The continuous X-ray background present in the spectrum is produced in two main processes. On the one hand, the slowing of bombarding particles in the thick (sample + backing) structure of the sample results in a component decreasing with increasing X-ray energy. The physical parameters influencing the differential cross section of the process are the mass numbers and atomic numbers of the bombarding particles and the slowing medium, as well as the bombarding energy. On the other hand, the slowing of secondary electrons released by the bombarding particles from the sample, results in another bremsstrahlung continuum. It has a sharp high-energy cutoff at the maximum kinetic energy of the secondary electron given by a simple kinematic relation for the particle–electron collision event.¹ Calculated curves are presented in panel (4) of [Fig. 33.1](#) for the model case of a series of thin monoelemental samples made of layers of atomic numbers Z with $1 \mu\text{g}/\text{cm}^2$ thickness deposited on a carbon backing of $1 \text{ mg}/\text{cm}^2$ thickness. Here a comparison of total K- and L-line yields is shown for atomic numbers between 15 and 90 with calculated yields of the secondary electron bremsstrahlung and particle bremsstrahlung. The values of the bombarding proton energy E_p , total integrated proton charge q , detector parameters such as efficiency ε , energy resolution δ , and solid angle Ω are given on the right side of the drawing (Folkmann 1975).
5. The detection limit of the method for any given element is determined by the height of the respective characteristic X-ray lines relative to the background level around the lines. Therefore, data like those shown in panel (4) of [Fig. 33.1](#) could be used for the determination of minimum detection limits as the function of atomic number Z and bombarding particle energy E_p . In panel (5) of the figure, the minimum detection limits are plotted as functions of Z and E_p for protons as bombarding particles (Johansson and Johansson 1976).

33.1.3 Instrumental Background

PIXE analytical measurements are based on the use of particle beams generated in a nuclear accelerator covering an energy range of a few MeV. Proper physical conditions for irradiation of the sample and spectroscopic detection of X-rays emitted in PIXE processes can be ensured by special beam transport channels. Here the beam is formed either by a magnetic quadrupole lens system in the conventional beam transport channel of the accelerator or by a microbeam focusing system in a particle microprobe configuration. As passive elements, a beam scatterer foil and a combination of collimator and antiscattering slits are used to get a uniform distribution of current density over the beam spot on the target and to remove any beam halo formed by scattered particles, respectively. Further elements are used for positioning the

■ Fig. 33.1

The characteristic features of the particle-induced X-ray emission (PIXE) process. See text for details

samples and the X-ray spectroscopic detector in well-defined detection geometry, as well as for the accurate measurement of the number of bombarding particles. Furthermore, tools are available for a physical modification of the detected X-ray spectra for minimizing spectrum background and overload of the detection system. With the use of these elements, optimum detection limits can be obtained for selected preferred ranges of atomic numbers in the sample.

The bombarding particle beam is accelerated and transported in the high vacuum system of the accelerator. The X-ray detector unit is encapsulated in a separate clean vacuum system. The irradiation of the sample may be performed in vacuum or under atmospheric conditions, depending on the size, physical state, and other parameters of the sample. To define the physical conditions mentioned above, special PIXE chambers of internal beam and external beam configurations are used for in vacuo and atmospheric irradiations, respectively.

33.1.3.1 Internal Beam PIXE Chambers

In such an arrangement, schematically shown in [Fig. 33.2a](#), the irradiation of the sample takes place in the vacuum of the beam transport channel, while the detector with its separate vacuum volume looks on the sample through the entrance window of the detector formed by a thin foil. The two vacuum volumes are normally separated from each other either by in vacuo

or through-the-window arrangements. In the former case, the detector head penetrates the irradiation chamber, while in the latter case it is separated from the vacuum system of the accelerator by an air gap formed between the entrance window of the detector and a thin foil exit window on the chamber wall.

Detector windows, optional chamber windows, and the air gap formed between chamber and detector windows are X-ray absorbers, which modify the shape of the detected X-ray spectrum in an energy-dependent way. Optionally, additional absorbers can be made use of to optimize the analytical parameters. They are partly to keep away elastically scattered protons from the detector, and partly to improve the detection limits for elements with $Z > 20$ by cutting the background X-ray continuum, which is enhanced at low atomic numbers as shown in panel (4) of [Fig. 33.1](#).

Manually operated or automatic sample changers normally accept a batch of samples arranged in a set to be loaded together in the vacuum chamber. They facilitate a sequential irradiation of the individual samples in a fast serial analysis. Other arrangements permit the measurement of longitudinal or transversal elemental distributions in extended samples through a fine continuous sample advance along an axis perpendicular to the direction of the bombarding beam.

The number of bombarding particles is determined as the time integral of the bombarding current over the total irradiation time divided by the ion charge. Special current measuring methods are needed for two reasons. First, large PIXE cross sections permit the use of particle beam currents as low as 10^{-9} A to decrease the heat load delivered by the beam on the sample. In this way, an almost perfectly nondestructive analysis can be achieved. Second, disturbing effects caused by the bombarding beam through secondary electron emission and charging up of insulating sample material should be diminished to a tolerable level. For thin targets, which are transparent for the beam, the beam current measurement can be performed in a Faraday cup located behind the sample. (Faraday cups are briefly explained at the end of [Sect. 50.1 of Chap. 50, Vol. 5](#), on “Particle Accelerators.”) For thick samples, the whole chamber should be formed as a Faraday cup and kept insulated from the ground to permit current measurements toward the ground. The disturbing effects of secondary electrons can be suppressed by the use of biased collimator elements, which cut the electron trajectories within the chamber as a Faraday cup. An alternative method for the determination of the number of bombarding particles is offered by the monitoring of the current through the yield of particles elastically scattered from a compact beam chopper intermittently cutting a small fraction of the beam near the sample to be analyzed (Bartha and Uzonyi 2000). In this way, all the difficulties of beam-current measurements can be avoided.

The charging up of insulating samples by the particle beam builds up an electrostatic acceleration field in the neighborhood of the sample, which results in an enhanced secondary electron bremsstrahlung. The suppression of this background component can be achieved by the use of a small compact electron gun, which neutralizes the positive charge of the sample (Ahlenberg et al. 1975). The current of the electrons from the source also gets stopped within the Faraday cup formed by the chamber, so it does not interfere with the measurement of the particle beam current.

33.1.3.2 External Beam PIXE Chambers

Technical difficulties may appear in exposing samples to chamber vacuum in the case of large size objects, art treasures, special biological specimens, samples of liquid form, of high volatility

and/or heat sensitivity. Such difficulties may be overcome by the application of an external beam configuration, in which the bombardment takes place under atmospheric pressure (Katsanos et al. 1976; Khan et al. 1979).

In this arrangement, the bombarding beam is led to the air through an exit foil located at the exit of the beam channel behind the collimator set as shown in ▶ Fig. 33.2b. Exit window can be made of thin beryllium, aluminum, or synthetic Kapton foil. Beam bombardment of the metal foils will generate high γ -ray background from nuclear reactions; therefore, Kapton foils are sometimes preferred in spite of their shorter lifetime.

A special source of disturbing background appears in this arrangement when the beam excites the characteristic X-rays of gases present in the gap between the exit foil and the sample.

■ Fig. 33.2

Internal beam and external beam PIXE chambers (a and b, respectively). See text for details

Nitrogen and oxygen are too light elements to be detected in standard cases, but argon contributes with an intense background composed of argon K, argon escape peaks, and argon pileup peak at 2.957, 1.205, and 5.914 keV, respectively. (For atomic-electron binding energies and K X-ray energies see ▶ Sect. 11.4 in Chap. 11 of Vol. 1.) As a result, elements lighter than Cl can hardly be detected. To overcome this limitation, in some external beam configurations the air is replaced by helium gas in the window-to-sample gap.

Local heating in the beam spot on the sample surface is efficiently reduced by the cooling effect of the surrounding gas volume; therefore, the nondestructive character of the PIXE method is improved in this version.

Ionization along the beam trajectory within the gaseous environment has two effects. Firstly, it eliminates the disturbing effect of the charging up of insulating samples. Secondly, however, ionization and the emission of secondary electrons from the exit window render the determination of the intensity of the bombarding beam more difficult. It is conventional to measure the sum of currents on the exit window and on the sample for monitoring the measurements. Alternative methods are to measure the height of the argon X-ray line or the intensity of the particles elastically scattered from the exit window.

33.1.3.3 Micro PIXE Facilities

Elaborate special ion-optical systems of particle accelerators composed of strong focusing and transversal beam scanning elements offer an analytical tool for lateral two-dimensional mapping of elemental constituents in a sample. The ion-optical and technical details of these equipments called scanning particle microprobe (SPM) facilities are briefly described in ▶ Chap. 50 of Vol. 5 on “Particle Accelerators.” Periodic transversal deflections generated in two perpendicular dimensions will drive the fine-focused beam to scan over a selected area of the sample. When equipped with X-ray spectroscopy, elements known from conventional PIXE technique and with data acquisition system arranging spectroscopic information in synchronism with beam scanning in two-dimensional elemental maps, the system permits the application of the PIXE technique with a typical lateral resolution of the order of 1 μm .

In a similar way, morphological (optical-type) images can be built up from simultaneously acquired counts of secondary electrons released from the sample during ion bombardment. Furthermore, scanning transmission ion microscopic (STIM) images may be obtained by mapping the numbers of ions passed through the scanned pixels in the sample. STIM images give information on the lateral distribution of areal density of the bombarded layer without giving any analytical information (Watt et al. 2009).

The quality of microPIXE maps combined with simultaneously built off-axis STIM image is illustrated in ▶ Fig. 33.3 showing the elemental localization in a root section of the plant *Bidens tripartitus* (Szikszai et al. 2008).

As best performance achieved in PIXE scans, a lateral resolution of <400 nm has been reported (Watt et al. 2002). Further decrease in beam spot size can be expected as a result of ongoing development work. Steps toward nanometer resolution are being taken by several groups (e.g., Watt et al. 2003; Glass et al. 2007; Andersson et al. 2008; Watt et al. 2009). In these nanobeam setups, the beam spot emerging from an above described microbeam system serves as an intermediate image for a second lens system. This system is formed by electron-optically optimized groups of quadrupole-lens configurations (doublets and/or triplets) and provides further demagnification. Several sets of precision-slit devices are arranged in proper positions

■ Fig. 33.3

The scanning transmission ion microscopic (STIM) energy loss image and true elemental PIXE maps of a *Bidens tripartitus* section. The thickness of the section was 20 μm , the scan size was $1,250 \times 1,250 \mu\text{m}^2$

to remove beam halos caused by ions scattered from construction elements of the long beam channel. In state-of-art nanobeam channels, a beam size of a couple of ten nanometers has been achieved.

Scanning particle microbeam facilities are competitive with commercially available electron microprobe analyzers. The replacement of electron beams by ion beams in SPM facilities results in highly improved minimum detection limits for elemental constituents in a sample. In the case of electron microprobe analyzers, characteristic X-rays are superimposed on the strong X-ray continuum from electron bremsstrahlung generated by the bombarding electron beam. This radiation background is orders of magnitude higher than the respective background component released by slowing ions in the PIXE process. Consequently, minimum detection limits determined by signal/background ratio in the spectrum, which amount typically to a few percent for most elements in the case of electron beams, will be improved by more than two orders of magnitude in micro PIXE analyses. The lateral resolution in optical and morphological information to be obtained in the form of maps built up from the intensities of secondary electrons released during beam scanning of the object is inferior in the SPM case due to larger beam sizes at the present normal level of ion beam focusing. However, the optical quality appearing in the X-ray maps in electron microprobes cannot be kept at the high level typical of the corresponding secondary electron image due to the broadening of bombarding electron beam through scattering in the depth of the sample. The interaction volume for the release of characteristic X-rays by bombarding electrons is increased in depth and diameter with respect to the volume participating in the emission of secondary electrons used in forming

the electron image. The lateral resolutions in X-ray elemental maps are comparable in electron and particle microprobe systems.

In recent years, the external beam technique has been subjected to successive steps of improvements to meet the serious requirements with respect to its application in microbeam setups. Among others, the objectives were solving the problems of increased accuracy of beam monitoring, reducing the scattering of the beam in exit windows, and making possible the simultaneous application of PIXE with other ion beam analytical (IBA) methods. A detailed description of one of the latest external microbeam facility can be found in the work of Salomon et al. (2008).

33.1.4 Quantitative Analysis

33.1.4.1 Spectrum Evaluation

The analytical information on the elemental composition of a sample can be deduced from a complex PIXE spectrum, in which characteristic X-ray lines emitted via transitions between different electron shells of the atoms in the sample are superimposed on an energy-dependent X-ray continuum. Yields $Y(Z)$ for a characteristic line of energy $E_{j,Z}^X$ belonging to a transition j in an atom of atomic number Z can be obtained by unfolding the spectra. For this purpose, computer codes have been elaborated. They are based on a least-squares fitting procedure optimizing a number of parameters in a model representing line shapes and background characteristics.² Corrections are also included for treating the dead-time problems and the effects caused by escape and pileup peaks. There are a number of software packages for the evaluation of PIXE spectra. Software packages known under the names of GEOPIXE (Ryan et al. 1990), GUPIX (Maxwell et al. 1989), PIXAN, PIXEKLM (Szabó and Borbély-Kiss 1993, 1999), PIXEKLM-TPI (Uzonyi and Szabó 2005), SAPIX (Sera and Futatsugawa 1996), WINAXIL (Vekemans et al. 1994), and WITSHEX (Lipworth et al. 1993) have been subjected recently to a systematic intercomparison procedure (Blaauw et al. 2002) and have been found to perform reasonably well in deducing peak areas belonging to elemental constituents.

33.1.4.2 Deducing Concentrations

The calibration of a PIXE system, i.e., the determination of sensitivity factors, which assign absolute concentration data to numbers of counts in X-ray peaks, can be performed in two different ways. First, sensitivity factors can be deduced theoretically or in a semiempirical way from calculated cross sections for X-ray excitation and from X-ray absorption data for the absorbents present between the points of emission and detection, in the actual experimental setup. Second, sensitivity factors can be deduced from measurements performed on standard samples consisting of pure elements or pure chemical compounds. The detection solid angle and the energy-dependent detector efficiency should also be determined.

The calibration procedure takes into account the slowing down and the absorption effects. The bombarding particle slows down along the depth of the sample, and thus the cross section of inducing X-ray depends on the depth of the sample. On the other hand, X-rays are absorbed along the thickness of the sample layer between the actual emission point and the entrance window of the X-ray detector.

For a thin uniform homogeneous sample with negligible energy, loss of the bombarding particle and no absorption of the X-rays in the sample, the yield of each X-ray peak can be calculated from the formula

$$Y(Z) = \frac{N_A \sigma_Z(E_0) \omega_Z b_Z \varepsilon_Z}{A_Z} M_a N = K(Z) M_a N, \quad (33.1)$$

where N_A denotes Avogadro's constant, $\sigma_Z(E_0)$ is the ionization cross section at proton energy E_0 , $\omega_Z(E_0)$ and b_Z denote fluorescence yield and branching ratio, respectively, ε_Z is the detection efficiency composed of solid angle $\Omega/4\pi$, absorption factors and absolute detector efficiency ε_{Z^*} for the bare detector, Z and A_Z are atomic number and molar mass, respectively, of the element with areal density M_a , while N stands for the number of bombarding particles. Calibration means the determination of thin target sensitivity factor $K(Z)$ as a function of the atomic number.

For a **thick homogeneous target** in which the bombarding particles are completely stopped and the emitted X-rays are subjected to considerable absorption in the source, the yield of each X-ray peak can be written as follows:

$$Y(Z) = \frac{N_A \omega_Z b_Z \varepsilon_Z}{A_Z} C_Z N \int_{E_0}^0 \frac{\sigma_Z(E) T_Z(E)}{S(E)} dE, \quad (33.2)$$

where C_Z is the concentration of element with atomic number Z , $S(E)$ denotes the stopping power (for its definition see [Eq. \(8.1\) in Chap. 8 of Vol. 1](#)), and

$$T_Z(E) = \exp \left(-\frac{\mu \cos \theta_i}{\rho \sin \theta_0} \int_{E_0}^E \frac{dE}{S(E)} \right) \quad (33.3)$$

gives the photon attenuation in the sample. Symbols θ_i and θ_0 denote the angles of beam incidence and X-ray detection, respectively, measured from the normal to the sample surface. For a sample of more than one bulk element, the resultant μ/ρ attenuation coefficient and stopping power should be deduced by summing over the corresponding data for the basic constituents.

A useful alternative method for calibration in the thick sample case is to perform thick target correction on thin-sample sensitivity factor $K(Z)$ by the help of a calculated function $I(Z)$ to be obtained by rewriting [Eq. \(33.2\)](#) to give

$$Y(Z) = N C_Z K(Z) I(Z) = N C_Z K(Z) \int_{E_0}^0 \frac{\sigma_Z(E) T_Z(E)}{\sigma_Z(E_0) S(E)} dE \quad (33.4)$$

The data should be made use of here on sample composition and thickness.

The above calibration methods are made somewhat inadequate by some effects pertinent to the matrix composition of the sample. They can easily be used in the case of samples the matrix of which is built of bulk elements of known concentrations, and the task is just the determination of trace elements, which do not contribute considerably to the slowing and absorption behavior of the matrix. In the opposite case, when bulk components of unknown

concentrations are to be analyzed, an iterative procedure can be used starting from arbitrary initial concentrations for the major constituents.

Another important matrix effect is the enhancement of X-ray emission through secondary X-ray fluorescence in thick samples. This effect can lead to a significant overestimation of concentration data for some combinations of elements, in which energy differences between the primary X radiation and absorption edge of the lighter component is small. Some numerical and analytical procedures offer more or less appropriate corrections for this effect.

It should be mentioned, that matrix effects disappear with decreasing sample thickness. In the calibration procedure for the thin-sample approximation, i.e., when measuring thin-sample sensitivity factors for K and L lines, standard foils of known areal density (also called surface density) are used regularly as calibration standards.

In the case of thick samples separate thick single-element standards can be made use of for each element to be analyzed with $C_{Z, \text{standard}} = 1$. In this procedure the concentration C_Z of element Z in the sample to be analyzed writes

$$C_Z = \frac{Y(Z) I_s(Z)}{Y_s(Z) I(Z)} \quad (33.5)$$

where the subscript “s” stands for standard.

An alternative way is given by the internal standard method, in which a particular element (most often yttrium) is added in known quantity to the sample to be analyzed. Special care should be taken of homogeneous mixing during addition. In this method an absolute determination of the bombarding particle current is not essential, furthermore matrix effects are well accounted for. The use of thick multielemental standards offers a relatively fast and simple way. However, differences in the composition of standards and samples to be analyzed make matrix corrections necessary if improved accuracy is needed.

Systematic comparison of the theoretical and experimental calibration methods proves that the determination of elemental concentrations can be performed with an overall accuracy of 3–5%; this number includes the errors appearing in spectrum evaluation as well.

33.1.4.3 Concentrations in Inhomogeneous Samples

In many practical cases, correction methods should be applied to allow for nonuniformities and inhomogeneities in the samples. Surface irregularities (Smit et al. 1984), clusterization of the minor components in binary alloys in the form of grains of different sizes (Respaldiza et al. 1987), influence of granular structure of the material (Markowicz et al. 1980), oxide layers appearing on the surface of samples (Rickards 1985) are cases to be treated using improved physical models. In the evaluation of micro PIXE data taken on single granules composing a sample, special care should be taken of the influence of the actual particle shape on slowing down and X-ray absorption processes (Jaksic et al. 1993; Bogdanovic et al. 1994).

The determination of in-depth distribution curves of minor constituents of a bulk may be of importance in the investigation of corrosion, diffusion, oxidation, and annealing processes and in studying surface coating layers. Within an interval of depth coordinate x not exceeding

the range of the bombarding particle such measurements can be evaluated on the basis of [Eq. \(33.2\)](#) by introducing the function $C_Z(x)$ in place of the concentration C_Z . Rewriting [Eq. \(33.2\)](#) with variable x the detected yield of the X-line at bombarding energy E_0 appears in the form

$$Y(Z) = kN \int_0^{R \cos \theta_i} C_Z(x) \sigma[E_0, E(x)] \exp(-\mu x / \cos \theta_0) dx, \quad (33.6)$$

where k is a constant, R is the range of the bombarding particle, $E(x)$ is the particle energy in depth x , and $\sigma[E_0, E(x)]$ is the local mean value of the cross section. Special deconvolution algorithms (Végh et al. 1978; Brissaud et al. 1985), applied to a series of experiments with incident bombarding energies varied over the appropriate energy interval, offer a technique for deducing the depth distribution of detected elements.

33.1.5 Analytical Characteristics of PIXE

Nondestructive character. The PIXE method is practically nondestructive. In many cases, samples can be used in their original form; external beam configuration can accept even large size objects. During analysis, samples are only subjected to a moderate heat load equivalent to the loss of beam energy within the small beam spot on the sample. This effect remains low in thin samples in which case the overwhelming part of the beam energy is dissipated outside the sample in the Faraday cup behind the target. For other sample thicknesses, too, the conventional values of 1–10 nA beam intensity and beam diameter of a few mm in macrobeam mode does not cause an appreciable modification of the state of the sample. However, in microbeam mode, a considerable increase may appear in beam current density in the well-focused beam spot. In internal beam version, the stability of the sample material against warm-up and vacuum environment should be considered. In external beam mode, local warm-up in the beam spot on the sample is efficiently reduced by the cooling effect of the surrounding gas volume; therefore, the nondestructive character of PIXE method is improved in this version.

Range of application. As explained in [Sect. 33.2.2](#), the lower and upper limits of the interval of atomic numbers to be covered by PIXE method are mainly determined by the thickness of detector window and detector crystal, respectively. In typical experimental setups, the lower limit is set at $Z = 13$, but it can be shifted down to $Z = 6$ with the application of extra thin detector windows. The upper limits can reach $Z = 92$. The PIXE method offers simultaneous multielemental analysis for the elements within the named intervals.

Analytical features. As a typical example of the form in which experimental data appear during PIXE analysis, [Fig. 33.4](#) presents an X-ray spectrum obtained on a sample of coarse fraction atmospheric aerosol deposited on a polycarbonate membrane filter of 7 μm thickness. The spectrum was taken with protons of 2 MeV bombarding energy in a run of 1,200 s and beam intensity of 30 nA. The physical conditions in this case correspond to the approximation of the thin uniform homogeneous sample. Full and dashed lines show curves fitted by the spectrum evaluation code to the total spectrum and to its continuous background, respectively. The general features of the spectrum can be well explained on the basis of the simplified diagrams in [Fig. 33.1](#).

The analytical parameters, minimum detection limits, accuracy, and speed, which determine the applicability of the PIXE method and are important from the point of view of its comparison with other competitive methods of instrumental analysis, can be deduced from the

complete evaluation of the experimental data. These parameters are functions of the atomic number of the elemental constituents and may depend on the composition of the sample matrix, the atomic number of the element in question, the detection parameters, and the energy, type, and total number of bombarding particles.

The **minimum detection limit** for a given element in a sample is defined as the minimum concentration at which the X-line intensity equals three times of the standard deviation of the background in the respective interval of the spectrum. Its value is normally expressed in $\mu\text{g/g}$ units and depends on the experimental conditions, mainly through the actual shape of the background and the number of counts in the X-ray line. As shown in panel (5) in [Fig. 33.1](#), calculated for proton beams of 10 μC total collected charge and 1–10 MeV energy in the case of sample thickness (i.e., surface density) of 0.1 mg/cm^2 on carbon matrix, the minimum detection limit is around 1 $\mu\text{g/g}$ for a broad interval of the atomic number. The capabilities of the method in practical applications are illustrated in [Fig. 33.4](#), in which the minimum detectable limits are given in units ng/m^3 air for the case of the spectrum shown in [Fig. 33.5](#).

The **accuracy** defined as the deviation of deduced concentrations from the respective true values depends first on the accuracy obtained in the calibration of the measuring configuration. For thin samples, a careful calibration and evaluation procedure can result in the estimated accuracy of 2–3% between $22 \leq Z \leq 30$ and 5% between $11 \leq Z \leq 20$. However, it should be kept in mind that the analytical accuracy in measurements performed on actual thin samples may be degraded by effects pertinent to the applied sampling technique. As described in [Sect. 33.1.4.2](#) special care should be taken with regard to stopping, absorption, and matrix effects in thick sample cases.

Fig. 33.4

PIXE spectrum taken on an aerosol sample of coarse size fraction

■ Fig. 33.5

Minimum detection limits in PIXE analysis of atmospheric aerosol samples

The **speed** of the analysis is a parameter inversely correlated with the detection limits required because an increased statistical accuracy can be achieved by a longer time of spectrum acquisition. A couple of thousand second long measuring time is a typical compromise in most cases.

Selectivity. The good selectivity of PIXE is reduced for some pairs of elements by interference between K and L or M lines, emitted with energies close to each other. The interferences between pairs of sulfur K and lead M, titanium K and barium L, potassium K and indium L lines, respectively, can be mentioned as examples of practical importance. However, the selectivity of the method can be kept at acceptable levels by taking into account the known intensity ratios of K, L, and M lines of the interfering elements.

Chemical specification with high-resolution spectroscopy. The replacement of the commonly used Si(Li) X-ray spectrometer with a high-resolution wavelength-dispersive crystal spectrometer (Petukhov et al. 1999) opens a new field of applications of PIXE by resolving the pattern of satellite lines that is dependent on the chemical state of the atom. In such investigations, beams of multiply charged light heavy ions are preferentially used. The underlying physical processes and the quantitative features of the fine structures in the spectra to be used in chemical state analysis are the subjects of recent investigations.

Combination of PIXE with other analytical techniques. Difficulties connected with the detection of low-energy X-rays characteristic of elements with atomic numbers below $Z \approx 12$ can be avoided by the complementary use of proton induced γ -ray emission (**PIGE**) (Kiss et al. 1985) and/or deuteron-induced γ -ray emission (**DIGE**) (Elekes et al. 2000), processes excited by accelerated particles of the MeV energy range. The combination of these nuclear reaction methods with PIXE may also provide concentration data for light constituents of the samples (e.g., in biological and biochemical applications). Such data, which are not provided by PIXE analyses, are needed in calculating stopping power and X-ray absorption data in the evaluation procedure of PIXE spectra.

The combination of PIXE with Rutherford backscattering spectroscopy (RBS) analysis finds applications mainly in materials science (Ishii and Nakamura 1993).

A combined use of PIXE with polyacrylamide gel electrophoresis (PAGE) provides a new biochemical method in studying separated groups of metalloproteins by permitting in situ

elemental analysis on thin layer electrophoretograms (Szőkefalvi-Nagy et al. 1987). The simultaneous use of PIXE and PAGE on cellulose acetate electrophoretograms makes it possible to determine the metal ion and protein content of samples. (Szőkefalvi-Nagy 1996). A recent application of PAGE method in microPIXE configuration has been reported by Szőkefalvi-Nagy et al. (2009).

Sampling and preconcentration. According to the needs of the application of PIXE in many interdisciplinary fields a broad variety of sample forms and sample preparation methods have been developed. Objects to be analyzed can in special cases be subjected to beam irradiation in their original form (art objects, biological, and biomedical tissues). In other cases, samples can be collected in simple physical processes (e.g., total, size-fractionated, and time-resolved aerosol sampling, lyophilization, and pelletization), prepared by methods of solid-state physics (materials science), separated into different fractions (e.g., erythrocytes, plasma, and serum in blood samples), sliced by microtomes (e.g., plant tissues), with internal standards added (thick biological and biomedical samples). Due to the physical simplicity of the case of differentially thin samples, it is advisable in many cases to prepare samples in this form. A critical compilation of the sample preparation methods specially elaborated for X-ray emission elemental analysis has been published in an International Atomic Energy Agency (IAEC) document (Valkovic 1983). The inherent detection limits of the PIXE procedure can be enhanced if sample preparation is combined with preconcentration of selected analytes.

33.1.6 Fields of Application

As outlined above, the PIXE procedure offers a well-developed, versatile, and useful method of present-day instrumental analysis. While the methodological improvement is still going on to meet all the requirements of accurate routine analysis on large series of various samples, PIXE is already being applied in many different fields. A broad scope of application is documented in the papers presented in the proceedings of the international PIXE and microbeam conferences referred to in [Sect. 33.1.1](#). Details of the investigations performed by using PIXE in different fields of science can be found in special journals of the respective fields.

Within the limits of this chapter, the variety of applications can only be illustrated by a list of most common application fields, arbitrarily selected from the wealth of recent publications.

Biological processes (metal uptake by microorganisms and plants, elemental gradients across membranes, physiological functions and root structure of plants, elemental analysis of lichens, matter exchange between symbiotic partners, and sea grasses).

Biomedical research (analysis of individual cells, essential trace elements and toxic elements, nutrition effects, diagnostic use of elemental concentrations, blood samples, hair samples and history of medical events, body fluids, biopsy samples, deposition and retention of dust in respiratory tract, oral and orthopedic implants, degenerating mechanisms in aging process, calcified tissues, elemental concentrations and processes during healthy and pathologic pregnancies, trace element changes in pathological tissues, penetration of nanoparticles into skin, calcification of carotid arteries, trace element changes in cancer therapy, selenium status in cancer and immune diseases, and trace elements in neurological diseases).

Environmental research (Tree ring analysis, natural and anthropogenic aerosol components, time dependent and sequential measurements of atmospheric aerosols, apportionment of aerosol pollutants to emission sources, global and regional air quality monitoring, desert

dust, aerosols from volcanic eruptions, interregional and intercontinental transport of aerosol, aging and transformation of aerosols during transport, regional signatures as tracers in long-range transport, meteorological effects, elemental constituents of aerosols in cave environment, qualification of individual aerosol particles, acid rains and aerosols, river water analysis, sea-air exchange of materials, marine and lake sediment, aerosols in work environment, respiratory health survey, occupational safety, and contaminated soils).

Materials science (microelectronics analysis, surface layers, multilayers, PIXE channeling of dopants in crystals, depth profiling, binary alloys, impurities deposited in nuclear fusion devices, magnetic relaxation in nanocrystalline iron, insulating materials, radiation-induced segregation, superconductors, catalysts, and diffusion studies).

Geology (cosmochemistry, meteorites and cosmic dust, trace elements in lunar rocks, origin of microspherules, impact material, volcanology, phenocrysts in obsidian glasses, radiolarite, microcrystals and inclusions, grain boundaries, trace element zoning, geogas analysis, dating of ice cores in ice sheets, arid regions as sources of atmospheric aerosol, coastal and river sediments, mixing of salt and fresh water in coastal regions, geochemistry, mineralogy and petrology, and raw materials).

Art and archeology (early development of metallurgy, early development of glassmaking, color additives in glasses, trace elements in bones, numismatics, obsidian tools, archeology of paperlike objects and manuscripts, pottery, ceramics, painting materials, provenance studies of artifacts, prehistoric stone tools, gemstones, jewels, corrosion, and smearing).

Methodology (PIXE evaluation software packages, detector systems [UTWSi(Li), PIN array], μ PIXE chambers with precision goniometer and sample location setup, and nanobeam configurations).

33.2 Analysis by Elastic Scattering of Charged Particles (RBS and ERD)

In the following, the basic principles of ion beam analytical (IBA) methods based on elastic scattering are briefly introduced. To provide hints as to whether or not these methods are suitable for a special problem, their advantages and limits are also shown. More detailed information can be found in the literature (Chu et al. 1978; Tesmer et al. 1990; Tesmer and Nastasi 1995). In case of concrete problems, it is advisable to consult the specialists in the field, since these measurements need rather elaborate technical background.

33.2.1 Theoretical Background

The elastic scattering of nuclei of ionic projectiles on target nuclei can be realized for any ion–target combination. Therefore, one of the most appealing features of the elastic-scattering-based IBA methods is their universality, i.e., through one single measurement, one can obtain almost the whole elemental composition of the target. Depending on which of the colliding partners is detected – the scattered ion or the target atom, which gets recoiled out from the target – the method is called Rutherford backscattering spectroscopy (RBS), or elastic recoil detection (ERD). [ERD is also referred as ERDA (ERD Analysis) or FRES (Forward Recoil Elastic Spectroscopy).] In both methods, the energy distribution, i.e., the spectrum of the particles leaving the target is determined with a suitable experimental setup (see ▶ Sect. 33.2.8), and the spectra are used to determine the composition of the target.

Such spectra are seen, e.g., in ► Figs. 33.6. (In a spectrum, the energy scale is divided into channels, and the numbers of particles with energies corresponding to the various channels are presented in a graph.)

It is worth noting that time-of-flight (TOF) spectra are also frequently used. In these spectra, instead of the energy, the speed of the ions is obtained through the time that they spent to cover a given distance. Actually, TOF spectra are equivalent to energy spectra; they are just reversed in a special way.

In elastic scattering, both the energy and the momentum remain conserved; hence, with the mass and energy of the incident ion, M_1 and E_0 , and the scattering/recoiling angle, Θ/Ψ , one can determine the mass of the scattering nucleus, M_2 , unambiguously from the energy of the detected particle E_d .

The scattering is caused by the electrostatic repulsion between the nuclei of the ion and the target atom; hence, it is called Coulomb scattering. The intensity of this process, i.e., the cross-section σ of the scattering, is precisely given through the formula introduced by Rutherford (see ► Eq. (33.12) in Sect. 33.2.2.2). It also contains the electric charge of the participating nuclei, Z_1 and Z_2 . These methods are absolute, i.e., the number of the scattering atoms is unambiguously given by the number of the observed particles. Since σ is large, the sensitivity of these methods is quite good, especially if one can detect the particles free of background.

■ Fig. 33.6

Experimental and simulated (RBX) spectra of a sandwich structure. To better see the influence of plural scattering and pileup, the square root of the yield is given on the vertical scale (*Plural scattering*: the ions suffer at least two large-angle scattering. *Pileup*: a signal from the detector arrives so fast after the previous one, that they are treated together as a single signal of higher energy.)

■ Fig. 33.7

Experimental elastic recoil detection (ERD) spectrum from a thin, 200 Å, deuterated polystyrene film (Composto et al. 2002)

Furthermore, the number of ions hitting the sample should not be high, so the sample will be damaged only slightly.

The impinging and outgoing ions continuously hit the electrons of the target and in each encounter they lose a small fraction of energy, i.e., slow down (see ▶ Chap. 8 in Vol. 1). Unfortunately, the intensity of this process cannot be calculated precisely from basic physical principles, however, thanks to precise measurements and detailed compilations, they are known with a precision of 10–20%. If the observed atoms are situated deep in the sample, due to slowing on their way inward and outward, the energy of the observed particles will be smaller than that for surface atoms. The amount of this energy deficit increases monotonically with the depth, so one can also determine the depth of the observed atom. Therefore, in principle, these methods provide, in a single measurement, not only the whole elemental composition, but its depth dependence as well.

Since RBS and ERD are based on nuclear scattering, to penetrate the electronic clouds of the atoms, the ion energy has to be sufficiently large, i.e., a few MeV. However, it may also be a problem if the ions can penetrate the Coulomb barrier of the target nuclei, because in this case σ differs from the Rutherford value because some nuclear reaction channel may open. In such cases, the situation may be too complicated to allow a precise interpretation of the obtained results. The above energy limits, of course, depend strongly on the atomic number of the investigated atoms and the applied ions. Anyway, even if the cross section differs from the Rutherford value, it can be found in the literature or can be determined by some additional measurements, and the methods, with suitable extra care, can still be applied. To be precise, in these cases, RBS used also to be called backscattering spectroscopy, BS.

Results obtained by RBS and ERD are not influenced significantly by low-energy phenomena such as chemical bonds; thus, they can provide the precise elemental composition of the

samples independently of the chemical state. Therefore, combining these methods with those sensitive to chemistry might be especially fruitful.

So far, RBS/ERD have been presented in a rather simplified and idealized way. In the following more detailed description, their drawbacks and limits are also given. Since RBS and ERD are similar to a large extent, first RBS is introduced, and then the main differences between ERD and RBS are pointed out.

33.2.2 Rutherford Backscattering Spectroscopy, RBS

33.2.2.1 Energies

For RBS, the energy of the scattered ion is

$$E_2 = KE_1, \quad (33.7)$$

where K is the kinematic factor,

$$K = \left[\frac{\sqrt{M_2^2 - M_1^2 \sin^2 \Theta} + M_1 \cos \Theta}{M_1 + M_2} \right]^2, \quad (33.8)$$

E_1 and E_2 are the ion energies just before and after the scattering and, as mentioned before, M_1 and M_2 are the mass of the ion and the nucleus, respectively. The scattering angle Θ is measured between the direction of incident and scattered ions. For a detailed description, see the work of Chu et al. (1978) and Leavitt et al. (1995).

In RBS, as indicated by its name, the backward scattered ions are detected in most cases. From [Eq. \(33.7\)](#), one can see that the ion can scatter backward only from atoms that are heavier than itself, i.e., RBS detects only atoms heavier than the ion. The heavier the scattering atom, the larger the energy of the scattered ions will be. The $E_2(M_2)$ function approaches asymptotically the incident energy. While for the light elements the mass resolution is good (even the isotopes can be resolved), the heaviest elements might remain unresolved.

Thin surface layers of known elementary composition can be used to calibrate the energy scale of the applied detector through their kinematic factors.

As was mentioned, if the atoms are situated deep in the sample, the ions lose energy along their inward and outward paths. The rate of the energy loss is given by the so-called stopping power, S (see, e.g., [Eq. \(8.1\) in Chap. 8, Vol. 1](#)), which depends on the following parameters: composition and density of the target, the energy, and the mass and atomic number of the ion. S is available in the literature in the form of tables and semiempirical expressions (Ziegler 1977; Ziegler et al. 1985; Ziegler et al. 2002). Stopping power data can also be found in various figures of [Sect. 11.5 in the Appendix of Vol. 1](#).

If the scattering atom is at a small distance, x , from the surface, then the energy, E_d , of the scattered ion leaving the surface will be

$$E_d(x) = KE_0 - [S] x, \quad (33.9)$$

where

$$[S] = \frac{KS_{\text{in}}(E_0)}{\sin \alpha} + \frac{S_{\text{out}}(KE_0)}{\sin \beta} \quad (33.10)$$

is the cumulative, or the so-called effective stopping power. (E_0 , as mentioned before, is the initial energy of the incident ion.) The quantities S_{in} , S_{out} , α , and β are stopping powers and angles between the ion trajectory and the sample's surface inward and outward, respectively. The angles α and β are often referred to as incident and outgoing angles. For large depths, it must also be taken into account that both the ion energy and/or the composition of the sample may change considerably; therefore, the above simple expression has to be substituted by a numerical integration. In this case, $[S]$ has to be replaced by the more general expression $-dE_d/dx$. The suitable treatment of large depths together with all the other necessary calculations is included in the various computer codes developed to evaluate the RBS measurements (Doolittle 1986; Vízkelethy 1990; Kótai 1994; Szilágyi and Pászti 1994; Barradas et al. 1997; Mayer 1997). Recently IAEA sponsored an intercomparison of seven depth profiling IBA softwares. The results were published by Barradas et al. (2007).

RBS is a direct method. In the simplest cases, an expert eye glancing at an RBS spectrum can see at once the approximate composition of the sample together with the depth profiles of the various elements. The peaks and steps at larger energies correspond to heavier elements, while those at smaller energies are due to the lighter ones. A narrow peak implies that the given element appears in a thin layer while distributions widening into trapezoids are due to thicker layers. If the distribution widens so much that it starts already at the beginning of the spectrum and it stops at the higher-energy side by a step, the considered element appears probably through all the thickness of the sample, i.e., it is a constituent of the bulk. In the first example spectrum (► Fig. 33.6), one can see a double-layered structure on bulk Si. The edges of Si and Ti are shifted to lower energies by the overlaying Au. The surface is slightly contaminated by O.

The heavier constituents of the sample impose a background at energies corresponding to lighter elements. This way, while one can see the heavier elements background-free, the sensitivity for the lighter ones is considerably worsened by an intensive background (see, e.g., the O signal in ► Fig. 33.6).

Due to the slowing of the ions in the sample, from the observed energy alone one cannot decide whether the atom that has scattered the ion is a light one near the surface or a heavier one situated deeper. In spite of this ambiguity, the elementary composition of the sample can still be determined, since, in most cases, the whole spectrum cannot be interpreted in terms of a wrong sample structure. Due to unobservable or weakly observable light elements, the above statement may not always hold. If one cannot exclude the wrong solutions a priori, it is worth repeating the measurement in different ways. For example, one can change the incident or exit angles or the type or energy of the incident ions. To observe the light elements as well, one can turn to ERD or some other method to be mentioned in ► Sect. 33.2.2.2.

Because of the above energy overlaps, the measured spectra frequently become too complicated to be understood without applying suitable computer codes. Of course, if one would like to obtain really precise numerical quantities, the above codes are indispensable. In some of these programs, the user has to construct the model structure of the sample and refine it until the simulated spectrum matches the measured one satisfactorily (Doolittle 1986; Vízkelethy 1990; Kótai 1994; Szilágyi and Pászti 1994; Mayer 1997). The Nuclear Data Furnace code constructs the best model of the sample all by itself; so even beginners might achieve satisfactory results (Barradas et al. 1997). Nevertheless, any of the codes has to be used with special care, since giving imprecise parameters for the measuring setup or neglecting some second-order processes, like plural scattering, might lead to completely wrong conclusions.

33.2.2.2 Intensity

So far, the energy scale (the horizontal extension of the spectra) has been detailed, which is related to the masses and depth positions of the various elements in the sample. The vertical extension of the spectra provides information also on the amount or concentration of these elements. The height, of course (beside the concentration) is also proportional to some other quantities, like the number of incident ions, Φ , and the solid angle $\Delta\Omega$ and effectivity η , of the detector observing the scattered ions.

If a thin layer contains N_t target atoms per surface area (atom/cm² units), the peak area of the corresponding peak is³

$$A = N_t \frac{\Phi \eta \Delta\Omega \sigma}{\sin \alpha}, \quad (33.11)$$

where σ is the differential cross section of the scattering (i.e., the cross section per solid angle), which by the Rutherford expression is⁴

$$\sigma \equiv \sigma_R(E_1, \Theta) = \left(\frac{Z_1 Z_2 e^2}{2E_1} \right)^2 \frac{\left(\sqrt{M_2^2 - M_1^2 \sin^2 \Theta} + M_2 \cos \Theta \right)^2}{M_2 \sin^4 \Theta \sqrt{M_2^2 - M_1^2 \sin^2 \Theta}}, \quad (33.12)$$

where e is the elementary charge and E_1 is the energy of the ion before scattering. (The subscripts 1 and 2 refer to the ion and the atomic nucleus, respectively.) As mentioned before, the cross section can be described by the above expression just in the energy region of pure Coulomb scattering and elsewhere one has to determine σ in separate experiments or get it from the literature. The validity region of [Eq. \(33.12\)](#) together with several $\sigma(E_1)$ graphs can be found in Tesmer and Nastasi (1995). A cross-section collection is also available in SIGMABASE (SIGMA 2003). Most of the evaluation codes either contain the non-Rutherfordian cross sections of interest, or can be made to contain them easily.

For thick layers the peaks widen to trapezoids, whose heights will be

$$H_i \propto \frac{\Phi \eta \Delta\Omega \sigma_i(E_1) n_i \delta E}{[S] \sin \alpha}, \quad (33.13)$$

where δE is the energy width of the measuring channels and n_i is the relative concentration (fraction) of the given element ($\sum n_i = 1$). From the height of the spectral contribution of an element, one can determine the depth dependence of its concentration, i.e., the depth profile. In the spectrum in [Fig. 33.6](#), e.g., Ti is confined in a narrow layer between the thick homogeneous Au layer and the Si substrate.

It can be seen from [Eqs. \(33.11\) and \(33.12\)](#) that, for Rutherford cross sections, the area of the peak of an element is quadratically proportional to its atomic number, so RBS is especially sensitive for heavy elements. Even a few hundredths of a monolayer (about 10^{13} atoms/cm²) or 0.1 atomic% can be easily detected. For light elements, the sensitivity might be worse than even a few atomic%. To enhance the sensitivity, non-Rutherford cross sections are also frequently used. For example, for backscattering of 1,600 keV protons, σ is more or less the same for all the elements lighter than Si, being 100–300 mb/sr. In this way, a simple proton backscattering provides around 1 atomic% sensitivity for all the light elements including deuterium.

It is especially favorable if in the cross section of a light element of interest (or, more precisely, in the cross section of one of its most abundant isotopes), there is a sharp resonance (see, e.g., [Fig. 3.25 in Chap. 3 of Vol. 1](#)), since in this case, a sharp peak corresponding to

the resonance over a more or less smooth background can be unambiguously identified. The resonance is seen only if the energy of the ion coincides with the resonance energy, E_r . Hence, to observe the surface, the incident energy E_0 has to be equal to E_r , while for larger depths $E_0 = E_r + xS_{in}/\sin\alpha$. In this way, by increasing E_0 over E_r , one can map the depth distribution of the investigated element step by step.

33.2.3 Elastic Recoil Detection, ERD

If an atom is not heavier than the incident ion, the corresponding element (or rather nuclide) cannot be observed through RBS. For example, ^1H cannot be observed by RBS; its presence is only indicated by the decreased height of the spectrum. In this case, one can try to observe scattering in the forward direction, where the ions scattered from the given light element appear under a limiting scattering angle. However, if one wants to get rid of the large background of the scattering from heavier elements, it is better to detect, instead of the scattered ions, the recoiled light atoms, i.e., to apply ERD (L'Ecuyer et al. 1976; Barbour and Doyle 1995).

For ERD, the expressions for both the kinematic factor and the cross section differ from those of RBS; furthermore, along the outward path, the stopping formula has to be applied to the recoiled atom. The kinematic factor is now

$$K_{\text{ERD}} = \frac{4M_1M_2\cos^2\Psi}{(M_1 + M_2)^2}, \quad (33.14)$$

where Ψ is the recoil angle measured between the directions of the incident ions and the recoils. The cross section for pure Rutherford scattering is

$$\sigma_{\text{ERD}}(E_1, \Psi) = \left(\frac{Z_1Z_2e^2}{2E_1}\right)^2 \frac{(M_1 + M_2)^2}{M_2^2\cos^3\Psi}. \quad (33.15)$$

As with RBS, the energy scale of ERD spectra can be calibrated by surface elements of a known sample or by observing the same element under various Ψ angles. If all the factors are precisely known, the intensity scale does not need calibration. In practice, however, to achieve better precision, calibration samples are frequently used.

33.2.4 Separation

In the measured spectra, it is necessary to prevent the overlap of recoils with the background of scattered ions. For this purpose, several methods have been developed. The ones most frequently applied are as follows.

The simplest method relies on the fact that the lighter ions lose energy more slowly than the heavier ones. Mounting in front of the detector a foil of suitable thickness, one can stop the scattered ions, while the light recoils can still cross at a tolerable energy loss. The result of such a measurement is shown in  Fig. 33.7. The scattered He ions give only a small background at the lowest energies, while the recoiled D and H atoms are detected background-free. (The He background would disappear for a slightly thicker absorber foil.) The sensitivity of the method is especially remarkable, 0.01–0.1 atomic%. The limit is actually set by the ions scattered from various parts of the setup, which also might contain hydrogen.

■ Fig. 33.8

2D ERD spectra (200 MeV Au ions, ΔE - E gas detector) from a contaminated GaN film on Si (Timmers et al. 2002)

Even better sensitivity can be reached for thin foils, if the recoils and the scattered ions are detected simultaneously in coincidence (Klein 1986; Rijken et al. 1992; Rijken 1993).

The method is widespread, especially for energetic heavy ions, which are not prevented from reaching the detector but, instead, the ions of various kinds are distinguished from each other somehow. For this, one has to determine at least two quantities simultaneously, i.e., spectra of at least two dimensions (2D). One of the dimensions might be the time of flight through a given distance, TOF, while the other might be the energy given to the detector stopping the ions (Gorleau et al. 1983; Thomas et al. 1986; Arai et al. 1992; Gujrathi and Bultena 1992). A ΔE - E telescope, which measures both the energy E and the energy loss ΔE may also be applied to a thin layer. ΔE depends also on the atomic number of the ion. ΔE can be measured, e.g., by a thin detector, which is set just in front of the main detector (Behrooz et al. 1987; Assmann 1992; Arnold Bik et al. 1992; Timmers et al. 2002). During evaluation, the counts corresponding to the various ions in the obtained 2D spectra are first separated, and then the background-free energies or TOF spectra are further processed. Further methods can also be found in the literature, but, owing to lack of space, they have to remain unmentioned.

The 2D methods are especially attractive, since through them, especially in combination with RBS, the full elemental composition can be readily investigated. Such methods can also detect the light elements background-free. The reader can find a sample spectrum in ► Fig. 33.8.

33.2.5 Channeling Effect

Mainly the RBS, but actually all the IBA methods can be combined with the so-called channeling effect (Chu et al. 1978; Feldman et al. 1982; Swanson 1995). Here one takes advantage of the fact that ions impinging parallel to one of the main axes or planes of a single-crystal target are subject to the following effect. Entering the sample most of them pass by the atoms in the first atomic layer undisturbed and enter the free space between the

atomic rows or planes of the lattice. This space, the channel, contains only electrons. Since both the ions and the atomic nuclei forming the channel walls are positively charged, they repulse each other and the ions are steered to follow trajectories zigzagging inside the channels. In this way, the ions cannot get close enough to the atomic nuclei in the wall to allow any of the processes applied in IBA to happen, i.e., the number of monitored events drastically decreases. This, of course, is true only if there are no extra atoms inside the channels, e.g., impurities sitting in non-substitutional places or interstitial atoms produced during some lattice damage. Extended defects (dislocations, stacking faults) also decrease the channeling effect.

From the picture just described, it is easy to see that by applying channeling, one can observe the lattice damage together with its depth distribution (see, e.g., Manuaba et al. 2001 and ▶ Fig. 33.9). Furthermore, the directions along which impurity atoms are positioned inside the channels can also be determined. This latter observation allows determining their localization in the lattice, i.e., their “lattice localization” (Davies 1973; Rebouta et al. 1992; Swanson 1995). For more precise lattice localization, not only are single spectra along the various channels taken, but one also investigates how the yield from the impurity changes when tilting the crystal axis or plane away from the incident direction step by step. During this process, the ionic distribution in the channels changes gradually: beside the axes or midplanes,

■ Fig. 33.9

Channeling Rutherford backscattering spectra (RBS) of a crystalline Si wafer that was implanted by He ions (10^{16} ion/cm² units) then annealed. Virgin and random spectra are also included (Manuaba et al. 2001)

places closer to the walls get also populated. Performing such “angular scan” measurements one can obtain lattice localization with a typical uncertainty of 0.01 nm.

33.2.6 Microbeam

Like other IBA methods, RBS/ERD can also be combined with a microbeam (e.g., Takai 1995). One has to be aware, however, that especially during longer measurements, besides the quickly appearing lattice damage, a continuously thickening hydrocarbon layer is also deposited over the tiny beam spot. Hence, during such measurements a hydrocarbon-free vacuum is crucial.

33.2.7 Secondary Effects

In RBS/ERD, the situation is never as ideal as it has been assumed above. Some secondary effects might significantly influence the observed spectra. For instance, the shape of the observed features is never sharp; it is smeared out by various effects as follows:

1. Finite detector resolution
2. Direction distribution and energy distribution of the incident ions
3. The exit and scattering/recoil angle fluctuates due to extended beam spot and detector size
4. Energy straggling⁵ in the sample
5. Multiple scattering: both incident and exiting particles suffer numerous small-angle scattering when penetrating the material that leads to continuously curving trajectories and fluctuating angles
6. DOPPLER broadening due to thermal vibrations of atoms

All the above processes are determined and taken into account by the DEPTH code (Szilágyi and Pászti 1994).

Incident ions or exiting particles might suffer additional large angle scattering(s) both in the sample and in the various parts of the measuring setup, especially in the final beam forming slits (plural scattering). As a result, the detected energy might depart from the ordinary one to a rather large extent (especially downward), leading to unwanted background (Moore 1980).

The incident beam is surrounded by a halo of scattered ions, which might involve in the measurement some other objects around the sample.

Spectrum shapes might also be distorted by rough sample surfaces and interfaces.

Although RBS/ERD are not too sensitive to the density or density inhomogeneities of the sample, the latter may give rise to energy spread. Applying suitable measuring arrangements and evaluation methods, one can turn this otherwise disturbing effect into a tool for studying the nanoscopic morphology of the samples, e.g., pore structure (Pászti and Szilágyi 1998).

33.2.8 Instrumentation

As in other IBA methods, it is a must to have fair quality ion beams. The energy stability of the accelerator is especially important in these measurements. For channeling measurements, the angular divergence of the ion beam should be small; this can be ensured by two collimators set far enough from each other.

It is also important to ensure an oil-free vacuum in the scattering chamber, since the hydrocarbon film deposited onto the sample surface gets polymerized gradually under ion bombardment, and, its reevaporation being hindered, grows without limit, influencing the measurements drastically. Therefore, in such measurements one has to consider a liquid-nitrogen cooled trap surrounding the internal wall of the chamber, or use only so-called dry pumps. In practice, oil diffusion pumps may cause serious problems in such systems.

It is useful to have a sample holder tiltable to large angles because with the use of glancing incident/exit angles, the sensitivity and depth resolution can be significantly improved. For channeling, the sample holder should be mounted on a goniometer. For routine measurements, the sample holder has to accept several samples, or it has to be easily changeable through a load-lock system.

The energy distribution of the ions is measured by suitable detectors of which the solid-state particle detectors are the most widely used. When their typically 10–15 keV energy resolution is not enough, a magnetic spectrometer⁶ or TOF system of good resolution is applied. For the latter, the START signal in most cases is generated by the ions crossing a thin carbon foil: the ejected secondary electrons are multiplied by a multichannel plate and their charge pulse is used. The STOP signal might be supplied by a similar unit, but the signal of a solid-state particle detector also may do. In the latter case, the energy may also be obtained, which in 2D ERD spectra is especially important. To reach good resolution for high-energy ions typical in IBA, the STOP detector should be far away from the sample, so large-area detectors are needed. In 2D ERD, the ΔE detector may be a totally depleted solid-state detector. An especially favorable setup is offered by a proportional gas counter divided into two parts, providing both ΔE and E signals simultaneously.

Nowadays, the spectra are collected and evaluated using suitable computer codes.

33.2.9 Fields of Application

RBS and ERD are especially useful when, not only the composition of the samples, but also their depth profiles are to be determined in the first few μm , and the measurements should be performed fast, e.g., in a few minutes. Typical things to study are diffusion, corrosion, solid-phase chemical reactions, and investigation of multilayers.

In many cases, it may be appealing that the sample is damaged only slightly. To examine large-size or vacuum-sensitive samples may be problematic since, although the measuring beam can be extracted to open air, when the ions cross the extraction foil and the air, they suffer significant energy straggling. By microprobes, 3D imaging of the samples may be achieved.

In summary, it can be concluded that RBS and ERD have a rather wide field of applications and, similarly to other IBA methods, there are situations when they are superior to all the other analytical methods.

33.3 Nuclear Reaction Analysis (NRA)

33.3.1 Characteristics of the Method

As was presented in the previous sections, when a beam of energetic ions impinges on a sample, it causes a variety of interactions. This section deals with the case when some particles of the beam interact with the atomic nuclei themselves. As a result, some nuclei are transformed into other nuclei by a nuclear reaction. The interaction between the bombarding particles and the

nuclei of the sample is followed by *prompt* emission of charged particles, neutrons, and/or γ rays. The energies and intensities of these interactions are determined by the internal properties of the nuclei in the sample and the conditions of bombardment. The study of these interactions is the subject of nuclear physics (see [Chap. 3 in Vol. 1](#)). From such studies, it was revealed that with the knowledge of some characteristic features of the emission (the nature and the energy of the outgoing particle or γ radiation and the yields of the nuclear reactions – i.e., the information given by a particle or γ -ray spectrum), the elemental (moreover isotopic) composition of a sample can be determined. Based on the huge amount of knowledge collected in basic nuclear physics, an analytical technique, called **nuclear reaction analysis** (NRA), has been developed. In NRA, the emission is considered *prompt* in the sense that it can only be detected during the irradiation. After the prompt emission, the product nucleus may itself undergo radioactive decay with a characteristic half-life; however, the detection and study of the *delayed* radiation is the basis of another technique called activation analysis (see [Chap. 30](#) in this Volume).

The nuclear reaction analysis technique can be characterized as follows. The particles of the beam have to pass the Coulomb barrier of the nuclei to produce a nuclear reaction with considerably high cross section, thus beam energies of at least several hundred keV are needed from a particle accelerator. The maximum particle energy usable for NRA is only limited by the capability of the particle accelerator itself. The most widely used particle accelerators for IBA are single-ended Van de Graaff and Tandetron machines (see [Fig. 50.15 of Chap. 50, Vol. 5](#), on “Particle Accelerators”), which usually cannot produce more than 5 MeV in the case of protons. The above restrictions have the following consequences:

1. Mostly light particles are used: protons, deuterons, and ^4He ions (A heavier ion, ^{15}N , is applied to special analyses – hydrogen depth profiling – at around 7 MeV.)
2. Mainly light elements can be characterized by NRA due to the increase of the Coulomb barrier height with increasing atomic number.
3. Because of the high energies involved in the process, chemical bonds in the sample material do not interfere; nor is, however, possible to get direct information on them.

Cross sections of nuclear reactions are generally much lower than those of fluorescence or elastic scattering. Moreover, nuclear reaction cross sections depend on atomic or mass numbers and energy rather erratically. Thus, NRA is competitive with PIXE and RBS only for certain light elements, which have increased yields in certain nuclear reactions, and where the difficulties of the detection of light elements due to the low energy of characteristic X-rays in PIXE or the high background from heavier constituents in RBS cause problems.

The main strength of NRA is, however, its capability of highly selective determination of the concentration of isotopes of the various elements. Furthermore, it is a method of determining the absolute areal concentration (atoms/cm²) of light impurities on and below the surface of a sample containing heavy elements and providing an absolute calibration for other surface sensitive techniques. An important advantage of NRA is its capability of high-resolution depth profiling of some elements in the first few micrometers as well.

Other features are the following: (1) the possibility of non-vacuum use, especially in the case of *ion- γ* reactions, where the outgoing γ rays are detected (this feature allows the analysis of volatile samples or those with extended dimensions), (2) the simultaneous applicability with RBS and/or PIXE, (3) the easy preparation of the samples, and last but not least, (4) it is a nondestructive analytical method.

The application of nuclear reactions for analytical purposes started in parallel with the development of low-energy nuclear physics itself, and started to expand in the 1960s, which

expansion is still continuing. Several reviews of the basic principles of the method and its applications can be found in the literature. One of the earliest and most detailed ones was written by Deconninck (1978) in 1978, which was followed by Amsel and Lanford (1984) in 1984, then by Feldman and Mayer (1986) in 1986. Monographs of ion beam analysis also contain detailed descriptions of the technique (Bird and Williams 1989; Tesmer and Nastasi 1995). The latest results and many applications were presented in the proceedings of International Conferences of Ion Beam Analysis (IBA) (1973–2007) and International Conferences on Nuclear Microprobe Technology and Applications (ICNMTA) (1981–2008). The proceedings of the latest IBA and ICNMTA conferences can be found in references Pathak et al. (2008) and Rajta et al. (2009), respectively.

33.3.2 Physical Background of NRA

The probability that a nuclear reaction takes place during bombardment with energetic particles depends on many circumstances and is discussed in detail in nuclear physics.

The energies of the outgoing particles can be determined by the nuclear reaction kinematics based on the energy and momentum conservation law. The case is more complicated than RBS in that in nuclear reactions the energy release of the reaction (*Q*-value) and the spacing between the energy levels of the final nucleus also have to be taken into account. In practice, the choice of the particle groups or γ rays suitable for the identification of an element (isotope) depends on many circumstances. First, on the properties of the ion beam (its type and energy), then on the nuclear reaction occurred, the isotope of the given element and its natural abundance, the cross section, the nuclear parameters of the excited states, etc. Possible interfering reactions in the sample matrix must be known as well.

Due to the complexity of nuclear forces, predictions from nuclear model calculations for the **cross sections** of nuclear reactions and their dependence on energy and detection angle are difficult, and even if it is possible, they are not precise enough for analytical purposes. Thus, one has to rely on measured data. There are many published experimental cross-section data in the basic literature on nuclear physics, but usually the same problem occurs again; neither are the experimental conditions the same, nor are the precisions good enough for NRA. For depth profile measurements, the knowledge of precise resonance parameters is crucial, and often the published experimental data have to be remeasured to fulfill the requirements of the technique.

For convenience, most of the information necessary to perform qualitative or quantitative NRA is collected in handbooks. In the analytical work, it is useful to consult catalogs of prompt nuclear reaction analysis, which give advice on the nuclear reaction and ion energy appropriate for the analysis of a certain element in a given matrix. The energies of the outgoing particles or γ rays to be detected are also given. Remeasured cross-section data at the optimum conditions, which are precise enough for NRA, are also published in those handbooks. The latest compilations for **ion-ion** and **ion- γ reactions** are found in Tesmer and Nastasi (1995). They have been complemented by the thick target yields of deuteron-induced γ -ray emission (DIGE) that were completely missing before (Elekes et al. 2000). Precise cross-section measurements for the reaction $^{19}\text{F}(\text{p}, \text{p}'\gamma)^{19}\text{F}$ were started by Jesus et al. (2000) and continued later by the same authors (see Mateus et al. 2005). In the case of deuteron-induced γ -ray emission analysis, fundamental cross-section data were measured for the reactions $^{14}\text{N}(\text{d}, \text{p}\gamma)^{15}\text{N}$ (Bebber et al. 1996) as well as for $^6\text{Li}(\text{d}, \text{p}\gamma)^7\text{Li}$, $^9\text{Be}(\text{d}, \text{n}\gamma)^{10}\text{B}$, $^{11}\text{B}(\text{d}, \text{p}\gamma)^{12}\text{B}$, $^{16}\text{O}(\text{d}, \text{p}\gamma)^{17}\text{O}$, and $^{19}\text{F}(\text{d}, \text{p}\gamma)^{20}\text{F}$ (Sziki et al. 2006). At present, a new nuclear cross-section database for ion

beam analysis is under development. The intention is to compile and assess existing cross sections and evaluate them (Gurbich et al. 2008).

33.3.3 Instrumentation

As NRA has grown from accelerator-based nuclear physics and expanded after the invention of solid-state detectors (the surface barrier Si detector for the detection of particles and Ge(Li) detectors for the detection of γ rays), its instrumentation is very much similar to those used in particle and γ -ray nuclear spectroscopy. The PIXE method also started to use an existing instrumentation, the Si(Li) X-ray detectors, nearly a decade later. Consequently, this review will refer to the previous [Sects. 33.1](#) and [33.2](#) on PIXE and RBS concerning the acceleration and the formation of energetic ion beams, the internal and external sample chambers, scanning particle microprobe facilities, particle detection, and data acquisition. It will only deal with the characteristic features of the detection of ions and γ rays produced in nuclear reactions. Neutrons are also produced in these reactions, but in practice they are rarely used for NRA. Because of space limitations, that technique (Bird and Williams 1989) will not be discussed.

As for the accelerated ion beams, contrary to PIXE and RBS, in NRA the use of deuterons is favored because of the high yields produced with them. However, the deuteron beam itself can produce more neutrons than any other ion beams; therefore, its use is associated with the possibility of neutron hazard. NRA requires only very small deuteron beam intensities, the orders of 100 pA–10 nA, contrary to basic nuclear physics, where μ A beams are common. Moreover, the energy of the deuteron beam used for analysis is quite low (usually lower than 2 MeV), thus practically no health hazard is expected around the experimental facility (Kiss et al. 1994). Nevertheless, radiation safety rules demand heavy shielding against neutrons for laboratories working with deuteron beams, which is not available around many accelerators. This is a limiting factor for the wide use of deuteron-induced NRA.

It is convenient to consider *ion–ion* and *ion– γ* reactions separately, since the product type determines the detectors and methods required.

33.3.3.1 Ion–Ion Reactions

The particles from nuclear reactions differ from the elastically scattered ions in two respects: their intensity is much lower because of the much lower cross section, but their energy is usually higher because of the mostly positive reaction Q -value. Thus, although the same experimental setup can be used for ion–ion reactions as for RBS, the sensitive depth of the Si surface barrier detector should be high enough to absorb the high-energy reaction products (usually protons) completely. The high-intensity scattered ions cause pileup and damage the detector. There is a need to eliminate them before they can reach the particle detector. Several methods, such as magnetic deflection or electrostatic deflection are used, but the simplest is the use of a uniformly thin foil of metal or Mylar in front of the semiconductor detector, placed usually at backward angles to the beam direction. The thickness of the foil is chosen to be close to the range of the scattered ions, but still allowing the higher-energy reaction products to pass.

High detection efficiency is particularly needed in nuclear microprobes, where the beam intensity is limited; furthermore, beam current density has to be kept below a certain level, depending on the sample material, to avoid irradiation damage. For example, for a $1\text{ }\mu\text{m}^2$ beam spot and 100 pA beam current the determination of ^7Li , ^{11}B , ^{12}C , ^{16}O , and ^{19}F is possible in

metals, alloys, or refractory materials, but for thick polymers and biological samples higher spot size is needed with this current to avoid sample damage (Trocellier et al. 1999). High detection efficiency can be achieved by one or more large surface barrier detectors set close to the sample and connected electronically, or by the use of an annular detector with large solid angle. For example, 1.63 sr was used for the determination of the boron distribution of about 7 ppm average concentration in cells from a rat brain (Sjöland et al. 1997).

More sophisticated methods, like ΔE - E telescopes for the simultaneous measurement of the speed and the energy of the detected particle, have also been applied recently (Trocellier et al. 1999).

33.3.3.2 Ion–Gamma Reactions

To exploit the resonance character of (p,γ) reactions, (see [Sect. 33.3.4.3](#)), one has to detect the γ rays. Similarly, in many (p,α) reactions the α particles have energies too low for efficient detection, thus the γ rays associated with the α particles are worth detecting. In the inelastic proton scattering $(p,p'\gamma)$ and in deuteron-induced reactions, the detection of γ rays instead of the particles also has many advantages. The main advantage of NRA with γ -ray detection is that, due to the very little attenuation of γ rays, it is not necessary to place the detector into the vacuum chamber. The external beam technique can also be easily realized.

The type of the γ -ray detector to be chosen depends on the aim of the analysis to be performed. The “old-fashioned” NaI(Tl) scintillation detector is conventionally applied when light elements in samples of high Z value are profiled using a well-isolated resonance, since here higher efficiency is needed due to the scanning with energy, while energy resolution is not critical. To the analysis of total average concentrations of several elements, Ge detectors are generally applied, because their energy resolution is high enough to distinguish nearby γ rays emerging from different elements, the laboratory background, and from other disturbing background peaks. The large-volume high purity germanium (HPGe) detectors available recently have efficiencies comparable to NaI(Tl) detectors, together with high-energy resolution. This statement is true between 0.1–2.5 MeV, in which region Ge detectors are predominantly used. When very high-energy γ rays (higher than 6 MeV) are to be detected [e.g., F and N determination by $(p,\alpha\gamma)$ and $(d,p\gamma)$ reaction, respectively], high-energy resolution is not needed and the NaI(Tl) scintillation detectors still have a role, although in some laboratories they are replaced by the even more efficient bismuth-germanate-oxide (BGO) detectors. To increase the detected yield, both types of γ -ray detectors are used such that they collect counts not only from the full-energy peaks but also from single- and double-escaped peaks, which are generally quite pronounced at very high γ -ray energies (see [Fig. 48.13 in Chap. 48 of Vol. 5](#)).

The efficiency of γ -ray detectors used in NRA is increased more and more. For example, in Bochum a γ -ray detection system of very high efficiency was built, which includes a 12 in. \times 12 in. (~ 30 cm \times 30 cm) NaI(Tl) bore hole detector. It covers a solid angle close to 4π , it has a good peak to Compton ratio, and there are practically no escape peaks due to the high volume. The total efficiency for the detection of γ rays reached almost 90% (Piel et al. 1996). Another development in NRA is the application of the so-called Clover-Ge-BGO detector system (Elekes et al. 1999), which was originally developed for the large EUROGAM multi-detector γ -ray spectrometer used in nuclear physics. This detector system consists of a so-called clover type composite HPGe detector surrounded by a BGO anti-Compton shield. The **clover detector** is built up from four separate coaxial HPGe crystals (with 20% relative

photo-peak-efficiency of each) packed together in the same cryostat in a four-leaf clover arrangement. In spite of high detection efficiency, the detector system has an improved peak-to-Compton ratio owing to the anti-Compton shield.

The detector used for the detection of γ radiation in NRA is generally placed either 135° or 90° to the direction of the incident beam. Higher count rates can be obtained at forward directions. Nuclear physics experiments often use a detector angle of 55° to obtain a measured yield proportional to that expected from the reaction cross section integrated over 4π angles.⁷ This geometry is suitable for the absolute determination of elemental concentrations from published total cross-section values, but it has no advantage when reference samples are used.

33.3.4 Quantitative Elemental Analysis

33.3.4.1 Spectrum Evaluation

Ion-ion reactions. A particle spectrum in NRA is very similar to a spectrum observed and discussed in RBS. Its advantage is that the particles from a nuclear reaction on a light constituent have higher energies than the elastically scattered particles, thus they are background free. [Figure 33.10](#) shows a typical NRA spectrum obtained by bombardment with 4 MeV α particles of a thin glass sample (with a thickness of 1.1 μm) having high boron content. The backscattered α particles are stopped by a 20 μm Al foil in front of the particle detector, while protons above 1,300 keV can penetrate it. The proton peaks from (α, p) reactions on the nuclei ^{10}B , ^{11}B , ^{23}Na , and ^{27}Al present in the glass appear background free at energies between 1,850 and 5,000 keV. Peaks labeled with p_i refer to protons emitted from the i th level of the corresponding nuclei (Peisach and Pretorius 1973). A general problem of ion-ion reactions is that in the spectrum different types of particles, protons, alphas, or deuterons, may appear due to the more than one open reaction channel. For their separation, one can use

Fig. 33.10

Proton spectrum of a thin glass sample having high boron content irradiated by a 4 MeV α -particle beam (Peisach and Pretorius 1973)

again the absorption foil technique discussed above or a detector of thin sensitive layer (Amsel et al. 1992). For spectrum simulation and deconvolution, the same program packages are available as for RBS (see references therein).

Ion- γ reactions. There is a remarkable difference between ion-ion and ion- γ reactions. In the case of ion-ion reactions, with thickening sample layer, the corresponding particle peaks also broaden like in the case of RBS. In the case of an infinitely thick sample (thicker than the range of the bombarding particle), which contains several light isotopes, the ions emerging from the depth slow down so much that it is a demanding task to separate them from each other. The emerging γ rays from the same thick sample fortunately do not change their energies. In [Fig. 33.11](#), a typical γ -ray spectrum is shown from the bombardment by 3.1 MeV protons of a thick borosilicate glass sample, which is often used as high-voltage insulator. The γ -ray peaks are resolved well, except the 429 keV energy peak from the $^{10}\text{B}(p,\alpha\gamma)^7\text{Be}$ reaction, showing a large kinematic Doppler broadening. The γ rays can penetrate through even the thin wall of the target chamber into the air only with a small attenuation; therefore, it is easy to install the detector out of the vacuum chamber. Moreover, using solid-state detectors, γ rays can be detected with much better energy resolution than particles.

These advantages make the ion- γ reactions a particularly useful elemental analysis technique. Because the detection technique is different from the detection of both X-rays in PIXE and particles in RBS and NRA, the method got in practice a distinctive name: **particle-induced γ -ray emission (PIGE)**, where the word “particle” means mostly proton. PIGE is often used simultaneously with PIXE, and its suitability for the analysis of light elements (mainly Li, B, F, Na, Mg, Al, and Si) complements the performance of PIXE well. Among γ -ray emissions induced by various types of particles, the **deuteron-induced γ -ray emission (DIGE)** deserves the most practical interest, because it is also sensitive to C, N, and O, and its high cross sections

■ Fig. 33.11

Particle-induced γ -ray emission (PIGE) spectrum from a borosilicate glass sample irradiated by a 3.1 MeV proton beam. The peaks are labeled with target nuclides giving the signal and the corresponding γ -ray energies in keV (Borbély-Kiss et al. 1985). Note the large Doppler broadening of the 429 keV peak explained in the text

can be exploited in nuclear microprobe applications. Systematic particle-induced γ yields are available in the literature also for heavier ions (^4He , ^7Li , ^{12}C , etc.) measured at higher beam energies for target elements from Li to Pb. Their possible applicability to NRA was compiled by Räsänen (2001).

Overlapping of γ lines from different reaction channels open on the various constituents of a sample may cause ambiguities in the evaluation of γ -ray spectra. In this case, the appearance of other γ lines can help in the analysis.

Since the yield curves of different reactions have different shapes with varying bombarding energy, a repeated measurement at another bombarding energy could also help. There are γ -ray catalogs containing energies, yields of γ lines, and also complete spectra at different ion energies for the elements to be analyzed, which are helpful in choosing the proper γ peaks for further evaluation (Gihwala and Peisach 1982; Kiss et al. 1985; Elekes et al. 2000).

As the response function for γ -ray detectors is quite complex, various computer programs were developed for the analysis of γ spectra in nuclear physics. Some of them were adapted also for NRA like the program package FORGAMMA (Székely 1985), which is capable of analyzing complex unresolved γ -peaks and special line shapes caused by the kinematic Doppler broadening. In most applications, it is satisfactory to subtract a linear continuum from prominent peaks or to fit overlapping Gaussian distributions and a continuum function to a group of closely spaced peaks in a selected region of interest (ROI) of the spectrum.

33.3.4.2 Determination of Concentrations

For the calculation of concentration from the intensity of a peak observed in an energy spectrum of a nuclear reaction the same rules are valid as for the other ion-induced processes discussed earlier in conjunction with the methods PIXE and RBS with minor differences coming from the particularities of the nuclear processes. Thus, for **thin samples** analyzed by nuclear reactions the considerations for RBS, started with [Eq. \(33.11\) in Sect. 33.2.2.2](#) are also valid, with the difference that σ is the differential cross section of a nuclear reaction. It is supposed that σ changes slowly in the vicinity of the energy of the ion beam. The effect of the increasing sample thickness, including stopping powers and the possibility of resonance behavior of the cross section for ion–ion reactions, is the same as for elastically scattered ions and it has already been discussed in [Sect. 33.1](#). Many experimentally measured cross sections are collected in handbooks of IBA and some of them are available also in digitized form in SIGMABASE mentioned in [Sect. 33.2.2.2](#). Nevertheless, for obtaining very precise results the remeasurement of old data under the actual experimental conditions is recommended.

In **thick samples**, the bombarding particles slow down gradually; thus, if the cross section of a nuclear reaction has resonance structure, the resonances appearing at different energies are summed up and the yield belonging to a particular bombarding energy varies smoothly with the ion energy. To calculate the concentration of a certain element in a sample, one has to integrate the cross-section curve over the energy interval of the slowing down ion by taking into account stopping powers. For nuclear reactions, many different energy dependences are possible. Each cross-section curve needs values measured with sufficient accuracy, and a well-established analytical relation is missing. Hence, the integration cannot be carried out so accurately as in RBS or PIXE. For the integral several approximations exist, with the use of average cross sections, average stopping powers, etc. These features are discussed in detail, e.g., by Bird and Williams (1989). In the case of ion– γ reactions, the energy of γ rays exceeds

100 keV, very often even 1 MeV. The attenuation of such γ rays is significant neither in the sample nor in the detector window. This is an important advantage as no corrections are needed for the absorption of γ rays.

The analysis can be simplified if calibration samples with similar compositions are available. Then, for a certain γ peak whose yield $Y(Z, N)$ is measured on the sample and on a standard will give the concentration $C(Z, N)$ of the nuclide ${}^{Z+N}_{Z}\text{X}_N$ in the sample by the following simple formula (based on the approximation of stopping power ratios, see Deconninck 1978):

$$C(Z, N) = C(Z, N)_{\text{st}} \frac{Y(Z, N)S(E)_{\text{st}}}{Y_{\text{st}}(Z, N)S(E)} \quad (33.16)$$

where st stands for standard.⁸ The stopping power values $S(E)$ can be obtained, e.g., from calculations using the SRIM computer program-package of Ziegler et al. (2002).

Recently, a code was developed for the quantitative PIGE analysis of light elements without standards in thick samples (Mateus et al. 2005). (The code works similarly to what is done for PIXE; via integrating cross sections deduced from precisely measured nuclear reaction excitation functions along the depth of the sample.)

33.3.4.3 Depth Profiling

The relation between the energy of an energetic ion and the depth it penetrates is given by the stopping power formula (see [Chap. 8 in Vol. 1](#)). On the basis of the energy loss process of ions, a powerful method was developed for nondestructive measurement of concentration profiles to depths of the order of 10 μm with a depth resolution better than 20 nm. In practice, the method has many variants, but they can be divided into two main categories according to the shape of the nuclear cross section as a function of energy. The method is called **nonresonant** when the cross section is varying smoothly with energy and the analysis is performed at a fixed energy of the analyzing beam. In this case, the depth profile is derived from the recorded energy spectrum of particles emitted by the reaction. The method is **resonant** when the cross section, as a function of energy, shows a sharp peak, a resonance. Then the depth profile can be obtained from the yield of the nuclear reaction as a function of the beam energy.

Nonresonant Profiling

A medium thick sample is bombarded by the analyzing beam, and the ions hitting the surface lose their energy continuously while penetrating into the depth of the sample. Because the cross section does not change sharply with energy, and the concentration of the examined element does not depend on the depth very strongly, the reaction adds nearly the same amount of counts to the lower energy side of the peak and causes a broadening, as already discussed in the previous [Sect. 33.2.2.1](#) at RBS. There is a minor difference between RBS and NRA in this respect: in the case of a nuclear reaction, the outgoing particle is not the same as the ingoing one and its energy is also different, which means that one has to use a different stopping power value in the calculation of energy loss. For more detail, see [Sect. 33.2.2](#) and references therein.

Resonant Profiling

Both in elastic scattering and in reactions, one can find examples where a strong isolated narrow resonance appears in the cross section as a function of energy. Although the first

application of this technique used the $^{18}\text{O}(\text{p},\alpha)^{15}\text{N}$ reaction (Amsel and Samuel 1962), the best examples can be found in ion- γ reactions, more precisely in (p,γ) reactions. The depth profiling method works as follows.

Consider a reaction with an isolated narrow and strong resonance. This means that reaction products can only be detected if the analyzing beam hits a target nucleus (usually a light element on the surface of a heavier sample) exclusively with the resonance energy E_r . The incident ion energy E_0 is scanned upward from the resonance energy E_r . As the incident ion energy is increasing, the resonance is excited at larger and larger depths in the sample, and the detected γ -ray intensity gives information on the concentration of the considered element at that depth. The depth scale at a certain angle with respect to the surface can be calculated from converting the energy increase $E_0 - E_r$ to the dimension of length by the use of the stopping power characteristic to the main components of the sample material studied: $x = (E_0 - E_r)/\text{d}E/\text{d}x$. The concentration is calculated from the yield and width of the resonance, the stopping power $\text{d}E/\text{d}x$ (assumed to be constant), and the detection efficiency. The depth resolution at the surface is determined by the resonance width and the beam spread. Below the surface, the increasing energy straggling decreases the depth resolution gradually. The scanning of the ion beam can be automatized in different ways, e.g., by modifying the accelerator stabilization system (Amsel et al. 1983) or by applying an acceleration or deceleration voltage on the sample.

To achieve the optimum depth resolution of both nonresonant and resonant nuclear reactions, one must have accurate knowledge of the charged particle stopping process and the energy straggling in solids. To improve depth resolution, these questions are the subjects of continuous research both in RBS and in NRA. The subject has been discussed in more detail, with several examples of applications by Cherniak and Lanford (2001). One of the latest figures is an estimated depth resolution of approximately 0.4 nm near the surface of an ultrathin Al_2O_3 film deposited on Si substrate, which could be obtained using the 404.9 keV resonance (width ≤ 40 eV) in the $^{27}\text{Al}(\text{p},\gamma)^{28}\text{Si}$ reaction. The excellent depth resolution obtained is due to the high-energy stability of the proton beam and the use of glancing incidence (da Rosa et al. 2002).

33.3.5 Fields of Application

Generally speaking, NRA is used in the same fields as the other IBA methods, PIXE and RBS, but their extension is needed down to the lighter elements (H, Li, B, C, N, O, F, and Na) and/or trace elements down to the level of 1–10 $\mu\text{g/g}$. In such a way, NRA is complementary to PIXE (ion- γ reactions) and RBS (ion-ion reactions). The excellent depth resolution (1–10 nm) for nondestructive depth profiling of some light nuclides, ^1H , ^{15}N , ^{19}F , ^{23}Na , and ^{27}Al , is also exploited.

Here is a list of some examples chosen arbitrarily: hydrogen depth profiling by the ($^{15}\text{N},\alpha\gamma$) nuclear reaction was reviewed by Lanford (1992). Recently a particle accelerator was dedicated to high-sensitivity depth profiling accelerating ^{15}N ion beam (Uhrmacher et al. 2005) and in an other work the evaluation of the nonresonant background of this reaction near 13.35 MeV for hydrogen depth profiling was studied (Wilde and Fukutani 2005). For other elements see  Table 33.1.

As an example of the application of NRA in environmental studies, the combined PIXE/PIGE investigations (with the determination of Na, Mg, Al, and Si by PIGE) of Gallien et al. (2001) may be mentioned, where the alteration of glasses by microorganisms were studied. The concentration of the elements Li, Be, F, Na, Mg, Al, and Si, or their lateral and/or depth

■ **Table 33.1**

distribution is applied to the characterization of art and archaeological artifacts: obsidians (Murillo et al. 1998), glasses (Jembrih et al. 2001), emeralds (Calligaro et al. 2000), and ancient human bones (Jankuhn et al. 2000).

33.4 Editors’ Note

1. Keeping in mind that the vertical axis of panel (4) in ➤ Fig. 33.1 is logarithmic, one can immediately see by comparing the bremsstrahlung curves why the radiation (bremsstrahlung) term is so important in the stopping power formula of electrons and why the same term is usually neglected for slowing heavy ions (see ➤ Sects. 8.3 and ➤ 8.2, respectively, in Chap. 8, Vol. 1, on “Interaction of Radiation with Matter.”) (p. 1699).
2. See for the statistical bases of fitting nuclear spectra in ➤ Sect. 9.6 of Chap. 9, Vol. 1, on “Stochastics and Nuclear Measurements” (p. 1705).
3. Remember that Φ is just a number here, not a flux density, and therefore the peak area A is again a dimensionless quantity giving the number of scattering events that make up the peak (p. 1717).
4. If the electric charge is measured in SI units, the right-hand side of ➤ Eqs. (33.12) and ➤ (33.15) must be multiplied by $(4\pi\epsilon_0)^{-2}$ to get correct results, where ϵ_0 is the permittivity of vacuum (see under “electric constant” in ➤ Sect. 11.2 in the Appendix of Vol. 1) (p. 1717).
5. “**Straggling**” is a technical term in the field of ionizing radiation – matter interactions. It refers to the fact that the energy (and the momentum) distribution of initially monoenergetic particles gets wider and wider as they penetrate a substance. This “energy straggling” is the result of a series of stochastic interactions (e.g., with electrons), which drain their energy and eventually stop them. Straggling is also reflected in the absorption curve of α particles, for instance, which shows that the individual ranges of particles are different (p. 1721).
6. **Magnetic spectrometers** are based on ➤ Eq. (50.38) in Chap. 50, Vol. 5, stating that a charged particle moving perpendicularly to the magnetic flux density \mathbf{B} will follow a circular path, the radius of which is proportional to the momentum of the particle

($p = qBr$), thus making energy determination possible ($E = p^2/(2m)$) by using a “magnetic sector field” (p. 1722).

7. The angle $\sim 55^\circ$ is used to eliminate the effects of possible “texture” in powder samples and is called the “magic angle” in Mössbauer spectroscopy (see ► Chap. 25 in this Volume) (p. 1727).
8. ► Equation (33.16) is basically the equivalent of ► Eq. (33.5) suggested for PIXE, except that the present one works for nuclides (i.e., isotopes of elements) and not elements (p. 1730).

Abstract: This chapter deals with the analytical applications of synchrotron radiation sources for trace-level analysis of materials on microscopic and submicroscopic scales. Elemental analysis with X-ray fluorescence is described in detail. Two-dimensional (2D) and three-dimensional (3D) analyses are discussed in their quantitative aspects. Related methods of analysis based on absorption edge phenomena such as X-ray absorption spectrometry (XAS) and near-edge scanning spectrometry (XANES) yielding molecular information, computerized X-ray fluorescence microtomography (XFCT) based on the penetrative character of X-rays, and microscopic X-ray diffraction (XRD) providing structural data on the sample are also briefly discussed. The methodological treatment is illustrated with a number of applications.

Abbreviations AES, Auger emission spectrometry; CRM, Certified reference material; DL, Detection limit; ED, Energy dispersive; ESRF, European Synchrotron Radiation Facility; EXAFS, Extended X-ray absorption fine structure; NEXAFS, Near edge X-ray absorption fine structure; PCI, Phase contrast imaging; RM, Reference material; SR, Synchrotron radiation; SRM, Standard reference material; TXRF, Total reflection X-ray fluorescence; XANES, X-ray absorption near edge structure; XAS, X-ray absorption spectrometry; XDM, X-ray diffraction microscopy; XFCT, X-ray fluorescence computerized microtomography; XPEEM, X-ray photoelectron microscopy; XPS, X-ray photoelectron spectrometry; XRD, X-ray diffraction; XRF, X-ray fluorescence

34.1 Introduction

For a number of decades, X-ray fluorescence analysis (XRF) has established itself as a multielement analytical technique, which is capable of yielding quantitative information on the elemental composition of a variety of materials in a nondestructive manner. In its wavelength-dispersive configuration, it has proved itself as very important for routine analysis and quality control. The energy-dispersive configuration, on the other hand, offers wide potential as a simple tool for various laboratory and field applications in multielement analysis (Van Grieken and Markowicz 2002).

Two important variants of the method have appeared during the last 2 decades. Both variants are based on confining the volume in which the primary X-ray beam interacts with the analyzed material. In total reflection XRF (TXRF), by irradiating a flat sample with a near-grazing X-ray beam below the angle of total reflection, the in-depth penetration of the primary X-rays can be confined to a few tens of a nanometer below the surface allowing very sensitive surface analysis. Alternatively, the method can be exploited for bulk elemental trace analysis of liquids when these are brought on a clean inert surface (Wobrauschek 2007).

The second major variant of the XRF technique, which in the last decade has received a lot of attention, both with respect to the methodological developments and regarding its applications in diverse fields, is micro-XRF (μ -XRF). This microanalytical variant of bulk XRF is based on the localized excitation and analysis of a microscopically (now even submicroscopically) small area on the surface of a larger sample, providing information on the lateral distribution of major, minor, and trace elements in the material under study. The μ -XRF can be exploited with laboratory X-ray sources but found its most important areas of application when combined with a synchrotron radiation (SR) source (Janssens et al. 2000).

The high intensity and directionality of SR sources implies that they are ideally suited for the generation of X-ray microbeams. The polarization of the incident radiation can be used to reduce the relative contribution of scattered radiation reaching the detector, as scattering cross sections are dependent on the polarization state, whereas photo absorption cross sections giving rise to fluorescence radiation are not. In addition, quasi-monochromatic micron size X-ray beams can be generated from the white radiation spectrum using X-ray monochromators, thanks to the high directionality of the radiation.

In what follows the present status of μ -XRF analysis with synchrotron radiation sources with respect to lateral resolution, achievable detection limits and sensitivity will be reviewed. The possibilities of third-generation synchrotron radiation storage rings, especially those of the European Synchrotron Radiation Facility (ESRF) in Grenoble, France, will be discussed in relation to existing second-generation storage rings and newly built synchrotron sources. The analytical characteristics will be discussed as well as the potential in sensitive and accurate elemental analysis by μ -XRF in general. Related methods of analysis based on absorption edge phenomena such as X-ray absorption spectroscopy (XAS), giving molecular information, computerized X-ray fluorescence microtomography (XFCT) based on the penetrative character of X-rays, and microscopic X-ray diffraction (XRD) providing structural data on the sample will be briefly mentioned.

34.2 Synchrotron Micro- and Nanoscopic X-Ray Fluorescence Analysis

Disregarding the inherent complexity of the SR X-ray source problems involved with monochromatization and focusing of the X-rays, the instrumentation for X-ray microanalysis is extremely simple – conceptually. It consists of a mechanical sample stage with precision computer-controlled micro-stepping motors for X, Y, and (optionally) rotational movement of the sample, a semiconductor type detector for the measurement of the fluorescent radiation, different visualization tools for observation of the sample and, finally, a range of diagnostic and control tools.

Figure 34.1 shows the ID18F as a typical setup for SR μ -XRF (Somogyi et al. 2001, 2002). The components are indicated in the figure. The different elements of the μ -XRF instrumentation will be discussed in sequence, starting with the SR source characteristics.

Fig. 34.1

Schematic layout of the ID18 beamline and the ID18F user end-station. Photodiode 1 (photo1) is placed either into the sample position if a sample was measured (geometry 1) or in front of the mini-ionization chamber (geometry 2). For other components, see text (Adapted from Somogyi et al. 2003)

The difficulties in focusing X-rays are the result of the refractive index being very close to unity for hard X-rays. The refractive index is defined as ($\tilde{n} = 1 - \delta - i\beta$) where δ is the refractive index decrement (typically 10^{-6} for hard X-rays) and β is the absorption index. For wavelengths in the X-ray range, the refractive index of materials is very close to (but less than) 1, with the consequence that manufacturing straightforward refractive lenses is difficult. In the soft X-ray range, this problem is compounded by the elevated absorption (attenuation) coefficient for most materials that effectively limits the use of reflective and refractive optical designs. For these reasons, soft X-ray microscopes commonly resort to diffractive optics. Focusing hard X-rays with the help of grazing-incidence on reflecting surfaces is the method mostly used on synchrotron beamlines. A typical example is a toroidal mirror that gives spots several hundreds of micrometers wide. The goal to decrease the spot size to a micrometer or less has triggered technological developments of a specific reflecting system, the so-called Kirkpatrick–Baez (KB) system. Two orthogonal mirrors focus the beam successively in the horizontal and in the vertical planes.

Microfocusing devices that are based on refraction operate in the same way as visible light optics but there are some differences (Schroer et al. 2005). Firstly, the X-ray refractive index of a material is smaller than in vacuum or air and, therefore, an X-ray focusing lens has a double concave shape. Secondly, because the refractive index of all materials is very close to unity for hard X-rays, the deflection is usually very small and many lenses have to be placed in series to achieve reasonably short focal lengths. In order to keep absorption to a minimum, these compound refractive lenses (CRLs) should be made from low-*Z* materials such as beryllium, carbon, aluminum, and silicon. CRLs with parabolic shapes made from polycrystalline aluminum by a pressing technique have proven to be well suited for microanalysis and full field microscopy applications for 20–120 keV X-rays (Lengerer et al. 1998).

In a number of μ -XRF installations (poly)capillary optics are used as focusing devices (e.g., Bilderback et al., 1994; Vincze et al., 2002a, b). These simple (pseudo) focusing devices exploit conditions for total reflection in single glass capillaries or in compound systems of capillary bundles to collimate and focus beams and provide a good lateral resolution but suffer from the short working distance (typically less than few millimeter) between the capillary tip and the sample.

When X-rays interact with matter, three main interaction types are possible: elastic (Rayleigh) scattering, inelastic (Compton) scattering, and absorption due to the photoelectric effect (see also ► Chap. 8 in Vol. 1 on this topic). Most of the X-ray applications during the last 100 years or so have used absorption contrast. In terms of the complex X-ray refractive index ($\tilde{n} = 1 - \delta - i\beta$) this means that the emphasis has been on the imaginary component $i\beta$. During the photoelectric effect, the incoming photon is fully absorbed by an atom and its energy is transferred to a bound electron that will leave the absorbing atom as a photoelectron. Either the measurement of the photoelectron or the fluorescent radiation resulting from the relaxation process can be used for analysis. The first possibility leads to methods of analysis such as X-ray photoelectron microscopy (XPEEM). Combined with a photoelectron microscope with nm lateral/depth resolution, the photoemission technique gives the unique possibility of true nondestructive compositional analysis with nm scale lateral and depth resolution, thus providing new means of measuring 3D morphologies in nanoscience and technology. Third-generation SRs provide beamlines for XPEEM, and thus photoemission measurements at a spatial resolution of better than 50 nm are now possible, and extrapolations indicate a 2 nm resolution to be attainable.

Little or no attention was paid until recently, to the real component δ , which becomes important when dealing with X-ray phase-contrast imaging (PCI). Coherent X-ray diffraction

microscopy (XDM) and imaging involves a method of image reconstruction from the coherent X-ray diffraction pattern of a sample. A lensless method is reliant on radiation *coherence* in high-brilliance X-ray sources for 2D or 3D reconstruction of the image of nanoscale structures.

A particular advantage of SR μ -XRF in comparison with the conventional X-ray tube sources is the extremely high brilliance. *Brilliance* is expressed as the number of photons emitted per unit source area over a unit angle of emission and per unit energy (photons $\text{s}^{-1} \text{mm}^{-2} \text{mrad}^{-2}$ per 0.1% of radiation bandwidth). In addition, in the plane of the storage ring the radiation is linearly polarized with the *E*-vector parallel to the ring plane and the *B*-vector normal to it. The radiation is highly collimated along a direction tangential to the movement of the electrons in the ring, which facilitates the delivery of the radiation to a predefined sample area.

The high intensity and directionality imply that SR is ideally suited for the generation of X-ray micro- and nanobeams with very high flux density, exceeding now 10^{13} photons $\text{s}^{-1} \mu\text{m}^{-2}$ by using, e.g., wide bandpass nanofocusing X-ray optics at the largest third-generation SR sources. Such high flux densities are achieved, e.g., at the ESRF ID22NI nanoprobe, where a nanoscopic hard X-ray beam is generated by bent KB multilayer mirrors, producing beam sizes of ~ 90 nm with intensities of approximately 10^{12} photons/s at an energy of 17.5 keV. At this instrument, absolute detection limits below 0.1 ag can be achieved for atomic numbers above 26 using a measuring (live) time of 1000 s (see [Fig. 34.2](#)). The extreme X-ray flux density within the submicron spot results in the possibility of detecting an amount of a few thousand of transition metal atoms. Using a thin Fresnel zone plate with outermost zone widths of 10 nm Kang et al. (2006) demonstrated focal sizes as small as 30 nm and an efficiency of up to 44% at 19.5 keV.

Fig. 34.2

Absolute mass detection limits for elements with atomic number above 14 measured at the European Synchrotron Radiation Facility (ESRF) ID22NI nanoprobe corresponding to a beam size of approximately 100 nm, beam intensity of 6×10^{11} photons/s and measuring times of 300 ms and 300 s

When performing measurements in the plane of the SR source, the polarization of the incident radiation increases the signal-to-background ratios by up to two orders of magnitude. In addition, thanks to the high directionality of the beam, quasi-monochromatic X-ray microbeams can be generated from the polychromatic (white) radiation spectrum using suitable X-ray monochromators. Using these by tuning the energy of the source, the strong energy dependence of the inner shell photoelectric cross sections can be exploited to increase specificity of measurements or to obtain chemically significant information (valence state, molecular information). On the other hand, polychromatic excitation has the advantage that (nearly) all elements in the sample are excited with quite comparable efficiency providing a more uniform spectrometer response over the Z range of interest. Hence, this type of excitation is more appropriate for general-purpose materials characterization. Since losses in flux due to the monochromatization process are excluded, the elemental efficiency of polychromatic setups is also higher than when monochromatic excitation is used. On the other hand, quantification of the detected X-ray intensities is in such circumstances more complicated and error-prone. For quantitative analysis the use of monochromatic radiation is, hence, preferable.

With such characteristics, it is not surprising that a number of existing storage rings have been employed in SR μ -XRF experiments combining the advantages of XRF as an elemental analytical tool with the unique possibilities of the SR. Of special significance are the new so-called third-generation storage rings that are specifically designed to obtain unprecedented intensity and brilliance. A number of these storage rings are now operational – the European Synchrotron Radiation Facility, ESRF; the Advanced Photon Source, APS, Argonne, USA; and the Super Photon ring-8 GeV, SPring-8, Harima, Japan, are the most important examples. Compared to earlier second-generation rings, these SR facilities are characterized by their high energy of 6 to 8 GeV. Significant in these devices also is the systematic use of insertion devices that are placed in the straight sections of the storage ring (wigglers and undulators). *Wigglers* are magnetic structures that create multiple oscillations around the beam path and hence increase both the energy and the intensity of the radiation. *Undulators* are designed to create smaller and more frequent deflections, giving rise to interference effects as a result of which the coherent radiation is concentrated around specific energies. In addition, X-ray optics of increased sophistication amplifies considerably both flux density and brilliance. Other newly built SR sources follow the design characteristics of these sources.

A double crystal monochromator (see [Fig. 34.1](#)) comprising a pair of crystals is a standard item in most μ -XRF setups because the exit direction is kept constant during energy scanning. Furthermore, mechanical systems are adopted to keep the beam height constant during the energy scan. The energy resolution of the double crystal monochromator is of the order of $\Delta E/E = 10^{-4}$ or better, and this is sufficient for XAS and XANES applications. However, in its primary mode of utilization, XRF analysis requires a high photon flux density rather than such high energy resolution, an energy resolution of the order of $\Delta E/E = 10^{-2}$ being sufficient for the purpose. Synthetic multilayers, which are made by vacuum deposition of alternate thin layers of two materials with different electron densities, provide this resolution while yielding a photon flux density one to two orders of magnitude higher than available with a double crystal monochromator. This is due to the wide energy bandpass of the multilayer.

Techniques for the formation of intense X-ray microbeams are readily available using various types of X-ray optics. Bent mirrors, crystals and multilayers, tapered glass monocapillaries, complex polycapillary lens systems, Bragg–Fresnel lenses, one- or two-dimensional waveguides, and refractive lenses have been developed and tested for use in micron (μm) size to

■ Fig. 34.3

Relative detection limits with ID18F (see Fig. 34.1) using a 100 component compound reflective lens set at 21 keV in a biological material (NIST SRM 1577a, bovine liver) and in NIST 613 glass SRM

submicron focusing at synchrotron beam lines. At present, it is possible to obtain sufficient beam intensity on microscale samples to allow reliable sub ppm level determinations of a large number of elements. Figure 34.3 shows relative detection limits obtained at ESRF with the instrument shown in Fig. 34.1 for two reference samples.

The measurement part of the μ -XRF setup is mostly a semiconductor detector, either a conventional Si(Li) or an intrinsic Ge detector or another type of semiconductor detector. Recent technological developments and new topology designs have made semiconductor detectors ideal devices for X-ray detection with reasonably high resolution at high pulse processing rate. The limited energy resolution of the energy-dispersive detection gives rise to complicated spectra with multiple spectral interferences, which need to be resolved through spectral deconvolution. Also, high count rates must be adequately taken into account, e.g., by using digital pulse processing (Adams 2003). To take full profit of the polarization and, hence, to increase signal-to-noise ratios, the X-ray detectors are placed in the plane of the storage ring at typically an angle of 90° to the incident beam direction. Wavelength-dispersive spectrometers are seldom used because of the slow measurement process and the resulting loss in sensitivity.

Techniques have been developed for fast and reliable nonlinear least squares deconvolution of X-ray spectra, which circumvent spectral interferences, e.g., the analysis of X-ray spectra by iterative least squares (AXIL) programme (Vekemans et al. 1994; Janssens et al. 1996). Also, powerful methodologies are now available for modeling by ab initio Monte Carlo simulation both the beam optics and the beam-sample interaction within the sample and the detector (Vincze et al. 1999a, b, c). The combined use of nonlinear least squares deconvolution of X-ray spectra and the powerful methodology for modeling the beam optics and beam-sample interaction allow the optimum use of all spectral information, including the use of Rayleigh and Compton scattering. A number of background effects that were never fully evaluated in XRF appear in the SR spectra, the most important being electron bremsstrahlung in the sample and the detector. Electron bremsstrahlung is able to generate fluorescence radiation from low Z elements and is, hence, an important factor in quantitative analysis. Also, specific spectral artifacts complicate the spectra, e.g., radiative Raman scattering. State-of-the-art multivariate statistical techniques for data reduction of image scans are available (Janssens et al. 1996, 2000).

For the measurement of elemental distribution maps, spectra are taken as the sample is moved over the beam path. Contrarily to t0068e vacuum requirements of most other microprobe methods, samples are normally observed in air, allowing the measurement of samples in their natural (e.g., wet) conditions.

As an example of the many setups available at SR sources, a brief description will be given of the ID18F configuration at ESRF, Grenoble, which is specifically devoted to μ -XRF applications. Some other SR installations exploit μ -XRF as a dedicated beamline, some others use it in combination with other applications.

Total reflection X-ray fluorescence analysis (TXRF) extends XRF down to the ultra-trace element range. Detection limits of picograms or nanograms per gram levels are reached with X-ray tube excitation. Using synchrotron radiation as excitation source, detection limits of femtogram levels are achievable, which is particularly important for the surface analysis of Si wafers. The use of SR as source is an elegant and powerful approach for TXRF to achieve ultimate results in terms of detection limits, reaching the 10^{-18} g levels and, if allowed at dedicated beamlines for low energies, even the determination of extremely light elements down to boron. Applying XANES in combination with TXRF allows the speciation of elements at ultra-trace levels (Ortega et al. 1998; Streli 2006; Streli et al. 2006; Wobrauschek 2007).

34.3 ID18f: A Dedicated X-Ray Microprobe End-Station

ID18F was constructed as a dedicated X-ray microprobe in the third experimental hutch (radiation shielding enclosure) of the ID18 beamline of the ESRF and using its optics infrastructure; the schematic layout is shown in  Fig. 34.1 (Somogyi et al. 2001). The energy of the excitation radiation can be tuned between 6 and 28 keV by changing the undulator gap, and monochromatic radiation of $\Delta E/E = 10^{-4}$ is created by a fixed exit double crystal Si (111) monochromator. The design goal was to improve procedures of μ -XRF in order to reach 5% average accuracy of quantification down to sub-ppm concentration levels for elements of $Z > 13$. To do this it is necessary to insure high reproducibility of the measurement geometry and instrumental parameters of the setup, a very good short- and long-term stability, and precise monitoring ($< 1\%$) of the intensity of the incoming beam.

The entire microprobe setup is positioned on a movable granite table. Compound refractive lenses are used for focusing to a routinely achievable spot size of 1–2 μm vertically and 12–15 μm horizontally. The intensity of the incoming, the focused, and the transmitted beam is monitored by ionization chambers and photodiodes. A miniature ionization chamber with an aperture of 50 μm diameter as an entrance window was developed at the ESRF for measuring the intensity of the focused beam close to the sample (Somogyi et al. 2003). The characteristic X-ray line intensities are detected with a Si(Li) detector of 30 mm^2 active area, 3.5 mm active thickness, and 8 μm thick Be window placed at 90° to the incoming linearly polarized X-ray beam. Fast scanning XRF measurements (> 0.1 s live time/spectrum) are possible.

The analytical characteristics (degree of polarization, absolute and relative limits of detection) of ID18F were determined by measuring a number of existing certified reference materials (CRMs). The degree of polarization is $> 99.5\%$. The available relative detection limits (DL) are < 0.1 ppm for elements of $Z > 25$. Relative DLs down to a few ppb are possible for a number of elements on the basis of 1,000 s live time measurements and ppm DLs can be reached for measurements of a few seconds. The absolute DLs are less than 1 fg for elements of $Z > 25$.

The photon flux in the focused beam is 10^9 – 10^{10} photons/s depending on the energy of the incoming beam (Adams 2003; Vekemans et al. 2003).

The design characteristics of other SR installations can be found in the literature, e.g., the X-26A beamline of the National Synchrotron Light Source in Brookhaven National Laboratory (Smith 1995) and beamline L at HASYLAB (Falkenberg et al. 2001).

34.4 Micro-X-Ray Fluorescence Analysis as an Accurate Method of Microanalysis

Accurate elemental analysis at the microscopic/submicroscopic level is very important in fundamental scientific research and is of growing importance for the characterization at submicron/nanoscale level in various areas of materials technology. All current micro-“beam” methods of analysis are relative, i.e., the signal measured requires either comparison to a reference material or validation through comparison with quantitatively reliable methods of analysis. Most so-called “beam” methods for microanalysis (e.g., electron probe microanalysis, micro-Auger spectroscopy, and secondary ion mass spectrometry) cannot yet be considered as accurate methods of analysis except when applied to compositionally or structurally quite simple samples. Their application to quantitative analysis must rely on the use of CRMs or standard reference materials (SRMs and RMs) for calibration, but, with very few exceptions, these materials are not available at present.

Microscopic methods such as quantitative X-ray photoelectron spectrometry (XPS) and Auger emission spectrometry (AES) are more difficult to apply as a quantitative tool as they require an understanding of the change in energy distribution of electrons as they move in solids. In comparison with XRF, they need to deal with the electron cloud of outer electrons instead of the core electrons. Nevertheless, as demonstrated, e.g., by Tougaard (1997), principles and rules of general validity (universal cross sections) can be defined, which give a reasonably accurate description of the inelastic scattering process and open the way for real quantification. The basic physical processes involved in particle induced X-ray emission (PIXE) and Rutherford backscattering spectrometry (RBS) are also well understood (see previous chapter), and they can also be modeled using readily available software codes (Grime 1996).

The reason for the lack of RMs is the absence of reliable and accurate methods of analysis. Microanalysis is, hence, in need of at least one method that can be used as a reference tool for other techniques and to link RMs or round robin exercises to the international unit of mass. Micro-XRF can be used for this potentially, especially when used for analyzing microscopic samples, where matrix absorption effects are relatively unimportant. At present, XRF is considered to be a rather poor method for certification purposes due to intense matrix effects resulting from intense radiation absorption and enhancement by secondary fluorescence. In wavelength-dispersive XRF, reliable results can only be obtained through calibration with a set of reference samples of closely similar composition to the unknown sample. In the case of energy-dispersive XRF using monochromatic excitation, the correction for matrix effects is simpler but in this case the method suffers from a number of other drawbacks, such as spectral overlap and poor statistics in the spectra.

Despite all these drawbacks, the physical basis of the X-ray – matter interaction is fully understood and the physical parameters governing the interaction and the extent of radiation absorption can be derived accurately from measurements obtained under well-defined

■ Fig. 34.4

Experimental (dots) and simulated (solid curve) synchrotron radiation–X-ray fluorescence (SR–XRF) spectra obtained for the NIST SRM 1577b bovine liver standard, corresponding to 21 keV excitation at the European Synchrotron Radiation Facility (ESRF) ID18F end-station (Adapted from Vincze et al. 2004)

conditions. In principle, it is thus possible to fully correct for deviations from linearity between measured intensities and elemental concentrations, provided time and efforts are spent to make the proper calculations. This is easily performed when the instrumentation is simplified as much as possible, essentially when using a high-intensity monochromatic primary excitation, by employing an energy-dispersive detector, and by using a sample of well-characterized shape and smooth surface.

It has been demonstrated earlier that experimental XRF spectra can be accurately modeled through Monte Carlo simulations starting from first principles (Vincze et al. 1999a, b; Vekemans et al. 2003). As an example, Fig. 34.4 shows a comparison of simulated and experimental SR–XRF spectra corresponding to the biological reference material NIST SRM 1577b (bovine liver). See Fig. 34.3 for the detection limits of these measurements.

Starting from a priori assumptions of the composition of the sample, e.g., on the basis of the measured intensities in the spectrum, it is possible to model spectra and by iteration to arrive at reasonable estimates of the sample composition. Such an approach is by no means easy but with inexpensive computing power available nowadays it becomes well feasible. The following section will review quantitative analysis according to such procedures.

34.5 Quantitative Elemental Analysis

34.5.1 X-ray Absorption

The first issue of concern is radiation absorption of the incoming and the fluorescent radiation.

Assume a monoenergetic X-ray beam with intensity I_0 that travels through a slab of material. The X-ray beam will then be attenuated exponentially with the path length d :

$$I = I_0 e^{-\mu_l d} = I_0 e^{-\mu_\rho \rho d} \quad (34.1)$$

with μ_l the linear absorption coefficient (attenuation coefficient). In practice, the mass absorption coefficient $\mu_\rho = \mu_l / \rho$ (with ρ meaning the density of the material) is being used, as the total absorption of a sample composed of different atom types at a certain photon energy E , can easily be calculated from

$$\mu_{\text{tot}}(E) = \rho \sum_i w_i \mu_{\rho,i}(E) \quad (34.2)$$

with w_i the weight fraction of element i in the sample. Mass absorption coefficient values for the different elements of the periodic table are given for example in volume III of the International Table for Crystallography.

As an example, the mass absorption coefficients of vanadium, silver, and gold in the 10 eV – 20 keV photon energy range are given in [Fig. 34.5](#).

On a log–log scale, the mass absorption coefficient decreases essentially monotonically from a certain energy value on (which is element specific and larger for higher Z elements; about 200 eV for V and about 1 keV for Au). Matter becomes more and more transparent to X-rays with increasing X-ray energy. Besides this monotonic decrease, a number of discontinuities can be observed at which the absorption increases suddenly. These jumps are called “absorption edges.” The energy positions of the absorption edges for a specific element correspond to the binding energies of electrons occupying different orbitals in that element. Suppose that the energy of the incoming photon beam is increased from just below an absorption edge for a certain element to an energy value just above the edge. As soon as the energy of the photon becomes equal or larger than the binding energy of that particular electron energy level in that atom type, the electrons of that level can contribute to the absorption via the photoelectric effect. A new channel for absorption opens up and the total absorption for that element increases suddenly.

Fig. 34.5

The mass absorption coefficients for V, Ag, and Au as function of photon energy

34.5.2 Quantitative Analysis

Computer modeling can be applied in an iterative manner for the quantitative evaluation of XRF spectra of homogeneous bulk samples and of particles with predetermined shape (Vincze et al. 2002a, b). Errors are mostly due to the uncertainties in the parameters responsible for the interaction process (cross sections, fluorescence yields, and transition probabilities).

The detected characteristic X-ray line intensity $I_{i,\text{meas}}$ of element i is expressed as

$$I_{i,\text{meas}} = I_0 C_i S_i A_i \quad (34.3)$$

where I_0 is the intensity of the primary X-ray beam, C_i is the concentration (fraction) of element i within the particle, S_i is the elemental sensitivity for element i , and A_i is the self-absorption factor of incident and emitted X-rays.

The net-peak intensity $I_{i,\text{meas}}$ can be determined by fitting the experimental spectra using nonlinear least squares fitting (Janssens et al. 1996, 2000). The self-absorption factor A_i depends on the matrix composition and on geometrical factors (size and shape of the sample).

The mass shape and matrix that are relevant to the irradiated part of the sample are not known; it is very difficult to determine these parameters experimentally. Hence, it is necessary to make some a priori assumptions on the basis of independent bulk measurements.

Initial concentration values, necessary to start the iteration, are obtained from the X-ray spectrum neglecting any self-absorption (i.e., $A_i = 1$) and using sensitivity factors (S_i) obtained from thin standard reference materials (e.g., NIST SRM1832, SRM1833 glass calibration standards).

The initial concentration of analyte i , $C_{i,0}$ with detectable X-ray line is calculated as

$$C_i^{(0)} = \frac{I_{i,\text{meas}}/S_i}{\sum_{j=m+1}^n (I_{j,\text{meas}}/S_j)} \times \left(1 - \sum_{j=1}^m C_j \right) \quad (34.4)$$

where n is the total number of elements in the sample and the first m elements are assumed to constitute the so-called *dark matrix*, the elements that do not give rise to detectable radiation. This *dark matrix* can be derived from stoichiometry (e.g., using the known oxygen content by assuming a common oxide form of the elements) or from other (bulk) measurements.

Concentration of low- Z elements ($Z < 14$, dependent on detector window and other windows attenuating the radiation) cannot be estimated from the spectrum: they do not provide detectable X-ray peaks under the experimental conditions used (detector and other windows, air absorption). The second step is to iteratively refine these initial concentration values according to

$$C_i^{(k+1)} = C_i^{(k)} \frac{I_{i,\text{meas}}}{I_{i,\text{calc}} \sum_{j=1}^n C_j^{(k)} \frac{I_{j,\text{meas}}}{I_{j,\text{calc}}}} \quad (34.5)$$

where $C_i^{(k)}$ is the calculated concentration of element i after k iterations. The procedure is terminated when one of the following conditions is met:

$$\left| C_i^{(k+1)} - C_i^{(k)} \right| < \varepsilon \quad (34.6)$$

$$\sum_{i=1}^n \frac{(I_{i,\text{meas}} - I_{i,\text{calc}})^2}{\sigma_{i,\text{meas}}^2} < \delta \quad (34.7)$$

where ε and δ are predefined constants.

It will be necessary to further refine all these methods, to adapt them to the ongoing scientific development and to the fast evolution of technology (both in terms of X-ray optics and computing power) in order to obtain highly accurate analytical data. An intensive effort is also required to take into account secondary effects that affect the precision and accuracy of measurements. These include geometrical factors in the setup, effects that influence the precision and accuracy of measurements in heterogeneous samples, secondary and higher order phenomena of radiation absorption and enhancement, particular artifacts in the X-ray spectra (contribution of resonant Raman scattering and photoelectron bremsstrahlung), effects due to the unique properties of synchrotron radiation (e.g., polarization, time structure), and detector characteristics (e.g., thickness of Be and other detector windows, inactive layers), all of which affect the spectral data obtained.

A systematic comparison of experimentally obtained spectral data with modeling results based on Monte Carlo simulations can pinpoint and show ways to correct for all these effects and eventually bring the measurement accuracy in line with the accuracy of the physical parameters characterizing the X-ray – sample interaction processes. Ultimately, the quality of results that can be reached with this method depends on the accuracy of available physical parameters, mainly the cross sections for X-ray interactions that are, in the most favorable circumstances, 5% for K radiation of elements between $Z = 20$ and 50, 10 – 15% for L radiation between $Z = 50$ and 80 (Elam et al. 2002; Somogyi et al. 2000).

A reasonable goal of this is to reach an average accuracy of quantification in the range of ca 5% for elements above atomic number 12 determined through their K and L fluorescence radiation. ▶ [Table 34.1](#) shows a few results obtained for the standard reference material NIST SRM 1577b bovine liver (see also the related ▶ [Figs. 34.2](#) and ▶ [34.4](#)).

■ **Table 34.1**

Certified and calculated concentrations for the analysis by iterative Monte Carlo calculation of NIST SRM 1577 bovine liver

Element	Certified conc./ppm	Calculated conc./ppm	Rel. deviation/%
Cl	(2,600)	2,300	–12
K	0.97 ± 0.06%	0.92%	–5

Mo	(3.2)	3.4	+6

34.6 Related Techniques

μ -XRF is the most important exploitation mode of X-ray microbeams in chemical analysis. All major SR sources are involved with this type of application with at least one instrumental setup. Detection limits in the ppb region and two-dimensional mapping of the repartition of elements in larger objects than the X-ray beam is possible. Other possibilities for fluorescence analysis based on the interaction of X-rays are less well advanced and are now being developed at several SR sources. In the application of X-ray absorption spectroscopy (XAS), the energy dependence of the inner shell photoelectric cross sections is exploited to increase specificity of measurements or to obtain information on the chemical environment (speciation analysis). X-ray absorption spectroscopy (XAS) is generally applied in the photon energy range of 0.1–100 keV where the scattering processes are 100 to 1000 times less probable than the photoelectric process. The presence or absence of pre-edge structure provides data on the oxidation and coordination state of an element (XANES, “X-ray absorption near edge structure” or NEXAFS, “near edge X-ray absorption fine structure”), while “Extended X-ray absorption fine structure” (EXAFS) analysis provides information on the number and the distance of neighboring atoms by measuring the oscillations from approximately 50 eV above the edge in EXAFS. The word extended is added to the name because the EXAFS oscillations can be found in certain cases up to 1,000 eV above the edge.

The technique is based on irradiation with a highly monochromatic X-ray beam of tunable energy and scanning over an absorption edge of an element of interest while recording either the absorption of the beam (*absorption* XAS), or the fluorescence radiation produced (*fluorescence* XAS) or another shell dependent phenomenon. The possibilities of the utilization of the X-ray absorption structure for obtaining more specific information will be discussed in a later section of this chapter. Recently, there were a number of demonstrations on the use of spatially resolved speciation to distinguish valence states of the elements Cr, Fe, Zn, U, Pu, etc., in geological, cosmo-chemical, and environmental studies.

In addition, the punctual measurement of X-ray diffraction pattern over a complex sample provides information on the variation of its crystallographic structure (XRD) over a heterogeneous object. Micro-XRD is becoming common on many X-ray microprobes. Micro-XRD maps can be obtained together with the maps of elemental information and can assist in characterizing heterogeneous samples.

Computerized X-ray fluorescence microtomography (XFCT) at high spatial resolution with absorption or fluorescence radiation from a spatially confined SR beam is based on the systematic measurement of the fluorescence radiation (and absorption) as it is impinging on the sample. It is then possible to reconstruct three-dimensional shape, density, and composition. By obtaining information on three-dimensional structures, XFCT exploits the penetrative nature of X-rays (which, otherwise, is a drawback for simple μ -XRF). Because of the penetrating nature of X-rays, namely, in the case of a regular scanning micro-XRF instrument, the detected analytical information represents the full line integral along the path where the micro-beam penetrates the sample. A typical scanning XRF experiment therefore results in a two-dimensional (2D) projection of the elemental distributions within the examined sample, without any, or very limited, depth information. The introduction of tomographic techniques, such as XFCT, however, allows the three-dimensional (3D) extension of the scanning XRF method. This computed tomography is one of the emerging methods of providing (potentially 3D) quantitative information on the elemental distribution in the probed sample volume with trace-level detection limits.

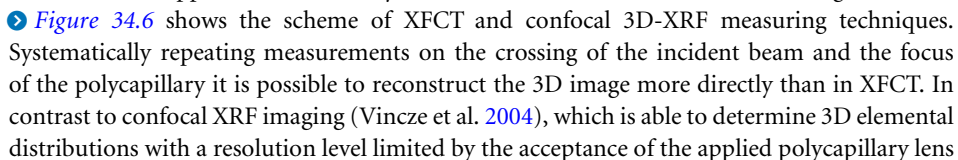

These techniques greatly enhance the capabilities of μ -XRF for the study of heterogeneous materials. Exhaustive recent reviews of applications of μ -XRF and related techniques are available in the literature (Schulze and Bertsch 1995; Potts et al. 2000; Revenko 2000; Bertsch and Hunter 2001; West et al. 2008; Janssens et al. 2000).

This section will discuss these techniques in some detail.

34.6.1 Three-Dimensional Micro-XRF Methods: X-Ray Fluorescence Computed Tomography (XFCT) and Confocal Imaging

The sample used in XFCT measurements, in addition to being measured, is also rotated over 360° (180° in case of dual-detector setups). For full XRF tomography, repetitive linear scans at a selected height in the sample are recorded for different rotation angles. The different line profiles, as a function of the rotation angle, form the so-called elemental sinograms. The absorption and fluorescence images can then be reconstructed from the combination of the data obtained, yielding elemental cross sections at well-defined heights of the sample. Imaging is possible with the white spectrum as well as with monochromatic radiation. It is now possible to carry out XFCT with volume resolutions better than $1 \mu\text{m}^3$ and with about 10^4 – 10^5 voxels. (Voxels are the 3D versions of pixels.) This information provides possibilities for nondestructive observation of the interior of the sample for the study of, e.g., inclusions, interior pore structures, buried phases, or other features within the sample. The technique is now in full development, the major problems being the complexity of calculations necessary for reconstructing the images, especially when fluorescence radiation is used for reconstructing elemental distributions. In principle, it is possible to combine XAS and XFCT by obtaining the fluorescence or absorption information with two closely spaced excitation energies that are characteristic of the valence states of different ions in the sample.

One of the main limitations associated with the XFCT technique is the lengthy data collection procedure required. Being a first-generation scanning tomography technique, typically 1–5 h of scanning time is needed for obtaining each two-dimensional tomographic slice. With the introduction of fast multielement energy-dispersive (ED) detectors coupled with digital signal processing technology and fast-scanning techniques, in the following years, this limitation is expected to be relaxed considerably or eliminated. Next to the time-consuming data collection procedure, another difficulty of the technique is associated with the quantitative reconstruction of the measured sinograms due to element-dependent self-absorption effects. Recently, generalized XFCT reconstruction algorithms were developed, including accurate correction for self-absorption effects in the matrix material (e.g., Schroer 2001; Golossio et al. 2003). Considerable effort has also been taken to develop a dedicated Monte Carlo simulation procedure for XFCT, based on the detailed modeling of photon–matter interactions (Vekemans et al. 2004).

An alternative approach for the three-dimensional (3D) variant of scanning micro-XRF is based on the excitation with an X-ray micro-beam and confocal detection using a polycapillary half-lens. This approach was recently evaluated at several SR facilities including the ESRF.  **Figure 34.6** shows the scheme of XFCT and confocal 3D-XRF measuring techniques. Systematically repeating measurements on the crossing of the incident beam and the focus of the polycapillary it is possible to reconstruct the 3D image more directly than in XFCT. In contrast to confocal XRF imaging (Vincze et al. 2004), which is able to determine 3D elemental distributions with a resolution level limited by the acceptance of the applied polycapillary lens

■ Fig. 34.6

Schematic representation of a generic XRF tomography setup (a) and of the polycapillary based confocal arrangement for three-dimensional X-ray fluorescence (3D-XRF) (b)

($\sim 10 \mu\text{m}$), the spatial resolution of XRF nanotomography is ultimately limited by the X-ray beam size that is used.

34.6.1.1 Nanoscopic X-ray Fluorescence Computerized Tomography (XFCT)

Submicrometer beam sizes are becoming available at third-generation sources, opening up the possibility of XRF imaging and also XFCT at the nanoscopic level. Using a submicron X-ray beam, full three-dimensional nano-XRF tomography results with a spatial resolution of approximately 200 nm has been demonstrated at the ESRF ID13 instrument (Silversmit et al. 2009a).

The high spatial resolution provided by the beam puts stringent conditions on the accuracy and reproducibility of sample positioning during linear and rotational scans. On the scale of the beam size ($\sim 200 \text{ nm}$), considerable sample displacements can be expected, especially after each rotational movement, because of imperfections of the rotation axis and vertical drifts of the sample stage assembly due to, e.g., gravity. To be able to correct for such instabilities after data collection, instead of analyzing a single sample slice by conventional XRF tomographic (linear) scans, full 2D-XRF projections can be recorded at each observation angle. While more time consuming than linear scans, this method allows for the off-line correction of sample positioning inaccuracies associated with rotational movements, and also gives the possibility of full 3D elemental reconstruction, instead of obtaining elemental distributions only in a single sample cross section. The combination of the reconstructed cross sections (slices) for all heights enables the visualization of the complete 3D view of elemental distributions in the investigated object. An example is given in Fig. 34.7, showing pseudo-color composite images of the low-intensity isosurface distributions of iron (red), chromium (green), and selenium (blue) for different azimuthal viewing angles for a cometary particle returned to Earth in the framework of the NASA Stardust mission (Brownlee and Zolensky 2006; Silversmit et al. 2009a). The heterogeneous nature of the elemental distributions within the terminal particle having a diameter of $2 \mu\text{m}$ could be visualized in a nondestructive manner in 3D on the nanoscopic level (see, e.g., the low-intensity isosurface for chromium).

■ Fig. 34.7

Reconstructed low-intensity isosurface composite images for different azimuthal viewing angles: red denotes iron, green represents chromium, and blue indicates selenium (Adapted from Silversmit et al. 2009a)

■ Fig. 34.8

Left panel: Schematic of the experimental set up for confocal 3D-XRF at the European Synchrotron Radiation Facility (ESRF) ID18F end-station. Right panel: Basic principle of confocal X-ray fluorescence analysis using polycapillary detector optics (Adapted from Vincze et al. 2004)

34.6.1.2 Confocal XRF-Imaging

The principle of confocal XRF detection is compared with XFCT in Fig. 34.6 and shown in more detail in Fig. 34.8. The combination of a polycapillary half-lens coupled with an energy-dispersive detector for 3D-XRF has been first proposed in the early 1990s by Kumakhov and coworkers; however, no experimental demonstration was given in this work for the proposed principle (see Romanov 2005 for a recent account on this issue). As the result of the rapid development of monolithic polycapillary optics in recent years, the principle was recently applied in practice by several authors (Kanngiesser et al. 2003; Vincze et al. 2004; Janssens et al. 2004).

Kanngiesser et al. (2003) demonstrated the principle of localized detection and sample depth-scanning for synchrotron radiation-induced XRF. Vincze et al. (2004) gave the full characterization of polycapillary-based confocal XRF and its applications for 3D trace-element analysis.

The polycapillary detector lens represents a significant modification to the regular scanning micro-XRF spectrometer, i.e., defining a specific micro-volume from which the XRF signal is detected in the coinciding foci of the detection side polycapillary and the incoming micro-beam. The detection-side polycapillary, which acts as an efficient detector collimator, accepts an energy-dependent section from the incoming beam path as it intersects the sample: this defines a microscopic volume element of detection within the investigated object. As shown here, the polycapillary detector optic accepts a limited section from the path of the penetrating incident beam within the sample, which is determined by the energy dependent focus size of the device. The energy dependence of this acceptance length is governed by the $1/E$ proportionality of the critical angle of total reflection as a function of increasing photon energy. With respect to 3D-XRF analysis, the energy dependent acceptance (depth resolution) of the setup was measured by thin glass calibration standards (NIST SRM 1832/1833), by scanning through the accepted volume with the confocal arrangement.

➤ Figure 34.9 shows the depth resolution (FWHM) expressed as a function of energy, as determined from Gaussian fits to the measured fluorescence line scan profiles. The depth resolution was determined to be about 35 μm at Ca- K_{α} and about 15 μm at the energy of the Sr- K_{α} fluorescent line. Extrapolation of the fitted curve suggests that with this particular polycapillary a depth resolution of 11–12 μm can be achieved in the energy range of 20–25 keV. Above these energies, the collimation properties of the polycapillary break down due to insufficient transmission efficiency and “halo” effects, caused by the penetration of high-energy X-rays through the glass fiber walls.

The energy dependent capillary acceptance has considerable consequence with respect to quantitative analysis of confocal-XRF data sets, since the sampled volume and mass vary with

■ Fig. 34.9

Depth resolution (acceptance) of detection side polycapillary optics as a function of detected fluorescence line energy

the energy of the measured characteristic lines. In the case of the above experiment, assuming a sample density of 2.20 g/cm^3 corresponding to glass material, the total analyzed sample mass has been estimated to be 0.78 ng at Ca-K $_{\alpha}$, 0.48 ng at Zn-K $_{\alpha}$, and about 0.34 ng at the Sr-K $_{\alpha}$ fluorescent line energy. While it is straightforward to estimate this probed sample volume (and the analyzed mass for a known density) for samples with thickness larger than the acceptance path of the detector optic, this becomes difficult when dealing with thin samples (thickness below $50 \text{ }\mu\text{m}$) where one needs to determine the intersection volume defined by the exciting microbeam, the energy-dependent polycapillary focus, and that of the analyzed thin sample itself. While this is not a fundamental limitation for the quantitative analysis of confocal XRF data, this difficulty is greatly reduced in cases when both the unknown sample and the employed standard have a thickness, which is significantly larger than the polycapillary acceptance path. In such cases, the analyzed volumes can be considered equal for the unknowns and the standards used for quantification.

As an example for confocal 3D-XRF microanalysis, [Fig. 34.10](#) shows the optical image (*left*) and measured elemental distributions (*right*) as a function of depth based on trace levels of Sr-, Zr-, and Th-K $_{\alpha}$ signals within a composite diamond inclusion of ca. $150 \text{ }\mu\text{m}$ diameter. As identified by micro Raman spectroscopy, the Sr-rich phase corresponds to larnite ($\beta\text{-Ca}_2\text{SiO}_4$), while the Zr-rich phase corresponds to CaSiO_3 -walsstromite. The detection of coexisting larnite ($\beta\text{-Ca}_2\text{SiO}_4$)/ CaSiO_3 -walsstromite phases allows constraining possible sources and conditions of formation for the diamond (Brenker et al. 2005).

An exciting direction in the development of nondestructive elemental imaging methods is represented by the combination of synchrotron-based scanning microspectroscopic techniques with complementary X-ray imaging methods, such as X-ray absorption microtomography. X-ray absorption microtomography offers the possibility to facilitate the interpretation and aid the quantification of 2D/3D elemental imaging results by providing a full 3D absorption model, an accurate frame of reference, for the very same sample that is analyzed by SR micro-XRF techniques. Absorption microtomography provides a complementary dataset with density/mass absorption coefficient information, which not only reveals the internal structure/morphology of the examined sample but also aids the quantitative analysis of the measured 2D/3D elemental distributions. By coupling information obtained by synchrotron radiation micro-XRF and absorption microtomography, it is possible to unravel the

■ **Fig. 34.10**

Optical image (*right*) and reconstructed slices at different depth x (measured in steps of $5 \text{ }\mu\text{m}$) of the inclusion based on trace-level Sr, Zr, and Th fluorescent signals. Voxel size: $5 \times 5 \times 6 \text{ }\mu\text{m}^3$

tissue-specific 2D/3D distribution of metals in situ in an essentially nondestructive manner within delicate biological samples. By the application of dynamic (fast) scanning techniques, radiation damage to the illuminated biological samples could be minimized; however, with more intense X-ray nanobeams the use of cryogenic sample stabilization techniques may be necessary for preserving the structural integrity of the sample (De Samber et al. 2008a, b).

The evaluation of μ -XRF images results in data sets that are multidimensional: intensity values for the elements are calculated from the spectra recorded at the positions of the image map (Somogyi et al. 2000). An elegant way to study the properties of such multidimensional data sets is to apply multivariate analysis methods. For example, principal component analysis (PCA) may assist in interpreting the data by the determination of which elements contribute to the principal components, and helps to classify the pixel data on the basis of their elemental properties. Using the set of principal components, one can depict variables (elements) and objects (pixels) with similar or different characteristics. Combining element-specific loading plots with their corresponding pixel-specific score plots, one needs to investigate only a very few graphs, very often those of the most important principal components. In addition to PCA, grouping of objects (pixels) can be done by means of dedicated clustering strategies. In this work, the k -means clustering method is successfully applied to group pixels that provide equal (or similar) compositional information. The additional advantage of this approach is that the resulting sum spectra corresponding to groups of pixels with similar composition feature lower noise levels than the individual pixel spectra (Vekemans et al. 2004).

34.6.2 X-Ray Absorption Spectroscopy: XANES and EXAFS

A close look above the absorption edge reveals that the dependency of μ_ρ as function of X-ray energy such as in [Fig. 34.5](#) is not smooth, but shows a fine structure. Note, that the hypothetical absorption spectrum for an isolated atom, denoted by $\mu_0(E)$, would only have an absorption edge and no fine structure. [Figure 34.11](#) shows the V K absorption edge of a V metal thin-foil sample. The fine structure up to around of the edge (XANES), and the oscillations above the edge (EXAFS) can be used for obtaining structural or chemical information.

Empirically, one finds that the fine structure around the absorption edge depends on the local structure around the absorbing atom. So, it should be possible to obtain the local structure from an XAS spectrum. The difference between EXAFS and XANES lies in the different kind of information that can be retrieved from them. The EXAFS signal is sensitive to structural parameters such as bond distances and coordination numbers (the number of neighbors at a certain bond distance), while the XANES is more sensitive to electronic properties such as oxidation states, symmetry of the local coordination, and density of states.

In contrast to X-ray diffraction (XRD), the workhorse for structural determination, the sample does not need to contain long-range order in case of XAS: short-range order is already sufficient. This has the advantage that a wide variety of samples can be studied with XAS: gases, solids, liquids, crystalline and amorphous materials, bulk layers, surfaces, adsorbed atoms, and interfaces. Due to the penetrating character of X-rays (of high enough energy) through gases and liquids, XAS can be applied for in situ studies in catalysis, during layer growth, and phase transitions, etc. The obtained information is only applicable to short-range order, so XAS is a complementary technique to XRD.

The simplest and direct way of recording an XAS spectrum is to measure the intensity of the X-ray beam before, I_0 , and after, I , the sample by ionization chambers (see [Fig. 34.12a](#)).

■ Fig. 34.11

■ Fig. 34.12

(a) Transmission and (b) fluorescence detection modes for X-ray absorption spectroscopy

This is the transmission mode XAS: for a sample with thickness x and linear absorption coefficient μ_l the absorption is given by

$$\mu_l x = \ln \frac{I_0}{I_t} \quad (34.8)$$

After the absorption of the X-ray photon and emission of the photoelectron, the absorbing atom is in an excited state, as it has a hole in one of its deep core levels. The atom will relax by the emission of a fluorescent X-ray photon or an Auger electron. The fluorescence (fluorescence yield) or Auger (electron yield) intensities are proportional to the absorption in the sample, and the detection of these signals gives an indirect way to measure the absorption.

In the fluorescence detection mode (■ Fig. 34.12b), the incoming X-ray intensity is monitored like in the transmission case and the fluorescence emission, I_f , is recorded at 90° with respect to the incoming beam. The measured absorption is then given by

$$\mu_I x \sim \frac{I_f}{I_0} \quad (34.9)$$

For recording an XAS spectrum, a highly monochromatic X-ray beam tunable over a range of about 1000 eV is needed. The first experiments were performed with rotating X-ray tube laboratory sources. It is only after 1970, with the increasing availability of synchrotron radiation sources, that EXAFS became a practical technique. Thanks to the increased X-ray intensity of synchrotron radiation sources compared to laboratory sources, the measuring time per spectrum has decreased from several days down to the minute time scale for conventional scanning XAS. Nowadays, full XAS spectra can be taken within a few milliseconds using bent polychromators, such as in case of dispersive XAS.

When the employed X-ray beam is focused to micro/nanoscale dimensions, the technique can be used to obtain local information concerning the chemical state and local chemical structure of the absorbing atom on micro/nano scale (e.g., Silversmit et al. 2009b).

34.7 Summary

Synchrotron radiation X-ray fluorescence microbeam techniques using third-generation SR sources offer the potential of nondestructive multielement analysis down to trace concentration levels with unrivaled spatial resolution among X-ray-based analytical techniques (Adams et al. 2005; Adams 2008). For these sources, relative detection limits at the sub-ppm (fg/ng) level can be achieved. With respect to absolute detection limits (DL), submicron-sized X-ray beams can offer DLs below 10 ag for the most efficiently excited transition elements, with a potential lateral resolution level better than 100 nm. There are a number of synchrotron sources in Europe that can be used for basic research on nanoscale analysis and characterization and subsequent applications in problems of materials research. Currently, operational third-generation national sources in Europe such as Bessy II (D) and SLS (CH) have significant activities in micro-focusing and -imaging technologies. Other sources such as Soleil (F) and Diamond (UK) have designated beamlines with micro-focusing capabilities for imaging and analysis. In the ESRF, the construction of eight new beamlines was started to deliver sharply focused beams of X-rays just tens of nanometers in diameter for imaging nanometer-scale features of various materials. Other synchrotrons have achieved similar-sized beams, but the ESRFs will be the first available for general use by scientists.

Within the field of the microanalytical techniques, SR-based μ -XRF emerges as an important new methodology for the characterization and analysis of diverse materials. The simultaneous application of μ -XRF with XAS, XFCT, and XRD greatly enhance the capabilities for the study of microscopically heterogeneous materials, providing three-dimensional elemental information and speciation in a nondestructive manner. The gains in brilliance of SR sources over the past decade and advances in focusing optics during the same period provide spatial resolution at the sub- μ m range while maintaining a high sensitivity.

Thanks to the full understanding of the interaction processes of X-rays with matter, computer techniques, particularly those based on Monte Carlo simulation, are able to predict the spectral response without limitations in approximations or idealizations of the sample geometry. Hence, they allow methods for calibration and correction for radiation absorption, thus opening up the way to perform reliable quantitative analysis.

Abstract: In radioactive tracer technique, radioactive nuclides are used to follow the behavior of elements or chemical species in chemical and other processes. This is realized by means of radioactivity measurement. In 1913, Hevesy and Paneth succeeded in determining the extremely low solubility of lead salts by using naturally occurring ^{210}Pb as a radioactive tracer. As various radioactive nuclides became artificially available, this technique has been widely employed in studies of chemical equilibrium and reactions as well as in chemical analysis. It is also an essential technique in biochemical, biological, medical, geological, and environmental studies. Medical diagnosis and industrial process control are the fields of its most important practical application. In this chapter, fundamental ideas concerning radioactive tracers will be described followed by their application with typical examples. Detailed description on their application to life sciences and medicine is given in Vol. 4.

35.1 Radioactive Tracers

35.1.1 Principles of Radioactive Tracer Technique

The fundamental principle of radioactive tracer technique is that the chemical behavior of radioactive isotopes is identical to that of their stable isotopes in any chemical process. Strictly speaking, the difference in atomic mass of radioactive and stable isotopes gives rise to a slight difference in both chemical reaction rate and equilibrium constant. This is the isotope effect (see [▶ Chap. 15 in Vol. 2](#)), which forms the basis of the isotope separation (see [▶ Chap. 51 in Vol. 5](#)). Except for very light elements, however, the isotope effect is negligibly small. This makes the isotope separation very laborious work requiring manifold repetition of a certain process. In ordinary tracer experiments, the isotope effect comes into question only in the case of tritium ^3H , which has an atomic mass approximately three times larger than that of the main stable isotope ^1H . Even in ^3H , however, the isotope effect turns out to be insignificant when the radioactive nuclide is incorporated in a large molecule, as is usually the case in organic chemistry and biochemistry, because the behavior of the molecule depends on the mass of the whole molecule.

The effect of radiation (see [▶ Chap. 23 in this Volume](#)) emitted by the radioactive tracers on a chemical or biological system under study is also usually negligible. The amount of a radioactive tracer necessary for an experiment is normally so small that no detectable radiolysis occurs in the system. However, in long-term storage of radiation-sensitive compounds, one must be cautious of the effect of radiation. And, of course, in application to human body, careful consideration is necessary on the effects of radiation during and after the experiment (see [▶ Chap. 47 of Vol. 5](#)).

35.1.2 Non-Isotopic Tracers

Radioactive nuclides not isotopic with the element to be traced are sometimes employed. In inorganic chemical studies, such non-isotopic tracers are allowed only when the similarity of their chemical behavior with that of the element to be traced is guaranteed as in the case of a pair of lanthanide elements. On the other hand, non-isotopic nuclides are often used for labeling large organic or biochemical molecules (see [▶ Chaps. 42–45 in Vol. 4](#)), because in many cases introduction of a different element to such molecules does not affect significantly their behavior. However, it is recommended to check the effect of labeling on the chemical or biological behavior

of the molecules in each experiment. For example, it is known that unsaturated fatty acids labeled with radioactive iodine do not necessarily show chemical properties expected for unsaturated fatty acids. When the movement of a mass much larger than a molecule is traced, chemical properties of the radioactive tracer do not matter at all and the only requirement is that it is firmly bound to the mass. For example, erythrocytes are easily labeled with $^{51}\text{CrO}_4^{2-}$, and this labeling is utilized in determination of life of erythrocytes in human body. In industrial applications, granules and aerosols labeled with a radioactive nuclide are often used to trace mass flow. This kind of tracer is often referred to as a physical tracer.

35.1.3 Activable Tracers

A version of radioactive tracer technique is the activable tracer method. In this, a stable element is added as a tracer to the system under study and the movement or partition of the tracer element is determined afterward by means of the radiation emitted by a radioactive nuclide produced in activation of the element. The activation is usually done by thermal neutrons in a reactor. The basic requirement for the element employed as an activable tracer is that it has an isotope with high activation cross section for the (n,γ) reaction, that its concentration is negligibly low in the original system to be studied, and that it is harmless to the system. Br, Sm, Eu, Gd, and Dy are frequently used as activable tracers. Activable tracers are especially suitable for environmental studies, where use of radioactive nuclides is often undesirable or not allowed.

35.1.4 Stable Isotopes as Tracers

Stable isotopes are also employed as tracers, though their sensitivity is much lower than that of the radioactive ones. Enriched ^2H , ^{13}C , ^{15}N , and ^{18}O are widely used as stable-isotope tracers. Their measurement is generally done by mass spectrometry, but emission spectrochemical analysis (^{15}N) and nuclear magnetic resonance (^{13}C) can also be used.

35.2 Advantages and Disadvantages of Radioactive Tracers

The advantage of the radioactive tracer technique lies first of all in its high sensitivity. When an appropriate carrier-free tracer is employed, a picogram (10^{-12} g) or less of an element can be easily detected with conventional detectors. In fact, hormones and other biomolecules are routinely determined down to a picogram or less in radioimmunoassay. Therefore, chemical and biological effects of carrier-free tracers on the metabolic system of a living body are insignificant. Tracers of toxic elements such as As and Hg or poisonous compounds such as HCN can be used with no hazardous effects.

Another advantage of radioactive tracers is their ease of detection and determination. The radiating properties of the tracers are not affected at all by the physical and chemical condition of the sample, i.e., temperature, pressure, presence and concentration of chemicals, and so on. This exempts one from laborious preparation and treatment of the sample before measurement. In the measurement of a nuclide emitting a γ ray, all one has to do is to put the sample near a detector and press a button to operate the electronic system. Radioactive tracers are also suitable for continuous-flow detection and some of them further for imaging.

There are applications that can only be performed with the use of an isotopic tracer. Among them are the studies on self-diffusion and isotopic exchange reaction. Examples of such studies are described in detail below.

An unavoidable limitation of the radioactive tracer technique is absence of nuclides suitable as tracers for some elements. For He, Li, B, Ne, for example, there is no radioactive nuclide employable as a tracer in ordinary chemistry. Only short-lived nuclides are available for N ($9.965 \text{ min } ^{13}\text{N}$) and O ($2.037 \text{ min } ^{15}\text{O}$).

The above statement that the radiations from tracers are not affected by the chemical state of the sample means that the radiation carries no chemical information on the tracer. All that the radiations inform about is the location, distribution, and amount of the tracer. Another disadvantage of the radioactive tracer technique is that it requires an experimental facility with the license for the use of a nuclide in the necessary amount.

35.3 Essential Points in Using Radioactive Tracers

35.3.1 Carriers

Radioactive tracers are as a rule accompanied with a certain amount of their stable isotope(s). When the amount of the stable isotope(s) is significant in the sense of ordinary chemistry or for the specific purpose of an experiment, they are called a “*carrier*.” When not, the tracer is “*carrier-free*.” Another term “*no carrier added*” is also used with almost the same meaning. The amount of carrier is expressed by its weight or in terms of the elemental specific activity of the tracer, that is, the activity divided by the mass of the element in question (Bq/g element) or by that of the chemical species in question (Bq/g species).

Carriers can originate in the preparation procedure of the tracers. When the target nuclide employed in the production of a tracer nuclide is its isotope as in (n, γ) and (d, p) reactions, a considerable amount of carrier is inevitable for the product nuclide. Carriers can also result from the impurities in the target material, from nuclear reactions producing the stable isotopes, and also from contamination of the reagents and vessels used for processing the target. Therefore, even when a nuclear reaction changing the atomic number such as (n, p), (p, n), and (γ, n) is used, the tracer is not completely free from its stable isotopes.

In view of the sensitivity of the radioactive tracer, it is desirable that the amount of its carrier is kept minimal. However, presence of a certain amount of carrier is favorable or even essential in many experimental procedures. In separation of a tracer of a metal ion by precipitation and filtration of a sparingly soluble salt, for example, the amount of the carrier must be large enough to exceed the solubility product.

A carrier-free tracer in a solution is sometimes adsorbed on the surface of the vessel or on colloid particles of dust in the solution, or may react specifically with a minute impurity species in the solution. Moreover, the behavior of a carrier-free tracer can be different from that of the same species in ordinary macro chemistry (Guillaumont et al. 1989; Choppin et al. 2002). Therefore, it is desirable in general to add a carrier to the tracer in an amount not disturbing the experiment. The carrier added must be in the same chemical form as, and thoroughly mixed with the tracer. In case of elements stabilized in two or more oxidation states, such as Fe, As, Se, Sb, and I, it is recommended to perform the so-called oxidation–reduction sweep, that is, oxidation of the tracer with the carrier to the highest possible oxidation state followed by reduction down to the lowest possible state preferably in repetition.

Occasionally a non-isotopic carrier is used, namely a carrier that is not isotopic with the tracer but behaves similarly. Usually, an element in the same group of the periodic table is used as a *non-isotopic carrier*. Coprecipitation of Ra with Ba salts is such a case. The non-isotopic carrier has an advantage that it can be removed later by an appropriate chemical technique.

35.3.2 Exchange Reactions

Radioactive tracers sometimes undergo exchange reactions with stable isotopes in a different chemical form. As a result, the chemical form of the tracers changes partly, which certainly disturbs the tracer experiment. Therefore, one must be careful when the system to be studied contains another chemical species having the same element as the tracer. Examples of exchange reactions are described below.

35.3.3 Purity

Two kinds of “purity” must be taken into consideration concerning a radioactive tracer, which are both essential in practice.

Nuclidic purity. The nuclidic purity is the fraction of the total activity due to the stated radioactive nuclide. Even another radioactive nuclide of the same element decreases the nuclidic purity and can disturb activity measurement. However, nuclidic purity turns out not to be essential if different nuclides can be distinguished in measurement as in γ -ray spectrometry with the use of a Ge detector.

Commercial radioactive nuclides are usually available with nuclidic purities exceeding 98%. However, one should remember that the purity decreases gradually when the contaminating nuclide has a longer half-life than that of the stated one. For example, ^{197}Hg (64.14 h) used for scan of kidney and spleen often contains ^{203}Hg (46.61 days) as an impurity. Even if the amount of the latter is 1% at the time of assay, it will exceed that of the former in about 20 days.

Radiochemical purity. The radiochemical purity is the fraction of the stated radioactive nuclide present in the stated chemical form. For tracers of elements stabilized in two or more oxidation states, it is necessary to check their oxidation state by their chemical behavior, ion exchange for example, preferably just before the experiment. In organic compounds labeled with a radioactive nuclide, it is desirable that the number and position of labeling of the radioactive nuclide are unique. However, when the number and position of the nuclide in a compound do not essentially affect its chemical behavior as is often the case in tritium-labeled ones, use of a mixture of a compound labeled with different number of the stated nuclide or labeled at different positions is acceptable. The purity of some labeled compounds decreases gradually due to oxidation, self- or radiolytic decomposition during long storage. Such a labeled compound should be assayed and purified, if necessary, before use.

35.4 Measurement of Radioactive Tracers

35.4.1 General

NaI(Tl) scintillation counters and Ge detectors are most commonly employed for γ rays, and GM counters, proportional counters, and liquid scintillation counters for β rays. A useful table

on the suitability of detectors for various kinds of radiations is given in the textbook of Lieser (2001). Autoradiography is widely used for determination of distribution of β emitters, but imaging cameras are still not in common use at present except in nuclear medicine.

In tracer experiments, determination of absolute activity, that is the total disintegration rate (disintegration per second) of the nuclide used, is rarely necessary. Usually, determination of the relative activities of a series of samples or determination of the ratio of the activity of samples to that of a standard is sufficient. In this relative measurement, the samples are measured under the same geometry, that is spatial disposition against the counter, and the ratio of counting rates (counts per second) is determined. The possible errors due to deviation in the distance between the samples and the counter and in the shape and size of the sample are diminished as the distance increases, though the counting rate decreases. When the geometry inevitably differs in a series of relative measurement, it is possible to correct the effect of this difference by calculation. However, this correction can give rise to an additional error.

The *standard deviation* accompanying a net counting rate of a nuclide depends on the counts accumulated and the *background* (counts due to sources other than the nuclide to be measured). (The error estimation is based on the rules of the error propagation as well as on the – reasonable – assumption that the counts N and N_{bg} follow Poisson statistics: see [Chap. 9 in Vol. 1.](#)) The net counting rate R_{net} and its standard deviation σ_{net} are given by

$$R_{net} = \frac{N}{t} - \frac{N_{bg}}{t_{bg}}, \quad (35.1)$$

$$\sigma_{net} = \sqrt{\frac{N}{t^2} + \frac{N_{bg}}{t_{bg}^2}}, \quad (35.2)$$

where N is the counts accumulated in time t with the sample, and N_{bg} is those accumulated in time t_{bg} without the sample. If $N = 10,000$, then in an ideal case of no background one obtains

$$\frac{\sigma_{net}}{R_{net}} = \frac{\sqrt{10000/t^2}}{10000/t} = 0.01 \quad (35.3)$$

that is the relative standard deviation is 1%. But, if $N = 10,000$ and $N_{bg} = 1,000$ in a measurement where $t = t_{bg}$,

$$\frac{\sigma_{net}}{R_{net}} = \frac{\sqrt{10000/t^2 + 1000/t^2}}{10000/t - 1000/t} = 0.0117. \quad (35.4)$$

The count to be accumulated in order to attain expected precision is estimated in the opposite way. Diminution of background by appropriate shields decreases the necessary duration of counting. Precision of a few percent is easily attainable in ordinary activity measurement.

However, in order to keep the error of counting less than 1%, it is necessary not only to increase the counts accumulated, but also to pay careful attention to other factors such as the geometry of counting, variation of background, and stability of the counter.

Dead time of the counters gives rise to loss of counts. The radiations coming in the detector are not counted during the dead time after a radiation is counted. Dead time can give rise to a serious error in the case of GM counter as described below.

Parent–daughter relationship. When the nuclide employed has a radioactive daughter, one must be cautious in its measurement. Even if the daughter represents the same element as

the parent as in $^{80m}\text{Br} \rightarrow ^{80}\text{Br}$, chemical behavior of the daughter nuclide may not be the same as that of the parent, because the chemical state of the daughter can be quite different due to the hot-atom chemical effects of isomeric transition (see [▶ Chap. 24](#) in this Volume). There are two cases concerning the measurement on a set of parent and daughter. When the parent and daughter nuclides are in radioactive equilibrium in the sample, the radiation of both nuclides is responsible for the behavior of the parent in the experiment. In case of nonequilibrium, however, only the radiation from the parent should be counted.

Decay during counting. It sometimes happens that the duration of counting is not negligible against the half-life of the tracer, when using a short-lived nuclide. In such a case, correction for the decay during measurement is necessary. When the mid-time of the measurement, instead of the starting time, is taken as the nominal time of measurement, the effect of decay is considerably reduced.

35.4.2 Gamma-Ray Measurements

In general, measurement of γ rays is much easier than that of α and β rays because of the much larger range (mean free path) of the γ rays. Moreover, different nuclides can be discriminated by energy analysis, because each γ ray has definite energy. Absolute counting of γ rays is also not difficult using a commercially available calibration source. In addition to IT nuclides (i.e., excited nuclear isomers), a large number of β -decaying nuclides emit γ rays too. The nuclides emitting positrons can be used in a similar manner as γ emitters, as positron emits two 0.511 MeV annihilation radiations (photons) in a short time. Moreover, since the two photons are emitted in the opposite direction, it is possible to locate the nuclides in the sample by detecting both of them. This is the principle of positron emission tomography (PET).

NaI(Tl) scintillation counters and Ge(Li) or pure Ge detectors are most commonly employed for γ counting. The former has a larger counting efficiency than the latter, but the energy resolution of the latter is better.

In γ counting, the requirements on the sample and its vessel and holder are much less demanding than in β counting. Self-absorption is negligible except for low-energy γ rays. Absorption by wall of ordinary plastic vessels is also neglected. So, samples are usually contained in a plastic vessel and put in contact with the detector or at an appropriated distance from it. Liquid samples are often put in a plastic or glass test-tube and mounted in the hole of a “well-type” detector. In relative measurement of liquid samples, the samples are put in plastic vessels of the same type and size (and, of course, the sample volume is also the same for each sample) and measured one by one in the same geometry against the detector. In relative measurement of solid samples of different shape and size, the sample-to-detector distance must be large enough so that the difference in geometry becomes negligible, or it must be corrected by calculation. In any case, a sheet or bag of polyethylene foil should be placed between the detector and the sample to avoid possible contamination. In case of tracers emitting low-energy γ rays around 100 keV or less, absorption especially by heavy elements can be serious. The extent of diminution of γ rays by absorption can be estimated with the help of mass absorption coefficients.

When the tracer emits β rays with a range exceeding the thickness of the vessel wall in addition to γ rays, it is recommended that the β^- or β^+ rays are shielded by an absorber. It is because a part of them can plunge into the detector, contribute to the counts, and bring about annoying problems concerning β counting described below.

A Lucite – poly(methyl methacrylate) – plate of 10 mm thickness is commonly used as an absorber of β rays.

If the purity of a radioactive tracer is guaranteed in ordinary single tracer work, no energy discrimination is necessary. However, when the γ -ray spectrum consists of a main intense peak and other minor ones, use of single channel analyzer set at the main peak will considerably decrease the background of counting and also possible interference by impurity nuclides.

When two or more tracers are used together as in the multitracer technique (see [▶ Sect. 35.6](#)), it is necessary to discriminate them from each other by energy analysis. This is done by means of a Ge detector connected to a multichannel analyzer followed by computer analysis of the observed γ -ray spectrum.

Along with the multitracer technique, a nondestructive analysis method is being developed. A γ -ray imager that employs the principle of Compton cameras has been proposed to realize this, and some successful demonstrations have been performed. This topic is mentioned later in [▶ Sect. 35.6](#).

35.4.3 Beta-Ray Measurements

When a β -emitting tracer is used, it must be born in mind that the energy of β rays is distributed from zero to a maximum and that their range is not large especially in solids.

Beta rays can be attenuated or even completely stopped by the sample itself (self-absorption), by the wall of the sample vessel, by the air layer between the sample and the counter, and by the window material of the counter. On the other hand, β rays can be detected with higher efficiency and lower background than γ rays. Various types of measurement of β rays are described below.

GM counters. For nuclides emitting relatively high-energy β rays, such as ^{32}P (maximum energy 1.711 MeV), ^{89}Sr (1.497 MeV), ^{90}Sr (0.546 MeV), ^{90}Y (2.282 MeV), a GM counter is most frequently used. Each sample for relative measurement must have exactly the same shape, thickness, composition, and also the same backing to eliminate the error caused by self-absorption and backscattering of β rays. The sample should be as thin as possible to minimize self-absorption. A thickness of 1% or less of the range of the β rays is preferable. Alternatively, samples with a thickness exceeding the range of the β rays can be used. In this case, the counting rate does not correspond to the total activity of the sample, but is proportional to the activity in unit volume of the sample. This type of “infinite thickness” sample is also useful in certain experiments.

In using a GM counter, it should be taken to heart that high counting rate results in considerable loss of counts due to long *dead time* of the counter. The dead time differs from one counter to another and is in the range of 100–500 μs . The counting rate should never exceed 10,000 cpm and should preferably be of the order of 3,000 cpm or less when no correction for loss of counts is made. This correction can be made with the help of a series of samples with known intensities.

Liquid scintillation counters. The tracers emitting only low-energy β rays are most conveniently measured by a liquid scintillation counter. The sample is mixed in a vial with an organic scintillator, such as PPO or butyl-PBD, in a solvent like toluene or xylene. A second scintillator is often added to the mixture in order to ensure matching of the wavelength of the scintillation with the photomultiplier tube detecting it. The resulting mixture is commonly called a “*scintillation cocktail*.” The most popular wavelength shifters are POPOP and DMPOPOP. Samples in an organic form are most suitable for this counter. In case of an aqueous solution sample, a second solvent such as alcohols or dioxane is necessary to ensure

mixing. Suspension and emulsion samples can also be measured. The β -emitting tracers frequently employed in organic chemistry and biochemistry, ^3H , ^{14}C , ^{32}P , ^{33}P , ^{35}S , and ^{45}Ca are usually determined by this method. It is also applicable to EC nuclides such as ^{51}Cr , ^{55}Fe , and ^{125}I . For a combination of two or three tracers with largely different maximum energy, ^3H (maximum energy 0.0186 MeV) and ^{14}C (0.156 MeV), for example, simultaneous determination of them in a sample is possible by energy discrimination. Correction for color quenching and chemical quenching is indispensable in liquid scintillation counting.

Proportional counter. Thin-window or windowless gas-flow proportional counter using CH_4 or $\text{CH}_4 + \text{Ar}$ at atmospheric pressure as a counter gas is another choice for tracers emitting low-energy β rays. In the windowless one, the sample is placed inside a counter and the counter is operated after flushing by a counting gas. With sufficiently thin samples, the counting rate is close to 50% (2π counter). The dead time of proportional counters is much shorter than that of the GM counters and the loss of counts is not serious either.

Cherenkov counters. Beta rays traveling in a medium with a speed higher than that of light in the same medium emit Cherenkov radiation, i.e., visible light in the blue region. Nuclides emitting β rays having maximum energy exceeding about 1 MeV can be determined by means of this radiation with high efficiency and low background. A liquid scintillation counter is employed as is to determine ^{32}P in solution samples, for example. No scintillator and, accordingly, no correction for chemical quenching are necessary.

Autoradiography and radioluminography. Autoradiography using a photographic emulsion is a convenient technique for tracers not only in thin or sliced samples, but also for spots of paper or thin-layer chromatograms. In the case of nuclides emitting β rays of 0.2 MeV or less, *microautoradiography* is possible, whose two-dimensional space resolution is comparable to that of an optical microscope. In case of ^3H , *supermicroautoradiography* is possible with the use of extremely thin films with minute particles of silver halide. Supermicroautoradiographs are observable only with the help of an electron microscope.

Radioluminography is a relatively new imaging technique using “*imaging plate*.” The imaging plate is composed of a flexible plastic plate coated with fine “phosphor” crystals. The phosphor is capable of absorbing and storing a fraction of the energy of incident radiations. When irradiated later by visible or infrared rays, it emits photo-stimulated luminescence, whose intensity is proportional to the absorbed energy. Imaging plates have higher resolution, wider dynamic range, and higher detective quantum efficiency compared with photographic emulsion films (Sonoda et al. 1983; Amemiya and Miyahara 1988).

Radiochromatography. Various types of radio-gas chromatographs and radio-high-performance liquid chromatographs are commercially available. They enable automatic separation of different components of a sample and activity measurement on each of them (Roberts 1979). In these instruments, gas or liquid chromatographs are coupled with a detector of β rays such as proportional counter, thin-window GM counter, or plastic or inorganic scintillation counter. Chromatogram scanners are also commercially available, which scan the β rays from spots of paper and thin-layer chromatograms.

35.4.4 Alpha-Ray Measurements

Alpha rays are counted with the use of an ionization chamber, a windowless gas-flow proportional counter, a liquid scintillation counter, or a Si barrier detector. Autoradiography is also effective for α particles. However, α -emitting nuclides are rarely used in ordinary tracer works,

because the range of α rays is very small (a few centimeters in air) and counting of them necessitates an extremely thin sample. Moreover monitoring of contamination during and after the experiment is not simple for α emitters. A unique study on diffusion taking advantage of the short range of an α emitter is described below.

35.4.5 Accelerator Mass Spectrometry

Some long-lived radioactive nuclides can be determined with very high sensitivities down to 10^3 – 10^5 atoms/sample by accelerator mass spectrometry (Liu et al. 1994). This technique, not relying on the radiation emitted, was first used in chronology and has developed in applications to nuclear, geological, environmental, material, and biomedical sciences. Tandem van de Graaff accelerators are most commonly used. Routine determination is made on ^{10}Be , ^{14}C , ^{26}Al , ^{36}Cl , and ^{129}I and many other nuclides are exploited. Because of the high sensitivity, the size of the sample necessary for determination of ^{14}C , for example, is as small as a few milligrams or less in contrast to several grams in conventional low-level β counting.

35.5 Selection, Acquisition, and Use of a Radioactive Tracer

35.5.1 Selection of a Radioactive Tracer

In selection of a radioactive nuclide as a tracer, attention must be paid to the following factors: half-life, radiation emitted, specific activity, chemical form, and purity along with license of use and availability. In the case of a non-isotopic tracer, the element of the tracer must be chosen after due consideration as stated above. In any case, radiation safety and legal regulations have to be carefully followed throughout acquisition, storage, use, and disposal of a radioactive tracer.

Radiations emitted. In general, radioactive nuclides emitting γ rays or positrons are the best choice as radioactive tracers for any element, because γ rays are easy to measure as described above. Quantitative measurement of β rays is not necessarily easy. However, β rays can be detected with high efficiency and low background. Therefore, in certain experiments, β emitters are more suitable than γ emitters. Radiochromatography is such a case. Beta-emitting tracers are in use for quite a number of light elements that are important for both chemistry and biology. For hydrogen, β -emitting ^3H is the sole radioactive nuclide that can be used as a tracer. Carbon has two radioactive isotopes, ^{11}C and ^{14}C , usable as a tracer. The former is a positron emitter convenient in counting, but its half-life is as short as 20.39 min, and therefore β -emitting ^{14}C is widely used. Phosphorus and sulfur only have β -emitting isotopes, ^{32}P , ^{33}P , and ^{35}S , as practical radioactive tracers. Nuclides emitting α rays are not commonly used as a radioactive tracer, because quantitative measurement of α rays is much more difficult than that of β rays and safety control of α emitters is troublesome. However, α emitters emitting γ rays too, ^{241}Am for example, are sometimes used as tracers, the γ rays rather than the α rays being measured.

Half-life. Half-life must of course be long enough so that sufficient counting rate giving required statistics is assured at the time of activity measurement. A half-life longer than at least one third of the passage of time between the beginning of an experiment and the counting will be preferable. Nitrogen and oxygen have only short-lived isotopes, as described above. Use of such short-lived tracers is limited to laboratories equipped with an accelerator producing the tracers or those with a rapid transportation system of the tracers from such an accelerator.

The specific activity of a carrier-free radioactive tracer is inversely proportional to its half-life. This will be problematic only for a tracer with an extremely long half-life in an experiment requiring high specific activity. When a long-lived radioactive tracer is employed, however, careful attention must be paid to contamination during the experiment and also to its storage and disposition afterward.

Necessary amount. The amount of a radioactive tracer to be used in an experiment depends on many factors. Among them are the fraction of the total tracer in each counting sample, the branching ratio of the decay giving the radiation counted, efficiency and background of counting, the precision required, and the time available for counting. When a tracer with the activity A is used in an experiment, the net count N_{net} of a sample in counting for the duration of t s is given by

$$N_{\text{net}} = A \times B \times E \times Y \times t. \quad (35.5)$$

Here, B is the branching ratio of the decay giving the radiation counted, E the efficiency of counting including geometrical factors and diminution by absorption, Y the fraction of the total tracer in the counting sample. When plural radiations emitted in a single decay are counted, N_{net} for each of them are summed. From the necessary precision and the background, N_{net} to be accumulated is estimated on the basis of [Eqs. \(35.1\)](#) and [\(35.2\)](#). Then, the activity A necessary for the experiment is estimated from [Eq. \(35.5\)](#). In biological experiments, Y is often less than 10^{-3} and is the dominating factor.

35.5.2 Acquisition of a Radioactive Tracer

A number of radioactive nuclides are commercially available. For use in organic and biochemical studies, a variety of labeled compounds are supplied. Some short-lived tracers are supplied by generators (see [Chap. 40 in Vol. 4](#)). Detailed information is obtainable from catalogs or home pages of the companies or agencies producing or supplying radioactive nuclides and labeled compounds. See Vol. 4 for customized synthesis of compounds labeled with ^3H , ^{11}C , ^{18}F , $^{99\text{m}}\text{Tc}$, radio-iodines, and radiometals.

For medical purposes, an enormous collection of techniques is accumulated regarding production of short-lived nuclides mainly by cyclotrons. The technique should undoubtedly be useful for application of radioactive tracers to other fields. Such nuclides include ^{11}C , ^{13}N , ^{15}O , ^{18}F , and also many nuclides of metals, halogens, and rare gases. Reactor and cyclotron production of medical radioisotopes is described in [Chaps. 38](#) and [39 of Vol. 4](#), respectively. Basic data for production of short-lived nuclides by cyclotron were compiled with substantial references by Qaim (1982). Another review by Waters and Silvester (1982) emphasizes cyclotron-produced nuclides useful for inorganic studies with many references, too.

35.5.3 Use of a Radioactive Tracer

The radioactive tracer obtained is to be assayed for its nuclidic and chemical purity. Then the tracer is converted to the chemical form used in the experiment, a certain amount of carrier being added when necessary. The tracer is commonly injected into the system to be studied instantaneously (pulse injection). Continuous injection is adopted, however, in certain cases such as process control in industry. Experiments using radioactive tracers are accompanied

with additional problems concerning safety not encountered in ordinary experiments. Therefore, careful and detailed planning of the experiment is indispensable. Moreover, it is recommendable to perform beforehand a cold run, i.e., the same experimental procedure using no tracer, and also a low-level run using a tracer in an amount much smaller than that necessary in the regular experiment. The latter is useful for checking possible contamination, for estimating the optimal amount of the tracer used, and for increasing efficiency of the experiment, which results in decrease of radiation dose to the experimenters.

35.6 Radioactive Multitracer Technique

35.6.1 Radioactive Multitracers

Radioactive tracer technique is not single-elemental anymore. In biochemical studies, two radioactive tracers emitting β rays, ^3H and ^{14}C for example, are often used together to trace the two elements simultaneously. In the case of γ -emitting tracers, literature contains not a few examples of applying up to several tracers together in an experiment. However, such works were sporadic, and there has long been no trial to develop the radioactive tracer technique as a multi-elemental one. Since 1991, the “*multitracer technique*” using heavy-ion reactions has been developed using a number of radioactive nuclides produced by nuclear fragmentation induced by heavy ions (Ambe et al. 1991; Ambe 2000). The nuclides are radiochemically separated from the target material and used together to trace many elements simultaneously. The technique has been applied in chemistry, biology, medicine, engineering, and environmental sciences. Examples of recent application are given in the sections below describing application of radioactive tracers.

Multitracers enable one not only to acquire data for various elements efficiently but also to determine the characteristic behavior of different elements under identical experimental conditions. The results obtained for different elements can be compared free from the peculiarities of the individual samples. This is very advantageous for environmental and biological samples. Multitracers are also useful in the search for an element behaving in a specific way.

35.6.2 Production of Radioactive Multitracers

A target is irradiated with heavy ions such as ^{12}C , ^{14}N , or ^{16}O accelerated up to 135 MeV/nucleon, for example. The fragmentation reaction of target nuclei produces a number of radioactive nuclides with proton numbers up to that of the target nuclei (eventually up to that plus one by proton transfer). As a typical example, a schematic of the multitracer production system installed on the beam line of the K540 RIKEN Ring Cyclotron (RRC) is shown in ► Fig. 35.1 (Haba et al. 2005). It consists of a gas-jet-coupled multitarget chamber (front chamber) and a simple gas- and water-cooled target chamber (rear chamber).

The beam diameter from RRC is first collimated to 7 mm in diameter with a four-sector Ta slit. Then, the beam passes through a HAVAR vacuum window of 6 μm thickness and enters 30 multiple targets, each of approximately 1 μm thickness with 10 mm spacing in the front chamber. The recoil nuclei are stopped in helium gas and attached to aerosols such as potassium chloride and carbon. The gas and activity-laden aerosol particles are sucked through

a Teflon capillary (2.0 mm in diameter, 10 m in length) to a chemistry laboratory just beneath the irradiation room by applying vacuum to the downstream end of the capillary, where the aerosol particles are collected on a glass filter. Thus, the multitracer solutions are obtained simply by washing the filter with a suitable solution. The performance of the gas-jet system was first investigated with 50 radionuclides of 18 elements produced in the reaction on ^{nat}Cu induced by 135 MeV/nucleon ^{14}N (Haba et al. 2005). The advantages of the gas-jet system are as follows: (1) The multitracers are separated from the target material without chemical separation and transported to the chemistry laboratory within a few seconds. Thus, radionuclides with short half-lives (less than 1 min) are available for tracer experiments. (2) The targets of almost all the elements can be prepared by electrodeposition or vacuum-evaporation techniques.

■ Fig. 35.1

Schematic of the multitracer production system installed on the beam line of the K540 RIKEN Ring Cyclotron

The composition of the radionuclides in the multitracer can be optimized by changing the target material and its array. (3) The radionuclides of interest are easily concentrated using a gas-jet-coupled liquid chromatography apparatus based on ion exchange or solvent extraction.

In the rear chamber, the beam enters a stack of thick metallic targets such as ^{nat}Ti , ^{nat}Ag , and ^{197}Au , which are each 100–250 μm in thickness, and finally stops in a water-cooled carbon beam stopper. After the irradiation, the targets are dissolved in acid and the target materials are removed leaving as many radioactive nuclides as possible in the final solution as a multitracer. Preparation of the multitracer solution from a silver target is straightforward (Ambe et al. 1995). Dissolution of the target in nitric acid and addition of hydrochloric acid followed by filtration of silver chloride yield a solution containing all the useful radioactive nuclides produced, except for those of silver and halogens. The solution contains almost all the essential elements for humans, animals, and plants. When radioactive tracers of heavier elements are required, a gold target is recommended (Ambe et al. 1995). After heavy-ion irradiation, the target is dissolved in aqua regia. The solution is evaporated under reduced pressure and the residue is dissolved in 1.5 M HCl. Gold is extracted with ethyl acetate, leaving a multitracer solution containing tracers of elements up to mercury. In this case, the number of radioactive nuclides produced is so large that overlap of peaks in their γ -ray spectrum is substantial. Therefore, it is recommended to separate the multitracer into two or more groups of elements (group tracers). Usually, rare earth elements are separated from other elements by cation exchange and used separately. For the production of ^{28}Mg and ^{47}Ca , a Ti target is used (Ambe et al. 2001). The chemical forms of the tracers in the multitracer solutions depend on the preparation procedure employed and can be estimated from the behavior in ion exchange, for example.

35.6.3 RI Beam

In recent years, the advent of radioactive isotope (RI) beams has opened up a number of fascinating new fields (Tanihata 2004). To further develop the new fields of science, the RI Beam Factory (RIBF) has been constructed at RIKEN (Kubo 2003). This new system consists of three ring cyclotrons: the K570 MeV fixed frequency Ring Cyclotron (fRC), the 980 MeV Intermediate-stage Ring Cyclotron (IRC), and the 2,500 MeV Superconducting Ring Cyclotron (SRC). It boosts the energies of the output beams from the existing RRC up to 440 MeV/nucleon for light ions and 350 MeV/nucleon for heavy ions up to ^{238}U . These energetic heavy-ion beams are converted into RI beams via projectile fragmentation or in-flight fission of ^{238}U by the superconducting isotope separator, BigRIPS. Thus, RIBF can derive 3,000 kinds of RI beams with the world's highest intensity. The beam intensities for radioisotopes near the line of stability – which have relatively long half-lives ($> \sim 1$ min) and are practically available for radioactive tracer studies and for radiopharmaceutical diagnosis and therapy – are over 10^{10} atoms s^{-1} . One can catch the RI beams directly with suitable materials such as water, acids, physiological saline, and radiopharmaceuticals. One can select a radionuclide of interest with suitable decay properties for its application. Since they are mass-separated from other fragment isotopes, no chemical separations may be required for preparations of tracer solutions. These tracer solutions should be infinitely pure and carrier-free compared with those produced by conventional cyclotrons or reactors with the aid of chemical separation. As examples, RIBF can generate the isotopes of ^{28}Mg and ^{67}Cu , which are not readily available at present, with intensities of 2.1×10^9 and 4.6×10^{10} atoms s^{-1} , respectively. These result in 1.2 GBq for ^{28}Mg and 11 GBq for ^{67}Cu after 1-day irradiation. Thus, the RI beams derived from the future

RIBF are expected to open new frontiers in nuclear and radiochemistry as next-generation producers of radioactive tracers.

35.6.4 Measurement of Radioactive Multitracers

Since the multitracers contain a large number of radioactive nuclides, γ -ray spectrometry using a Ge detector is essential. The kind of elements traceable by the nuclides in the multitracer solution obtained from a target depends on the time elapsed after the irradiation, because radioactive nuclides of different half-lives are produced. Therefore, repetition of measurements increases the number of elements that can be traced. The data obtained are analyzed by means of a computer program and a database of radioactive nuclides.

However, even the method of γ -ray spectrometry performed with Ge detectors in the ordinary manner cannot make full use of the potential of multitracer technology. For example, if one needs to perform time-course analysis of multitracers in living biological samples, one has to prepare the same number of samples as that of the time points. This inherently causes individual differences, while elimination of such differences is one of the significant features of the multitracer technology.

In order to take full advantage of employing multitracer technology, a γ -ray imager for nondestructive analysis of multiple radioactive tracers is being developed (Yang et al. 2001; Motomura et al. 2007, 2009). The imager (► Fig. 35.2), which is called Gamma-Ray Emission Imaging (GREI), employs the principle of the Compton camera, the original idea of which was inaugurated in the early 1970s for γ -ray astronomy (Schoenfelder et al. 1973). GREI adopted position-sensitive Ge detectors to constitute the Compton camera, and succeeded in showing the first successful demonstration of nondestructive and simultaneous imaging analysis of multitracers in biological samples (► Fig. 35.3). After this demonstration, GREI has found an

■ Fig. 35.2

Schematic diagram of the principle of γ -ray imaging with the Compton camera GREI (Motomura et al. 2007)

■ Fig. 35.3

Results of the imaging of the radioactive tracers simultaneously administered to a soybean sample. (a) Measured γ -ray energy spectrum; (b)–(d) reconstructed distribution images of the tracers (Motomura et al. 2007)

innovative application in nuclear medical molecular imaging, and succeeded in the first proof of the concept (► Fig. 35.4). Multiple molecular imaging, enabled by GREI, results in simultaneous analysis of multiple biological processes within intact living subjects, and will enable exceedingly accurate and early diagnosis of many common diseases.

35.7 Chemical Application of Radioactive Tracers

Radioactive tracers have been used in the study of equilibrium and reactions in various branches of chemistry, including inorganic and organic and also basic and industrial. Solubility, vapor pressure, diffusion, precipitation, deposition, erosion, corrosion, etc., have been extensively studied with the use of radioactive tracers. Early studies were extensively compiled by Wahl and Bonner (1951).

■ Fig. 35.4

Demonstration of multiple molecular imaging in radiopharmaceutical studies. The images clearly show the difference between the reaction processes of iodinated (^{131}I) methyl-norcholestenol (^{131}I -adosterol), strontium chloride ($^{85}\text{SrCl}_2$), and zinc chloride ($^{65}\text{ZnCl}_2$) that were simultaneously injected in a living mouse (Motomura et al. 2008). 35.7.1 Chemical Equilibria

Distribution ratios. An example of the determination of distribution ratio in solvent extraction will show the simplicity of application of radioactive tracers to the study of chemical equilibrium.

A hydrochloric acid solution of $^{59}\text{Fe}^{3+}$ is shaken with diisopropyl ether in a separatory funnel. After settling, the two phases are separated and an aliquot of the same volume is pipetted from each of them and put in a plastic vessel of the same shape and size. The γ rays from the samples are counted in the same geometry with a $\text{NaI}(\text{Tl})$ scintillation counter or a Ge detector. The distribution ratio of Fe^{3+} in this system is simply given by

$$K = \frac{c_{\text{org}}}{c_{\text{aq}}} = \frac{A_{\text{org}}}{A_{\text{aq}}}. \quad (35.6)$$

Here, c_{org} and c_{aq} are the concentrations of Fe^{3+} in the organic and aqueous phase respectively, and A_{org} and A_{aq} the activities of the aliquots from both phases. For precise measurement of K , mutual pre-equilibration of both phases and check of equilibrium by back-extraction is necessary.

Solubility. The first radioactive tracer study was the determination of the solubility of poorly soluble PbCrO_4 by Hevesy and Paneth (1913). Lead chromate labeled with the naturally occurring ^{210}Pb was prepared, shaken with water, and filtered. The filtrate was evaporated to dryness on a nickel plate and the β activity of ^{210}Bi in equilibrium with ^{210}Pb was measured.

A detailed study on silver halides AgX ($\text{X} = \text{Cl}, \text{Br}, \text{and I}$) was reported by Lieser (1957, 2001). Using ^{110}Ag and ^{111}Ag as tracers, solubility of the halides was determined as a function of the concentration of the corresponding halides, NaCl , NaBr , and NaI up to 2 M. Starting from water, the solubility decreases with the concentration of halide ions as is expected from the solubility product. Then, passing through a minimum, the solubility increases with the halide concentration (Fig. 35.5). The increase of solubility in the higher halide concentration region corresponds to formation of complexes such as $[\text{AgX}_2]^-$ and $[\text{AgX}_3]^{2-}$. The minima are given by the solubility of the undissociated species inaccessible by electrochemical methods.

Water is poorly soluble in hydrocarbons and determination of its solubility by ordinary chemical analysis requires a large amount of hydrocarbon samples. The solubility of water in benzene (Joris and Taylor 1948) and other hydrocarbons (Black et al. 1948) was determined with the use of tritium (^3H , T) as tracer. These studies give an example where correction for the mass difference between an element of natural isotopic composition and its radioactive tracer is necessary. Water labeled with T was prepared by bombardment of heavy water (D_2O) with

■ Fig. 35.5

The solubility of silver halides (Lieser 1957, 2001)

deuterons. A hydrocarbon was saturated with the labeled water by bubbling it with air in a closed system. An aliquot portion of the saturated solution was taken and the labeled water was converted into ethanol. This labeled ethanol was introduced into a GM counter as a part of counting gas and the β activity of T was measured. Since the ratio of T in the labeled heavy water used was of the order of 10^{-12} mol T per mol D, T was essentially all in the form of TDO. Assuming that the Henry's law constant is the same for H_2O and TDO, the solubility determined for TDO was converted to that of H_2O . In this way, the solubility of water in hydrocarbons was determined down to the order of 1 mg water per 100 g hydrocarbon.

35.7.2 Reaction Kinetics and Mechanisms

A number of organic reactions were studied by the use of radioactive tracers and their kinetics and mechanism clarified (Arnstein and Bentley 1950; Ropp and Neville 1951). Isotopic-exchange reactions are treated in detail separately in the next section.

In kinetic studies, use of a radioactive tracer is especially advantageous for slow reactions because of its high sensitivity. For example, decarboxylation of alanine was studied using this compound labeled with ^{14}C at C of the carboxyl group (Conway and Libby 1958). This reaction

in aqueous solutions was followed at 298–427 K. The half-time for the reaction at room temperature was found to be about 10 billion years, subtracting the effect of side reactions.

An early study on Favorskii reaction gives a plain explanation how radioactive tracers are used in elucidation of reaction mechanisms (Loftfield 1950). The reaction is the rearrangement of an α -haloketone in alkaline medium. Two mechanisms (1 and 2) had been proposed for the reaction.

Mechanism 1 is closely related to that of the benzilic acid rearrangement. In this case, the chlorine-bearing carbon atom of the 2-chloro-1-cyclohexanone **I** becomes exclusively the α -carbon atom of the cyclopentanecarboxylic acid **II**. In Mechanism 2, which proceeds via

cyclopropanone intermediate, the chlorine-bearing carbon atom of **I** appears in both the α and β positions of **II**. The reaction was studied using α -chlorocyclohexanone labeled with ^{14}C at the chlorine-bearing carbon atom. The results supported strongly Mechanism 2 contrary to expectation of most investigators.

35.7.3 Exchange Reactions

Isotopic tracers are essential in studying exchange reactions, namely exchange of a common component between different molecules or ions. Although the change of enthalpy is negligible in an isotopic-exchange reaction, the entropy term of the free energy drives the reaction to the direction of uniform distribution of the isotopes between the two reactants. A number of exchange reactions have been studied with the use of radioactive tracers, though enriched stable isotopes have also been employed for certain elements.

The simplest case of exchange reactions is that occurring reversibly in a homogeneous system between two chemical species each with only one exchangeable common component.

Here, C and C^* indicate two isotopes of an element. The molar concentration of each molecule and isotopic species in this reaction shall be designated as follows.

$$a = [\text{AC}] + [\text{AC}^*]$$

$$b = [\text{BC}] + [\text{BC}^*]$$

$$x = [\text{AC}^*]$$

$$y = [\text{BC}^*]$$

The rates of the rightward and leftward isotope-exchange reactions above are given by

$$r_{\text{right}} = R \left(\frac{a-x}{a} \right) \frac{y}{b} \quad (35.9)$$

$$r_{\text{left}} = R \frac{x}{a} \left(\frac{b-y}{b} \right) \quad (35.10)$$

where R is the rate of the overall reaction including exchange of C by C and C^* by C^* .

Then, the formation rate of AC^* is

$$\frac{dx}{dt} = r_{\text{right}} - r_{\text{left}} = R \frac{ay - bx}{ab}. \quad (35.11)$$

Designating the values of x and y at equilibrium as x_{eq} and y_{eq} ,

$$\frac{x_{\text{eq}}}{a} = \frac{y_{\text{eq}}}{b} \quad (35.12)$$

and

$$x + y = x_{\text{eq}} + y_{\text{eq}}. \quad (35.13)$$

Then,

$$\frac{dx}{dt} = R \frac{(a+b)}{ab} (x_{\text{eq}} - x) \quad (35.14)$$

and, by integration, the McKay equation

$$\ln \frac{x_{\text{eq}} - x}{x_{\text{eq}} - x_0} = -R \frac{a+b}{ab} t \quad (35.15)$$

is obtained, where $x_0 = x$ at $t = 0$. The plot of $\ln[(x_{\text{eq}} - x)/(x_{\text{eq}} - x_0)]$ against t yields the value of R .

A lot of exchange reactions fit the above analysis. More complex exchange reactions including multiple and catalytic exchanges were discussed by Logan (1990).

Electron-transfer reactions. Exchange reactions between two chemical species differing only in charge occur through transfer of electrons. The rate of the exchange reaction

was measured in perchloric acid solutions by Dodson (1950). The tracer used was ^{55}Fe and the separation was based on formation of the very stable complex between α , α' -dipyridyl and ferrous ions. The reaction was rapid but still measurable. The reaction half-time is 20 s for 1.1×10^{-3} M Fe^{2+} and 1.0×10^{-3} M Fe^{3+} reactants in 0.4 M HClO_4 at room temperature, for example. The reaction is second order, presumably first order in Fe^{2+} and in Fe^{3+} . Later, the Fe^{2+} – Fe^{3+} -exchange reaction in perchloric and hydrochloric acid solutions was studied (Silverman and Dodson 1952). The reaction is first order in the overall concentration of each oxidation state and the rate increases with decreasing acid concentration and with increasing Cl^- concentration. On the basis of these observations, four reaction paths involving Fe^{2+} with Fe^{3+} , FeOH^{2+} , FeCl^{2+} , and FeCl_2^+ were suggested.

The exchange reaction involving transfer of two electrons

is slow and its rate is also dependent on the first power of both Tl^+ and Tl^{3+} concentrations. Mechanisms of the electron transfer reactions were reviewed by Sutin (1962).

Molecular halogen, halide, halate, and perhalate ions. The exchange rate between halide ions and molecular halogens, namely Cl^- and Cl_2 , Br^- and Br_2 and also I^- and I_2 , in aqueous solutions is too large to be measured by an ordinary radiochemical method.

The exchange between molecular halogen or halides and halates or perhalates is slow. The iodine–iodate-exchange reaction was investigated in detail by Myers and Kennedy (1950). The reaction is complex and a possible mechanism was proposed, which involves two-electron transfer from a chemical species containing I^- to one containing IO_2^+ as a rate determining step.

Metal complexes. Radioactive tracer studies on exchange reactions of metal complexes have greatly contributed to the understanding of the nature of chemical bonding in them and also of the mechanism of their reactions. Exchange of both ligands and central metal ions has been extensively studied. Relative rates of ligand exchange of octahedral complexes of transition metals are related to the electron configuration and ligand field (Taube 1952).

Alkyl halides and halide ions. Halogen atoms of alkyl halides exchange with halide ions in particular solvents such as ethanol and acetone. This substitution reaction occurs ordinarily through *Walden inversion*. The negative halide ion approaches the positive end of the carbon–halogen dipole in the alkyl halide and, displacing the halogen atom, forms a new chemical bond with the carbon atom. When the carbon atom is asymmetric, this exchange reaction leads to optical inversion. This mechanism was confirmed by studies of exchange reaction using radioactive tracers along with optical measurement. For example, Hughes et al. (1935) studied the exchange reaction of radioactive iodine between racemic mixture of *dl*-*sec*-octyl iodide and Na^{128}I in acetone. The reaction was stopped after a suitable time by addition of water and

crushed ice. The *sec*-octyl iodide was extracted with carbon tetrachloride and the activity of the resulting organic and aqueous phases was measured. The observed rate of exchange was found to be the same as the rate of racemization of *d*-*sec*-octyl iodide determined by optical measurement within the experimental error. This agreement confirmed the causal connection between aliphatic substitution and optical inversion. Really, investigations of this type gave a basis for discrimination of the two types of fundamental organic reactions: the first-order nucleophilic substitution (S_N1) and the second-order one (S_N2).

35.7.4 Reactions at Equilibrium

Every textbook of physical chemistry describes that chemical equilibrium is a state where the forward and reverse reactions are taking place at exactly the same rate, and that the equilibrium constant K is the ratio of the forward-rate constant k_f to the reverse one k_r . This universally accepted principle of great importance in chemistry had been conventionally justified on the basis of k_f and k_r determined far from equilibrium since the reactions cannot be followed by conventional chemical methods in the state of equilibrium. This crucial relationship between chemical reaction rate and equilibrium was first proved by the use of radioactive tracers.

A representative study on the reaction rates at equilibrium was made by Wilson and Dickinson (1937) on the exchange reaction between trivalent and pentavalent arsenic, which proceeds in the presence of easily oxidizable or reducible substances like iodine.

A reaction mixture in this equilibrium was prepared, in which H_3AsO_3 was labeled with ^{76}As . The exchange was quenched by dilution with water and addition of an excess of ammonium hydroxide. The AsO_4^{3-} ions were precipitated as ammonium magnesium arsenate and subjected to activity measurement. The rates of oxidation and reduction measured in this way were in agreement with the kinetic expressions and rate constants, which hold for the same reaction remote from equilibrium.

35.7.5 Surface and Solid Reactions

Radioactive tracers, with their high sensitivity and ease of detection, are also an excellent tool for the study of surface reactions. Usually, rapid exchange occurs between a chemical species in a solution or gas and that on a solid. Then follow much slower processes involving species in the deeper layers of the solid, i.e., diffusion and recrystallization. These reactions are easily observed by establishing contact between the solid and a solution of a tracer followed by the separation of the two phases and activity measurement.

A study on the exchange of ^{14}C between carbon dioxide and barium carbonate

was reported by Armstrong and Schubert (1947). This exchange reaction was found to proceed only in the presence of water vapor, and, in the atmosphere saturated with water, more than one third of ^{14}C in $\text{Ba}^{14}\text{CO}_3$ was lost in 65 h. Therefore, a mechanism involving

was proposed for the reaction. This observation is very important for experiments using ^{14}C , because ^{14}C is often supplied or stored in the form of $\text{Ba}^{14}\text{CO}_3$. $\text{Ba}^{14}\text{CO}_3$ loses its radioactivity when it is in contact with humid air, and in the opposite way BaCO_3 in contact with $^{14}\text{CO}_2$ in humid air is contaminated with ^{14}C .

Radioactive tracers have been extensively and successfully applied to the studies of mechanism of precipitation and also aging or ripening of precipitates. Studies of corrosion and erosion using radioactive tracers have greatly contributed to improvement of industrial processes.

Emanation means the release of a radioactive gas, typically a noble gas produced in a solid by radioactive decay or nuclear reaction, from the solid. This phenomenon has been utilized in both basic and industrial studies. The emanation is measured as a function of the temperature and increase of emanation at a certain temperature indicates structural or chemical change in the sample. For example, Zimens (1937) studied emanation of ^{220}Rn from calcite and aragonite, the hexagonal and orthorhombic forms of CaCO_3 . Calcite and aragonite samples doped with ^{224}Ra were prepared and heated in dry CO_2 gas and the activity of ^{220}Rn , the daughter of ^{224}Ra , released from the sample was measured with a flow counter. In the case of aragonite, emanation due to the structural change of CaCO_3 from aragonite to calcite is observed at 530°C as a peak of radioactivity. Then, strong emanation accompanying decomposition of calcite into CaO and CO_2 is observed around 920°C . Finally, emanation increases again above $1,100^\circ\text{C}$, where the Ca^{2+} and O^{2-} ions begin to become mobile in the matrix.

35.7.6 Diffusion

Diffusion is a suitable target of study with radioactive tracers. By ordinary chemical methods, only diffusion occurring in a system with a concentration gradient is observable. However, isotopic tracers enable observation of “self-diffusion,” that is diffusion of atoms or ions in a system having no chemical concentration gradient. Ordinary diffusion and self-diffusion have been extensively studied not only in solid but also in liquid state using radioactive tracers.

Diffusion in solids. In a diffusion study on solids, a layer as thin as possible of a radioactive tracer is formed on the surface of the sample by electroplating, for example. In some cases, an isotope-exchange reaction can be used to prepare a thin layer. Diffusion is allowed to proceed at an elevated temperature for a definite time. Then, the thin sections of the sample surface are removed stepwise by grinding or chemical etching. The activity of the tracer in the sections removed is determined to yield the diffusion constant. Microautoradiography of a section cut vertically against the surface of the sample helps to distinguish between uniform diffusion and that through grain boundaries. An example of geological application is described below.

A historical diffusion study by Hevesy and Obrutsheva (1925) is a unique example of taking advantage of the short range of α particles. Two thin foils of lead, one of inactive lead and the other of lead containing ^{212}Pb , were pressed together. The thickness of the inactive foil was chosen slightly greater than the range of the α particles to be measured. The rate of self-diffusion of lead was determined on the basis of α particles emitted by ^{212}Bi and ^{212}Po (the daughter and granddaughter nuclides of ^{212}Pb) diffused into the inactive foil and observed from the backside of it.

A more elaborate technique in this line was developed by the use of recoil atoms (Hevesy and Seith 1929). Vapor of $^{212}\text{PbCl}_2$ was condensed on the surface of a PbCl_2 disk and the disk was kept at $166\text{--}270^\circ\text{C}$. After waiting for the establishment of radioactive equilibrium in the decay series $^{212}\text{Pb} \rightarrow ^{212}\text{Bi} \rightarrow ^{208}\text{Tl}$, ^{208}Tl atoms recoiled out of the surface as a result of the α

decay of ^{212}Bi were collected and their β activity was measured to yield the diffusion constant of ^{212}Pb in lead halide. The extremely short range of the recoil of ^{208}Tl (about 3×10^{-5} mm in Pb) enabled determination of diffusion constants as small as of the order of $10^{-18} \text{ cm}^2 \text{ s}^{-1}$ and those at a temperature as low as 166°C for PbCl_2 .

Diffusion in liquids. Diffusion in liquids is most commonly measured by the diaphragm cell method. In a self-diffusion study, a radioactive tracer is applied to one of two cells containing a liquid of the same chemical composition and separated by a porous diaphragm. Aliquots taken from one or both of the cells in time sequence are subjected to activity measurement. In the capillary method, a series of uniform capillaries, typically 0.5 mm in diameter and 4 cm long, are filled with the solution containing the radioactive tracer. The capillaries are held in a vertical position below the surface of a circulating bath of a nonradioactive solution for different lengths of time. The activity remaining in the capillaries give the diffusion constant. Isotopic self-diffusion studies on ions in aqueous solutions have an advantage that the diffusion coefficients are determined independent of the diffusion of counter ions, which is inevitable in ordinary determination in solutions with a concentration gradient.

35.7.7 Search for Formation of New Compounds

The multitracer technique is useful in search for new compounds. The formation of metallofullerenes had been established by ordinary chemical methods only for the group 2 elements, Ca, Sr, and Ba; and for the group 3 elements, Sc, Y, and the lanthanide elements. Formation of new metallofullerenes was examined for a number of elements from those in groups 2 through 16 in the periodic table with a multitracer and metallofullerenes with group 4 and 5 elements were successfully discovered (Sueki et al. 1999).

A multitracer containing tracers of 28 elements and macro amount of lanthanum nitrate were dissolved in ethanol and absorbed by a graphite rod. After heat treatment, the rod was used as an electrode for fullerene production by the arc-discharge method in a vacuum chamber. The fullerene-like species in the soot produced inside the chamber were extracted into CS_2 . The CS_2 extract was injected into a High-Performance Liquid Chromatography (HPLC) system with a 5 PBB column and eluted with CS_2 . The elution curves are given in  Fig. 35.6. Thus, formation of metallofullerenes of Zr, Hf (group 4), and Nb (group 5) was radiochemically ascertained. At the same time, it has also been shown that no metallofullerenes are formed for the elements of group 6 and higher ones under the experimental conditions.

35.8 Analytical Application of Radioactive Tracers

Radioactive tracers have shown their usefulness in many aspects of analytical chemistry (Elving 1986). Basic data for separation techniques, solvent extraction, ion exchange, various types of chromatography, etc., have often been obtained by the use of radioactive tracers. Mechanism of coprecipitation and aging of precipitates, important in gravimetric analysis, was also extensively studied.

■ Fig. 35.6

Elution curves of metallofullerenes labeled with a multitracer (Sueki et al. 1999). (a) Shows the UV elution curve of empty fullerenes, (b) radioactivity elution curve of tracers mostly eluted before C_{60} , and (c) that of tracers eluted as metallofullerenes (the elution peaks observed for trivalent La, Ce, Pm, Gd and divalent Eu, Yb are not shown)

Radiometric analysis, or radiometry, is a method of analysis in which a radioactive tracer is employed as an indicator or a reagent. Among them, the most important one is the isotope dilution analysis discussed separately below. Isotope dilution analysis is also used to determine the amount of radioactive elements or compounds (inverse isotope dilution analysis).

35.8.1 Isotope Dilution Analysis

Since the early works of Hevesy in the 1930s, this technique has yielded abundant variations and has been used not only in research but also in industry (Tölgyessy and Braun 1972). Radioimmunoassay is the most developed form of the technique and is routinely used in medicine.

Direct isotope dilution analysis. This method is employed to determine the mass (weight) of an ordinary inactive compound (or an ion) in a solution, being efficacious when quantitative separation of the compound from the mixture is difficult but partial separation of the

compound in the pure state is feasible. The unknown mass of the compound to be determined in the sample solution is taken to be X . To this sample solution is added a solution containing W_0 of the same compound labeled with a radioactive tracer (commonly called a “spike”) with activity A_0 and hence with a specific activity

$$S_0 = \frac{A_0}{W_0}. \quad (35.21)$$

The resulting solution is thoroughly blended so that the original inactive compound and the added radioactive compound attain equilibrium. Now, the specific activity S' of the compound in the solution is given by

$$S' = \frac{A_0}{X + W_0}. \quad (35.22)$$

Then, a portion of the compound is isolated in the pure state. The mass W and the activity A of the portion is measured to yield the specific activity

$$S = \frac{A}{W}. \quad (35.23)$$

As the specific activity remains unchanged during the separation procedure of the compound from the mixed solution,

$$S = \frac{A}{W} = S' = \frac{A_0}{X + W_0}, \quad (35.24)$$

$$X = \frac{S_0 - S}{S} W_0. \quad (35.25)$$

For example, direct isotope dilution analysis is used for mercury inventory in industry (Cowley et al. 1966; Enomoto et al. 1975). The mass X of mercury in electrolytic chlorine cells is determined using ^{197}Hg , ^{203}Hg , or a mixture of them. An aliquot of known mass W_0 and activity A_0 and hence known specific activity S_0 is taken from a stock of mercury labeled with the tracer, added to each electrolytic cell, and left to mix. After homogenization, a sample of mercury is taken from each cell. The samples are shaken with 15–20% HCl to decompose amalgam. The mass W and activity A of the samples are measured to yield to S and, accordingly, X . The accuracy is better than 1%.

Substoichiometric isotope dilution analysis. It is often inconvenient to determine the mass of the isolated compound in the above direct isotope dilution analysis, as is the case for a large number of samples. Substoichiometric isotope dilution analysis is an excellent solution to this problem (Ruzicka and Stary 1968; Stary and Ruzicka 1976). In this method, the same amount of the compound is separated from each of the standard and mixed solutions using a reagent in an amount stoichiometrically less than that of the compound in the solutions. The activity of the portion separated from the standard solution (A_0) and that from the mixed solution (A) are measured. Since the mass of the portions counted are the same, the ratio of their specific activities S_0/S equals the ratio of their activities A_0/A .

Thus, the mass of the compound in the original sample is given as

$$X = \frac{A_0 - A}{A} W_0. \quad (35.26)$$

When the separation is not strictly stoichiometric, a calibration curve determined from a series of known samples is used. Radioimmunoassay is based on this principle of substoichiometric isotope dilution analysis.

Inverse isotope dilution analysis. This variation is a method to determine not an inactive compound but a radioactive one. To be determined is the mass X of a certain radioactive compound (or ion), whose specific activity is known to be S_0 , in a sample. To the sample solution is added a solution containing W of the same but inactive compound (spike). If the specific activity of the compound after this addition and thorough blending is taken to be S , then

$$S_0 X = S(X + W). \quad (35.27)$$

This is so because the total activity of the compound naturally remains unchanged by addition of the inactive one. The specific activity S of a portion of the compound purely isolated from the blended solutions is obtained from its mass and activity. Then, the mass X of the compound in the original sample solution is given by

$$X = \frac{SW}{S_0 - S}. \quad (35.28)$$

The weak point of the above inverse isotope dilution analysis is that the specific activity S_0 of the compound to be determined in the original sample solution must be known. This can be avoided by *double isotope dilution analysis*. In this type of analysis, two portions of exactly the same amount are taken from the sample solution. The mass of the radioactive compound in each portion is taken to be X . To the portions are added different masses W_1 and W_2 of the inactive compound. Taking the specific activities of the compound in the portions after this to be S_1 and S_2 ,

$$S_0 X = S_1(X + W_1), \quad (35.29)$$

$$S_0 X = S_2(X + W_2), \quad (35.30)$$

X and S_0 can be expressed as follows:

$$X = \frac{S_2 W_2 - S_1 W_1}{S_1 - S_2}, \quad (35.31)$$

$$S_0 = S_1 S_2 \frac{W_2 - W_1}{S_2 W_2 - S_1 W_1}. \quad (35.32)$$

35.8.2 Radiometric Analysis

Radiometric methods other than the isotope dilution analysis are not necessarily versatile. But they provide convenient and reliable technique in certain cases (Braun and Tölgyessy 1967). In *radiometric titration*, a radioactive indicator is used to monitor the end-point of the titration. For example, Cl^- ions in an aqueous solution sample are titrated with a standard solution of Ag^+ solution labeled with $^{110\text{m}}\text{Ag}$. Until the equivalence point is attained essentially all the Ag^+ ions are precipitated as AgCl , giving little activity in the supernatant solution. At the equivalence point, the activity begins to increase linearly. Plotting the activity of the solution against the amount of Ag^+ solution added, the equivalence point is clearly determined as the intersection of two lines. This technique is reliable and convenient, if both the separation of the supernatant solution from the precipitate and the activity measurement are made automatically.

Another example of radiometry worth mentioning is determination of a chemical species by precipitation with a radioactive reagent. For example, the amount of K^+ ions in an aqueous solution is determined by the use of ^{60}Co . An excess of a standard solution of $\text{Na}_3[^{60}\text{Co}(\text{NO}_2)_6]$ is added to the sample solution and the precipitate of poorly soluble $\text{K}_2\text{Na}[^{60}\text{Co}(\text{NO}_2)_6]$ is collected by filtration. From the activity of the precipitate, K^+ is determined referring to a calibration curve obtained on samples containing known amounts of K^+ ions. This method is used, for example, to determine 0.1–0.002 mg of K^+ ions in rainwater.

35.8.3 Surface-Area Determination

Area determination of ionic crystals by measurement of exchange reactions of radioactive tracers was established by Paneth and Vorwerk (1922). When a radioactive tracer is uniformly distributed between the solid surface and a solution

$$\frac{N_{\text{surf}}^*}{N_{\text{surf}}} = \frac{N_{\text{sol}}^*}{N_{\text{sol}}} \quad (35.33)$$

where N and N^* designate the number of the total chemical species in question and that of the species labeled with the tracer, and the subscripts “surf” and “sol” refer to solid surface and the solution, respectively. The value of N_{surf} is readily calculated from the measured values of N_{sol} and $N_{\text{surf}}^*/N_{\text{sol}}^*$. The average distance L between the adsorbed species is given by

$$L = \left(\frac{W}{n N_A \rho} \right)^{\frac{1}{3}} \quad (35.34)$$

where W is the molar mass of the solid, n the number of exchangeable species in one formula unit of the solid, N_A the Avogadro constant, and ρ the density of the solid. Then, the surface area S is given by

$$S = N_{\text{surf}} L^2 = N_{\text{surf}} \left(\frac{W}{n N_A \rho} \right)^{\frac{2}{3}}. \quad (35.35)$$

On the basis of this principle, Paneth and Vorwerk (1922) measured the surface area of PbSO_4 using ^{212}Pb as the tracer. In this type of measurement, it is necessary to repeat the activity measurement as a function of time and to subtract the component due to the slow processes of diffusion and recrystallization.

35.9 Biochemical Application of Radioactive Tracers

Radioactive tracers have played and are still playing an extremely important role in the fields of biochemistry and other biological sciences. Their application to medicine is described in detail elsewhere (see Vol. 4). Even apart from medicine, the ways of application are too many to mention. Here, the historic study of photosynthesis by Calvin and coworkers is briefly described as the representative one, followed by a recent multitracer study.

The photosynthesis of carbohydrates by plants

was studied by a series of tracer experiments using ^{14}C . Plants were cultivated in atmosphere containing $^{14}\text{CO}_2$. After exposure to light for different periods of time, sections of the plants were digested and organic constituents were separated by paper chromatography and the distribution of ^{14}C among various species was determined by autoradiography (Benson et al. 1950). On the basis of this kind of tracer studies, the well-known mechanism of photosynthesis was established (Bassham and Calvin 1957).

In *positron emission tomography* (PET) of brain tumors, ^{18}F -fluorodeoxyglucose (FDG) is widely used. However, ^{18}F -FDG often fails to detect tumors because of its relatively high uptake in the normal parts of brain. So, a search for a brain tumor-specific element was performed by the multitracer technique (Tamano et al. 2001). A multitracer solution prepared from a silver target was intravenously injected into the rats having C6 glioma in brain. One hour after the injection, the rats were killed and their brain was divided into tumor, cerebral cortex, cerebellum, and the rest, each being subjected to γ -ray spectrometry.

Among radioactive nuclides of 15 elements detected, ^{65}Zn , ^{83}Rb , ^{54}Mn , and ^{22}Na , were found to be preferentially taken up in the tumor. The preferential uptake of ^{65}Zn in C6 glioma is consistent with the result of a single-tracer study and suggests the possibility of imaging of malignant cell proliferation in the brain using relatively short-lived $^{69\text{m}}\text{Zn}$ (13.76 h). Similarly, the above result on ^{54}Mn suggests use of $^{52\text{m}}\text{Mn}$ (21.1 min) for positron emission tomography of brain tumors. The high uptake of ^{83}Rb is suggestive of ^{82}Rb (1.273 min) or ^{81}Rb (4.576 h) in place of ^{201}Tl (72.91 h).

35.10 Geological Application of Radioactive Tracers

Radioactive tracers have been extensively employed in both laboratory and field works of geological studies. Here, only a recent study using a multitracer on diffusion of ions through granite is described.

Diffusion behavior of various elements in micropores of rocks is important from the viewpoint of disposal of radioactive waste in deep underground repository. Diffusion experiments were conducted by the through-diffusion method using a multitracer containing radioactive tracers of 14 elements (Egawa et al. 2001). Granite samples were cut into a 5 mm thick and 40 mm diameter disk. Disks of granite samples were fitted tightly between two cells filled with a 0.10 M NaCl solution (pH 4). The multitracer solution was injected into one of the cells. Activity of the tracers diffusing into the other cell was determined using a Ge detector after various time intervals for about 3 months. Diffusion path of each element in the granite was determined by autoradiograph using an imaging plate.

Diffusion of ^7Be , ^{54}Mn , ^{58}Co , ^{65}Zn , ^{75}Se , ^{83}Rb , ^{85}Sr , and ^{88}Y was observed in the weathered granite, while only ^{54}Mn , ^{75}Se , ^{83}Rb , ^{85}Sr in the fresh one. This difference is attributed to the larger porosity of the former than that of the latter. The autoradiography showed that diffusion paths of the tracers are in the grain boundaries and cleavages of biotite and plagioclase in the granite.

35.11 Industrial Application of Radioactive Tracers

Radioactive tracers are widely used in various fields of industry (Charlton 1986; Földiák 1986). Different ways of application are compiled in a guide published by International Atomic Energy Agency (IAEA; Ferronsky et al. 1990). The present authors rely much on the guidebook

for the following description. An example of industrial application of isotope dilution analysis was described above.

Flow rates of solutions or suspensions are measured with tracers such as ^{82}Br and ^{24}Na . For gas flows, radioactive rare gases, ^{41}Ar , ^{85}Kr , and ^{133}Xe are commonly used. Mixing processes are followed by measuring the tracer concentration. In mixing of solid particles, the best tracer is a fraction of the material itself made radioactive by neutron irradiation.

Radioactive tracers are also used for troubleshooting in industrial processes. Location of a leak is detected by applying a radioactive tracer to the suspected part of a system and monitoring the tracer leaking out of the system. For example, leak problem in a plant is solved by pulse injection of ^{41}Ar and detection of it along the lines of the plant. Leak location of long-buried pipelines with large diameter is economically achieved as follows. The suspected section of a pipeline is filled with water in which $\text{NH}_4^{82}\text{Br}$ is dissolved. The section is pressurized for a while and then thoroughly washed with water. A detector system with recorder mounted on a "pig" is moved through the line by hydraulic pressure to detect ^{82}Br having leaked into the surrounding of the pipe. This method was successfully used to detect five leaks in a 140 km long crude oil pipeline.

Refractory lining wear in blast furnaces is monitored by radioactive tracers. Sources of ^{60}Co are embedded in refractory bricks during lining. The γ rays of ^{60}Co are monitored from outside the furnace and erosion of the bricks is detected as the extinction of the γ rays. Tritiated water ($^3\text{H}_2\text{O}$) provides a very sensitive way of testing watertightness of pieces connected with elastomer joints.

Testing of corrosion resistance of materials is most commonly done with the use of *kryptonates*, i.e., solids into the surfaces of which ^{85}Kr has been incorporated by ion bombardment. Kryptonates of test materials are exposed to corrosive atmosphere and the residual β activity of ^{85}Kr is measured. Surfaces labeled with a radioactive tracer by isotope exchange, electrodeposition, or vacuum deposition are also employed.

An excellent way of measuring the material loss at the surface is use of *thin-layer activation*. A thin layer of radioactive tracer is produced on the surface by irradiation with charged particles. This technique can be applied to all types of iron, steel, nonferrous metals and alloys. It is particularly suitable for metal wear studies, because, if done carefully, the charged-particle activation little alters the mechanical properties of the surfaces of specimens. As the charged particles for irradiation, protons, deuterons, α particles, and occasionally ^3He -particles accelerated by a cyclotron or other accelerators are used. Choosing the kind and energy of the charged particles, a radioactive layer of 10–1,000 μm thickness is produced. Typical nuclear reactions used are as follows.

Iron	$^{56}\text{Fe}(\text{p},\text{n})^{56}\text{Co}$
Nickel	$^{58}\text{Ni}(\text{p},\text{pn})^{57}\text{Ni} \rightarrow ^{57}\text{Co}$
Copper	$^{65}\text{Cu}(\text{p},\text{n})^{65}\text{Zn}$
Molybdenum	$^{95}\text{Mo}(\text{p},\text{n})^{95\text{m}}\text{Tc}$

Loss of surface material due to wear is estimated by measuring the decrease of the activity of the surface or by measuring that of the powder lost from the surface and accumulated in the lubricating oil. The activity is converted to wear depth by a calibration curve obtained on a standard sample. This technique is widely and efficiently used in development of automobile engines, for example, because it is applicable to actual engines and their parts and enables real-time estimation of wear with high sensitivity.

E : energy of the level, $T_{1/2}$: half-life, α : internal conversion coefficient, a : natural abundance, I : nuclear spin, Q : nuclear quadrupole moment, b: barn, μ : nuclear magnetic moment, μ_N : nuclear magneton, σ_0 : nuclear absorption cross section, W_0 : natural line width expressed as Doppler-speed interval. Absence of sign in the Q and μ values means that the sign is undetermined (Cohen and Taylor 1987; Raghavan 1989; Pyykkö 2001, 2008; NuDat 2009).

36.2 Thermal Neutron Reaction Data

Richard B. Firestone · Zsolt Révay · Gábor L. Molnár

36.2.1 Thermal Neutron Radiative Capture Cross Sections, g -Factors, and Resonance Integrals

► **Table 36.2** gives *thermal neutron capture cross sections* from Mughabghab et al. (1981, 1984), and (2003). Atomic abundances are taken from the latest IUPAC compilation (Rosman and Taylor 1998). The Westcott g -factors, which are a measure of the deviation of the cross section from the regular $1/u$ -behavior, were calculated by Trkov (2003) in the framework of a coordinated research project (IAEA 2003). *Resonance integrals* are from Mughabghab (2003), except for those in square brackets that are from the earlier compilation (Mughabghab et al. 1981, 1984) but have been omitted in the later reference. The notations in ► **Table 36.2** are the following:

Column 1: Atomic number and element name.

Column 2: Isotope symbol, followed in parentheses by energy of isomeric level in keV or reaction if not (n, γ).

Column 3: Isotopic abundance (%).

Column 4: Cross section at 2,200 m/s neutron speed (representing the most probable speed at 20°C), in barn (b) or millibarn (mb) units. 1 b = 10 $^{-28}$ m 2 .

Column 5: Westcott g -factor for 300 K Maxwellian flux distribution.

Column 6: Infinite dilution resonance integral, in barn (b) or millibarn (mb) units.

36.2.2 Thermal Neutron Capture γ Rays

The prompt gamma-ray cross sections were derived from a comparison of measurements with the neutron beam at the Budapest Reactor and other data from the literature (Molnár 2004; Choi et al. 2007). In some cases, these values were renormalized to better agree with the adopted total radiative cross section from all measurements. Delayed gamma-ray cross sections were derived from a comparison of Budapest Reactor measurements, corrected for activation and decay times, values derived from the k_0 database, and values adopted from total radiative cross sections and emission probability values from either the “Table of Radionuclides” (Bé et al. 2004) or the ENSDF (2010) nuclear structure and decay database (🔗 Table 36.3).

■ Table 36.3

Energy, half-life and partial gamma-ray production cross section of the most important prompt and decay gamma lines of elements

36.3 Fast Neutron Reaction Data

J. Csikai · R. Dóczi

The status of available *neutron reaction data* is published regularly in the CINDA (Computer Index of Neutron Data) series. CINDA (see, e.g., CINDA 2003) contains bibliographical references to measurements, calculations, reviews, and evaluations of neutron cross sections and other microscopic nuclear data. It also includes index references to computer libraries of

numerical neutron data available from regional nuclear data centers, such as the International Atomic Energy Agency's Nuclear Data Section (IAEA 2003), the OECD Nuclear Energy Agency's Data Bank (NEA 2003), the US National Nuclear Data Center (NNDC 2003), and the Russian Nuclear Data Center (RNDC 2003). Though the CINDA bibliography allows the users to find the references to specific types of cross-section information on *neutron-induced reactions*, recommended numerical data are indispensable in real applications.

The major fields of application of neutron data, in addition to nuclear theory, are as follows (Csikai 1987): fission reactor technology, fast-reactor design and control calculations, shielding calculations, radiation damage, neutron flux/fluence monitoring, fusion reactor technology, safeguards, neutron therapy, medical physics, activation analysis, prompt radiation analysis, radionuclide production, transmutation of radioactive waste, radiobiology, nuclear geophysics, earth sciences, dosimetry, space sciences, and nuclear astrophysics. Hundreds of requests exist for data at neutron energies up to 20 MeV, with an emphasis on 14 MeV neutrons produced in the $^3\text{H}(\text{d},\text{n})^4\text{He}$ (D-T) reaction. In some cases, however, to avoid the disturbing effects of interfering reactions and gamma-lines the use of $^2\text{H}(\text{d},\text{n})^3\text{He}$ (D-D) reaction is preferred. The IAEA has established a coordinated research project with the objective of providing a library of neutron-activation cross sections for the reactions relevant to a wide range of applications (IAEA 2002).

36.3.1 Status of 14 MeV and 3 MeV Neutron Cross Sections

Low voltage (100–200 kV) neutron generators are widely used for the production of neutrons by the **D-D** ($Q = 3.26$ MeV) and **D-T** ($Q = 17.588$ MeV) reactions. There are about 600 radioisotopes producible by the 14 MeV D-T neutrons on the 290 stable isotopes of the elements via different reactions. The number of nuclei producible by the 3 MeV D-D neutrons via (n,γ) reactions is about 170. Considering the high neutron yield and energy for the D-T reaction as compared to the D-D reaction, the different applications are based almost exclusively on 14 MeV neutrons. In this case, the use of (n,p) , (n,α) , and $(\text{n},2\text{n})$ reactions are recommended. Therefore, the evaluated experimental data are summarized only for these reactions in [Tables 36.4–36.6](#).

Data available in different activation files were completed with the measurements of Dóczi et al. (1997), Majdeddin et al. (1997), Filatenkov and Chuvaev (1999), Osman and Habbani (2000), Filatenkov and Chuvaev (2001), and Kasugai et al. (2001). The cross section curves change at around 14 MeV; therefore, the data are normalized to 14.7 MeV on the basis of the slopes. Different systematics were established for the estimation of the unknown data and to deduce the *production rate* of long-lived and stable isotopes. Comprehensive reviews of the systematics of (n,p), (n, α), and (n,2n) *reaction cross sections* are given in Dóczi et al. (1997), Majdeddin et al. (1997), and Osman and Habbani (2000).

36.3.2 Recommended Dosimetry Reactions

The knowledge of the flux density spectra, $\Phi(E)$ of neutrons at a given point of a sample or averaged over a large volume is indispensable for various applications of neutrons. The multiple-foil activation method renders possible the determination of the $\Phi(E)$ function with high accuracy especially below the 1–2 MeV region as compared to the time-of-flight (TOF) technique. Further advantage of the activation foil method is that the disturbance of the neutron field can be neglected. In general, about 12 reactions indicated in ► Table 36.7 are used for the unfolding of a given $\Phi(E)$ function with cross sections taken from the International Reactor Dosimetry File (IRDF). A new version of IRDF-90 contains cross sections for 53 *dosimetry reactions*, together with uncertainty information (Zsolnay 1998). The unfolding procedure

► Table 36.7

List of reactions used for the unfolding of a given $\Phi(E)$ function

Reaction	Response energy range (MeV)	Half-life	E_γ (keV)	I_γ (%)
$^{56}\text{Fe}(n,p)^{56}\text{Mn}$	5.4–13.6	2.5785 h	846.812	98.9

			1,120.51	99.987

based on the multiple-foil activation method has been described, for example, in Sudár (1989), Zsolnay (1998).

It is well known that the following variables can strongly influence the neutron energy distributions from a given reaction: the types of target atoms, the ratio of atomic to molecular ions, the energy spread of ions, the slowing down, and scattering of projectiles in the target. For absolute normalization of the energy scale mainly the D-T neutrons are recommended accepting a value of (14.00 ± 0.07) MeV at $96\text{--}98^\circ$ emission angles. The measurements of relative activities of ^{89}Zr and $^{92\text{m}}\text{Nb}$ produced in $^{90}\text{Zr}(n,2n)$ and $^{93}\text{Nb}(n,2n)$ reactions, respectively, render the determination of neutron energy with high precision at around 14 MeV possible. A value of (460 ± 5) mb is recommended for the cross section of $^{93}\text{Nb}(n,2n)^{92}\text{Nb}$ *fluence monitor* in the 13.5–15 MeV range. The $^{27}\text{Al}(n,\alpha)$ reaction is also a good *fluence monitor* in the 13.8–14.2 MeV range of D-T neutrons. The $\sigma(E_n)$ curves for $^{90}\text{Zr}(n,2n)^{89}\text{Zr}$ and $^{52}\text{Cr}(n,2n)^{51}\text{Cr}$ energy standards are approximated by the following polynomials:

$$\sigma(E_n)/\text{mb} = -13244.5 + 1668.16(E_n/\text{MeV}) - 48.543(E_n/\text{MeV})^2$$

and

$$\sigma(E_n)/\text{mb} = -2210.0 + 176.32(E_n/\text{MeV}),$$

respectively.

The sensitivity of this activation ratio method between 13 MeV and 15 MeV, on average, is 50%/MeV and 64%/MeV for Zr and Cr, respectively. This method is also applied to determine the mean neutron energy for an extended sample. In this case, the Zr and Nb foils are placed back-to-back in different positions inside the sample. The angular yield of D-D neutrons can be measured either by the $^{238}\text{U}(n,f)$ using a depleted U layer in a fission chamber or by the $^{115}\text{In}(n,n')^{115\text{m}}\text{In}$ reaction. The $\sigma_{n,f}(E_n)$ curve is relatively well known and its change between 2 MeV and 3 MeV is within 2%. For the $^{115}\text{In}(n,n')^{115\text{m}}\text{In}$ reaction the high cross section value of $\sigma = (325 \pm 5)$ mb in this energy range is advantageous; however, this inelastic process is sensitive to the scattered neutrons.

The $^{64}\text{Zn}(n,p)^{64}\text{Cu}$, $^{58}\text{Ni}(n,p)^{58}\text{Co}$, and the $^{31}\text{P}(n,p)^{31}\text{Si}$ reactions are recommended as *energy monitors* for D-D neutrons in the 2–3 MeV range. The product of the latter reaction is a pure beta-emitter. For the D-D reaction, the neutron energy at $\sim 100^\circ$ emission angle is almost constant in the $50 \text{ keV} \leq E_d \leq 500 \text{ keV}$ range. In this case a value of $E_n = (2.414 \pm 0.010)$ MeV can be used for normalization of the energy scale using 100–200 keV incident deuteron energies. The angular dependences of neutron energies and cross sections for monoenergetic neutrons produced by two-body nuclear reactions can be found in Drosch and Schwerer 1987. These data for D-D and D-T neutrons are discussed also in detail in Csikai 1987.

36.3.3 Recommended Reactions and γ Rays for Activation Analysis

In general, the relative method using standards of well-known compositions is preferred in *neutron activation analysis* (NAA). However, the knowledge of decay data and cross sections is indispensable when absolute measurements are performed, and also for choosing the most favorable reaction or estimating the *expected activity* and the role of *interfering reactions*. The *recommended reactions* for NAA with small neutron generators summarized in [Table 36.8](#)

Table 36.8

Recommended reactions for neutron activation analysis (NAA) with small neutron generators; note that (n,γ) relates to thermal energy; other reactions to $E_n = 14.5$ MeV. X stands for X-rays, -annih. for 511 keV annihilation radiation

were selected on the basis of the specific activity. Using ▶ Eq. (32.7) in Chap. 32 of this Volume, the specific activity $R(t_i)$ becomes

$$R(t_i) = \frac{A(t_i)}{m_i} = N_A \frac{\sigma f \Phi}{M_i} (1 - e^{-\lambda t_i}) \tag{36.1}$$

where $A(t_i)$ is the activity at the end of irradiation time t_i , m_i is the mass of the irradiated element, σ is the reaction cross section, N_A is the Avogadro constant, Φ is the neutron flux density, M_i is the molar mass of the element, λ is the decay constant of the activated product, and f is the abundance (in fraction) of the isotope to be activated. The $R(t_i)$ values in ▶ Table 36.8 were calculated for the reactions of maximum yield for each element, assuming $\Phi = 10^9 \text{ cm}^{-2} \text{ s}^{-1}$ neutron flux and $t_i = 1$ h irradiation time. In addition to the 1 h irradiation time the $R(t_i)$ values have been determined for $t_i = 10$ min and $t_i = \infty$ conditions (Bödy and Csikai 1987). An analysis of these data has indicated that the use of (n,p), (n,2n), (n, γ), (n, α), and (n,n' γ) reactions are recommended for the determination of 22, 57, 13, 8, and 7 elements, respectively. In some cases, there are overlaps in the selected reactions and isotopes. When selecting the most suitable reactions for NAA, the possible overlapping gamma lines were considered in addition to the interfering reactions and the half-lives. The number of interfering

Pb/52.4	$^{208}\text{Pb}(n,n'\gamma)^{208}\text{Pb}$	2,614	100

gamma lines can be significantly decreased if a high-resolution detector, for example, HPGe is used.

For the estimation of the most suitable reactions in the case of complex geological samples, special attention should be paid to the cross sections, the interfering reactions, and gamma rays. These data including the neutron-induced prompt and nuclear decay gamma rays with intensities higher than 5% are summarized in IAEA 1993. Considering the high penetrating ability of fast neutrons and high-energy gamma rays, the neutron-induced reactions listed in ► Table 36.9 are recommended for the observation and identification of concealed objects (illicit drugs, explosives, and landmines).

Radiochemistry and Radiopharmaceutical Chemistry in Life Sciences

37 Introduction to the Fourth Volume

For the first time, a *Handbook of Nuclear Chemistry* systematically and comprehensively acknowledges the various aspects of radiopharmaceutical chemistry. It thus reflects the significant progress that has been made over the last decades leading to the establishment of an independent field of modern science. The development of radiopharmaceutical chemistry was, nevertheless, a century-long route. It is paved by persons, their ideas and scientific results, being of historical dimensions.

It all began with the discovery of the phenomenon of radioactivity (1903 Nobel prize to H. Becquerel, M. and P. Curie for *the discovery of spontaneous radioactivity... and researches on the radiation phenomena...*). Next in that row were I. Curie and F. Joliot (1935 Nobel prize for *... their synthesis of new radioactive elements...*). Their utilization of nuclear reactions to create artificial radionuclides was in fact applied for the subsequently intensively used “radiopharmaceutical” radionuclides, namely ^{13}N and ^{32}P . In addition to the radionuclides isolated from naturally occurring decay chains, these artificially produced, no-carrier-added radionuclides opened the window for the oncoming tracer concept: The tracer principle applied to biology adopted radionuclides and labeled compounds at a nano-molar scale for the investigation of physiological processes in vivo (1943 Nobel prize to G. Hevesy for his work on *... the use of isotopes as tracers in the study of chemical processes...*). This pioneering application of radioactive nuclides for biochemistry and physiology provided the first insights into the dynamics of reactions in living systems.

In 1938, the experimental and theoretical cognition of nuclear fission by O. Hahn and F. Strassmann, and the theoretical explanation by L. Meitner and O. R. Frisch (1944 Nobel Prize to O. Hahn for *... discovery of the fission of heavy elements...*) made our last century the Uranium century. Radiopharmaceutical chemistry, interestingly, has made a significant and exclusively peaceful profit from this nuclear phenomenon, as the fission of uranium today provides an unrenounceable resource of radionuclides applied in nuclear medicine diagnosis and therapy. The uranium fission product ^{131}I , for example, became a key radionuclide in the 1950s, when R. S. Yalow and S. A. Berson developed the approach of radioimmunoassay for quantitative in vitro analysis of physiological and biochemical processes (1977 Nobel prize to R. S. Yalow for *... the development of radioimmunoassays...*).

The experience in hot atom chemistry, and the bridging of radiochemistry with organic chemistry, for example, further facilitated the production and use of radionuclides and labeled compounds adequate for diagnostic and therapeutic application in vivo. This part of the route of radiopharmaceutical chemistry was accompanied not only by sciences like mathematics, physics, and biology, but also by industry and technology, providing the necessary equipment such as detectors and tomographs, reactors, and cyclotrons. In fact, radiopharmaceutical chemistry shows itself as an excellent example of modern interdisciplinarity in today's world of science and technology. Isn't it breathtaking, that hundreds of thousands of diagnostic procedures are performed every year, with a variety of tracers labeled with $^{99\text{m}}\text{Tc}$, a radioisotope of an element, absolutely non-relevant to our biological nature? Or that a naturally

nonexisting ^{18}F -labeled derivative of glucose is routinely used for the quantification of glucose metabolism of the human brain, the heart and of tumors?

Over the last years, national and international societies of radiopharmaceutical chemistry have been founded. Dedicated national and international journals are devoted to various aspects of radiopharmacy and radiopharmacology. A large number of national and international meetings, symposia, and conferences find the attention of thousands of participants from radiochemistry, radiopharmacy, radiopharmacology and nuclear medicine, attracting particular attention by the new generation of scientists.

Today, radiopharmaceuticals do belong to the standard instrumentation of nuclear medicine in particular, and medicine in general, both in the context of diagnosis and therapy. Parallel to the application of radiopharmaceuticals in hospitals, radiopharmaceutical chemistry demonstrates its capability to contribute to the industrial development of new drugs. Furthermore, radiopharmacy is adding its value to fundamental biochemical and medicinal research. A main focus will be on its unique contribution to brain research, probably the most exciting area of research of this new century.

This Volume 4 of the *Handbook of Nuclear Chemistry* covers the *Radiochemistry and Radiopharmaceutical Chemistry in Life Sciences*. It starts with the radionuclides themselves, that is, their production directly at reactors and cyclotrons or indirectly via radionuclide generator systems. For selected radionuclides, dedicated chapters follow on their individual labeling chemistry and on the correspondingly labeled compounds, the focus being on in vivo application. It begins with the most relevant isotopes used for PET such as ^{11}C or ^{18}F , and for SPECT such as radioiodine and $^{99\text{m}}\text{Tc}$. Other metallic radionuclides are summarized in a separate chapter. The increasing significance of therapeutic applications required a specific discussion. A few other topics might have been covered, such as radiopharmacology or the synthesis of ^{14}C and tritium compounds as the most important representatives of the many labeled compounds used for in vitro application. For the latter aspect, the reader is referred to a recent comprehensive book on “*Preparation of compounds labeled with Tritium and Carbon-14*” by R. Voges, J. R. Heys and T. Moenius, Wiley, Weinheim, Germany, 2009, or comprehensive reviews such as, for example, K. E. MacCarthy, *Recent advances in the design and synthesis of carbon-14 labeled pharmaceuticals from small molecule precursors*, Current Pharmaceutical Design 6, 1057–1083, 2000; M. Saljoughian and P. G. Williams, *Recent developments in tritium incorporation for radiotracer studies*, Current Pharmaceutical Design 6, 1029–1056, 2000; and M. Saljoughian, *Synthetic tritium labeling: reagents and methodologies*, Synthesis, 13, 1781–1800, 2002.

This Volume of the *Handbook of Nuclear Chemistry* reflects the state-of-the-art of radiopharmaceutical chemistry and its own intellectual, apparative, methodological, and logistical structure. With deep routes in basic nuclear chemistry, a solid tribe in hot atom and radio chemistry, with many fruitful trees in radiopharmaceutical chemistry, there are, finally, beautiful leaves and flowers in nuclear medicine and pharmaceutical research. Radiopharmaceutical chemistry is ready today to meet the requirements and challenges of modern life sciences. It will thus continuously contribute to the progress in the understanding of the molecular function of the human body, to the development of new drugs, and will provide in parallel a very strong benefit for patient care.

Abstract: The therapeutic use of radionuclides in nuclear medicine, oncology, and cardiology is the most rapidly growing use of medical radionuclides. Since most therapeutic radionuclides are neutron rich and decay by β^- emission, they are reactor-produced. This chapter deals mainly with production approaches with neutrons. Neutron interactions with matter, neutron transmission and activation rates, and neutron spectra of nuclear reactors are discussed in some detail. Further, a short discussion of the neutron-energy dependence of cross sections, reaction rates in thermal reactors, cross section measurements and flux monitoring, and general equations governing the reactor production of radionuclides are presented. Finally, the chapter is concluded by providing a number of examples encompassing the various possible reaction routes for the production of a number of medical radionuclides in a reactor.

38.1 Introduction

The majority of radioactive nuclides (radionuclides) are man-made, created by transforming a stable nuclide into an unstable state by irradiation with neutrons, protons, deuterons, alphas, gammas, or other nuclear particles. The source of these particles may be a radionuclide, a nuclear reactor, or a particle accelerator (Van de Graaff, cyclotron, linac, etc.). The tremendous variety of radionuclides discovered in this manner has given rise to many applications in physics, chemistry, biology, and, of course, medicine. The production of those medically useful radionuclides created by exposure to neutrons in a nuclear reactor is discussed in this chapter.

Soon after World War II, the importance of the peaceful use of nuclear reactors for the production of radionuclides for biological research and clinical applications was foreseen. The Graphite Reactors at the Oak Ridge National Laboratory (ORNL) and Brookhaven National Laboratory (BNL) were the first full-scale operating reactor prototypes and were put to use immediately to investigate production of a variety of radionuclides. Carbon-14 was the first reactor-produced radionuclide for clinical use in nuclear medicine, and was produced at ORNL in 1946 for use at the Barnard Free Skin and Cancer Hospital in St. Louis, Missouri. In the first decade following World War II, a variety of reactor-produced radionuclides were distributed for research through the ORNL Radionuclide Development Center and BNL Hot Laboratory Division. This early work, which has been reviewed in a number of publications (see, e.g., Bizzell 1966), included production of carbon-14 and phosphorus-32 and radioisotopes of iodine (^{130}I , ^{131}I , etc.), which rapidly became invaluable tools for application in modern biological research.

Beginning in the 1950–1960s there was also an intensive period of research on *radionuclide generator systems* utilizing reactor-produced parent nuclides (Winsche et al. 1951; Richards 1966a, b; Subramanian 1976). The first strontium-90/yttrium-90 generator and most importantly, the molybdenum-99/technetium-99m ($^{99}\text{Mo}/^{99\text{m}}\text{Tc}$) generator system were developed at BNL (Tucker et al. 1958; Richards 1966c) and marked the beginning of a new era in nuclear medicine. With the availability of generator systems, local production facilities were no longer central factors in providing short-lived radionuclides for clinical use. After a period of evaluation, the utility of the “moly generator” was realized and the $^{99}\text{Mo}/^{99\text{m}}\text{Tc}$ technology was transferred from BNL to industry. Since this early work, $^{99\text{m}}\text{Tc}$ has continued to be the “work horse” for clinical nuclear medicine, and is presently used in approximately 75% of all nuclear medicine procedures. Recent studies have estimated that the annual sale of $^{99}\text{Mo}/^{99\text{m}}\text{Tc}$ generators and associated “kits” for the preparation of various tissue-specific agents exceeds \$200 million in the USA, but the finished radiopharmaceuticals containing $^{99\text{m}}\text{Tc}$ are worth at

least tenfold more. In addition to the $^{99}\text{Mo}/^{99\text{m}}\text{Tc}$ generator system, a variety of other reactor-produced radionuclides, such as ^{131}I , continue to play an important role both in clinical nuclear medicine and in radiopharmaceutical and biological research.

This chapter describes radionuclide production approaches with neutrons. Neutron interactions with matter, neutron transmission and activation rates, and neutron spectra of nuclear reactors are discussed in some detail. Further, a short discussion of the neutron energy dependence of cross sections, reaction rates in thermal reactors, cross section measurements and flux monitoring, and general equations governing the reactor production of radionuclides are presented. Topics such as targetry, chemical processing, and required facilities are only briefly discussed. Finally, the chapter is concluded by providing a number of examples encompassing the various possible reaction routes for the production of a number of medical radionuclides in a reactor.

38.2 Nuclear Reactions

See also [▶ Chap. 3 in Vol. 1.](#)

38.2.1 Types of Nuclear Reactions

Many processes can occur when a neutron strikes an atom. Neutrons carry no charge and their interaction with electrons is negligible, but when an incident neutron comes close enough to the very small atomic nucleus to transfer some kinetic energy to the nucleus as a whole, the nucleus moves but has no internal excitation. This process is called *nuclear elastic scattering* and may be visualized as billiard balls colliding. The energy of nuclear motion eventually dissipates as heat.

More typically, the neutron may be absorbed by the target nucleus to form a new heavier nucleus, sometimes very briefly. The highly excited intermediate nucleus can nearly instantaneously deexcite in several ways. It can emit electromagnetic radiation in the form of γ -rays. These γ -rays are called “prompt” to distinguish this mechanism from γ -ray emission following radioactive decay. This process is called *radiative neutron capture*. If the nuclear excitation energy is concentrated on a few nucleons (i.e., neutrons and protons), either by direct collision with the incident particle or by statistical processes, nucleons can be ejected. If the total excitation energy of the intermediate state is greater than the binding energy of nucleons within the nucleus, nucleon emission is favored. If not, simple prompt γ -ray emission returns the new isotope nucleus to a more stable state. This process of conversion of the original nucleus into a new one is a nuclear reaction, and the residual nucleus is the reaction product. The process in which the reaction product is radioactive is the subject of this chapter.

38.2.2 Nuclear Reaction Models

Initial approaches to understanding reaction phenomena considered the incident particle to be scattered by the nucleus as a whole. Similar to scattering and attenuation of light by a crystal ball, this model was first named the “cloudy crystal ball” and is now known as *the optical model* (reviewed in Hodgson 1967). It represents the reaction process as the interaction of an incident

particle with a potential energy well. It has been successful in calculating elastic scattering results and total reaction probabilities. The optical model is, however, poor in predicting nuclear deexcitation processes or reaction product yields.

An early model useful for radionuclide production reactions was the *compound nucleus model*, introduced by Niels Bohr (1936). An incident particle encountering a nucleus can be absorbed, distributing its kinetic energy and binding energy randomly throughout the nucleus and becoming indistinguishable from other nucleons. The resulting “compound” nucleus is excited and nucleons exchange energy rapidly through many collisions. Due to random statistical fluctuation in energy exchanged in these collisions, enough energy may be concentrated on a nucleon, or a small cluster of nucleons, to cause it to be ejected. Since it is improbable for the total excitation energy to be concentrated on a single nucleon, there may be sequential emission of several particles (protons, neutrons, deuterons, alpha particles), each carrying a fraction of the excitation energy. These emission modes do not proceed with equal probability, since the electrostatic barrier reduces the likelihood of emission of a charged particle compared to a neutron. This process is similar to that of molecules escaping from the surface of a hot liquid and is called nucleon “evaporation.” Thus, the compound nucleus model views the nuclear reaction as two independent steps, projectile capture followed by nucleon evaporation.

A special mode of nuclear deexcitation in the region of high atomic numbers is fission (see ► Chap. 4 in Vol. 1 for more detail). In *spontaneous fission*, the mutual electrostatic repulsion between protons of a very heavy nucleus can overcome the Coulomb barrier and cause the separation of a heavy nucleus into two lighter positively charged fragments, usually of unequal mass. There are over 60 nuclides known which fission spontaneously. For particle-induced fission, the bombarding particle supplies enough energy to overcome the barrier. In particular, thermal neutron fission of ^{235}U has had great significance for society. The 200 MeV energy release per ^{235}U atom and liberation of an excess of neutrons made possible the development of both the atomic bomb and the nuclear reactor (see ► Chap. 57 in Vol. 6 for details). Over 75 useful radionuclides are produced in this manner and are called *fission products*. Many of these can be separated and purified for medical, industrial, and research applications. Of interest for nuclear medicine are the light fragments resulting from induced fission, especially the radionuclides ^{99}Mo , ^{131}I , and ^{133}Xe .

The production of ^{99}Mo is of paramount importance to nuclear medicine. Molybdenum-99 is not directly used, but serves as the parent radionuclide for the daughter $^{99\text{m}}\text{Tc}$, now used diagnostically in dozens of radiopharmaceuticals. Iodine-131 is widely used to treat thyroid cancer and hyperactive thyroid conditions. Production of both of these nuclides is discussed in some detail in ► Sect. 38.8. Xenon-133 is used for studies of pulmonary ventilation and sometimes for cerebral blood perfusion.

38.2.3 Energy Considerations in Nuclear Reactions

Nuclear reactions, like chemical reactions, release or absorb energy. This energy accounts for the difference in mass of reactants and products and is called the reaction “**Q value**.” Energy is related to mass by Einstein’s famous formula $E = mc^2$, where c is the speed of light in vacuum. Since c is large, a small change in mass equals a large amount of energy. The energy changes in nuclear reactions millions of times greater than in chemical reactions. If the summed reactant mass is greater than the summed product mass, Q is positive and energy is released (exoergic reaction). Conversely, if the product masses are greater, the reaction is endoergic ($-Q$) and

kinetic energy from the incident particle must be supplied to drive the reaction. For example, the production of ^{67}Cu by the neutron capture of ^{67}Zn can be written as

Frequently, the *mass excess* (also called *mass defect*) is used to calculate Q . The mass excess, defined as the difference between the total atomic mass and mass number, $\Delta = M - A$, has been tabulated for all nuclei (Firestone et al. 1996, see also [Sect. 11.6 in the Appendix of Vol. 1](#)). Thus

$$\begin{aligned}\Delta(^{67}\text{Zn}) + \Delta(n) &= \Delta(^{67}\text{Cu}) + \Delta(p) + Q, \\ (-67.877) + (8.071) &= (-67.300) + (7.289) + Q, \\ Q &= 0.205 \text{ MeV, an exoergic reaction.}\end{aligned}$$

However, conservation of momentum requires that some of the incident particles' kinetic energy be transferred to the products and is not available to drive the reaction. For an exoergic reaction ($Q > 0$) such as the above reaction, there is no threshold condition. However, for an endoergic reaction requiring external energy, the minimum or “*threshold*” energy is always higher than the Q value by the factor $(M_t + M_p)/M_t$ where M_t and M_p are the target and projectile atomic masses, respectively.

For charged particle-induced reactions, in addition, the projectile has to have sufficient energy to overcome the *Coulomb barrier*. For a projectile of positive charge Z_2e and radius R_2 , the height of Coulomb barrier V around a nucleus of charge Z_1e and radius R_1 can be estimated as the energy of the Coulomb repulsion, $V = Z_1Z_2e^2/(R_1 + R_2)$, when the two particles are just in contact. Obviously, uncharged neutrons are not affected by the Coulomb barrier of the nucleus. However, there is a Coulomb barrier for charged particles leaving a nucleus during deexcitation even if the reaction was caused by an incident neutron. Therefore, these particles must have substantial energy to penetrate or overcome the barrier and are emitted with considerable kinetic energy (generally > 1 MeV). The Coulomb barrier for a particle of positive charge Z_2e leaving a nucleus of charge Z_1e is $V = Z_1Z_2e^2/r$, where $R_1 < r < (R_1 + R_2)$, and for a first approximation r is typically taken as $1.2 R_1$. Taking the nuclear radius as $1.5 \times 10^{-13} \text{ A}^{1/3} \text{ cm}$ (see [Chap. 2 in Vol. 1](#)), e as $1.602 \times 10^{-19} \text{ C}$ ($1 \text{ C}^2 \text{ cm}^{-1} = 5.61 \times 10^{24} \text{ MeV}$), the barrier height for a proton leaving ^{67}Cu has a value of about 5.5 MeV. Correcting this value to conserve momentum, a proton must have at least $1.02 \times 5.5 = 5.6 \text{ MeV}$ kinetic energy to exit the ^{67}Cu nucleus. Since the energetic threshold for this reaction is 0.21 MeV, the neutron entering the ^{67}Zn nucleus has to provide additional energy. There exists, however, a finite probability for tunneling through the barrier by lower-energy particles, but this probability drops rapidly as the energy of the particle decreases. As shown in [Fig. 38.1](#), when neutron energy is $\sim 6 \text{ MeV}$, the cross section for the above reaction drops to one hundredth of its peak value.

38.3 Main Production Approaches with Neutrons

[Table 38.1](#) lists some examples of reactor-produced radionuclides important to nuclear medicine. There are three general reaction types used: neutron radiative capture (n, γ); neutron capture followed by particle emission, e.g., (n, n'), (n, p), and (n, α); and fission (n, f). The radionuclides in [Table 38.1](#) are arranged in order of mass numbers.

The most widely used route is the (n, γ) reaction with thermal neutrons. The advantage of this production process is its simplicity and high yield. It is straightforward in that, in many

■ Fig. 38.1

$^{67}\text{Zn}(n,p)^{67}\text{Cu}$ cross sections. Data points are from CSISRS (2003); the curve is a cubic polynomial fit of the data

cases, elemental targets may be used and no chemical separation of target and product is required (or possible). Since cross sections tend to be higher than for most other reaction types, yields are generally good. The primary disadvantage of this reaction also relates to the fact that the radioactive product cannot be chemically separated from the target. Thus stable atoms dilute the radioactive atoms and the specific activity will be much lower than that of “carrier-free” radionuclides. Radioimpurities may arise from (n,γ) reactions on other isotopic forms of the target or chemical impurities in the target. The use of isotopically enriched targets can minimize production of impurities and improve yield, but often at high cost. Nevertheless, enriched targets are essential if the natural abundance of the target nuclide is low and significant impurities are produced.

In selected cases, there is a technique that can be utilized to improve the specific activity of (n,γ) -produced radionuclides. This method is known as the *Szilard–Chalmers process* (Szilard and Chalmers 1934). The Szilard–Chalmers process depends upon the fact that, following neutron absorption, prompt γ -rays are emitted, which may cause nuclear recoil and subsequent molecular bond disruption. This excitation sometimes leaves the resulting hot atom in a chemical state different from that of unreacted atoms, which makes it chemically separable. This separated fraction is relatively “enriched” in radioactive atoms and has a specific activity higher than that of the rest of the target.

The enrichment factor (E) is the ratio of specific activity of the recoiled fraction to that of the bulk irradiated target. The target in this case must be a compound that is thermally stable and resistant to radiolytic decomposition by fast neutrons and γ -rays. For example, the Szilard–Chalmers effect has been utilized with tetraphenyl tin to improve the specific activity of $^{117\text{m}}\text{Sn}$ (Mausner et al. 1992). This process can have large enrichment factors in a low flux, but the enrichment factor generally declines in a high flux due to accumulated radiation damage to the target molecule. Therefore, the Szilard–Chalmers effect is often not practiced in modern high flux reactors.

Table 38.1

Examples of reactor-produced radionuclides of current interest to nuclear medicine

Radionuclide ($T_{1/2}$)	Production	Reaction cross section (b) ^a	
		σ	I_0
⁶⁴ Cu (12.7 h)	⁶³ Cu(n,γ)	4.50 ± 0.02	4.97 ± 0.08
⁶⁷ Cu (2.6 days)	⁶⁷ Zn(n,p)	Fast neutrons: (1.07 ± 0.11) × 10 ⁻³ b	
⁹⁰ Y (64.00 h)	⁹⁰ Sr(β ⁻ , 28.79 a)	N/A	N/A
	⁸⁹ Y(n,γ)	1.28 ± 0.02	1.0 ± 0.1
	⁹⁰ Zr(n,p)	Fast neutrons: 0.175 × 10 ⁻³ c	
⁹⁹ Mo (66 h)	²³⁵ U(n,f) (6.07%)	582.6 ± 1.1	144 ± 6
	⁹⁸ Mo(n,γ)	0.13 ± 0.06	6.9 ± 0.3
¹⁰³ Pd (16.99 days)	¹⁰² Pd(n,γ)	3.4 ± 0.3	10.0 ± 2.0
^{114m} In (49.51 h)	¹¹³ In(n,γ)	8.1 ± 0.8	220 ± 15
^{117m} Sn (14.0 days)	¹¹⁶ Sn(n,γ)	(5.8 ± 1.2) × 10 ⁻³ d	(3.50 ± 0.53) × 10 ⁻¹ d
	¹¹⁷ Sn(n,n')	Epithermal neutrons: (2.22 ± 0.16) × 10 ⁻¹ d	
¹²⁵ I (59.4 days)	¹²⁴ Xe(n,γ) ¹²⁵ Xe(β ⁻ , 16.9 h)	165 ± 20	(3.6 ± 0.7) × 10 ³
¹³¹ I (8.02 days)	²³⁵ U(n,f) (2.89%)	582.6 ± 1.1	144 ± 6
	¹³⁰ Te(n,γ) ^{131g} Te(β ⁻ , 25.0 min)	0.27 ± 0.06	0.46 ± 0.05
¹⁵³ Sm (46.28 h)	¹⁵² Sm(n,γ)	206 ± 6	2,970 ± 100

Another situation occurs as a result of an (n,γ) reaction, in which an intermediate radionuclide decays to the product of interest. This route is followed to make ^{125}I , for example, with the $^{124}\text{Xe}(n,\gamma)^{125}\text{Xe} \xrightarrow{\beta^-} ^{125}\text{I}$ process. The neutron capture product ^{125}Xe beta decays to ^{125}I with a 16.9 h half-life. Because the final product can be chemically separated from the target, specific activity may approach the theoretical value for the pure radionuclide. Obviously, the use of high chemical purity targets and processing reagents is necessary to avoid introducing stable nuclides of the same element as the product. In the ^{125}I example, this means that both the target and reagents should be free of stable iodine. It is also usually desirable to use an enriched target to minimize the coproduction of long-lived or stable isotopes with the desired product. For example, irradiation of ^{124}Xe containing a few percent of ^{126}Xe (0.09% natural abundance) will result in production of stable ^{127}I through the decay of ^{127}Xe , and hence result in lower specific activity of the ^{125}I product. In this case, since target and product are chemically separable, it is possible and may be worthwhile to recover the enriched target material for reuse.

At somewhat higher energies, *neutron inelastic scattering* can be used to produce metastable nuclei. Inelastic scattering is a process in which the emitted particle is the same as the captured particle, but there is loss of kinetic energy in the system, which appears as excitation energy in the product nucleus. In the case of neutron inelastic scattering, it has been shown that the cross section of the $^AZ(n,n')^{Am}Z$ reaction (where the atomic number Z stands for the chemical symbol of the element) is, in some cases, substantially higher than the cross section for the $^{(A-1)}Z(n,\gamma)^{Am}Z$ route (Mausner et al. 1985). For the cases of ^{117m}Sn , ^{119m}Sn , and ^{195m}Pt , the magnitude of gain in the cross section has been shown to compensate for the relatively lower fast neutron flux from a well-moderated fission spectrum in the typical irradiation location of most research reactors (Mirzadeh et al. 1997).

A few useful radionuclides are produced with fast neutrons by (n,p) reactions (e.g., ^{35}S , ^{47}Sc , ^{64}Cu , ^{67}Cu), or by indirect reactions, such as that used for production of ^{18}F . The (n,p) process shares many features with the (n,γ) reaction followed by beta decay process described above, since the target and product are chemically separable. The indirect mechanism involves the use of an outgoing particle from an initial nuclear reaction to cause a second reaction in another target nucleus. Thus the neutron irradiation of ^6Li creates a triton ($^3\text{H}^+$) with sufficient energy to react with a neighboring ^{16}O nucleus (in Li_2CO_3) to form ^{18}F . The product is separable from the target(s).

Neutron-induced fission of ^{235}U creates fission products with atomic numbers ranging predominantly from $Z = 30$ – 66 . The mass distribution of radioactive products from fission of ^{235}U peaks at about mass 100 and mass 140. For the purpose of radionuclide production, targets containing about 25 grams of highly enriched ^{235}U are irradiated and then chemically processed. Fuel rods also contain large amounts of ^{235}U and its fission products, but are not processed for their radionuclide content. Given the large numbers of radionuclides created by the fission process, the chemical procedures to recover the radionuclides of interest may be quite involved. The most important medical radionuclides produced by fission are ^{131}I , ^{133}Xe , and, of course, ^{99}Mo . The special role of ^{99}Mo and its daughter ^{99m}Tc in nuclear medicine must be underscored.

38.3.1 Neutron Interactions with Matter

Due to the fact that a neutron carries no net electrical charge and there is no Coulomb repulsion to hinder its interaction with nuclei, a neutron is able to cross the nuclear boundary

even when moving at very low velocity. Consequently, neutrons of an extremely wide energy range are able to interact with nuclei, and the energy region over which neutrons cause nuclear interactions is much wider than it is for charged particles such as protons. As the neutron's energy increases, its de Broglie wavelength decreases (see ▶ Eq. (38.2)), and at the lowest energy, its wavelength is much larger than the distance between atoms in ordinary matter (see ▶ Chap. 29 in Vol. 3). At the upper energy, neutron wavelength becomes much smaller than the size of the nucleus, eventually reaching a size about the range of nuclear forces. At low energy or long wavelengths, the optical properties of neutrons predominate – resulting in refraction and reflection of neutrons in ordinary matter. The particle characteristics of neutrons become more dominant as neutron energy increases. In this energy range, neutrons can be considered as projectiles colliding with the individual particles that make up the nuclei. The similarity of cross sections for fast neutrons from nuclide to nuclide and the gentle change with energy is a direct result of the fact that for short wavelengths the particle aspects of the neutrons are dominant.

The *cross section* is a measure of the probability of interaction of neutrons with matter. It is measured in units of area, given in “barns” ($1 \text{ barn} = 10^{-28} \text{ m}^2$). The numerical magnitudes of cross sections vary from millions of barns (megabarns) down to millionths of barns (microbarns). The simple concept of cross section in terms of area is applicable to many situations, and in this elementary sense, the cross section is the πR^2 target area displayed by the nucleus to an approaching neutron on a plane perpendicular to the neutron motion. The cross section, however, varies inversely with the velocity of the neutron, whereas the actual size of the nucleus is not dependent on the velocity of the incoming neutron. In classical mechanics, this concept can be explained as decreased residence time near the nuclei as neutron velocity increases and therefore the reaction probability becomes smaller. A better description requires a quantum and wave mechanical analysis of cross sections (Evans 1955). Note that a slow neutron has a longer wavelength than a fast neutron and the reaction probability increases with increasing particle wavelength.

The cross section related to the probability that a neutron will interact with a nucleus regardless of what happens after the collision is called the *total cross section*, being equal to the total probability of all interactions. The total cross section can be subdivided into *partial cross sections*, each equal to the probability of a particular event following the collision of the neutron with the nucleus. For instance, the neutron may collide elastically, it may be captured by the nucleus followed by emission of γ -radiation, it may emerge from the nucleus with its energy decreased (inelastic scattering), or it may cause the nucleus to emit perhaps a proton or an alpha particle or, for several heavy nuclei, it may even cause the nucleus to split (i.e., to fission). The sum of the partial cross sections of course is equal to the total cross section.

The number of interactions taking place per unit time when N_t nuclei with the same total cross section σ_t are bombarded by neutrons of density n (concentration is defined as the number of neutrons per cm^3) and velocity v (cm s^{-1}) is given by

$$N_t n v \sigma_t = N_t \phi \sigma_t \quad (38.1)$$

interactions per second, assuming that N_t is small enough so that the nuclei do not change the neutron density appreciably. The product of neutron density n and velocity v is the neutron flux density, ϕ , or, as is more often called, the *neutron flux*. Thus, a unit cross section gives one interaction per second when a unit neutron flux is incident on a single nucleus. Note in ▶ Eq. (38.1) that the interaction rate depends on the total number of nuclei, N_t , rather than on the number of nuclei per cm^2 , N' . In this model, a target consisting of N_t nuclei is submerged in

a pool of neutrons having a flux of ϕ neutrons per second per unit area. Alternatively, one may consider a case where a beam of neutrons with intensity f per second are incident on a target with a surface density of N' nuclei per unit area.

For high-energy neutrons (for which the wavelength corresponds to the neutron's size), the cross section is about equal to the geometrical cross section of the nucleus itself. For a nucleus of radius R , the geometrical cross section is πR^2 , about $3 \times 10^{-24} \text{ cm}^2$ (3 barns) for a heavy nucleus. Although the total cross section for fast neutrons is typically of the order of a few barns, the partial cross sections may differ greatly from element to element. At lower neutron energy, where the neutron wavelength is larger than the nucleus, the situation becomes much more complicated, as the wave properties begin to emerge. When the neutron wavelength is much larger than the nucleus, the interaction probability is given by the size of the neutron, $\pi\lambda^2$ (where λ is the reduced wavelength, $\lambda/2\pi$) rather than the size of the nucleus, πR^2 . For nonrelativistic velocities (such as those available from nuclear reactors), the neutron wavelength is given by

$$\lambda = \frac{h}{mv} = \frac{h}{\sqrt{2mE}} = 2.86 \times 10^{-9} E^{-1/2} \text{ cm} = 0.286 E^{-1/2} \text{ \AA} \quad (38.2)$$

where h is Planck's constant ($\sim 6.626 \times 10^{-34} \text{ J s}$), m is the neutron mass, mv is the momentum of the neutron, and E is the neutron energy measured in eV. For example, the wavelength of a neutron having 1 eV of energy is $2.86 \times 10^{-9} \text{ cm}$ ($\lambda = 4.6 \times 10^{-10} \text{ cm}$), several hundred times larger than a typical nuclear radius. The total cross section for slow neutrons ($<1 \text{ eV}$) is, however, much smaller than $\pi\lambda^2$. The reason for the low cross section values and the rapid variations in energy is that the wave properties of the neutron necessitate a wave-mechanical treatment of the nuclear interaction and the results are not at all what one would expect from a classical view of an object with a cross section of $\pi\lambda^2$ colliding with an area of πR^2 . In addition, the variation in cross section from nuclide to nuclide is very large.

Typically, a cross section is identified with a process as it is manifested experimentally, such as the radiative capture cross section (detection of capture γ -rays), activation cross section (radioactivity of end product), cross section of compound nucleus formation, reaction cross section, etc. The total cross section, which is the sum of all the partial cross sections, represents all the interaction processes that may result from the collision of a neutron with an atom. At lower energies, where the neutron waves scattered by different atoms interfere, the observed scattering cross section may strongly depend on the physical state of the material, for example, whether it is crystalline or liquid. The *scattering cross section* refers to all processes in which the only particle emitted in the interaction is a neutron. When the energy of the emitted neutron is identical with the incoming neutron energy, the scattering is elastic scattering, and in the case that the energy changes it is inelastic scattering. Inelastic scattering is a process in which energy is lost by the neutron and emitted as γ -radiation. The *activation cross section* refers to interactions which were measured by the resulting radioactivity of the nucleus formed. The activation cross section usually is the same as the capture cross section, but activation can sometimes be the result of reactions other than neutron capture, such as the (n,p) and (n,α) reactions. Note that neutron capture can result in a stable nucleus which has a zero activation cross section. The *fission cross section* refers to the case where the heaviest nuclei undergo fission after colliding with neutrons.

In general, below about 0.003 eV, the total neutron cross section rises with decreasing energy; this rising cross section may be a combination of inelastic lattice vibration scattering and simple neutron capture. Above the neutron diffraction region, $\sim 0.03 \text{ eV}$, the cross section

■ Fig. 38.2

Total neutron cross section of ^{197}Au (plot of evaluated nuclear data file)

decreases very slowly with increasing neutron energy due to the capture cross section (although small at this point but still not negligible). An example of a material with a very large neutron capture cross section is ^{197}Au (see ► Fig. 38.2). Here, the capture cross section is so large that it dominates the total cross section.

For neutrons at specific energies, usually in the range of 1–100 eV kinetic energy, some nuclei show very large cross sections, much larger than predicted by the πR^2 geometric cross section area of the target nucleus. This situation can be explained as being due to enhanced neutron capture because the neutron energy exactly matches that of discrete energy levels in the compound nucleus. This phenomenon is called *resonance capture*. Each of the resonances represents an excitation of the compound nucleus to a discrete energy level formed after addition of a neutron to the nucleus. For various atomic masses, resonances become important at different energies. For very heavy elements, the resonances are so closely spaced that they are not distinguishable even in the region of thermal neutrons (~ 0.02 eV). For light elements, on the other hand, such as beryllium and carbon, the resonances are so widely spaced that they are usually not seen until neutron energies of several MeV.

As the neutron energy further increases the resonances seem to disappear (► Fig. 38.2). This effect occurs because the width of the levels increases with increasing neutron energy and eventually attains a value equal to the spacing between levels and at even higher energies it reaches a continuum. Because of the merging of levels, the properties of the neutron cross sections in the continuum region become much simpler and cross sections become relatively smooth with a slow variation with energy; this continuum is known as the *unresolved resonance region*. The energy region where individual resonances have become completely merged occurs at different neutron energies depending on atomic mass. For the lightest elements, resonances occur for neutrons of several MeV, whereas for the heaviest elements individual resonances vanish at energies above about 100 keV. Further, the energy at which resonances merge decreases with increasing atomic mass, with the exception of heavy nuclei containing magic numbers of neutrons which behave as if they were much lighter nuclei.

38.3.2 Neutron Transmission and Activation Rates

The interaction of neutrons with electrons is very weak and therefore primary ionization of atoms by neutrons is negligible. Highly energetic neutrons lose large amounts of energy in inelastic collisions, especially with heavier nuclei. After slowing to intermediate energies, this process is ineffective due to decreasing cross sections of inelastic reactions and most additional slowing proceeds by many successive elastic, “billiard ball” collisions with nuclei. Because of conservation of momentum, a neutron of energy E_0 gives up no more energy than $4AE_0/(A+1)^2$ to the recoil nucleus, where A is the mass number of the target. Clearly, the lighter the nucleus with which a neutron collides, the greater the fraction of its energy that can be lost in a single elastic collision. Thus, hydrogen-containing matter, such as water or paraffin, is most effective at slowing neutrons. Eventually after many collisions, a thermal neutron in a hydrogenous material will be captured by a proton to form a deuteron. For these reasons, shielding for high-energy neutrons usually has layers of steel, graphite, and then water (or paraffin).

The net effect of all these slowing down processes is an exponential attenuation. The rate of transmission of monoenergetic neutrons as they pass through matter is given by

$$\phi_x = \phi_0 e^{-N_t \sigma_t x} \quad (38.3)$$

where ϕ_0 is the incident neutron flux, ϕ_x the flux at thickness x , N_t the number of nuclei per cm^3 , and σ_t the total cross section. The transmission T is defined as ϕ_x/ϕ_0 or $\exp(-N_t \sigma_t x)$. In practice, however, a strictly monoenergetic flux is never available, but the exponential law will still hold if the cross section remains constant over the neutron energy range in the beam. If the cross section changes over the energy range, the transmission will be exponential for each individual energy value, but the net effect will be a gradual depletion of the neutrons of higher cross section.

For a very thin sample, where the neutron transmission is near unity, [Eq. \(38.3\)](#) becomes simply

$$1 - T = N \sigma_t x \quad (38.4)$$

and the term $(1 - T)/Nx$ gives the average total cross section, weighted according to the neutron distribution. In this case, the incident distribution is undistorted by the sample and all atoms in the sample “see” neutrons having a Maxwell distribution of velocities provided that the neutron “gas” is in thermal equilibrium. Subtracting the scattering cross section, which is typically small and rather independent of energy, from the total cross section gives the average absorption cross section for a Maxwell distribution. If the absorption cross section of the sample varies with the reciprocal of neutron velocity, i.e., $\sigma_a = k/v$, one obtains (see [Eq. \(38.15\)](#)):

$$\bar{\sigma}_a = \frac{\int \sigma_a v^2 e^{-\left(\frac{v}{v_{mp}}\right)^2} dv}{\int v^2 e^{-\left(\frac{v}{v_{mp}}\right)^2} dv} = \frac{2}{\sqrt{\pi}} \frac{k}{v_{mp}}, \quad (38.5)$$

$$\bar{\sigma}_a = \frac{2}{\sqrt{\pi}} \sigma_{v_{mp}} = 1.128 \sigma_{v_{mp}}, \quad (38.6)$$

where v_{mp} is the “mode” of the Maxwell distribution of velocities, or the most probable velocity of the “thermalized” neutrons (see [Chap. 9 in Vol. 1](#)).

► Equation (38.6) shows that for a material with $\sigma_a = k/v$, the average cross section obtained from a thin sample transmission measurement (with scattering subtracted) is 1.128 times the cross section at the most probable velocity (it will be shown after ► Eq. (38.14) that $v_{mp} = 2,200 \text{ m s}^{-1}$ for room temperature). The statistical accuracy of the cross section obtained from a thin sample (transmission near unity) is typically very poor, and in practice thick samples must be used, resulting in an increase in distortion of Maxwell distribution. Thus, the cross section measured for a thick sample will be an average over a neutron distribution that changes shape as it penetrates through the absorber.

In the case of reaction or activation rates, for example, when calculating the amount of radioactivity produced in a sample, the fundamental equation is again described by a simple first order differential equation

$$\frac{dN}{dt} = N_t \phi \sigma_{act} \quad (38.7)$$

where dN/dt is the activation rate (per second), N is the number of activated atoms, and N_t is the total number of target atoms that are in the neutron flux ϕ . The activation cross section, σ_{act} , refers to the production of the particular radioactive species regardless of the reaction involved, which is usually (n, γ) but may be (n, p) , (n, α) , $(n, 2n)$, (n, f) , or other reactions. Although the flux in ► Eq. (38.7) is the number of neutrons that cross $1 \text{ cm}^2/\text{s}$, the activation rate, dN/dt , depends on the total number of atoms present, N_t , regardless of the volume over which they are distributed. ► Equation (38.7) holds for isotropic fluxes, such as those within a reactor, equally well. For non-monoenergetic neutrons, an appropriate average flux is used. In practice, whereas the transmission equation, ► Eq. (38.3), often holds extremely well, the activation equation, ► Eq. (38.7), holds only for small targets. The reason is that the neutron flux is often disturbed by the sample itself, the atoms in the center not receiving the full neutron flux. This effect is called *self-absorption* (*self-shielding*), and it is generally difficult to estimate. For accurate measurement of a cross section by reaction rate, it is necessary to use small enough samples so that self-absorption is negligible, but in the case of radionuclide production, for example, a balance must be maintained between self-absorption (which lowers the specific activity, $\lambda N/N_t$) and sample size, which increases the total activity produced, λN , see ► Eq. (38.7).

When the product of activation is radioactive with a *decay constant* of λ ($\lambda = \ln 2/T_{1/2}$), the decay of the activated atoms will decrease the rate of formation as time progresses, and the rate of change of the number of produced or activated atoms per unit time (s) is given by

$$\frac{dN}{dt} = N_t \phi \sigma_{act} - \lambda N. \quad (38.8)$$

The decay rate of activated atoms, or *activity* ($A = \lambda N$), at any time during or at the end of irradiation is then obtained by integration of ► Eq. (38.8):

$$A = \lambda N = N_t \phi \sigma_{act} (1 - e^{-\lambda t}). \quad (38.9)$$

(See also ► Sect. 7.4.2 in Chap. 7, Vol. 1.) In practice, a finite time θ would elapse between the end of irradiation and the actual counting. The activity is then given by

$$A = \lambda N = N_t \phi \sigma_{act} (1 - e^{-\lambda t}) e^{-\lambda \theta}. \quad (38.10)$$

If $\lambda t \ll 1$, for example, because the product nuclei are very long-lived (the decay constant is small, and therefore, the number of activated atoms that have decayed during time t is

negligible), or because the irradiation time is very short, then the term $(1 - e^{-\lambda t}) \approx \lambda t$, and hence [Eq. \(38.9\)](#) will reduce to

$$N = N_t \phi \sigma_{\text{act}} t \quad (38.11)$$

that is, the activation will increase linearly with time. If, however, $\lambda t \gg 1$, for example, because the activated atoms have a relatively large decay constant (very short half-life), or because the irradiation time is very long, the number of activated atoms will increase until the rate of radioactive decay is equal to the rate of formation, $dN/dt = 0$, or the term $(1 - e^{-\lambda t}) \approx 1$, and hence

$$\lambda N = N_t \phi \sigma_{\text{act}}. \quad (38.12)$$

The number of activated atoms will then remain constant on further irradiation. This equilibrium activity is called the saturation activity, and the term $(1 - e^{-\lambda t})$ is called the *saturation factor*. In practice, most irradiations for radionuclide production are for a duration approximately equal to the half-life of the desired product, or half-saturation. As doubling the irradiation time increases the amount of product only by 50%, it becomes increasingly inefficient to irradiate any longer.

The formation of a typical radionuclide, ^{90}Y , as a function of irradiation time is shown in [Fig. 38.3](#). In this example, ^{90}Y is produced by neutron irradiation of an ^{89}Y target, $^{89}\text{Y} (n, \gamma) ^{90}\text{Y}$, at a neutron flux of $1 \times 10^{14} \text{ n cm}^{-2} \text{ s}^{-1}$. The corresponding activation cross section is 1.3 b (Mughabghab et al. 1981).

The half-life of ^{90}Y is 64.00 h and its decay constant is $1.083 \times 10^{-2} \text{ h}^{-1}$. As seen, one half of the final activity is produced in one half-life, three-quarters in two half-lives, etc., and the activity formed approaches the saturation limit of 23.9 mCi mg^{-1} (884 MBq/mg) of ^{89}Y very slowly after the first few half-lives. The general equations governing reactor production of radionuclides are discussed in [Sect. 38.3.7](#).

Fig. 38.3

Reactor production of ^{90}Y via neutron capture by ^{89}Y in a neutron flux of $1 \times 10^{14} \text{ n cm}^{-2} \text{ s}^{-1}$

38.3.3 Neutron Spectrum of Nuclear Reactors

The neutron spectrum from a nuclear reactor is typically divided into two components: a thermalized flux with a Maxwell energy distribution and an epithermal flux whose energy distribution is proportional to the reciprocal of the neutron energy, $1/E_n$.

38.3.3.1 Thermal Neutrons

In most nuclear reactors, *thermal neutrons*, that is, neutrons that are in thermal equilibrium with matter at room temperature, have by far the highest density. The velocity of thermal neutrons exhibits a Maxwell distribution known from the kinetic theory of gases, where the number of neutrons having a velocity between v and $v + dv$ is expressed in terms of the total number of neutrons, temperature, and velocity. Neutron density per unit velocity is given by the equation

$$\frac{dn_v}{dv} = 4\pi \left(\frac{m}{2\pi kT} \right)^{\frac{3}{2}} v^2 e^{\frac{-mv^2}{2kT}} \quad (38.13)$$

where m is the neutron mass, T is the absolute temperature, k is Boltzmann's constant, and n is the total number of neutrons per unit volume, obtained by summing dn_v over all possible velocities between zero and infinity

$$n = \int_{v=0}^{v=\infty} dn_v. \quad (38.14)$$

The most probable velocity, v_{mp} , corresponding to the maximum of the probability curve, as determined from the condition $dn_v/dv = 0$, is $(2kT/m)^{1/2}$. At room temperature (293.6 K), the most probable velocity is $2,200 \text{ m s}^{-1}$, corresponding to a kinetic energy of 0.0253 eV and a wavelength of 1.8 \AA ($1.8 \times 10^{-10} \text{ m}$), which is about the magnitude of interatomic spacing in matter.

By substituting v_{mp}^2 for $(2kT/m)$, [Eq. \(38.13\)](#) can be rewritten as

$$\frac{dn_v}{dv} = \frac{4}{\sqrt{\pi}} \frac{v^2}{v_{mp}^3} e^{\frac{-v^2}{v_{mp}^2}}. \quad (38.15)$$

The table of thermal cross sections typically includes values for monoenergetic neutrons, 0.0253 eV (velocity of $2,200 \text{ m s}^{-1}$) rather than cross sections averaged over the entire Maxwell distribution. In practice, however, thermal cross sections are measured or used, not for a single velocity, but for the entire Maxwell distribution of velocities present in a nuclear reactor. In the design of nuclear reactors, for example, neutron flux and cross sections appropriate for the entire Maxwell distribution are of course essential, whereas the monoenergetic neutron flux (ϕ_0) and the corresponding cross sections are most useful in computations of production rates of radionuclides in nuclear reactors.

The velocity distribution, expressed by [Eqs. \(38.13\)](#) and [\(38.15\)](#), can be converted to an energy distribution by replacing v and dv with E and dE , using the energy and velocity relationship ($E = mv^2/2$). Therefore, neutron density per unit energy is given by

$$\frac{dn_E}{dE} = 2\pi n \left(\frac{1}{\pi kT} \right)^{\frac{3}{2}} e^{\frac{-E}{kT}} \sqrt{E} \quad (38.16)$$

■ Fig. 38.4

Thermal neutron density with a Maxwell energy distribution as a function of neutron energy

where dn_E is the number of neutrons per unit volume (neutron density) having kinetic energy between E and $E + dE$. From ► Eq. (38.16), the most probable energy, E_{mp} , corresponding to the maximum of the probability curve, $dn_E/dE = 0$, is $kT/2$, and at room temperature (293.6 K) $E_{mp} = 0.0126$ eV. Note that there is a difference between E_{mp} and the energy corresponding to v_{mp} that was shown to be 0.0253 eV (this energy is equal to kT). This difference is due to the fact that E_{mp} and v_{mp} are derived from different distribution functions given in ► Eqs. (38.13) and ► (38.16), respectively.

► Figure 38.4 shows a graph of the Maxwell energy distributions (► Eq. (38.16)) of thermal neutrons at two temperatures. The normalized functions shown represent the probability of finding a neutron having an energy between E and $E + dE$. (Being normalized means that the area under the curves shown in ► Fig. 38.4 is equal to unity for both temperatures.) ► Equation (38.16) also indicates that an increase in temperature broadens the energy distribution and shifts the maximum to a higher value of E .

The energy-dependent *thermal neutron flux* can be obtained by substituting $n(E)$ from ► Eq. (38.16) in the following equation

$$\begin{aligned}\phi_{th}(E) &= \frac{dn_E}{dE} \frac{dv_E}{dE} \\ &= n(E) v(E) \\ &= \frac{2\pi n}{(\pi kT)^{3/2}} \left(\frac{2}{m}\right)^{1/2} e^{-\frac{E}{kT}}\end{aligned}\quad (38.17)$$

where m is the neutron mass and $v(E) = (2E/m)^{1/2}$.

The one-group thermal flux, ϕ_{th} , is then given by

$$\phi_{th} = \int_{th} \phi_{th}(E) dE \quad (38.18)$$

where the integration is carried out over the thermal range, normally defined to be from zero to about $5kT \approx 0.1$ eV (Lamarsh and Baratta 2001). Since $\phi_{th}(E)$ decreases to very small values above $5kT$, the integration can be taken to infinity and by combining Eqs. (38.17) and (38.18) one obtains

$$\phi_{th}(E) = \frac{2\pi n}{(\pi kT)^{3/2}} \left(\frac{2}{m}\right)^{1/2} \int_0^\infty e^{-\frac{E}{kT}} dE = \frac{2n}{\sqrt{\pi}} \left(\frac{2kT}{m}\right)^{1/2}. \quad (38.19)$$

Let E_T , the neutron energy corresponding to kT , and its associated velocity v_T be defined as $E_T = kT = mv_T^2/2$. The numerical values of E_T and v_T are $8.617 T \times 10^{-5}$ eV and $1.284 T \times 10^4$ cm s⁻¹, respectively, and T is in kelvin. It is important to emphasize that ϕ_{th} is the total neutron flux in the thermal region and is computed by the integral in Eq. (38.19), whereas ϕ_0 (equal to nv_0 , where n is the Maxwellian neutron density, Eq. (38.16)) is a pseudo flux assuming that all the neutrons are monoenergetic with $E_0 = 0.0253$ eV (i.e., that all the neutrons have a velocity equal to the most probable velocity at $T = 20^\circ\text{C}$, namely $\sim 2,200$ m s⁻¹). As defined, ϕ_0 yields the actual reaction rate when used with the corresponding cross section at E_0 , σ_0 , which is typically given in cross section tables.

From rearranging Eq. (38.19), one can deduce the following useful relations between ϕ_{th} and ϕ_0

$$\frac{\phi_{th}}{\phi_0} = \frac{2}{\sqrt{\pi}} \left(\frac{v_T}{v_0}\right) = \frac{2}{\sqrt{\pi}} \left(\frac{T}{T_0}\right)^{1/2}. \quad (38.20)$$

Therefore, the ratio of ϕ_{th} to ϕ_0 depends on the temperature T . If T is equal to the standard temperature T_0 (i.e., 293.60 K), then $\phi_{th}/\phi_0 = 2\pi^{-1/2} \approx 1.128$. In other words, ϕ_{th} will exceed ϕ_0 by 12.8%. In many nuclear reactors where the neutron temperature is considerably higher than 20°C , the difference between ϕ_{th} and ϕ_0 will be significant.

38.3.3.2 Epithermal Neutrons and Resonances

Epithermal neutrons are distinguished from thermal neutrons because many neutron resonances are observed in the epithermal neutron region. Since there is an overlap of the thermal and epithermal fluxes, it is not possible to divide all Maxwellian neutrons from those in the $1/E_n$ distribution. It is generally assumed that the resonance flux goes to zero when the neutron energy is five times kT (Westcott 1955). Because of the rapid decrease in the Maxwellian function with energy (see Eq. (38.16) and Fig. 38.4), only $\sim 1.7\%$ of the Maxwellian neutrons are more energetic than $5kT$. In practice, an effective cutoff determined by the neutron spectrum transmitted through a cadmium filter is used. Such a cutoff varies with the thickness of the filter and for thin filters it also varies with the Maxwellian to epithermal flux ratio.

Epithermal flux is generally assumed to be proportional to $1/E$. In the absence of leakage and epithermal absorption, the $1/E$ assumption is expected to hold rather well for moderators containing hydrogen (e.g., H₂O) from 1 to 2 MeV (the average neutron energies from fission) down to about 1 eV where the scattering cross section is energy-dependent. In practice, however, where the leakage and epithermal absorption in a reactor may not be negligible or where moderators other than water may be used, deviation from $1/E$ dependence would be expected. In general, the resonance flux energy dependence must change at least somewhat

with reactor type and size and with geometrical configuration. Also, at positions very near to any large concentrated absorber, there must be some flux depression at energies close to its resonances.

38.3.3.3 Fast Neutrons

In classifying neutrons according to energy, *fast neutrons* range in energy from about 0.1–20 MeV. From the standpoint of the type of interaction observed, fast neutrons are usually distinguished from epithermal (or resonance) neutrons, because for the great majority of nuclei, apart from the lightest ones, individual resonances are not observed above ~ 100 keV. This distinction between fast and resonance neutrons is extremely vague because the energy at which resonances are observed is a function of the particular resolving power used in the measurement and of the atomic mass of the nucleus investigated. However, one can consider “fast” neutrons as those above 100 keV, for which individual resonances are not resolved in “typical” nuclei. Another criterion appropriate to fast neutrons is the angular momentum involved in collisions. For the majority of the resonances, $l = 0$ is the only angular momentum involved. However, for neutrons with energy in the MeV range, higher angular momentum is transferred to the compound nucleus. The restriction of $l = 0$ for slow neutrons is of course a restriction that changes somewhat with atomic mass. Interactions involving higher angular momentum (e.g., $l = 1$) become appreciable only when the neutron wavelength is equal to the nuclear radius. For example, $l = 1$ collisions become important at about 2.5 MeV for $A = 10$ and 0.33 MeV for $A \approx 200$ (Hughes 1957).

38.3.4 Neutron Energy Dependence of Cross Sections

Many nuclides have absorption cross sections that vary with neutron velocity or energy in the thermal range essentially as $1/v$ or $(1/E)^{1/2}$. All neutron absorption can be formulated in terms of resonance absorption at certain distinct energies. In the region of neutron resonances, the cross section is determined by a few parameters, which are properties of the nuclear excitation level represented by the neutron resonances. These parameters include neutron and radiation widths and the spin of the compound nucleus. In the resonance region, in which only elastic scattering and capture reactions are possible, neutron energies are sufficiently low such that only $l = 0$ interactions are involved, resulting in isotropic angular distributions. The analytical form of a neutron resonance is given by the dispersion formula, analogous to the formula for optical dispersion or for a resonating electrical circuit. The dispersion, or Breit–Wigner formula, gives the cross section as a function of energy, taking into account the contributions of many levels at the same time (Lamarsh and Baratta 2001). When the magnitude of the resonance energy E_r is much greater than the neutron kinetic energy E , the cross section varies essentially as $(1/E)^{1/2}$ or as $1/v$. This situation occurs in the thermal range when the nearest resonance is at an energy considerably higher than thermal. Boron is a good example of an element whose absorption cross section follows the $1/v$ law over a wide energy range, i.e., from about 0.001 to a few hundred eV. The treatment of cross section data when deviating from the $1/v$ law is more complicated (Lamarsh and Baratta 2001). The cross section varies very rapidly with neutron energy and just above a resonance, the radiative capture cross section $\sigma_\gamma(E)$ varies as the inverse square of the difference $E - E_r$. At higher energies, where $E \gg E_r$,

$\sigma_\gamma(E)$ depends on $E^{5/2}$. Because of this great variation of cross section with neutron energy above a resonance, it is possible to use absorbers with resonances near the thermal region to effectively absorb all neutrons below a particular energy E_c and transmit all those above E_c (e.g., cadmium of a given thickness). The cutoff, however, is not very sharp and depends on the thickness of the absorber. For infinitely dilute or very small samples the *resonance integrals* are given by Stoughton and Halperin (1959) as

$$I = \int \sigma(E) \frac{dE}{E} \quad (38.21)$$

where the integration is typically taken from $5kT$ or E_c (the effective cadmium cutoff) to ~ 1 MeV. In order to judge the latter value, note that the average energy of prompt fission neutrons is ~ 2 MeV, while the most probable energy is ~ 0.75 MeV (Lamarsh and Baratta 2001). The lower limit is rather important whereas the upper limit is not. Thus,

$$I_0 = \int_{E_c}^{1 \text{ MeV}} \frac{\sigma(E)}{E} dE \quad \text{and} \quad I'_0 = \int_{5kT}^{1 \text{ MeV}} \frac{\sigma(E)}{E} dE. \quad (38.22)$$

The integrals I_0 and I'_0 are called the *infinitely dilute resonance integrals*, the difference depending on the lower limit of integration (i.e., E_c or $5kT$, respectively). Further, in [Eq. \(38.22\)](#), it is assumed that the resonance flux varies as $1/E$ down to $5kT$ and vanishes below this energy. Values of I_0 and I'_0 can be computed by putting values for $\sigma(E)$ (obtained from the Breit–Wigner formula) into [Eq. \(38.22\)](#) and carrying out the integration from E_c (or $5kT$) to infinity over a particular resonance. Further simplification can also be made by letting $E = E_r$ and then integrating from zero to infinity. The resultant value

$$I_0 \approx I'_0 \approx \frac{\pi \sigma_{r\gamma} \Gamma}{2E_r} \quad (38.23)$$

provides a reasonable approximation of the integral under the $\sigma_\gamma(E)$ vs. $\ln E$ curve at and near a particular resonance “r,” if E_r is a few electron volts or higher (so that the width of the resonance is small compared to the energy E_r). In [Eq. \(38.23\)](#), $\sigma_{r\gamma}$ is the maximum value of the radiative capture cross section at a particular resonance energy E_r and Γ is the total width of the resonance at half the maximum. The contributions to I_0 from all known resonances must then be added to obtain the resonance integral.

An alternative method of determining the resonance integral is to integrate numerically under the cross section vs. $\ln E$ curve if experimental data are available. In principle, the numerical integration should provide a more accurate result.

38.3.5 Reaction Rates in Thermal Reactors

Earlier, it was shown that the reaction rate per atom is the product of the monoenergetic neutron flux and the corresponding cross section. In a reactor, both neutron flux and cross section are functions of neutron energy. The general equation describing the reaction rate is given by

$$R = \int \frac{d(\phi\sigma)}{dE} dE. \quad (38.24)$$

It is customary, however, to divide Eq. (38.24) into two parts (two-group theory), representing the contributions from thermal and epithermal neutrons.

$$R = \int_0^{5kT} \frac{d(\phi\sigma)}{dE} dE + \int_{5kT}^{\infty} \frac{d(\phi\sigma)}{dE} dE. \quad (38.25)$$

As stated earlier, in a reactor, the general reaction rate per atom for a substance at high dilution or very small amount includes contribution from both thermal and epithermal interactions and is given by

$$R = \phi_0 \sigma_0 + \phi_{ep} I_0 \quad (38.26)$$

where I_0 was defined in Eq. (38.22). In Eq. (38.21) it is assumed that the resonance flux varies as $1/E$ down to $5kT$ and vanishes below this energy, and that the Maxwellian neutrons follow Eqs. (38.13), (38.15), and (38.16) at all energies. Thus, just above $5kT$ the flux consists of two components. Typically, Eq. (38.26) is written as

$$R = \phi_0 \left(\sigma_0 + \frac{1}{r} I_0 \right) = \phi_0 \sigma_{eff} \quad (38.27)$$

where r is the $2,200 \text{ m s}^{-1}$ to epithermal flux ratio, ϕ_0/ϕ_{ep} , and σ_{eff} is the effective cross section. It is obvious that the exact values of r and σ_{eff} depend on the position of the sample within a given reactor. If the sample is present in substantial amounts, then the resonance integral may need to be corrected for self-absorption of neutrons at the resonance energies.

An obvious advantage can be seen to using ϕ_0 since cross section tables usually give a list of σ_0 values and since it is necessary to know the temperature corresponding to the Maxwellian velocity in order to determine other fluxes and cross sections. Often, the neutron temperature is not known, and this lack of knowledge is reflected in the uncertainty in any cross section measurement if the species in question is not known to obey the $1/v$ law in and near the thermal region. In any case, it is customary to measure the thermal flux with a $1/v$ absorber of known cross section and then to use the same flux for determining an unknown cross section.

38.3.6 Cross Section Measurements and Flux Monitoring

The problem of measuring an unknown cross section by the activation method involves the determination of ϕ_0 and ϕ_{ep} by choosing appropriate monitors and the determination of R . Usually, the amount of product formed is determined by its radioactivity or by its mass using a mass-spectrometer, making a correction for any product destroyed by other reactions (spontaneous decay or neutron transmutation). A usual procedure is to measure both ϕ_0 and ϕ_{ep} by irradiating one or more monitors with and without cadmium metal covers; or irradiations can be carried out simultaneously at two or more different positions in a reactor if the relations between the fluxes are known. The *cadmium ratio* (CR), that is, the rate of product formed without cadmium to that with a cadmium cover is given by the equation

$$CR = \frac{N(\phi_0 \sigma_0 + \phi_{ep} I_0)}{N \phi_{ep} I_0} = \frac{\phi_0 \sigma_0}{\phi_{ep} I_0} + 1. \quad (38.28)$$

Using one or more monitors of known σ_0 and I_0 , both ϕ_0 and ϕ_{ep} can be determined. If an unknown is irradiated with the monitors, the values of CR for the monitors are measured and used to determine $r = \phi_0/\phi_{ep}$ from [Eq. \(38.28\)](#), the value of CR for the unknown is measured, and then σ_0 and I_0 can be calculated using [Eqs. \(38.26\)](#) and [Eq. \(38.28\)](#).

Cadmium shows an effective cutoff of a few tenths of an eV depending on the Cd thickness and flux spectra. Gadolinium with a resonance at 0.03 eV has also been used; with proper thickness an effective cutoff at about 0.10 eV should be obtainable.

It is important to use different monitors for the resonance and thermal fluxes, and to use positions of different ϕ_0/ϕ_{ep} ratios because the error in the measured ϕ_0/ϕ_{ep} ratio is proportional to $(CR - 1)$ (see [Eq. \(38.28\)](#)) and this error will be greater under conditions where CR is near unity (in which case $CR - 1$ approaches 0). In order to minimize the errors in the experimental value of ϕ_0/ϕ_{ep} , it is necessary to use a resonance flux monitor with a large I_0/σ_0 ratio to minimize thermal absorption and the significance of uncertainties in the cutoff. On the other hand, a nearly $1/v$ thermal flux monitor should be used to minimize epithermal absorption. This source of error may also be reduced by irradiating in a position with a higher thermal to resonance flux ratio. For an unknown sample of low cadmium ratio, only this latter approach will minimize the uncertainty. It has been customary to report values of σ_0 and I_0 rather than σ_{th} and I_0' since σ_0 and I_0 are obtained directly from experimental data. These distinctions have not usually been made clear, probably because the difference between σ_0 and σ_{th} is small for a $1/v$ absorber.

38.3.7 General Equations Governing the Reactor Production of Radionuclides

In general, the number of nuclei produced in a nuclear reactor can have several sources and several routes that reduce the number. Direct formation by nuclear reaction and decay of a parent nuclide formed in the bombardment increase the desired product and radioactive decay of the product decreases it. Also, neutron absorption by the radioactive product, transforming it into another species may be significant. An important example of this situation occurs in the production of the medically useful gold isotopes ^{198}Au and ^{199}Au (Hainfeld et al. 1990). The cross section for thermal neutron capture in ^{197}Au is a respectable 98.7 b, but the neutron capture cross section of ^{198}Au going to ^{199}Au is a huge 25,000 b.

Here, it is considered an m -member reaction chain of nuclei undergoing nuclear transmutation by neutron capture in addition to spontaneous decay:

where c_{n-1} is the formation rate constant (λ_{n-1} or $\sigma_{n-1}\phi$) of the n th species from the $(n-1)$ th species and is independent of time or nuclide concentrations.

It is well known that the decay and growth of genetically related species follow a set of simultaneous linear differential equations where the transmutation rate of nuclei of species n , dN_n/dt ($N_n \equiv$ concentration of species n), is governed by a constant coefficient, λ_n , referred to as the “spontaneous radioactive decay constant” (Rutherford et al. 1930). Note that λ_n is independent of time and the concentration of nuclei.

The solution of the corresponding differential equations has been known for a long time, and is referred to as the *Bateman equations* (Bateman 1910, see in [Chap. 7, Vol. 1](#)).

Later Robinson (1949) generalized the equations to include transmutation of nuclei by neutron capture in addition to spontaneous decay. The governing factor in this case is $\sigma_n \phi$, where σ_n is the neutron capture cross section (cm^2) of species n , and ϕ is the neutron flux ($\text{n cm}^{-2} \text{s}^{-1}$).

The exact solution to the corresponding differential equations, the Bateman equations, can be written as

$$N_n(t) = \left(\prod_{i=1}^{n-1} c_i \right) N_1^0 \sum_{i=1}^n a_i e^{-A_i t} \quad (38.29)$$

$$a_i = \prod_{j \neq i} (A_j - A_i)^{-1} \quad (j = 1, 2, \dots, n)$$

where $N_n(t)$ is the number of atoms of the n th species at time t , and N_1^0 is the number of target atoms (which includes appropriate corrections for isotopic mass and enrichment). A_n is the total depletion constant of the n th species, defined as $\lambda_n + \sigma_n \phi$ and t is the irradiation time (s).

► Equation (38.29) only allows for the initial presence of the first species in the chain, N_1^0 . A more general equation accommodating initial quantities of any members of the chain is

$$N_n(t) = \sum_{k=1}^n \left(\prod_{i=k}^{n-1} c_i \right) N_k^0 \sum_{i=k}^n a_i e^{-A_i t} \quad (38.30)$$

$$a_i = \prod_{j \neq i} (A_j - A_i)^{-1} \quad (j = k, k+1, \dots, n).$$

Chains involving more than two species result in lengthy equations that are tedious to evaluate, so computer programs are indispensable for these complex calculations. An algorithm based on the Robinson (1949) approach was used to develop the code LAURA (Mirzadeh and Walsh 1998).

As seen in ► Sect. 38.3.5, care must be taken in using appropriate values for cross sections and fluxes. Since most reported cross sections are $2,200 \text{ m s}^{-1}$ values (σ_0), the thermal flux used in production calculations must be the $2,200 \text{ m s}^{-1}$ flux (ϕ_0) rather than the Maxwellian flux (ϕ_{th}). If necessary, convert ϕ_{th} to ϕ_0 using ► Eq. (38.20). Also, the very definition of the resonance integral, I_0 , requires the use of *epithermal flux per unit lethargy* (lethargy is defined as the natural log of an arbitrary energy divided by a lower energy) rather than total epithermal flux; that is, since I_0 is defined as an integral with respect to energy, the flux used with ► Eq. (38.26) must also be expressed in terms of energy. If necessary, convert total epithermal flux to epithermal flux per unit lethargy by dividing the total epithermal flux by the natural log of the epithermal energy range, i.e., $\ln(E_{\text{upper}}/E_{\text{lower}})$. The appropriate values for cross sections, resonance integrals, and flux ratio (the ratio of $2,200 \text{ m s}^{-1}$ flux to epithermal flux per unit lethargy) can then be used to derive effective cross sections given in ► Eq. (38.27) by substituting ϕ_0 for ϕ in ► Eq. (38.29) or ► (38.30).

38.4 Targetry

Upon determining the production reaction and irradiation conditions, one must select an appropriate target material. Indeed in special cases, for example, when reaching very high specific activity or ultra high purity is the goal, the effort required in target design can be as demanding as the rest of the experiment. There are several general factors to be considered.

38.4.1 Physical and Chemical Form

Pure metals or elements are generally best. If these are not suitable due to the constraints below, favorable materials also include alloys as well as simple compounds such as oxides, carbonates, halides, etc. The form must also be compatible with postirradiation processing. Thus, easily dissolved compounds are sometimes preferable over metal targets.

38.4.2 Thermal Properties

There can be substantial sample heating during irradiation. Incident particles impart energy and some nuclear reactions are exothermic. Although thermal neutrons do not transfer much energy, fast neutrons can. Additionally, some of the energy of prompt γ -rays from (n,γ) reactions generated in the sample, fuel elements, reactor containment, and other nearby samples can be absorbed in the sample. The “gamma heating” is proportional to sample mass and can be substantial for samples in excess of a gram. Target cooling is thus essential in reactors in order to prevent target overheating and possible destruction. In addition, the target material should have good thermal conductivity and a high melting point. For these reasons, organic compounds and aqueous solutions cannot usually be used.

38.4.3 Chemical Stability

The target must not decompose at elevated temperature or evolve gases that would pressurize and rupture the containment capsule. Also, the target material should not react with the encapsulating material or cause corrosion. Finally, the sample must not be substantially decomposed by radiation damage, which is hard to predict in advance. This requirement generally excludes all organic material as a target for large-scale production of nuclides.

38.4.4 Purity

Targets with high chemical purity are often necessary to minimize radiocontaminants due to the activation of impurities. In compounds, the activation of all atoms must be considered, because partner atoms will not lead to the nuclide of interest and thus reduce yield. Sometimes, isotopically enriched material is necessary to suppress competing reactions on other naturally occurring isotopes in the target. To achieve high specific activity, the amount of the final product element in the target is crucial. For example, the Cu content of ZnO targets for ^{67}Cu production must be <0.1 ppm.

38.4.5 Encapsulation

For safety and to prevent cross-contamination, the target is almost always sealed in a primary container and sometimes in a secondary as well. The container should be leak-free and not corrode or overheat during irradiation. For reactor irradiation at low neutron flux and short periods, small plastic tubes (e.g., polypropylene) are useful as they do not activate appreciably

and are inexpensive. At higher neutron flux and longer irradiation time used for most nuclide production, samples are typically encapsulated in high-purity synthetic quartz ampoules. It should be noted that pyrex and soda glass are poor choices because of their boron and sodium content. The $^{10}\text{B}(n,\alpha)^7\text{Li}$ reaction has a large capture cross section and deposits substantial energy in the glass, while the $^{23}\text{Na}(n,\gamma)^{24}\text{Na}$ reaction causes significant activation of the capsule and subsequent handling problems from the high-energy (1,369 keV) γ -ray of ^{24}Na . In practice, it is usually advisable to use gloves when preparing a quartz capsule to minimize depositing sodium from perspiration. Some activation of ^{30}Si (3.1% natural abundance) to ^{31}Si ($T_{1/2} = 2.62$ h, $E_\gamma = 1,266$ keV (0.07%), $\sigma(^{31}\text{Si}) = 0.11$ b) is unavoidable. These quartz ampoules are often placed in aluminum or magnesium holders specific to the irradiation facility. There is some γ -activity produced in these metals, but the formation cross sections of ^{28}Al and ^{27}Mg are small ($\sigma = 0.23$ b and $\sigma = 0.039$ b, respectively) and the half-lives are short ($T_{1/2} = 2.24$ and 9.46 min, respectively).

38.4.6 Availability

The target material should be readily available commercially in high purity. The presence of elements even in trace amounts can degrade product radiopurity if they have large capture cross sections.

38.4.7 Target Transport Systems

Capability for the production of short-lived radionuclides in a nuclear reactor is another important criterion to be considered. Access to the reactor irradiation facilities during normal reactor operation allows for short irradiation periods, which are required for the production of many useful short-lived radionuclides such as ^{64}Cu , ^{67}Cu , ^{105}Rh , ^{109}Pd , ^{153}Sm , ^{166}Ho , ^{165}Dy , and ^{199}Au . These nuclides all have half-lives of about 3 days or less. Production of ^{99}Mo can also be enhanced by on-line access to the targets.

On-line access to the reactor irradiation facilities can be accomplished pneumatically, hydraulically, or mechanically by cables, tubes, or rods. Pneumatic tube facilities are typically used for irradiation of small samples in plastic or graphite capsules for accurate time intervals of a few seconds to 10 min or longer depending on the neutron or γ -heating of the facility. Pneumatic facilities are typically located in the reflector region of the reactor, and the capsule loading and unloading station is located in the experiment room of the neutron activation laboratory. Capsules are inserted into the reactor and returned to the laboratory using compressed air.

A hydraulic “rabbit” permits insertion and removal of samples while the reactor is operating. The water pressure-drops that exist in the primary coolant system are typically utilized as the driving forces for moving the capsules through the system. Normally, the heat flux at the surface of the capsule, due to neutron and/or γ -heating of the capsule and its contents, is limited. For the hydraulic tube facility at ORNL HFIR, for example, this limit is on the order of 200 kW m^{-2} per capsule. In addition, the use of materials with very high thermal neutron capture cross sections is limited such that the reactor is not subjected to a significant reactivity change during the insertion or removal of capsules.

“Thimble” mechanisms allow access to the reactor simply by attaching the irradiation capsule to the end of long aluminum tubing and lowering the capsule into the reactor and withdrawing it after the irradiation. The thimbles are fitted with a set of reentrant tubes connected to a separate cooling system that can circulate cooling water downward through the center and upward through the outer annular region of each tube. Samples can be placed in aluminum cans that are immersed in the cooling water, and thimble tubing can be used to vent the capsule, to fill it with gas in order to enhance heat transfer, and to bring out a pair of thermocouple leads, if desired.

38.5 Chemical Processing

In order to achieve high specific activity, radionuclides require chemical separation from the target material and induced radioactive byproducts.

This is not feasible for neutron capture reactions where there are only subtle differences between the chemical properties of different isotopes of the same element (see ► Chap. 15 in Vol. 2). In principle, however, a mass separator can be used for separation of isotopes of the same element (see ► Chap. 51 in Vol. 5). The standard techniques of analytic separation chemistry are used, such as chromatography, solvent extraction, distillation, and precipitation. Other techniques include electrolysis and electro-deposition, and separations based on sublimation. These processing techniques must then be adapted to the unique requirements of radiochemistry – the hazards of radiation exposure and contamination, rapid separation times in order to minimize decay losses, and the separation of essentially massless (carrier-free) amounts of product from bulk target. A great deal of effort has gone into developing processes suitable for each application. For example, solvent extraction is commonly used for purification of reactor-produced ^{191}Os in the form of OsO_4 which is trapped as perosmate in a NaOH solution (Brihaye et al. 1989). With the proper choice of conditions, ion exchange is very useful for separating carrier-free radionuclides from bulk target (mass ratio $> 10^8$) having significantly lower affinity toward the resin. This method has been particularly successful in separating transition metals from each other and from the rare earth elements. A relevant example is the separation of ^{55}Co from an Fe target (Lagunas-Solar and Jungerman 1979). Ion exchange is also most readily adaptable to remote or automated operation. It can be combined with solvent extraction for better separation factors, as was demonstrated in the case of ^{67}Cu (Dasgupta et al. 1991). More recently, many labs are moving away from the use of solvent extraction for hot cell use because of the difficulty of waste disposal of radioactive toxic organic solvents. It is also readily adaptable to remote or automated operation. High pressure liquid chromatographic (HPLC) systems in combination with cation-exchange resins have been employed for the separation of individual radiolanthanides (Dadachova et al. 1994). Some radiochemical separations can be effected by exploiting differences in volatility in selected cases. For example, ^{131}I can be separated from Te targets by dry distillation at high temperature (Evans and Stevenson 1956) or from a dissolved target (Hupf 1976). One can also distill the target away from the product, as was done to separate ^{32}P from an elemental sulfur target (Evans and Stevenson 1957; Mani and Majali 1966). Alternatively, Re and Os radioimpurities were separated from W targets by dry distillation in air (Mirzadeh et al. 2000). Occasionally, precipitation is useful for a first bulk separation or for low specific activity radionuclides, but precipitation rarely has the desired selectivity for nuclear medicine requirements. Adsorption on walls of glassware and filter paper can be troublesome, and handling precipitates under remote conditions may be difficult.

38.6 Shielded Facilities

The handling and processing of reactor- or accelerator-produced radionuclides usually has to be carried out in specially designed radiochemistry laboratories with controlled ventilation and air conditioning, shielded remote handling facilities, and radioactive waste collection and storage tanks (Mausner 1999). In most cases involving processing of reactor or cyclotron targets, radiation shielding for the personnel is required. At lower dose levels, this may be as simple as some stacked lead bricks inside a standard chemical fume hood, providing some whole body shielding, but no shielding for hands and arms. For pure beta emitters, small lucite disks mounted on tongs to shield the hands are all that is necessary. At higher levels of γ -radiation, a completely enclosed hot box or hot cell will be required. Hot cells usually have 10–20 cm of lead encased in steel panels for the walls or 50–100 cm of concrete, along with lead glass windows and master slave manipulators.

38.7 Current Requirements and Challenges

Specific activity is an important parameter since in many cases, the availability of very high specific activity or carrier-free radionuclides is required for biological applications. One example of the importance of high specific activity is the *radiolabeling* of tumor-specific antibodies or peptides for both diagnostic and therapeutic applications where only very small amounts of the radiolabeled antibodies are administered to ensure maximal uptake at the limited tumor cell surface antigen sites.

Another important need is the use of receptor-mediated radiopharmaceuticals that are potentially very important for the clinical evaluation of neurological diseases. Since the population of neurotransmitter sites is very limited, high specific activity agents are required to evaluate site-specific uptake and not saturate these binding sites with stable cold isotope.

Since the specific activity of a radionuclide produced by particle-induced reactions is a direct function of the incident particle flux, an increase in the incident particle flux results in an absolute increase in the specific activity of the product. This relationship is linear for simple reactions and nonlinear for complex reactions. It is important to note that the half-lives, production and depletion cross sections, and irradiation time are equally important. Several important radionuclides have long physical half-lives and low production cross sections requiring long irradiation periods even in the highest neutron flux available. An example in this category is tungsten-188 (half-life 69 days; parent for rhenium-188).

In addition, the increased flux not only results in higher specific activity products, but can allow utilization of smaller amounts of the enriched (expensive) target material. The limited availability of many enriched materials makes conservation or recycling mandatory.

38.8 Selected Examples

A list of reactor-produced radionuclides of current interest to nuclear medicine is given in [▶ Table 38.1](#) along with modes of production and corresponding nuclear cross sections. From this list, the production and a brief description of chemical processing of the following radionuclides will be discussed:

- Molybdenum-99 produced by fission and neutron capture reactions
- Iodine-131 produced by fission and neutron capture reactions
- Indium-114m produced by neutron capture reactions

- Lutetium-177 produced by neutron capture reactions
- Iodine-125 produced by neutron capture followed by β^- decay
- Tungsten-188 produced by double neutron capture
- Tin-117m produced by neutron inelastic scattering
- Copper-67 produced by fast neutron-induced reactions

38.8.1 Molybdenum-99 Produced by Fission and Neutron Capture Reactions

Radionuclide uses in diagnostic medicine have increased tremendously in the past several decades, and today, one-third of the annual 40–50 million diagnostic procedures in the United States are performed with radionuclides. The most widely used radionuclide in nuclear medicine is technetium-99m (^{99m}Tc , $T_{1/2} = 6.0$ h), the daughter of 66 h molybdenum-99 (^{99}Mo). Tc-99m is used in 70% of all radionuclide diagnostic procedures with an estimated 16 million medical tests per year (approximately 45,000 per day) and 4–5 billion dollars cost to patients annually in the USA.

Tc-99m decays by $>99\%$ IT to the ground state of ^{99}Tc ($T_{1/2} = 2.1 \times 10^5$ a) with emission of a 140.5 keV γ ray with probability of 89% and about 10% of all IT effects occurs via internal conversion, i.e., by the emission of a K electron of ^{99}Tc . The β^- decay of ^{99}Mo feeds to ^{99m}Tc and ^{99}Tc , 87% and 13% of the disintegrations, respectively. Because Tc does not have a stable isotope in nature, the ^{99m}Tc -specific activity (SpA) approaches $169.5 \text{ GBq } \mu\text{g}^{-1}$ ($4.58 \text{ Ci } \mu\text{g}^{-1}$, 87% of the theoretical value of $195.0 \text{ GBq } \mu\text{g}^{-1}$) in daily elution.

The common sources of ^{99}Mo are the fission of ^{235}U and neutron capture by a ^{98}Mo target (► Table 38.2):

Other reactions for the production of ^{99}Mo include $^{100}\text{Mo}(\gamma, n)^{99}\text{Mo}$, $^{96}\text{Zr}(\alpha, n)^{99}\text{Mo}$, and $^{102}\text{Ru}(n, \alpha)^{99}\text{Mo}$. It may also be possible to produce ^{99m}Tc directly by the $^{100}\text{Mo}(p, 2n)^{99m}\text{Tc}$ reaction. Over the past 40 years, several versions of a $^{99}\text{Mo}/^{99m}\text{Tc}$ generator have been developed. The most common is based on the original generator developed at Brookhaven National Laboratory (Richards 1966a, b, c; Subramanian 1976). In this system, Mo is adsorbed on alumina and separation of ^{99m}Tc is achieved by saline elution. This chromatographic generator has the advantage of being portable and simple to operate. Most commercially available generators provide a sterile vial of saline at the inlet and an evacuated rubber septum sealed vial at the outlet. As soon as the septum is penetrated by a needle on the outlet port, the saline is simply sucked through the column, carrying the nuclide with it. It provides ^{99m}Tc in high efficiency ($\sim 70\%$) and with acceptable quality. Other $^{99}\text{Mo}/^{99m}\text{Tc}$ generators in use include extraction-based and sublimation generators. A review of the latter generators can be found in Boyd (1982) and Mirzadeh and Knapp (1996); cf. also ► Chap. 40 in this Volume.

In North America, ^{99}Mo is solely available from reactors in Canada and is exclusively produced from fission of uranium-235 (^{235}U). The typical yield of fission-produced ^{99}Mo is on

■ Table 38.2

General information on fission-produced ^{99}Mo

Yield	$6.1\%, 5.25 \times 10^3 \text{ GBq g}^{-1} (142 \text{ Ci g}^{-1})$ of ^{235}U ($t_{\text{irr}} = 7 \text{ days at } \phi = 7 \times 10^{13} \text{ n cm}^{-2} \text{ s}^{-1}$)
Maximum SpA	$1.78 \times 10^4 \text{ GBq mg}^{-1} (4.8 \times 10^2 \text{ Ci mg}^{-1})$ of ^{99}Mo
Achievable SpA (at EOB)	$2.66 \times 10^4 \text{ GBq mg}^{-1} (7.2 \times 10^1 \text{ Ci mg}^{-1})$ of Mo ($t_{\text{irr}} = 7 \text{ days at } \phi = 7 \times 10^{13} \text{ n cm}^{-2} \text{ s}^{-1}$)
Required SpA (at EOB)	$37\text{--}74 \text{ GBq mg}^{-1} (1\text{--}2 \text{ Ci mg}^{-1})$
Radioisotopic purity	99.9999%
Chemical purity	99.99%
Other	For each Ci of ^{99}Mo , $3.7 \times 10^3 \text{ GBq} (100 \text{ Ci})$ of other fission products are produced.

EOB: end of bombardment, SpA: specific activity.

the order of 148–370 GBq (4–10 Ci) per g of ^{235}U irradiated for 50–200 h in a neutron flux of $1.5 \times 10^{14} \text{ n cm}^{-2} \text{ s}^{-1}$. This target consisted of 45% enriched ^{235}U in the form of U/Al alloy clad in a $0.45 \times 2 \text{ cm}$ aluminum plate (IAEA Report 2003).

Due to the logistical difficulties associated with ^{99}Mo production and distribution (i.e., short half-lives of ^{99}Mo and $^{99\text{m}}\text{Tc}$, complex chemical processing, status of reactors and processing facilities, and wide distribution of users), only 5–10% of the produced ^{99}Mo typically reaches the users. Since ^{99}Mo cannot be stockpiled, even short-term disturbances in labor situations and interruption of transport systems can have very serious consequences. Multiple production reactor shutdowns have recently impacted ^{99}Mo severely. Among the strategies being considered to replace old reactors is the use of high intensity electron linacs to irradiate a low enriched uranium target to create secondary neutrons which in turn irradiate highly enriched uranium to drive fission.

Another important issue associated with Mo production is the waste and environmental impact of fission-produced Mo. Fission waste contains several radioactive gases, thus requiring dedicated facilities, and highly enriched ^{235}U targets requiring extensive security.

An important alternative non-fission route for production of ^{99}Mo is via neutron capture by ^{98}Mo , a process that does not present any of the disadvantages listed above. A comparison of fission- and neutron-produced ^{99}Mo is given in [Table 38.3](#).

For fabrication of $^{99}\text{Mo}/^{99\text{m}}\text{Tc}$ generators, the principal issue that differentiates fission-produced ^{99}Mo from the direct neutron capture route is specific activity (SpA). Commercial manufacturers of $^{99}\text{Mo}/^{99\text{m}}\text{Tc}$ generators require a SpA of $37\text{--}74 \text{ GBq mg}^{-1} (1\text{--}2 \text{ Ci mg}^{-1})$. Fission-produced ^{99}Mo has a SpA of $\sim 2.6 \times 10^3 \text{ GBq mg}^{-1} (\sim 70 \text{ Ci mg}^{-1})$, whereas the SpA of neutron capture-produced ^{99}Mo , even in the highest available neutron flux (Oak Ridge National Laboratory High Flux Isotope Reactor hydraulic tube), is approximately $1.9\text{--}3.7 \text{ GBq mg}^{-1} (50\text{--}100 \text{ mCi mg}^{-1})$, a factor of 10–20 times lower than required for the traditional single-stage generator system.

In the most widely used generator, ^{99}Mo is loaded onto a column of alumina and $^{99\text{m}}\text{Tc}$ is eluted from the column with normal saline. The required bolus volume for the quantitative elution of $^{99\text{m}}\text{Tc}$ obviously depends on the size of the column which in turn is inversely proportional to the specific activity of ^{99}Mo . Thus the lower SpA of neutron capture-produced ^{99}Mo requires a larger alumina column, resulting in a lower activity concentration of $^{99\text{m}}\text{Tc}$.

Table 38.3
Comparison of fission and neutron-produced ⁹⁹Mo

²³⁵ U(n,f) ⁹⁹ Mo	⁹⁸ Mo(n,γ) ⁹⁹ Mo
Produces high specific activity ⁹⁹ Mo	Produces low specific activity ⁹⁹ Mo
Requires highly enriched ²³⁵ U target	Requires highly enriched ⁹⁸ Mo target
Complex chemical processing	Simple chemical processing
Requires dedicated processing facility	Requires high flux nuclear reactor
Generates high-level radioactive waste	Generates minimal waste

(Bq ml⁻¹). One approach to concentrating ^{99m}Tc is by adsorbing TcO₄⁻ on a tandem anion-exchange resin with the subsequent elution of Tc in a small volume with ethylenediamine containing SnCl₂ (Mirzadeh et al. 1998).

38.8.2 Iodine-131 Produced by Fission and Neutron Capture Reactions

Radioactive isotopes of iodine have played a major role in nuclear medicine and a great deal of work has been reported with regard to radioiodination of various biological molecules. Three isotopes of iodine that are in common use are ¹²⁵I, ¹³¹I, and ¹²³I. Two other isotopes of iodine, ¹²²I and ¹²⁴I (both positron emitters), are also of interest as sources for Positron Emission Tomography (PET).

Iodine-131 has a half-life of 8.02 days and decays with 100% β⁻ emission to stable ¹³¹Xe (99%) and to 11.8 days ^{131m}Xe (1%), with an average β⁻ particle energy of 182 keV. The decay of ¹³¹I is followed by emission of an intense γ ray at 364.5 keV (81.2%). Other γ rays include 637.0 keV (7.27%), 284.3 keV (6.06%), 80.2 keV (2.62%), and a number of weaker γ rays. The total equilibrium dose constant of ¹³¹I is 1.21 rad g μCi⁻¹ h⁻¹ or in a more SI-conforming unit 3.3 × 10⁻¹⁰ Gy kg Bq⁻¹ h⁻¹ (see Sect. 10.4.2.3 in Chap. 10). The common sources of ¹³¹I are the fission of ²³⁵U and neutron capture in a ¹³⁰Te target:

The half saturation yield of ¹³¹I from fission is ~2.2 GBq mg⁻¹ (~60 mCi mg⁻¹) of ²³⁵U at a neutron flux of 1 × 10¹⁴ n cm⁻² s⁻¹ (t_{irr} = T_{1/2} = 8 days, and ϕ₀/ϕ_{ep} = 40), with a specific activity of ~0.67 GBq μg⁻¹ (~18 mCi μg⁻¹) at EOB. The theoretical specific activity of ¹³¹I is 4.58 GBq μg⁻¹ (124 mCi μg⁻¹); however, fission-produced ¹³¹I is contaminated with stable ¹²⁷I and ¹²⁹I (T_{1/2} = 1.57 × 10⁷ a) as the fission yields leading to masses 127 and 129 are 0.157% and 0.54%, respectively, vs. 2.89% leading to mass 131. The actual ratio of ¹³¹I to ¹²⁷I and ¹²⁹I, however, will be a function of neutron flux, irradiation time, and postirradiation decay period

(the age of ^{131}I preparation). Also, fission yields for shorter-lived iodine isotopes are substantial (most importantly mass 133 with a yield of 6.70%), requiring postirradiation decay to increase the radionuclidic purity of ^{131}I (^{131}I has a half-life of 20.8 h). Similar to fission-produced ^{99}Mo , the waste and environmental impact of fission-produced ^{131}I is another important issue associated with ^{131}I production.

Production of ^{131}I by neutron irradiation of a Te target proceeds through β^- decay of 30 h $^{131\text{m}}\text{Te}$ and 2.75 days $^{131\text{g}}\text{Te}$ intermediate radionuclides. The reported reactor cross section to $^{131\text{m}}\text{Te}$ is only 20 mb, more than a factor of 10 smaller than the cross section through the ^{131}Te ground state ($^{131\text{g}}\text{Te}$) path (▶ [Table 38.1](#)). The contribution of both pathways to the theoretical yield of ^{131}I produced by neutron irradiation of a Te target (100% enriched ^{130}Te) is shown in ▶ [Fig. 38.5](#), where the yield of ^{131}I is given as a function of the irradiation time at a neutron flux of $1 \times 10^{14} \text{ n cm}^{-2} \text{ s}^{-1}$. Since the natural abundance of ^{130}Te is 33.8%, the ^{131}I produced from a natural Te target always contains ^{127}I and ^{129}I created by neutron captures by ^{126}Te and ^{128}Te having natural abundances of 19% and 32%, respectively. Similar to fission-produced ^{131}I , the specific activity of Te-produced ^{131}I not only is dependent on neutron flux, irradiation time, and ^{131}I age, but also highly depends on the degree of Te target enrichment. Reported ^{131}I yields from large natural Te metal and oxide targets (20–100 g) range from 22 to 33 GBq g^{-1} (600–890 mCi g^{-1}) of ^{130}Te irradiated for 5–21 days in a flux of $1 \times 10^{14} \text{ n cm}^{-2} \text{ s}^{-1}$ with a specific activity of $\sim 0.74 \text{ GBq } \mu\text{g}^{-1}$ ($\sim 20 \text{ mCi } \mu\text{g}^{-1}$) (IAEA-TECDOC-1340 2003). The experimental yields are 24–57% of the theoretical prediction for thin targets (▶ [Fig. 38.5](#)), with dry distillation processing producing higher yields than wet distillation.

The types of procedures that have been used for the separation of ^{131}I from irradiated U and Te targets include dry distillation methods in which molecular iodine is volatilized from the target at high temperature (600–800°C) and wet methods in which the target is dissolved in an appropriate medium and iodine is converted to the elemental form. Then free iodine is either distilled from acidic or basic solutions containing an oxidizing agent or extracted into a nonpolar solvent such as carbon tetrachloride, benzene, or toluene. In the distillation process, the iodine evolved is trapped in an alkaline Na_2SO_3 solution or on a cold finger. In the extraction process, I_2 is typically back-extracted into an alkaline Na_2SO_3 solution. Several

■ **Fig. 38.5**

Reactor production of ^{131}I via neutron capture by ^{130}Te ($\phi_0 = 1 \times 10^{14} \text{ n cm}^{-2} \text{ s}^{-1}$, $\phi_0/\phi_{\text{ep}} = 40$)

oxidation–reduction cycles can then be carried out to achieve the desired purity. These general procedures, often with some variation, are still in common use. Oxidation of iodide to elemental form can readily be accomplished by hydrogen peroxide in an HCl medium. An excellent review of the radiochemistry of iodine can be found in Kahn and Kleinberg (1977), and a review of the properties of radioiodine in relation to its use in labeled compounds can be found in Baldwin (1986), and more recently in Finn (2003).

38.8.3 Indium-114m Produced by Neutron Capture Reactions

In-114m is a potential radionuclide for radioimmunotherapy and a potential source for brachytherapy. In-114m has rather complicated nuclear decay properties. It decays with a half-life of 49.51 days with 96.75% isomeric transition to 72 s ^{114}In ground state (3.25% electron capture to ^{114}Cd). In-114g, in turn, decays by 99.5% β^- emission with an end-point energy of 2 MeV to stable ^{114}Sn (0.5% electron capture to ^{114}Cd). In other words, the high energy β^- particle is actually emitted from the very short-lived daughter of $^{114\text{m}}\text{In}$ which is in secular equilibrium with its parent at all times:

The average β^- particle energy of In-114m is 773 keV with a total equilibrium dose constant of $1.66 \text{ rad g } \mu\text{Ci}^{-1} \text{ h}^{-1}$. Isomeric transition of $^{114\text{m}}\text{In}$ to $^{114\text{g}}\text{In}$ takes place with emission of a 190 keV γ -ray with a probability of only 16%; thus, greater than 80% of this transition is internally converted resulting in emission of very short-range secondary electrons and X-rays (approximately 20 keV). A 3.25% branch of the decay of $^{114\text{m}}\text{In}$ takes place by electron capture to stable ^{114}Cd . Although the secondary electrons do not contribute to the total dose in sealed sources used in brachytherapy, they will contribute to the total dose in other potential unsealed applications of this nuclide. Indeed, if $^{114\text{m}}\text{In}$ can be localized on or near a tumor cell nucleus by an appropriate carrier molecule, the high LET Auger electrons can be very effective in cancer therapy, cf. also [Chap. 46](#) in this Volume.

A homogeneous alloy of indium and aluminum can be made up to ~ 17 mass percent indium thus enabling manufacturing of very fine wires of In/Al (~ 0.3 mm in diameter) which are required for brachytherapy sources. Further, In-114m can be produced with high specific activity ($0.37\text{--}3.7 \text{ GBq mg}^{-1}$, $10\text{--}100 \text{ mCi mg}^{-1}$) in a moderate-size nuclear reactor within a short period of time. Alternative production routes via charged particle-induced reactions are also feasible. From the point of view of energy deposition, activation level, manufacturing, and shelf life, the $^{114\text{m}}\text{In}/\text{Al}$ source has advantages relative to other brachytherapy sources.

High-energy beta particle emitters have been recognized as suitable sources for brachytherapy, but to date, only a few radionuclides, ^{90}Y , ^{186}Re , ^{32}P , and ^{188}W ([Table 38.4](#)), have been tried. While ^{90}Y and ^{186}Re suffer from lack of shelf life, ^{188}W has the disadvantage of low specific activity (requiring long irradiation time), manufacturing difficulty associated with the high melting point of tungsten, and availability (only a few nuclear reactors in the world are

■ Table 38.4

High energy β^- particle emitters used in brachytherapy

Radionuclide	$T_{1/2}$	E_{β}^{av} (keV)	$E_{\gamma}(I_{\gamma})$ (keV) (%)	Equilibrium dose constant (rad g μCi^{-1} h $^{-1}$)
^{32}P	14.3 days	695	–	1.48
^{90}Y	64.0 h	934	–	1.99
$^{114\text{m}}\text{In}/^{114\text{g}}\text{In}$	49.51 days/71.9 s	773	190 (16)	1.66
^{186}Re	3.72 days	350	Many low	0.776
$^{188}\text{W}/^{188}\text{Re}$	69.78 days/17.0 h	764	155 (15)	1.78

capable of producing ^{188}W with useful specific activity). Manufacturing ^{32}P sources is time consuming and expensive because of the nonmetallic character of phosphorous.

In contrast, In/Al alloy wire can be manufactured relatively simply employing enriched ^{113}In and the wire can be activated to contain the desired level of radioactivity in a moderate-size nuclear reactor within a rather short irradiation time. The thermal neutron cross section and epithermal resonance integral for $^{113}\text{In}(n,\gamma)^{114\text{m}}\text{In}$ are 8.1 b and 220 b, respectively. The expected yield of $^{114\text{m}}\text{In}$ for 1 week of irradiation at a neutron flux of 1×10^{15} n cm $^{-2}$ s $^{-1}$ is ~ 6.7 GBq mg $^{-1}$ (~ 180 mCi mg $^{-1}$) of ^{113}In . A typical seed wire, 2 cm in length, 0.03 cm in diameter, containing ~ 0.12 mg of ^{113}In (2% In), would contain ~ 0.74 GBq (~ 20 mCi) of $^{114\text{m}}\text{In}$. Experimental results are summarized in [Table 38.5](#). As seen, theoretical calculations are within a factor of 2 of experimental results.

38.8.4 Lutetium-177 Produced by Neutron Capture Reactions

Lutetium-177 (^{177}Lu), attached to biological targeting molecules such as tumor-associated antibodies and peptides, is under active investigations for radioimmunotherapy. Examples of these investigations include ^{177}Lu -labeled peptides (Kwekkeboom et al. 2001, 2005) and DOTA-TOC (Oeksuez et al. 2009) for lung tumors; and ^{177}Lu -labeled antibodies for treatment of prostate cancer (Kelly et al. 2009), for ovarian cancer (Meredith et al. 1996), RS7 for lung cancer (Stein et al. 2001), and for lymphoma (Chakraborty et al. 2008). However, for a number of years, ^{177}Lu radiolabeled receptor-binding somatostatin analogues (octreotide and lanreotide) is routinely used for the treatment of Neuroendocrine tumors constituting a heterogeneous group of tumors that frequently express cell membrane-specific peptide receptors. A review article of the topic is available (Kaltsas et al. 2005).

Lutetium-177 decays with a half-life of 6.647 days to the ground state of stable ^{177}Hf 79.4% of the time ($E_{\beta 1}^{\text{max}} = 0.498$ MeV), to the first excited state 9.0% of the time ($E_{\beta 2}^{\text{max}} = 0.385$ MeV), and to the 0.321 MeV level 11.6% of the time ($E_{\beta 3}^{\text{max}} = 0.177$ MeV). Deexcitation from the first excited state level (0.1129 MeV) provides an imageable γ -ray at 113 keV with an intensity of 6.17%. About 12% of this transition converts at the electronic shell of the Hf providing low range secondary electrons and X-rays (Mirzadeh 1995). Deexcitation from the 0.321 MeV level to the first excited state level provides a γ -ray at 208 keV (10%) suitable for deep-organ imaging. The average β energy of ^{177}Lu is 0.134 MeV and the average equilibrium dose rate constant for ^{177}Lu is estimated to be ~ 0.5 g-rad/ $\mu\text{Ci}\cdot\text{h}$ (0.1342 MeV/Bq-s) (Weber et al. 1989). Some relevant nuclear data for ^{177}Lu and $^{177\text{m}}\text{Lu}$ are given in [Table 38.6](#) (ENSDF 2009; Mughabghab 2006).

Table 38.5

Production of ^{114m}In in the ORNL-HFIR hydraulic tube irradiation facility. Irradiations were performed in hydraulic tube no. 1 at 85 MW power. The thermal neutron flux at this position is $9.0 \times 10^{14} \text{ n cm}^{-2} \text{ s}^{-1}$ with a thermal to epithermal flux ratio of ~40

^aAs the burn-up cross section of ^{114m}In is not known, a value of 2 b was used in the calculations.

Table 38.6

Nuclear data for ^{177}Lu and ^{177m}Lu

Mode of decay					Reaction cross sections (b)			
					Production		Burn-up	
Radionuclide	$t_{1/2}$	E_{β}^{av} (keV)	$E_{\gamma}(I_{\gamma})$ (keV)(%)	Mode of production	σ	I_0	σ	I_0
^{177}Lu	6.647 days	β^- (100%) $E_{\beta}^{\text{av}} = 134$	113(6.17) 208(10.36) Many low	$^{176}\text{Lu}(n,\gamma)$ $^{176}\text{Yb}(n,\gamma)^{177}\text{Yb}$ (β^- , 1.9 h)	2,017 ± 70 2.85	1,087 ± 40 6.3	1,000 ± 300 –	– –
^{177m}Lu	160.4 days	IT (21.4%) β^- (78.6%) $E_{\beta}^{\text{av}} = 40.8$	113(21.9) 208(57.4) 228(37.1) 379(29.9)	$^{176}\text{Lu}(n,\gamma)$	2.8 ± 0.7	4.7 ± 1.4	3.18 ± 0.30	–

The rather longer half-life of ^{177}Lu (6.6 days) is most suited for slow-targeting antibodies, and its lower equilibrium dose rate constant make ^{177}Lu useful for radiotherapy of soft tissues (Mirzadeh 1995; Mirzadeh et al. 1996; Ma et al. 1996). In addition, ^{177}Lu has chemical characteristics suitable for protein labeling with bifunctional chelating agents such as the eight coordinated DTPA, DTPA derivatives, or DOTA. Although Lu is the heaviest member of lanthanides, the ionic radius of Lu^{3+} is comparable to that of Y^{3+} as the result of lanthanides contraction. In coordination number 6, the ionic radius of Lu^{3+} is 89.1 pm, ~4 pm smaller than that of Y^{3+} . At 25°C and 0.1 M ionic strength, the equilibrium constant of Lu-DTPA complex (ML/M·L) is $2.51 \times 10^{22} \text{ M}^{-1}$ in comparison with $1.12 \times 10^{22} \text{ M}^{-1}$ for the Y-DTPA complex (Martel and Smith 1974).

Benefitting from a rather large thermal neutron cross section, high specific activity ^{177}Lu can be obtained directly by the $^{177}\text{Lu}(n,\gamma)$ reaction (the theoretical specific activity of ^{177}Lu is

109.94 mCi/ μg). The natural abundance of ^{176}Lu is only 2.6%, but highly enriched ^{176}Lu is available from the US DOE National Isotope Development Center and Trace Inc. (Russian-made material). Alternatively, ^{177}Lu can be obtained indirectly from β^- decay of 1.9-h ^{177}Yb , which is produced in a fission nuclear reactor via neutron capture by ^{176}Yb (Lebedev et al. 2000). Ytterbium-176 has a natural abundance of 12.7%, but highly enriched ^{176}Yb (up to 99.7%) is available. It is clear that the indirect route yields carrier-free preparations of ^{177}Lu if Lu at a trace level can be separated efficiently from bulk mg amounts of Yb target material. The indirect route produces ^{177}Lu with substantially less contamination from 160-day $^{177\text{m}}\text{Lu}$ which is unavoidably coproduced with ^{177}Lu by the $^{176}\text{Lu}(\text{n},\gamma)$ reaction. The scheme for production of ^{177}Lu in a reactor is shown below (Lederer and Shirley 1978; ENSDF 2009), and a number of reports are available on the production of ^{177}Lu either by direct or indirect route (Lebedev et al. 2000; Hashimoto et al. 2003; Pillai et al. 2003; Mikolajczak et al. 2003; Knapp et al. 2004, 2005; Dvorakova et al. 2007; Zhernosekov et al. 2008).

For 1-h irradiation of natural and 43% enriched Lu targets (as Lu_2O_3 , ~ 1 mg target) at the ORNL-HFIR (HT, position 4), the average experimental yields of ^{177}Lu are reported to be $(9.4 \pm 0.8) \times 10^4$ MBq/mg of ^{176}Lu in comparison to the theoretical yield of 6.1×10^4 MBq/mg of ^{176}Lu for an experimental to theoretical ratio of 1.5. The ratio of $^{177\text{m}}\text{Lu}/^{177}\text{Lu}$ was $(4.7 \pm 0.1) \times 10^{-3}\%$.

The theoretical yield of ^{177}Lu as a function of irradiation time is shown in [Fig. 38.6](#). From these data, it is clear that saturation will be reached within 4 days in the ORNL HT#4 or 6 with an expected yield of $\sim 1.7 \times 10^6$ MBq (~ 46 Ci)/mg of ^{176}Lu . As the $^{177\text{m}}\text{Lu}/^{177}\text{Lu}$ ratio will increase with irradiation time ([Fig. 38.6](#)), for a 4-day irradiation, the fraction of $^{177\text{m}}\text{Lu}$ at EOB is expected to be less than 0.012% (Mirzadeh 1995).

The yield from the indirect route (from decay of ^{177}Yb) is 75 ± 5 MBq/mg of ^{176}Yb (2.0 mCi/mg of ^{176}Yb) for 1 h irradiation in the HT #5 using ~ 4 mg of 96% enriched ^{176}Yb . This experimental yield is $\sim 20\%$ lower than the theoretical value (Mirzadeh 1995). In this case, calculations were performed allowing a 12-h decay period postirradiation. The theoretical yield of ^{177}Lu as a function of time is shown in [Fig. 38.7](#). As shown, the yield of ^{177}Lu will reach a saturation value of $\sim 8 \times 10^3$ MBq (217 mCi)/mg of ^{176}Yb within 21 days of irradiation in the HT#5, followed by a 12-h decay. The contribution from the decay of ^{176}Yb to the total activity of ^{177}Lu decreases rapidly as a function of irradiation time. This contribution becomes negligible ($< 1\%$) for irradiation time of more than 20 h. The yield of the indirect route is lower than the direct route by a factor of $\sim 1,300$, but the specific activity of ^{177}Lu from both routes will be roughly the same assuming that carrier-free Lu can be separated from Yb in 1 part per thousand. Separation of ^{177}Lu from macroscopic amounts of Yb (both in the lanthanide family) is not very efficient, although the procedures have been improved (Lebedev et al. 2000; Mirzadeh et al. 2004; Horwitz et al. 2005). In fact, MDS Nordion Inc. distributes ^{177}Lu produced via the “indirect” route with effective specific activity < 45 mCi mg^{-1} of lanthanides

■ Fig. 38.6

Production of ^{177}Lu from a ^{176}Lu target ($\phi_0 = 2 \times 10^{15} \text{ n cm}^{-2} \text{ s}^{-1}$, $\phi_0/\phi_{\text{ep}} = 20$)

■ Fig. 38.7

Production of ^{177}Lu from an ^{176}Yb target ($\phi_0 = 2 \times 10^{15} \text{ n cm}^{-2} \text{ s}^{-1}$, $\phi_0/\phi_{\text{ep}} = 20$)

which is half of the theoretical value (MDSTM NordionTM ^{177}Lu fact sheet, 2004). The main advantage of the indirect route is that the contamination with $^{177\text{m}}\text{Lu}$ is significantly reduced ($<1 \times 10^{-4}\%$) at 12 h postirradiation, but it cannot be totally eliminated due to the presence of a small fraction of ^{174}Yb in the highly enriched ^{176}Yb target (Mirzadeh 1995). Lu-177, produced

via indirect route, with a specific activity of >81 mCi/ μ g is also available from ITG Garching, Germany (ITG Garching 2010).

High energy proton irradiation of natural Ta and Hf targets was very recently attempted (Medvedev et al. 2008) to make no-carrier-added ^{177}Lu . However, the authors concluded that production of ^{177}Lu by this method is not practical mainly because of very low yield and high levels of contamination with ^{171}Lu and ^{172}Lu that have comparable half-lives with that of ^{177}Lu . These radioisotopes are generated through the decay of short-lived W, Ta, and Hf isotopes, which, in turn, are created directly by $^{\text{nat}}\text{Ta}(\text{p},\text{xn})$, $^{\text{nat}}\text{Ta}(\text{p},\text{pxn})$, $^{\text{nat}}\text{Hf}(\text{p},\text{pxn})$, and $^{\text{nat}}\text{Hf}(\text{p},\text{xn})$ reactions. More recently, Siiskonen et al. (2009) investigated the use of low-energy protons on natural Hf to produce ^{177}Lu . They measured excitation functions from 5.6 to 16.7 MeV and calculated cross sections up to 30 MeV. Nevertheless, they conclude that this route is not feasible for producing ^{177}Lu because of very small cross sections below 20 MeV and numerous radioactive Lu contaminants above 20 MeV.

As pointed out, indirect production of ^{177}Lu from an Yb target requires an efficient method of separating trace amounts of Lu from macroscopic amounts of Yb. It is well known that separation of the individual members of the lanthanide series can be achieved by liquid-liquid extraction utilizing organophosphate ligands (e.g., di(2-ethyl hexyl) phosphoric acid, HDEHP) dissolved in organic solvent (e.g., toluene or n-heptane) and dilute mineral acids (Peppard et al. 1957). More conveniently, a similar separation can be conducted by column extraction chromatography using commercial LN resin in dilute nitric acid (Ln resin is manufactured by Eichrom Technologies Inc USA, www.eichrom.com) (Horwitz et al. 2005). A more efficient separation, however, was reported in HCl media (Mirzadeh et al. 2004). In this case, a typical reactor target consisting of ~ 10 mg of Yb target in 10 mL of 2 M HCl was loaded on a 10 mL bed volume (BV) of a LN column (0.7×32 cm, 5 g, ~ 100 mesh). The column was then washed with 800 mL of 2 M HCl at a flow rate of ~ 0.17 mL min^{-1} , followed by 70 mL of 3 M HCl, and finally the purified Lu was stripped off the column by 50 mL of 6 M HCl. The 1st peak in the chromatogram (Fig. 38.8) belongs to ^{170}Tm which is formed by neutron capture by the stable ^{169}Tm impurity in the enriched ^{176}Yb target material. As shown, the Yb target was eluted from the column in a broad peak but under the above conditions, a good separation was achieved between Yb and Lu. The specific activity of ^{177}Lu was found to be >100 Ci mg^{-1} . Alternatively, cementation was used for separation of no-carrier-added ^{177}Lu from macro amounts of Yb. This procedure is based on selective extraction of Lu from bulk of Yb by Na(Hg) amalgam from $\text{Cl}^-/\text{CH}_3\text{COO}^-$ electrolyte, followed by a final cation exchange purification. The process provides a decontamination factor (DF) of >104 for the 1st step and a DF of 102 for the 2nd step. The reported overall yield is $75 \pm 5\%$, and the process can be completed within 4–5 hours (Lebedev et al. 2000).

38.8.5 Iodine-125 Produced by Neutron Capture Followed by β^- Decay

Iodine-125 has a half-life of 59.4 days and decays by 100% electron capture to the first excited state of ^{125}Te (35.5 keV, 1.49 ns). Deexcitation from this level to the ground state of stable ^{125}Te is highly converted, and as a result, the 35.5 keV γ -ray emission occurs in only 6.7% of the total disintegrations (the 35.5 keV emission is just above the 33.2 keV K-absorption edge of iodine). The energy averaged over all photons (X- and γ rays) in the decay of ^{125}I is 26.4 keV.

I-125 is widely used as a tracer in biology and medicine. Some current applications include biodistribution studies of ^{125}I -labeled drugs, peptides and antibodies, and the use of

Fig. 38.8
Separation of no-carrier-added ^{177}Lu from Yb target on LN resin in HCl medium. As expected, ^{170}Tm impurity elutes ahead of Yb target

^{125}I -labeled nucleic acid precursors (e.g., ^{125}I -dU, 5'-iododeoxyuridine, a thymidine analog) in cell-targeted therapeutics (Daghighian et al. 1996; Kassis et al. 1987). In this case, the radiotoxicity is due to the fact that the decay of ^{125}I is followed by a shower of short-range secondary electrons of only a few hundred eV and $\sim 1\text{ }\mu\text{m}$ path-length in tissue. Consequently, a significant fraction of the decay energy is deposited in microscopic volumes in the vicinity of nuclear DNA, leading to multiple strand breaks. Such molecular lesions have been shown to have profound biological consequences (Adelstein and Kassis 1987; Howell et al. 1992); cf. also [Chaps. 46](#) and [47](#) of this Volume.

Recently, permanent implants into the prostate with ^{125}I seeds have become increasingly popular. Typical implant seeds (1 mCi of ^{125}I per seed) are designed to deliver a dose of 160 Gy during the full decay. The initial dose rate is 7.72 cGy h^{-1} and 87.5% of the full dose is delivered over a period of 6 months (three half-lives).

Reactor production of ^{125}I involves irradiation of a xenon target, followed by a postirradiation decay time to allow the 16.9 h ^{125}Xe to decay ^{125}I .

The activities of ^{125}I and ^{126}I (mCi mg^{-1} of Xe) as a function of time (100 days irradiation at a neutron flux of $1 \times 10^{14}\text{ n cm}^{-2}\text{ s}^{-1}$, followed by 100 days decay) are depicted in [Fig. 38.9](#). Applicable nuclear data for these calculations are presented in [Table 38.7](#).

Fig. 38.9

Production of ^{125}I from a natural xenon target ($\phi_0 = 1 \times 10^{14} \text{ n cm}^{-2} \text{ s}^{-1}$, $\phi_0/\phi_{\text{ep}} = 40$, $t_{\text{irr}} = 100 \text{ h}$, $t_{\text{decay}} = 100 \text{ h}$)

Table 38.7

Nuclear data for neutron irradiation of a natural Xe target for the production of ^{125}I

Nuclide	Natural abundance (%)	$T_{1/2}$	Cross section (b)	
			σ	I_0
^{124}Xe	0.096	Stable	165	3,600
^{125}Xe	–	16.9 h	N/A	N/A
^{125}I	–	59.4 days	894	13,730
^{126}I	–	13.11 days	5,960	40,600
^{126}Xe	0.090	Stable	3.5	60
^{127}Xe	–	36.4 days	N/A	N/A
^{127}I	–	Stable	6.2	147
^{128}I	–	24.99 min	N/A	N/A

N/A – not available

Radionuclidic contamination (defined as the ratio of $^{126}\text{I} + ^{128}\text{I}$ to ^{125}I) is obviously dependent on the enrichment of the ^{124}Xe target (the natural abundance of ^{124}Xe is only 0.096%). A practical complication is that the ^{124}Xe target contains ^{126}Xe ; this leads to additional reactions and radioimpurities that can lower the ^{125}I SpA.

Alternative production routes for ^{125}I include proton- and deuteron-induced reactions in an enriched ^{125}Te target in an accelerator, $^{125}\text{Te}(\text{p}, \text{n})^{125}\text{I}$ and $^{125}\text{Te}(\text{d}, 2\text{n})^{125}\text{I}$, respectively.

Elemental Xe and solid XeF_2 can be used as targets. The elemental Xe can be either in the form of pressurized gas, adsorbed on charcoal, or ion-implanted on synthetic SiO_2 . The melting point of XeF_2 is fairly high (130°C) and large amounts can be irradiated. Owing to

the nuclear properties of fluorine, no radio-contaminants are produced due to the presence of fluorine. After irradiation, the XeF_2 target is dissolved in water at 0°C , and the evolved gaseous Xe is collected in a cold trap at -40°C (isopropyl alcohol/dry ice). After a few days of decay, ^{125}Xe is cryogenically transferred to another cold trap and ^{125}I in the first cold trap is dissolved in a dilute $\text{NaOH}/\text{Na}_2\text{SO}_3$ mixture (Kahn and Kleinberg 1977). Inasmuch as ^{125}I is produced by neutron irradiation of Xe the isotopic impurities are limited to ^{126}I and ^{127}I , which are both made through nuclear reactions, i.e., $^{125}\text{I}(\text{n},\gamma)^{126}\text{I}(\text{n},\gamma)^{127}\text{I}$ and $^{126}\text{Xe}(\text{n},\gamma)^{127}\text{Xe} \xrightarrow{\text{EC}} ^{127}\text{I}$. The total amount of iodine in a ^{125}I preparation is represented primarily by ^{125}I and ^{127}I with only a negligible amount contributed by ^{126}I , which can be experimentally measured by neutron activation analysis (NAA).

High specific activity ^{125}I is available from different manufacturers in an aqueous solution containing NaOH or Na_2SO_3 , with activity claimed to be in the form of I^- . This may be true of freshly prepared solutions, but in the course of a few weeks, significant amounts of this iodide activity are transformed into unidentified species. These species may be volatile and do not exchange with added I^- even after the addition of Na_2SO_3 or $\text{Na}_2\text{S}_2\text{O}_3$.

38.8.6 Tungsten-188 Produced by Double Neutron Capture

Currently, there is considerable interest in rhenium-188 (^{188}Re) for various medical applications (see Lambert and de Klerk 2006; Jeong and Chung 2003; Knapp et al. 1997, and references therein). The convenient 17.0 h half-life and 100% beta emission with high end-point energies ($E_{\beta}^{\text{av}} = 764 \text{ keV}$) make ^{188}Re an attractive candidate for radiotherapy of larger tumors. Rhenium-188 decay provides an imageable γ ray of 155 keV with an intensity of 15%. About 5% of this transition also converts in the electronic shells of the ^{188}Os daughter providing secondary electrons and X-rays of short range. The average equilibrium dose rate constant for ^{188}Re is $1.78 \text{ rad g } \mu\text{Ci}^{-1} \text{ h}^{-1}$. Another major advantage is the availability of ^{188}Re in the carrier-free state from a generator system with a shelf life of many months.

The long-lived (69.78 days) parent nuclide, ^{188}W , is produced in a nuclear reactor by double neutron capture by highly enriched ^{186}W .

Thin-target production yields of ^{188}W as a function of irradiation time at neutron fluxes of $2 \times 10^{15} \text{ n cm}^{-2} \text{ s}^{-1}$ (HFIR) and $4 \times 10^{14} \text{ n cm}^{-2} \text{ s}^{-1}$ (MURR) are shown in [Fig. 38.10](#). The chemical form of the target can be either metallic or oxide. The principal advantage of a metal target is a net increase in the yield per unit target, as a larger amount of the more dense W metal can be packed into an irradiation capsule. This is an important factor for the large-scale production of ^{188}W which has to be balanced against neutron self-absorption by a massive W target. Chemical processing of the neutron-irradiated WO_3 targets involves dissolution in an excess of hot 1 M NaOH in the presence of H_2O_2 or NaOCl or both (Knapp et al. 1994). A favored method to process metallic W is to take advantage of the reactivity of molecular oxygen toward metallic W powder at elevated temperatures, and subsequent dissolution of the WO_3 as above. This approach has an additional benefit in that the technique can be used for simultaneous separation of W from Re and Os which form volatile oxides (Mirzadeh et al. 2000).

■ Fig. 38.10

Production of ^{188}W from a ^{186}W target in the Oak Ridge High Flux Isotope Reactor (HFIR) and the Missouri University Research Reactor (MURR)

The elements W and Re are in Groups VIb and VIIb of the periodic table under Mo and Tc, respectively, and similar to the Mo/Tc system, the most common generator is based on adsorption of W on alumina, where selective elution of ^{188}Re is achieved by saline as the eluant (Kadina et al. 1990). The interaction of tungsten ions with alumina has been studied in some detail by Dadachova et al. (1995). The chromatographic generator is portable, simple to operate, and it provides ^{188}Re with a radiopurity of $\sim 75\text{--}85\%$ (Kamioki et al. 1994). Other proposed $^{188}\text{W}/^{188}\text{Re}$ generators include gel-type (Ehrhardt et al. 1990) and sublimation types. A review of the latter can be found in Boyd (1982); cf. also Chap. 40 in this Volume.

38.8.7 Tin-117m Produced by Neutron Inelastic Scattering

Tin-117m has been in Phase II/III clinical trials for palliation of pain caused by breast and prostate cancer metastasized to bone (Atkins et al. 1993, 1995). This isotope of tin can be produced in a reactor by $^{116}\text{Sn}(n,\gamma)^{117\text{m}}\text{Sn}$ and $^{117}\text{Sn}(n,n')^{117\text{m}}\text{Sn}$ reactions. Alternative production routes via proton-induced reactions on Sb isotopes in an accelerator are also possible.

The production of metastable nuclei such as $^{117\text{m}}\text{Sn}$ via neutron radiative capture reactions is characterized by small neutron cross sections and, hence, low production rates. Metastable nuclei typically have excitation energies on the order of 100 keV and large differences in angular momentum from the ground states (most metastable nuclei have high angular momentum which delays de-excitation).

An alternative route for producing metastable nuclei is through neutron inelastic scattering where the cross section of the $^AZ(n,n')^{Am}Z$ reaction is, in some cases, substantially higher than the cross section for the $^{(A-1)}Z(n,\gamma)^{Am}Z$ route. As has been shown for the case of ^{117m}Sn (Mausner et al. 1985), the magnitude of gain in the cross section may compensate for the relatively lower fast neutron flux from a well-moderated fission spectrum in the typical irradiation location of most research reactors. Note that the excitation energies of metastable nuclei represent the thresholds for inelastic scattering. Large research reactors such as HFIR, with significant epithermal and fast neutron fluxes, are well suited for these types of reactions.

A thorough study of the production of ^{117m}Sn in the hydraulic tube (HT) of the HFIR has been reported (Mirzadeh et al. 1997), and it was shown that the yield from the (n,n') reaction was higher than that obtained from the (n,γ) reaction and the relative gain in the specific activity was 3.3. The cross section for the inelastic neutron scattering reaction for the production of ^{117m}Sn was 222 ± 16 mb. A value of 176 ± 14 mb for the cross section of the $^{117}\text{Sn}(n,n')^{117m}\text{Sn}$ reaction obtained at HFBR was reported earlier (Mausner et al. 1985).

The measured thermal neutron capture cross section (σ_{th}) and resonance integral (I_0) for the $^{116}\text{Sn}(n,\gamma)^{117m}\text{Sn}$ reaction are 5.8 ± 1.2 and 350 ± 53 mb, respectively. As demonstrated in this case, in the determination of neutron capture cross sections, the contribution from inelastic neutron scattering to the overall reaction is significant and appropriate corrections are required even when highly enriched target isotopes are used. Consequently, measured cross sections for capture reactions to metastable states are often lower than reported values.

The large-scale production yield of ^{117m}Sn via inelastic scattering reactions was recently measured at the HFIR for a number of targets ranging in mass from 4 to 200 mg with an enrichment of 87–92%. For one reactor cycle (~ 21 days) irradiation at position 5 of the HT facility (corresponding to the reactor midplane), the average yield for 87% enrichment is 0.29 ± 0.03 GBq mg^{-1} (7.9 ± 0.8 mCi mg^{-1}) of Sn (corresponding to 0.34 GBq mg^{-1} of ^{117}Sn). The average yield at saturation is 0.48 ± 0.04 GBq mg^{-1} (12.9 ± 1.2 mCi mg^{-1}) of Sn.

For a one-cycle irradiation, at the end of bombardment (EOB) the radionuclidic impurities in ^{117m}Sn samples include 115 days ^{113}Sn (0.10%), 2.7 days ^{122}Sb (0.22%), 2.7 a ^{125}Sb (0.03%), and 12.4 days ^{126}Sb (0.03%). These values represent the average of nine runs using 84.23% enriched ^{117}Sn . In three runs with a 92% enriched target, the impurities were ^{113}Sn (0.03%), ^{122}Sb (0.13%), ^{125}Sb (0.05%), and ^{126}Sb (0.01%). The more highly enriched target produces a more pure product as expected. Antimony-125 is primarily produced from the β^- decay of 9.5 m ^{125m}Sn . This isotope of Sb can also capture a neutron to form ^{126}Sb . The ^{122}Sb is created by neutron capture of stable ^{121}Sb formed from the beta decay of ^{121}Sn . Two other potential contaminants are 27 h ^{121}Sn (a pure beta emitter and not detectable with γ -ray spectroscopy), and 9.64 days ^{125}Sn (also a parent of ^{125}Sb). The level of ^{121}Sn at 7 days post-EOB is estimated to be $\sim 0.1\%$. No ^{125}Sn was detected in any run and its level was estimated to be $\ll 0.01\%$.

The DTPA complex of ^{117m}Sn very selectively localizes in bone (Srivastava et al. 1985). Its synthesis and use for bone pain palliation has been described by Srivastava et al. (1998).

38.8.8 Copper-67 Produced by fast Neutron-Induced Reactions

There is considerable interest in exploring the potential use of copper-67 (^{67}Cu) for therapeutic applications (DeNardo et al. 1991; Roberts et al. 1989; Green et al. 1988; Roberts et al. 1987). Copper-67 is a pure β^- emitter and decays with a half-life of 67.01 h to the ground state of stable ^{67}Zn in 20% of the disintegrations and to the 93.3 and 184.6 keV excited states in 23%

■ Table 38.8

Reactor production of carrier-free ^{67}Cu

Reactor/position	Fast neutron flux ($E_n \geq 1 \text{ MeV}$) ($\text{n s}^{-1} \text{ cm}^{-2}$)	Sat. yield of ^{67}Cu at EOB (GBq mg^{-1} of ^{67}Zn)	Cross section (mb)
HFIR (85 MW)			
Hydraulic Tube	4.4×10^{14}	4.14 ± 0.37	1.07 ± 0.11^a
HFBR (60 MW)			
In-core, V15	3.0×10^{14}	3.34 ± 0.35	1.23 ± 0.13^b
Core-edge, V11	6.4×10^{13}	0.53 ± 0.01	0.91 ± 0.10^b

^aMirzadeh and Knapp (1992)^bMirzadeh et al. (1986)

and 56% of the disintegrations, respectively. The average β^- particle energy of ^{67}Cu is 142 keV with an equilibrium dose constant of $0.575 \text{ rad g } \mu\text{Ci}^{-1} \text{ h}^{-1}$. The medical interest derives from its convenient several day half-life, medium energy beta emissions, and facile labeling chemistry. The photon energy is also useful for imaging.

The suggested nuclear reactions for the production of ^{67}Cu , in quantities relevant to nuclear medicine applications, include the $^{67}\text{Zn}(\text{n,p})^{67}\text{Cu}$ reaction in a reactor, and the $^{68}\text{Zn}(\text{p},2\text{p})^{67}\text{Cu}$ reaction and spallation of RbBr or As targets in a proton accelerator. Other reactions include $^{68}\text{Zn}(\text{d},2\text{pn})^{67}\text{Cu}$, $^{67}\text{Zn}(\text{d},2\text{p})^{67}\text{Cu}$, $^{64}\text{Ni}(\alpha,\text{p})^{67}\text{Cu}$, and $^{68}\text{Zn}(\gamma,\text{p})^{67}\text{Cu}$ (Mirzadeh et al. 1986, and references therein, Polak et al. 1986).

For the reactor route, the saturation yield of ^{67}Cu from the $^{67}\text{Zn}(\text{n,p})$ reaction at EOB is $4.14 \pm 0.37 \text{ GBq mg}^{-1}$ ($112 \pm 10 \mu\text{Ci mg}^{-1}$) of ^{67}Zn at position no. 5 in the High Flux Isotope Reactor (HFIR) hydraulic tube (reactor midplane). Production data and fast neutron fluxes available in irradiation facilities in HFIR and the High Flux Beam Reactor (HFBR, this reactor was permanently shut down in 1999) are summarized in Table 38.8.

Many approaches for separation of copper at trace concentrations from other metal ions including extraction, ion-exchange (Dasgupta et al. 1991), dry distillation, and electrolytic separation (see Mirzadeh and Knapp 1992, and references therein) have been studied. The application of the *spontaneous electrodeposition technique* for separation of carrier-free radionuclides of copper from proton- or neutron-irradiated zinc targets was reported by Mirzadeh and Knapp (1992). In this process, electrodeposition occurs without an external EMF. The absence of measurable current in this process eliminates hydrogen overvoltage and preserves the nobility of the Pt electrode. Consequently, the highest degree of separation of $^{67}\text{Cu}^{2+}$ from interfering metal ions (i.e., ions of Co, Fe, Ni, etc.) was obtained. Separation factors of $\geq 1 \times 10^7$ were easily achieved from macro amounts (grams) of Zn within 30 min. However, since even trace quantities of stable impurities can compete for binding with a carrier molecule, chelates that are selective for the copper ion are preferred (Srivastava et al. 1995).

38.9 Conclusion

This chapter has summarized a number of approaches to produce medical radionuclides with neutrons in a nuclear reactor. The combination of generally large production cross sections and high neutron flux has made this method the principal route to create medical radionuclides.

Overall demand for the most widely used radionuclides such as ^{99}Mo and ^{131}I continues to grow somewhat, and there is a very large potential demand for newer neutron-rich radionuclides for cancer therapy.

This is occurring in parallel with large increases in demand for short-lived diagnostic radiopharmaceuticals for cancer detection and staging, especially cyclotron produced ^{18}F (fluorodeoxyglucose). While the number of small cyclotrons to supply ^{18}F is increasing rapidly at present, at least one per month in the United States alone, the situation with reactors is not as sanguine. In recent years, the closure of the High Flux Beam Reactor and Brookhaven Medical Research Reactor both at BNL, the closure of the Fast Flux Test Facility at the Hanford Site (Washington State), and the cancelation of the Advanced Neutron Source project at ORNL, have led to a large decline in reactor nuclide production capability in the United States. The most useful remaining reactors for nuclide production are the High Flux Isotope Reactor at ORNL, and the Missouri University Research Reactor. Both are quite old, but very flexible and capable. Outside the US the situation is not dramatically better. Construction of two new production reactors in Canada to replace the aging, unreliable NRU reactor has been canceled and the Petten reactor in Holland has experienced major outages. Fortunately, the new OPAL reactor in Australia has commenced operation, and there is a stable situation in Russia.

Acknowledgments

Research at ORNL was supported by the U.S. DOE under contract DE-AC05-00OR22725 with UT-Battelle, LLC. Research at BNL was supported by the U.S. DOE under Contract DE-AC02-98CH10886 with Brookhaven Science Associates.

Abstract: Cyclotron products are gaining in significance in diagnostic investigations via PET and SPECT, as well as in some therapeutic studies. The scientific and technological background of radionuclide production using a cyclotron is briefly discussed. Production methods of the commonly used positron and photon emitters are described and developments in the production of some new positron emitters and therapeutic radionuclides outlined. Some perspectives of cyclotron production of medical radionuclides are considered.

39.1 Introduction

Radionuclides find applications in many fields. Their major use, however, is in medicine, in both diagnosis and therapy. The production of radionuclides is carried out using nuclear reactors as well as cyclotrons. The reactor produced radionuclides are generally neutron excess nuclides. They mostly decay by β^- emission. The cyclotron produced radionuclides, on the other hand, are often neutron deficient and decay mainly by EC or β^+ emission. They are especially suitable for diagnostic studies. The reactor production of radionuclides is described in ► Chap. 38 of this Volume; this chapter treats radionuclide production with cyclotrons. It is worth pointing out that today more than 300 cyclotrons exist worldwide (cf. Directory of Cyclotrons, IAEA-DCRP/CD, 2004), many of them in hospitals; they produce short-lived radionuclides for medical use. Thus, radionuclide production science and technology at cyclotrons has become a very important feature of modern nuclear medicine.

While production of radionuclides at both reactors and cyclotrons has some common features, such as chemical processing of the irradiated material and quality control of the separated product, there are several aspects that are distinctly specific to the production at a cyclotron. These relate to nuclear reaction data and targetry for high current irradiations. As an accelerated charged particle impinging on a material loses energy very sharply, it is not meaningful to use an average cross section of the nuclear process; instead, a full knowledge of the excitation function is required. A second characteristic is that the loss of energy of the charged particle generates a lot of heat in the target material. High current production irradiations thus demand sophisticated methods of heat dissipation.

The application of radionuclides in medicine has been constantly increasing and both reactor- and cyclotron-produced radionuclides are needed. Besides the availability of radionuclides, two other important factors have contributed tremendously to the recent progress. These include radiopharmaceutical chemistry and medical imaging instrumentation. Fast labeling of a molecule with a suitable radionuclide, combined with a stringent quality control of the product, is a prerequisite for any meaningful application of the radioactive material. Similarly, fast and high resolution imaging methods, e.g., positron emission tomography (PET) and single photon emission computed tomography (SPECT), are now commonly available for diagnostic studies. In recent years, radionuclides are also finding increasing applications in internal therapy.

This chapter deals with the production of medically interesting radionuclides using a cyclotron (or an accelerator). Some of the basic aspects of production of radionuclides are discussed in ► Sect. 39.2, while the details on the production of specific groups of radionuclides (positron emitters, photon emitters, therapy related radionuclides) are given in ► Sects. 39.3–39.5. Finally, some perspectives for further use of cyclotrons for production of radionuclides are discussed.

39.2 Principles, Equipment and Methodology

39.2.1 Types of Cyclotrons

Over the last 2 decades several types of cyclotrons and accelerators have been developed to meet the specific demands of radionuclide production; a summary is given in [Table 39.1](#) (cf. Wolf and Barclay Jones 1983; Qaim 2001a; Ruth 2003). The smallest machine is a cyclotron that accelerates deuterons only up to 4 MeV, i.e., below the breakup threshold of the deuteron (to avoid neutron background). It is used exclusively in a hospital environment to produce ^{15}O . A small linear two particle (p, d) accelerator with energies below 3.7 MeV has also been developed, but its use has been limited. The next stage accelerator is a single particle negative ion machine for proton acceleration up to an energy of 11 MeV or 12 MeV. It can be used to produce the four major β^+ emitters, viz. ^{11}C , ^{13}N , ^{15}O and ^{18}F , although the absence of the deuteron beam is somewhat disadvantageous with regard to the production of ^{15}O , and the rather low proton energy gives a low yield of ^{13}N . The next higher group of machines generally comprise two particle machines with $E_p \leq 20$ MeV and $E_d \leq 10$ MeV. It is ideally suited for production of the commonly used PET radionuclides. The even higher energy machines have capabilities of producing many more radionuclides, in particular when, besides p and d, ^3He and α -particle beams are also available. On the other hand, when energies above 100 MeV are under consideration, only the proton beam is of interest.

Table 39.1

Types of accelerators used for radionuclide production

Classification	Characteristics	Energy [MeV]	Major radionuclides produced
Level I	Single particle ^a (d)	<4	^{15}O
Level II	Single particle (p)	≤ 11	^{11}C , ^{13}N , ^{15}O , ^{18}F
Level III	Single or two particle (p, d)	≤ 20	^{11}C , ^{13}N , ^{15}O , ^{18}F , ^{64}Cu , ^{86}Y , ^{124}I (^{123}I , ^{67}Ga , ^{111}In)
Level IV	Single or multiple particle (p, d, ^3He , ^4He)	≤ 40	^{38}K , ^{73}Se , $^{75-77}\text{Br}$, ^{123}I , ^{81}Rb (^{81}Kr), ^{67}Ga , ^{111}In , ^{201}Tl , ^{22}Na , ^{57}Co , ^{44}Ti , ^{68}Ge , ^{72}As , ^{140}Nd
Level V	Single or multiple particle (p, d, ^3He , ^4He)	≤ 100	^{28}Mg , ^{67}Cu , ^{72}Se , ^{82}Sr , $^{117\text{m}}\text{Sn}$, ^{123}I
Level VI	Single particle (p)	≥ 100	^{26}Al , ^{67}Cu , ^{68}Ge , ^{82}Sr , etc.

^a A small linear two particle accelerator (p,d) has also been suggested.

39.2.2 Significance of Nuclear Reaction Cross Section Data

As mentioned above, in cyclotron production of radionuclides, the reaction cross section data play a very important role (for detailed discussion cf. Qaim 1982, 2001a). One needs the full excitation function of the nuclear process to be able to calculate the yield with reasonable accuracy. Another important point is the number of competing reaction channels. At an incident projectile energy of 20 MeV, for example, about six reaction channels with significant cross sections may occur. It is imperative to know the cross sections of all those processes. The demands on the data may thus be extensive. At small-sized cyclotrons, low energy reactions like (p,n), (p, α), (d,n), (d, α), etc., are used. At higher energies, on the other hand, (p,xn) reactions are commonly utilized. In some special cases, the (p,spall) process is applied.

The nuclear reaction cross section data are needed in radioisotope production programs mainly for optimisation of production routes, i.e., to maximize the yield of the desired product and to minimize the yields of the radioactive impurities. From a given excitation function, the expected yield of a product for a certain energy range, i.e., target thickness, can be calculated using the expression:

$$Y = \frac{N_L H}{M} I (1 - e^{-\lambda t}) \int_{E_1}^{E_2} \left(\frac{dE}{d(\rho x)} \right)^{-1} \sigma(E) dE \quad (39.1)$$

where Y is the activity (in Bq) of the product, N_L the Avogadro number; H , the enrichment (or isotopic abundance) of the target nuclide; M , the mass number of the target element; I , the projectile current; $dE/d(\rho x)$, the stopping power; $\sigma(E)$, the cross section at energy E ; λ , the decay constant of the product; and t , the time of irradiation. The calculated yield value represents the maximum yield that can be expected from a given nuclear process. It should be pointed out that the non-isotopic impurities produced can be removed by chemical separations, whereas the level of isotopic impurities can be suppressed only by using enriched isotopes as target material and/or by a careful selection of the particle energy range effective in the target.

The radioisotope ^{123}I ($T_{1/2} = 13.2$ h), a commonly employed halogen nuclide for labeling organic compounds for diagnostic studies using SPECT, for example, can be produced via various routes. Its production via the $^{124}\text{Te}(p,2n)^{123}\text{I}$ reaction furnishes a good example of the importance of nuclear data. In order to decrease the level of isotopic impurities in the ^{123}I produced, it is essential to use highly enriched ^{124}Te as target material. However, due to the competing $^{124}\text{Te}(p,n)^{124}\text{I}$ reaction it is not possible to eliminate the ^{124}I impurity ($T_{1/2} = 4.2$ days) completely, even if ^{124}Te is 100% enriched.  Figure 39.1 shows that the suitable proton energy range for the production of ^{123}I is $E_p = 25.0 \rightarrow 18.0$ MeV, i.e., the energy of the incident protons should be selected as 25.0 MeV and the thickness of the tellurium target should degrade the incident energy only to 18.0 MeV. Under these conditions, the yield of ^{123}I at the end of bombardment (EOB) amounts to $565 \text{ M Bq } \mu\text{A}^{-1} \text{ h}^{-1}$ and the level of ^{124}I impurity in ^{123}I to about 1%. If a still lower impurity level is desired, the energy window has to be narrowed. Evidently, it is necessary to know the excitation functions of the various competing reactions accurately.

It is worth pointing out that in recent years ^{124}I has gained considerable significance in positron emission tomography for investigating slow metabolic processes (see  Sect. 39.3.2). The data shown in  Fig. 39.1 can be used for the production of pure ^{124}I as well. The suitable energy range then is $E_p = 12 \rightarrow 8$ MeV, the thick target yield of ^{124}I amounting to $16 \text{ M Bq } \mu\text{A}^{-1} \text{ h}^{-1}$.

■ Fig. 39.1

Excitation functions of $^{124}\text{Te}(p,n)^{124}\text{I}$ and $^{124}\text{Te}(p,2n)^{123}\text{I}$ reactions. The suitable energy range for the production of ^{123}I is $E_p = 25.0 \rightarrow 18.0$ MeV (after Qaim 2001a, based on data reported by Kondo et al. (1977) and Scholten et al. (1995)). The same data can be used for the production of pure ^{124}I as well. The suitable energy range then is $E_p = 12 \rightarrow 8$ MeV

The γ -emitting radioactive impurities have a dual effect: first, they adversely affect the line spread function in SPECT-imaging and second, they cause enhanced radiation dose to the patient. If the amount of a longer-lived impurity is too high, it may jeopardize the whole advantage of the short-lived radioisotope used. It may then be necessary to look for an alternative route for production of the desired radioisotope.

Besides isotopic impurities, the awareness of isomeric impurities has also increased, in recent years. Several medically interesting research type radioisotopes have isomeric states that are rather disturbing. A few examples are $^{94\text{m}}\text{Tc}$ ($^{94\text{g}}\text{Tc}$), $^{120\text{g}}\text{I}$ ($^{120\text{m}}\text{I}$), etc. The isomeric impurities cannot be controlled through a careful adjustment of the energy window (as mentioned above). As the isomeric cross section ratio is primarily dependent on the type of reaction involved (cf. Strohmaier et al. 1997), it is essential to investigate all the possible production routes and then to choose the reaction and the energy range giving the best results. Obviously, nuclear data play a very important role here.

The question whether nuclear model calculations can provide cross section data, or only perform tedious measurements is often discussed. Experience has shown that model calculations have so far met with a varying degree of success. The cross sections of the light mass target nuclei can hardly be described by model calculations. In the medium and heavy mass regions, however, both the compound/precompound and precompound/hybrid models (using, for example, the codes STAPRE/GNASH and ALICE-IPPE, respectively) have been partially successful. In recent years, some advanced codes, like EMPIRE and TALYS, have been more successful in reproducing the experimental data. In general, *a priori* calculations do not meet the accuracy requirements needed in radionuclide production programs. Experimental studies are thus often indispensable.

For a detailed discussion of various experimental and theoretical aspects of nuclear reaction cross section data relevant to cyclotron production of radionuclides, the reader is referred to two recent IAEA-coordinated efforts (cf. Gul et al. 2001; Qaim et al. 2008).

39.2.3 High Current Targetry

As mentioned above, one of the major efforts in cyclotron production of medically important radionuclides consists of the development of a suitable target system for irradiations (cf. Qaim 1989; Schlyer 2003). Due to the use of high beam currents, the power density effective at a target is rather high (up to a few kW/cm²). An efficient heat transfer is thus one of the prime requirements in target construction. Some other considerations for target design are: (1) ease of chemical separation of radioactive product; (2) chemical reactivity and specific activity of the product obtained; (3) recovery of the target material, if necessary; and (4) high yield of the product.

In principle, several nuclear reactions may have cross sections that are high enough for use in the production of a radionuclide. In the choice of a target material, however, the mechanical and chemical properties of the substance play an important role, occasionally higher than the role of a nuclear reaction cross section. Solids like metals, alloys or oxides, liquids and gases can all be used, provided they can withstand high beam currents, do not lead to radiation induced strong chemical changes, give rise to a high yield of the radionuclide, and allow its easy chemical separation.

The chemical reactivity of the product is of paramount importance for subsequent labeling of an organic compound with the radionuclide. Often the chemical state of the product isotope is determined by the chemical composition of the target filling and the reaction within the target, especially in the case of gaseous target materials. ¹⁸F production via the ²⁰Ne(d,α)¹⁸F reaction, for example, leads to [¹⁸F]F₂ if a mixture of Ne + 0.1% F₂ is used as target filling (cf. Casella et al. 1980), but to ¹⁸F_{aq}[−] if a mixture of Ne + H₂ is used and the target rinsed with water after irradiation (cf. Blessing et al. 1986). The [¹⁸F]F₂ is suitable for electrophilic labeling and the ¹⁸F_{aq}[−] for nucleophile substitution.

High specific activity of the product is often essential for application in humans, e.g., if receptor-binding ligands are prepared. The recovery of the target material is an important consideration in the case of isotopically enriched isotopes (see below). The high level of radioactivity involved demands the use of remotely controlled or, if possible, automated methods of production. In general, cyclotron targets can be divided into three broad groups described below.

39.2.3.1 Targets for Irradiations with Internal Beams

The use of internal beams generally demands irradiations within the vacuum system of a cyclotron. Materials having high vapor pressure or showing large sputtering effects as a result of irradiation should therefore be avoided. Metals, electroplated targets, and alloys that have high melting points and good thermal conductivity are preferred. As the beam generally falls on the target at a grazing angle, the positioning of the beam on the target may present some difficulty, especially if irradiations with different accelerated particles are envisaged. Use of a temperature sensor may help overcome this difficulty (cf. Blessing and Qaim 1984).

39.2.3.2 Targets for Irradiations with Extracted Beams

Most of the irradiations for medical radioisotope production at cyclotrons are done using extracted beams. There is more versatility in working with the extracted beam than with the internal beam. Through controlled defocusing and wobbling, it is possible to decrease the

power density effective at a target. Nonetheless, due to the high beam currents used, there is a severe strain on the window foil separating the cyclotron vacuum from the target. Materials like Al, V, Ti, Ni, Cu, Nb, Havar, etc., have found extensive use. The target body (or target holder) has to be a good heat conductor, and materials like Al, Ti, Ni, Cu, Pt, stainless steel, Inconel, etc., have found wide application. The chemical nature of the radioactive product and the method of chemical separation are often deciding factors in the choice of a material of construction.

Irradiations of materials in all the three forms, viz. solid, liquid and gaseous, have been done. In the case of metal targets 2π water-cooling is generally sufficient. In the case of oxides and poor heat conducting materials, however, 4π cooling is often mandatory. In general, the back of the target is cooled by a stream of water and the front by a thin layer of flowing water (cf. Michael et al. 1981) or, more commonly, by a stream of He gas. The latter is in fact a standard technique. A typical irradiation system for the production of ^{124}I utilizing $^{124}\text{TeO}_2$ as target material is shown in Fig. 39.2 (Qaim et al. 2003). Beam currents of up to 20 μA have been used.

For poor thermal-conducting target materials with low melting points, the element is occasionally transformed into a suitable alloy. The thick target yield of the desired product is lower, but the batch yield may be high due to the possibility of use of much higher currents. A typical example is the use of Cu_3As alloy in the production of ^{75}Br and ^{75}Se via ^3He - and p -induced reactions on ^{75}As , respectively (cf. Blessing and Qaim 1984; Blessing et al. 1994). Another example is the use of Cu_2Se for production of radiobromine (cf. Vaalburg et al. 1985; Tolmachev et al. 1998).

Fig. 39.2

Typical target system for irradiation of solid material, in this case $^{124}\text{TeO}_2$ or $^{120}\text{TeO}_2$ withstanding 16 MeV proton wobbled beam of intensity up to 18 μA . Front cooling: helium, 1.5 bar, 10°C , Rear cooling: water jet, 10°C (after Qaim et al. 2003)

Another concept regarding the irradiation of solid targets with extracted beams involves the use of *slanting beams* (cf. Spellerberg et al. 1998; Sheh et al. 2000) (similar to that in the case of internal beam). The target holder is cooled from the back with flowing water. Using a better cooling, for example a chilled system (cf. Sheh et al. 2000), it has been shown that $^{124}\text{TeO}_2$ could withstand proton beam currents of up to 35 μA .

Large-sized liquid targets are not common, mainly on account of hydrolysis and radiation chemical effects. In contrast, small-sized water targets for production of ^{13}N and ^{18}F have attracted considerable attention. Molten salt and flowing-loop liquid targets have found only limited application.

Production of several radionuclides is done using gas targets. Both continuous flow system and batch mode (i.e., irradiation in a closed system and removal of activity at the end) are applied. The target dimensions and the gas pressure are chosen in such a way that the optimum part of the excitation function is utilized. In general, a He-cooled double foil window in front is mandatory to withstand the high beam (up to 50 μA) and high pressure within the target (up to 30 bar when the beam is on). The target body is cooled by air or water. A few measurements show that within the gas target there is a strong density reduction along the beam direction (cf. Wieland et al. 1984; Heselius 1986), and the beam itself becomes broader along its path due to scattering. These effects deserve special consideration while designing a gas target.

If the energy of the extracted particle is sufficiently high, occasionally a series of targets (tandem mode) is irradiated (cf. Ruth 1985). It is then possible to produce two or more radionuclides simultaneously. However, this technique has found only limited application.

39.2.3.3 Targets for Irradiations with Parasitic Beams

At several high energy proton accelerators, only a small fraction of the beam intensity is used for physics experiments, and the rest is diverted to a beam dump. This is of considerable advantage in the production of some longer-lived radionuclides (e.g., $^{68}\text{Ge}/^{68}\text{Ga}$ and $^{82}\text{Sr}/^{82}\text{Rb}$ generators). Because of the long ranges of high energy protons, relatively thick solid targets are used. However, those irradiations are not selective, especially when the spallation process is involved. Due to the formation of a large number of radioactive products, radiochemical separations are rather difficult, and isotopic impurities cannot be completely separated. In a few special cases, mass separation has been applied (e.g., at ISOLDE in Geneva).

39.2.3.4 Recent Developments

As a result of the enhanced use of small cyclotrons and highly enriched isotopes as target material, considerable effort has been devoted in recent years to the development of small-sized high current, liquid and gaseous targets. These developments involve precise nuclear data and sophisticated technology. In particular, for the production of short-lived positron emitters, several efficient and remotely controlled (or even automated) systems are now commercially available (see below). The results of such developments are periodically reported at international Targetry Workshops. During the most recent Workshop in Cambridge (2008), considerable attention was devoted to high-current targets at low-energy machines.

In the case of gas targets, targets of conical shape are preferred for containment of the beam within the gas. An extra advantage of this shape is that the amount of gas required for target

filling is smaller. This is an important consideration in the case of enriched gases (cf. Blessing et al. 1997). As far as liquid targets are concerned, the new thrust is on high pressure design. This reduces radiolytic effect but demands special material and heat dissipation concepts. Regarding solid state targetry, the emphasis in recent years has been on the utilization of extracted high-intensity slanting beams. In particular, for the production of rather commercial radionuclides such as ^{67}Ga , ^{111}In , ^{103}Pd and ^{201}Tl , suitable targets have been developed and beam currents of up to 1 mA are employed. Attempts to use very thin frozen layers of gases or water (e.g., ^{124}Xe , ^{18}O CO₂, H₂ ^{18}O) for high-current irradiations to produce ^{123}I or ^{18}F have not been very successful (cf. Firouzbakht et al. 1993; Mahunka et al. 1996).

39.2.4 Use of Isotopically Enriched Target Material

Highly enriched isotopes as target materials have found considerable use in the production of radionuclides, especially at cyclotrons. In recent years, their utilization has been intensified. About 2 decades ago it was considered uneconomical to bring an isotope of very low natural abundance to ultrahigh enrichment and use it as target material. Today it is a well accepted method, provided it leads to high yield and high purity of the product. The high cost of the enriched material, however, demands very sophisticated target technology. Presently, the most important PET radionuclide (^{18}F) and some of the common SPECT radionuclides (^{67}Ga , ^{111}In , ^{123}I) are produced using highly enriched target isotopes. Similarly the production of most of the research type radionuclides is based on the use of enriched target material (for an overview see Qaim 1989). It should, however, be mentioned that for many of the isotopes under consideration alternative nuclear processes employing natural targets may be available. The development of a method using enriched isotope is necessitated either due to the non-availability of a cyclotron with suitable particles and energy, or due to greater demands on yield and/or purity of the product. On the other hand, for a production process to be economically feasible, it is imperative that the loss of the enriched material during irradiation is minimum, and its recovery after the separation of the desired radioactive product is efficient.

39.2.5 Chemical Processing of the Irradiated Material

In contrast to the reactor production of radionuclides, in cyclotron production, the chemical processing starts in many cases during the irradiation itself. There are two reasons for this: first, the neutron irradiation in a reactor does not cause such intense radiation damage and chemical effects as the charged particle irradiation at a cyclotron, and second, the use of gaseous and liquid targets is much more common in cyclotron production of radionuclides than in reactor production. As expected, in those targets the radiation induced chemical reactions and nuclear recoil effects may lead to the formation of the desired radionuclide in different species (cf. Ferrieri and Wolf 1983). In a nitrogen gas target for the production of ^{11}C via the $^{14}\text{N}(\text{p},\alpha)^{11}\text{C}$ reaction, for example, the product radionuclide occurs as $^{11}\text{CO}_2$ or ^{11}CO , depending on the target filling (see below), the beam current used and the time of irradiation. Similarly, in a water target for the production of ^{13}N via the $^{16}\text{O}(\text{p},\alpha)^{13}\text{N}$ reaction, the radioactive product could occur as $^{13}\text{NO}_2^-$ or $^{13}\text{NO}_3^-$, depending on the radiation dose effective in the target. Also, in solid targets the radioactive product may exist in several oxidation states. The chemical processing to be applied must therefore take all these aspects in consideration.

Gaseous and liquid targets are commonly used for the production of short-lived radionuclides, especially positron emitters. The chemical separation techniques of some important positron emitters are described in the next section. It should be pointed out here that the methods used have to be fast and efficient, in terms of the purity of the product as well as the recovery of the enriched target material. Furthermore, the chemical form of the separated radionuclide has to be well defined to allow a convenient synthesis of the desired radiopharmaceutical.

Occasionally, a gas target is also used for the production of a radionuclide, which sticks to the inner walls of the target instead of being removed with the gas. Some typical examples are ^{38}K , ^{81}Rb and ^{123}I , formed via $^{38}\text{Ar}(p,n)^{38}\text{K}$, $^{82}\text{Kr}(p,2n)^{81}\text{Rb}$ and $^{124}\text{Xe}(p,x)^{123}\text{I}$ processes, respectively. Subsequent proper rinsing of the target leads to almost complete removal of the activity (see below).

As regards solid targets, both dry and wet chemical separation methods are used. The dry method involves distillation and thermochromatography. The best example of the dry distillation technique is furnished by separation of radioiodine from irradiated TeO_2 at 755°C and a typical separation apparatus is shown in [Fig. 39.3](#). Optimisation experiments have revealed that above the m.p. of TeO_2 the removal of radioiodine is fast and almost quantitative, and the loss of the target material is negligible (cf. Beyer and Pimentel-Gonzales 2000; Qaim et al. 2003). Furthermore, the target is regenerated for the next production run. Thermochromatography, on the other hand, generally involves the formation of a chemical species of the radioactive product, which allows its removal from the irradiated target, but the vapor pressure is not high enough to allow its transport to large distances, such as in distillation (for a review on thermochromatographic separations see [Chap. 53 in Vol. 5](#)). The activity thus gets deposited in the cooler part of the thermochromatographic tube from where it is removed by rinsing, or is transferred to solid or liquid absorbers. A typical example is depicted in [Fig. 39.4](#).

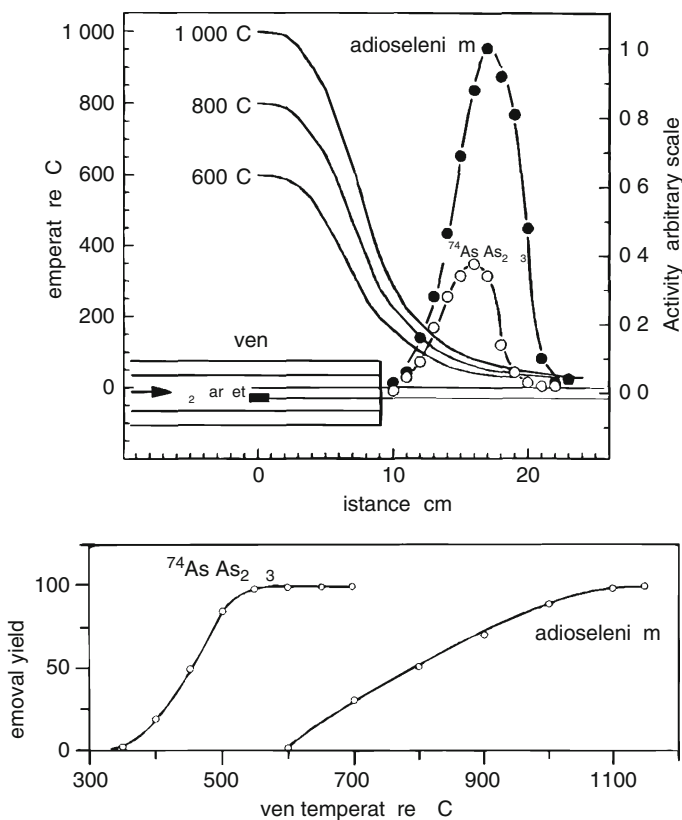

Fig. 39.3

Simplified sketch of quartz distillation apparatus for separation of radioiodine from irradiated $^{\text{nat}}\text{TeO}_2$, $^{124}\text{TeO}_2$ or $^{120}\text{TeO}_2$ target. The tube area outside the oven is heated by a stream of hot air (after Qaim et al. 2003)

■ Fig. 39.4

(Top) Deposition zone of $^{74}\text{AsAs}_2\text{O}_3$ and radioselenium in an O_2 atmosphere for an oven temperature of $>1,000^\circ\text{C}$, after 30 min processing of the irradiated Cu_3As target. (Bottom) Removal of $^{74}\text{AsAs}_2\text{O}_3$ and radioselenium from the Cu_3As target in an oxygen stream as a function of oven temperature (after Blessing et al. 1994)

A Cu_3As target irradiated with protons contains both ^{75}Se and ^{74}As , formed via $^{75}\text{As}(p,n)^{75}\text{Se}$ and $^{75}\text{As}(p,pn)^{74}\text{As}$ reactions, respectively. Detailed removal studies as a function of temperature revealed that $^{74}\text{AsAs}_2\text{O}_3$ is removed at 600°C , whereas for removal of radioselenium, a temperature of about $1,100^\circ\text{C}$ is required. Thus, by a two step thermochromatographic treatment, it is possible to separate radioselenium from the matrix.

It is worth mentioning that a multipurpose vertical thermochromatographic separation module has been developed to separate various target radionuclide systems, including $^{94}\text{MoO}_3/^{94\text{m}}\text{Tc}$, $^{110}\text{Cd}/^{110\text{m}}\text{In}$ and $^{186}\text{WO}_3/^{186}\text{Re}$ (cf. [Chap. 53 in Vol. 5](#) and [Chap. 40](#) in this Volume). On the other hand, it should also be pointed out that thermochromatography serves to concentrate the desired activity at one point and does not necessarily give a very clean separation. For a more clean separation, a subsequent wet chemical step is often necessary. The advantage of this dry separation lies in the easy regeneration and cyclic use of the highly enriched target materials.

In many production processes, a wet chemical procedure is unavoidable. In general, solvent extraction and ion-exchange techniques are commonly used, but occasionally methods like coprecipitation, adsorption, wet distillation, electrodeposition etc., are preferred. The separation procedure finally adopted often depends on the speciality of a laboratory.

39.2.6 Yield and Purity

The yield of a radionuclide from a nuclear process over a certain energy range can be calculated using the excitation function. It is generally expressed as MBq $\mu\text{A}^{-1} \text{h}^{-1}$ or MBq μA^{-1} , i.e., for an irradiation at 1 μA for 1 hour or for saturation, respectively. This calculated thick target yield represents the maximum yield that can be expected via the nuclear process under consideration. In practice, the experimentally obtained yields in high current production runs are invariably lower than the theoretical values. The experimental yield generally decreases as a function of the integrated current. In the case of gaseous targets, the decrease is presumably due to density reduction along the beam direction, and in liquid targets, due to local boiling and bubble formation (cf. Heselius et al. 1989). In solid targets, the decrease in yield is possibly due to inhomogeneity in the incident beam, radiation damage effects, etc. The experimental yields thus reflect a cumulative effect of the specific conditions prevalent during the production process. In general, the negative ion beams can be better homogenized than the positive ion beams. The agreement between theoretical and experimental yields, therefore, tends to be better when cyclotrons with negative ions are used.

In a good production method, besides high yield, a low level of radionuclidic impurities is expected. This is achieved via the choice of a suitable nuclear process and chemical separation scheme. The chemical impurities, on the other hand, are introduced via the reagents used and, to some extent, via radiation induced effects like radiolysis, sputtering from the target body, etc. These inactive impurities may have toxic effects and may also form complexes with the radioactive product, thereby decreasing its chemical reactivity. The product of $^{18}\text{F}_{\text{aq}}^-$ using a small-sized H_2^{18}O target was often associated with this problem. The sputtered metal ions from the target walls possibly formed complexes with $^{18}\text{F}^-$ and rendered it rather unreactive for subsequent labeling work (cf. Kilbourn et al. 1985). A chemical purification step to remove the metal ions was found to be mandatory. The problem is even more acute in the case of metal radionuclides like ^{64}Cu . Even the slightest impurity jeopardizes the formation of metal complexes. Production of the radionuclide under very clean conditions is therefore absolutely necessary.

The radiochemical state of the radionuclide produced deserves special consideration before initiating labeling work. In the case of a solid target, the separated radionuclide is generally brought into a desired radiochemical form through oxidation/reduction cycles. As discussed above, however, in liquid and gaseous targets, the presence of additives and radiation dose effects (i.e., radiation induced chemical reactions) are often deciding factors regarding the chemical state of the product radionuclide.

Whenever high specific activity is demanded, special precautions are required in target construction. For example, the N_2 gas used for target filling in the case of ^{11}C production has to be ultrapure (especially free of CO), and carbon containing seals or joints must be avoided. In the case of ^{18}F production, the presence of Teflon in immediate contact with a water target may give rise to inactive F^- under the impact of radiation and decrease the specific activity of ^{18}F .

39.3 Production of Positron Emitters

39.3.1 Standard Positron Emitters

The number of positron-emitting radionuclides is large. To date, however, PET studies are carried out mostly with the three short-lived organic positron emitters, viz. ^{11}C ($T_{1/2} = 20.4$ min), ^{15}O ($T_{1/2} = 2$ min) and ^{18}F ($T_{1/2} = 110$ min), and to a lesser extent with ^{13}N ($T_{1/2} = 10$ min). The radionuclides ^{11}C , ^{13}N , and ^{15}O are generally used at the site of production. ^{18}F , on the other hand, is extensively employed for transport to nearby PET centers without a cyclotron. For a comprehensive discussion of the ^{11}C - and ^{18}F -labeling chemistry and labeled compounds see [Chaps. 41](#) and [42](#) in this Volume. There is also considerable interest in ^{68}Ga ($T_{1/2} = 68$ min) and ^{82}Rb ($T_{1/2} = 1.3$ min), which are obtained via longer-lived generator parents.

39.3.1.1 Organic Positron Emitters

The common production methods of the short-lived organic β^+ emitters are summarized in [Table 39.2](#) (Qaim et al. 1993; Stöcklin et al. 1995). In general, low energy nuclear reactions like (p,n), (p, α), (d,n), (d, α), etc., are used, and a small-sized cyclotron is adequate for production purposes. The excitation functions have been measured in several laboratories. The cross sections show strong fluctuations with changing incident particle energies, probably due to the population of known discrete levels of the product nucleus. Recently an evaluation of the excitation functions was performed (Qaim et al. 2001). Reliable recommended curves for all the reactions listed in [Table 39.2](#), except for the $^{18}\text{O}(\text{p,n})^{18}\text{F}$ reaction, were made available.

Regarding the $^{18}\text{O}(\text{p,n})^{18}\text{F}$ reaction, only one group had reported the activation cross sections (Ruth and Wolf 1979). A recent detailed study (Hess et al. 2001) established the data base firmly for this production route of the most commonly used PET radionuclide ^{18}F . The results are shown in [Fig. 39.5](#). The yield can now be calculated up to 30 MeV. The resonances at 5.1, 6.1 and 7.2 MeV are in agreement with those found in spectral measurements of emitted neutrons.

Table 39.2

Common methods of production of short-lived organic positron emitters

Nuclide	$T_{1/2}$ (min)	Mode of decay	Production route	Energy range [MeV]	Thick target yield [$\text{MBq}\mu\text{A}^{-1}\text{h}^{-1}$]	Target	In-target product
^{11}C	20.4	β^+ (99.8) EC (0.2)	$^{14}\text{N}(\text{p},\alpha)$	13→3	3,820	$\text{N}_2(\text{O}_2)$	^{11}CO , $^{11}\text{CO}_2$
^{13}N	10.0	β^+ (100)	$^{16}\text{O}(\text{p},\alpha)$	16→7	1,665	H_2^{16}O	$^{13}\text{NO}_2^-$, $^{13}\text{NO}_3^-$
^{15}O	2.0	β^+ (99.9)	$^{14}\text{N}(\text{d},\text{n})$	8→0	2,368	$^{14}\text{N}_2(\text{O}_2)$	^{15}OO ,
		EC (0.1)	$^{15}\text{N}(\text{p},\text{n})$	10→0	2,220	$^{15}\text{N}_2(\text{O}_2)$	^{15}OO
^{18}F	109.6	β^+ (97)	$^{18}\text{O}(\text{p},\text{n})$	16→3	3,893	H_2^{18}O $^{18}\text{O}_2/(\text{F}_2)$	$^{18}\text{F}_{\text{aq}}^-$, $^{18}\text{F}(\text{F}_2)$
		EC (3)	$^{20}\text{Ne}(\text{d},\alpha)$	14→0	1,110	$\text{Ne}(\text{F}_2)$	$^{18}\text{F}(\text{F}_2)$

■ Fig. 39.5

Excitation function of the $^{18}\text{O}(p,n)^{18}\text{F}$ reaction. Results of both neutron and activation measurements are shown. The rather bold curve is an eye-guide to the activation data (after Hess et al. 2001)

The thick target yield over the optimum energy range for the production of each radionuclide was calculated using the known excitation function. In the case of ^{11}C , ^{13}N , and ^{15}O , the recently evaluated data of Qaim et al. (2001) were utilized and for ^{18}F , the data of Hess et al. (2001). The calculated values are given in Table 39.2.

Considerable effort has been devoted to targetry related to production of short-lived organic positron emitters. For production of ^{11}C and ^{15}O , generally pressurized gas targets in batch mode are used. The product activity is removed from the target by simple expansion and led to vessels where conversion to other chemical forms (known as precursors) suitable for labeling of organic compounds is done. The chemical form of the activity leaving the target depends upon the additive given to the N_2 gas in the target and, in the case of ^{11}C , also on the radiation dose effective in the target. The resulting ^{15}O from an $\text{N}_2(\text{O}_2)$ target, for example, is $[\text{O}_2^{15}\text{O}]$. In the case of ^{11}C production, at high radiation doses mostly $^{11}\text{CO}_2$ is formed. The production of both ^{11}C and ^{15}O is rather simple, and GBq quantities can be easily obtained (cf. Crouzel et al. 1987). There is, however, a problem with ^{11}C if it is to be of high specific activity. Special precautions regarding gas composition, construction material, and chemicals are needed (cf. Crouzel et al. 1987; Suzuki et al. 2000). The most reliable production of ^{15}O demands a deuteron beam at the cyclotron. If it is not available, the (p,n) reaction on highly enriched ^{15}N is utilized. An efficient recovery system for the enriched target gas must then be incorporated in the target system.

The production of **electrophilic** ^{18}F is also carried out using a gas target. However, the removal of the activity from the target demands addition of some F_2 carrier. In the case of $^{20}\text{Ne}(d,\alpha)^{18}\text{F}$ reaction, the F_2 (0.1–0.2%) carrier is added directly to the neon gas target (cf. Bida et al. 1980; Blessing et al. 1986). While using the $^{18}\text{O}(p,n)^{18}\text{F}$ reaction, however, a two-step irradiation is necessary (Nickles et al. 1983). In the first step, highly enriched gaseous O-18 is irradiated with protons, and the ^{18}F formed is deposited on the inner target surface. In

the second step, after cryogenic recovery of oxygen-18 target gas, a mixture of F_2 and Kr is introduced and a short proton irradiation is done, whereby an isotopic exchange between the gaseous F_2 and the deposited ^{18}F occurs. The second step leads to the recovery of radiofluorine as $[^{18}F]F_2$. Optimisation studies show that the yield and the specific activity of the ^{18}F obtained are much higher in the case of the $^{18}O(p,n)$ reaction than in the $^{20}Ne(d,\alpha)$ reaction (Roberts et al. 1995; Bishop et al. 1996; Hess et al. 2000). A correlation between the added F_2 -carrier and the specific activity of ^{18}F is given in ► Fig. 39.6. In many cases, the achieved specific activity of about 600 GBq per mmol may be sufficient. However, it is still about a factor of 50 lower than that needed in preparation of several radiopharmaceuticals, for example, ^{18}F -labeled neuro-receptor ligands.

The radionuclides ^{13}N and ^{18}F are commonly produced using water targets, and several types of water targets have been developed, particularly for ^{18}F production (for reviews cf. Qaim et al. 1993; Schlyer 2003). A typical pressurized water target for medium-scale production is shown in ► Fig. 39.7. It consists of a titanium body, electron-beam welded to two titanium foils (75 μm thick), which act as front and back windows. The target takes 1.3 ml of water with no expansion space and the thickness of the water filling amounts to 3.5 mm. During irradiation, the back window is water-cooled, typically to 8–10°C, and the front window is helium-cooled to –7°C. It withstands pressures of up to 7 bar and proton beam currents of up to 20 μA . A polyethylene-polypropylene copolymer tube with an i.d. of 0.8 mm and a He drive pressure of 1.3 bar is considered a reliable transfer system.

Transfer over 40 m through this tubing from the target to the nearest hot cell takes only 2 min, and >90% of the product activity is recovered. The same target can be used for the production of both ^{13}N and ^{18}F . In the former case, natural water ($H_2^{16}O$) is used, and the proton energy range within the target corresponds to $E_p = 16 \rightarrow 7$ MeV. In the latter case,

► Fig. 39.6

Yield and specific radioactivity of $[^{18}F]$ fluorine as a function of fluorine carrier; 30 min after end of the activation irradiation (after Hess et al. 2000)

■ Fig. 39.7

Typical medium pressure water target system for production of ^{13}N and ^{18}F (after Qaim et al. 1993)

however, enriched water (H_2^{18}O) is employed and the effective projectile energy is $E_p = 16 \rightarrow 3$ MeV. In high current irradiations, the resulting products are $^{13}\text{NO}_3^-$ and $^{18}\text{F}_{\text{aq}}^-$, respectively. In the latter case, the recovery of the enriched water is essential. This is commonly achieved by transferring the irradiated water to an ion-exchange bed whereby the ^{18}F activity is adsorbed, and the enriched water passes through and is collected. The ^{18}F activity is removed from the column by washing it with a 0.1 M solution of Na_2CO_3 , and the batch yield amounts to about 70 GBq. A recently developed method involves electrolytic separation of $^{18}\text{F}^-$ from the irradiated H_2^{18}O (Hamacher et al. 2002). The defluorinated target water is removed from the electrolytic cell by a gentle stream of helium, and the release of $^{18}\text{F}^-$ from the electrode is effected using a suitable solvent and a low strength electric field.

Due to the increasing significance of ^{18}F in PET, several modified designs of high-pressure (>10 bar) water target have been developed in recent years. They can withstand beam currents of up to about 50 μA . The resulting batch yield of ^{18}F amounts to about 150 GBq. These quantities are desired for producing the most commonly used radiopharmaceutical [^{18}F]2-fluoro-2-deoxy-D-glucose (2-FDG) on an industrial scale. A novel spherical niobium target (Zeisler et al. 2000) has proved to be very effective for use at cyclotrons with proton energies above 20 MeV. A further concept stipulates high current irradiation of ^{18}O gas followed by removal of the ^{18}F activity from the target wall by rinsing (cf. Becker et al. 2001). The full effectivity of the procedure has not been demonstrated as yet.

The radionuclidic and chemical purity of all the four organic positron emitters produced is generally $>99\%$. Reference has been made above to radiochemical purity and specific activity, but they are more relevant to the subsequently labeled product rather than to the radionuclide itself. Thus the production technology of the commonly used PET radionuclides is well established.

39.3.1.2 Generator Produced Positron Emitters

The generator produced positron emitters find application mostly in PET studies at centers without a cyclotron. A discussion of generator preparation is beyond the scope of this article (for a detailed discussion, cf. [Chap. 40](#) in this Volume). Here a very brief account is given of the production of the two long-lived parent radionuclides concerned (cf. Qaim [1987](#); Qaim et al. [1993](#)).

The β^+ emitter ^{68}Ga ($T_{1/2} = 68$ min) is widely used for PET attenuation correction and, to some extent, also for labeling. In recent years, it has been gaining more significance. Some radiopharmacists believe that if suitable labeled compounds are developed, this radionuclide may compete with or even replace ^{18}F . The parent ^{68}Ge is rather difficult to produce. The $^{69}\text{Ga}(p,2n)^{68}\text{Ge}$ reaction has a high cross section, but due to the long half-life of the product, the achievable batch yield is low. The method of choice is thus the spallation process. It is therefore exclusively produced at large accelerators where long irradiations in parasitic positions are possible. The purification of the product involves a multi-step wet chemical process. However, with the availability of modern accelerators that deliver high-intensity 70 to 100 MeV proton beams, the use of the (p,2n) reaction is receiving enhanced attention.

The β^+ emitter ^{82}Rb ($T_{1/2} = 1.3$ min) has found application in myocardial blood flow studies with PET. The possible production methods for the parent ^{82}Sr include the ^3He - and α -particle induced reactions on natural krypton, the (p,4n) reaction on ^{85}Rb and the spallation of molybdenum with high energy protons. In practice, however, the $^{\text{nat}}\text{Rb}(p,xn)^{82}\text{Sr}$ process is commonly used, and the major quantity of ^{82}Sr is presently produced at intermediate energy accelerators (cf. Waters and Coursey [1987](#); Philipps et al. [2000](#)).

Besides the above mentioned generator systems, two other cyclotron produced generators have also found some application. They are $^{62}\text{Zn}/^{62}\text{Cu}$ and $^{122}\text{Xe}/^{122}\text{I}$. The former is clinically established and commercially available, but because of the short half-life of the parent ^{62}Zn ($T_{1/2} = 9.2$ h), its use is rather limited. Due to the difficulty in producing ^{122}Xe ($T_{1/2} = 20.1$ h), the use of the $^{122}\text{Xe}/^{122}\text{I}$ generator system is still more limited.

39.3.2 Non-Standard Positron Emitters

The number of these radionuclides is relatively large. However, they are regarded as research tools and their relative importance keeps on changing. They can be placed under the following categories: (1) alkali metals (e.g., ^{38}K , ^{81}Rb , etc.); (2) longer-lived positron emitters, consisting of halogens and other elements suitable for labeling organic compounds (e.g., $^{75,76}\text{Br}$, ^{124}I , ^{73}Se , etc.), and metals forming complexes with suitable organic ligands (e.g., ^{52}Fe , ^{55}Co , ^{64}Cu , etc.); (3) analogs of SPECT and therapeutic radionuclides (e.g., $^{94\text{m}}\text{Tc}$ for $^{99\text{m}}\text{Tc}$, ^{86}Y for ^{90}Y , $^{120,124}\text{I}$ for ^{123}I and ^{131}I , etc.).

The production of typical radionuclides in each group is discussed in some detail below.

39.3.2.1 Alkali Metals

Three radionuclides, namely ^{38}K ($T_{1/2} = 7.6$ min), ^{81}Rb ($T_{1/2} = 4.6$ h), and $^{82\text{m}}\text{Rb}$ ($T_{1/2} = 6.3$ h), have found some use as blood flow tracers. For production of ^{38}K , three methods have been used, the $^{35}\text{Cl}(\alpha,n)^{38}\text{K}$ process on NaCl, the $^{38}\text{Ar}(p,n)^{38}\text{K}$ reaction on highly enriched ^{38}Ar , and the $^{40}\text{Ar}(p,3n)^{38}\text{K}$ reaction on natural argon (cf. the reviews by Qaim et al. [1993](#); Nagatsu et al. [1998](#)). The $^{81,82\text{m}}\text{Rb}$ tracers are produced via proton irradiation of highly enriched ^{82}Kr : over

the energy range of 20 to 25 MeV, the (p,2n) reaction dominates and the main product is ^{81}Rb ; at lower energies on the other hand, e.g., in the range of 10 to 15 MeV, $^{82\text{m}}\text{Rb}$ is preferentially produced. The enriched gas irradiation technology has been well developed and beam currents up to about 30 μA are commonly used. The gas recovery is efficient and the removal of the alkali metal activity from the inner walls of the target is almost quantitative. A typical system is shown in ► Fig. 39.8.

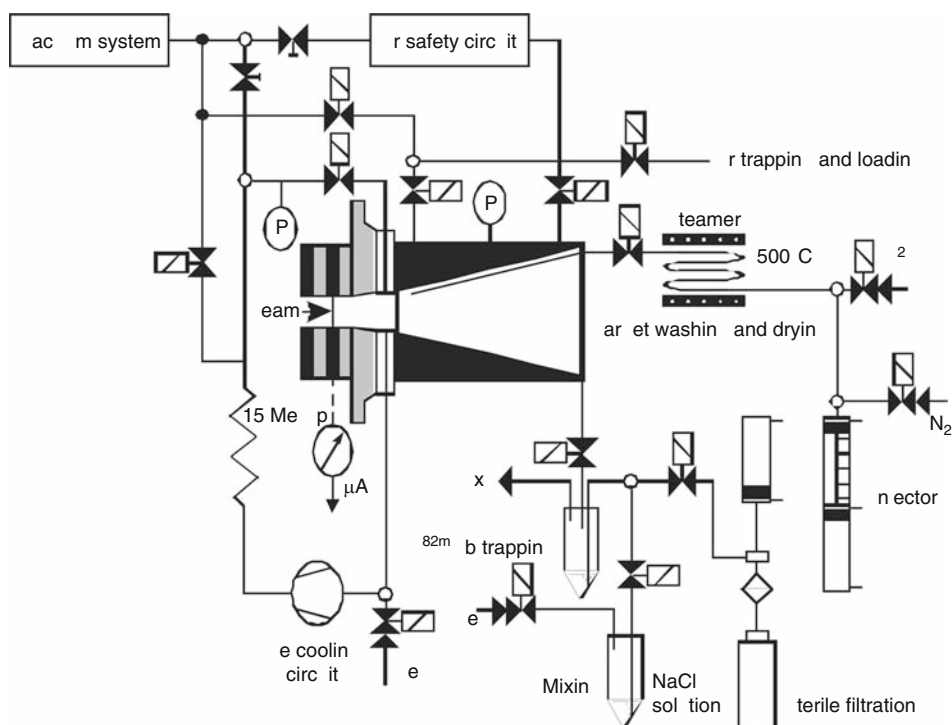

In this particular case, after the recovery of the enriched target gas, the removal of $^{82\text{m}}\text{Rb}$ from the target inner walls was achieved by introducing steam in the target (Blessing et al. 1997). In this way, the radioactivity was collected in about 2.5 mL of water. It may be mentioned here that besides its use as a blood flow tracer, ^{81}Rb is also used as a parent nuclide in the preparation of the $^{81}\text{Rb}/^{81\text{m}}\text{Kr}$ generator system (see below).

39.3.2.2 Longer-Lived Positron Emitters

With increasing significance of PET in diagnostic nuclear medicine, the need for longer-lived β^+ emitters (half-life between a few hours and a few days) is increasing. These radionuclides

► Fig. 39.8

Schematic representation of remotely controlled compact system developed for irradiation, safe handling and recovery of highly enriched rare gas (e.g., ^{82}Kr) and efficient removal of the product alkali metal activity (e.g., ^{81}Rb , $^{82\text{m}}\text{Rb}$) by steam (after Blessing et al. 1997). The system is also used for preparation of ^{83}Sr via the $^{82}\text{Kr}(^3\text{He},2\text{n})$ reaction

could be employed to study slow metabolic processes. Their use could extend to the labeling of organic compounds leading to analog tracers (e.g., with halogens) and the preparation of metal complexes (e.g., with copper). Some of the important or potentially important β^+ emitting radionuclides applied to study slow pharmacokinetics are given in [Table 39.3](#). For each radionuclide, several production routes have been studied. Many more nuclear reactions that use p, d, ^3He and α -particles as projectiles may be possible. In [Table 39.3](#), however, only the most commonly used or the most promising nuclear routes are given, together with the energy ranges over which those processes could be advantageously applied (cf. Qaim 2002, 2008). Some of the radionuclides can already be produced on a medium scale, while for the others, further technical developments are called for. A variety of chemical techniques, involving both wet and dry methods, have been applied in the separation of radioactive products.

In general, investigation of low-energy reactions like (p,n), (p, α), (d,n) etc., on highly enriched target isotopes has been very advantageous in developing production routes of

■ **Table 39.3**

Production routes of some longer-lived β^+ emitters suggested for study of slow pharmacokinetics

Nuclide	Decay data ^a			Useful production route	
	$T_{1/2}$	Positron branching [%]	E_{max} of positron [MeV]	Nuclear reaction	Energy range of interest [MeV]
^{45}Ti	3.1 h	85	1.04	$^{45}\text{Sc}(\text{p},\text{n})$	5–20
^{52}Mn	5.6 days	29	0.57	$^{52}\text{Cr}(\text{p},\text{n})$	5–20

^{124}I	4.2 days	22	2.13	$^{124}\text{Te}(\text{p},\text{n})$	5–20
				$^{124}\text{Te}(\text{d},2\text{n})$	5–20
				$^{125}\text{Te}(\text{p},2\text{n})$	15–30

^a Decay data taken mostly from Browne and Firestone (1986) or Qaim et al. (2007).

longer-lived β^+ emitters at small cyclotrons. However, there are a few radionuclides that can be produced only via intermediate-energy reactions. Some of the examples are $^{55}\text{Mn}(p,4n)^{52}\text{Fe}$, $^{75}\text{As}(p,3n)^{73}\text{Se}$, $^{76}\text{Se}(p,2n)^{75}\text{Br}$, etc. Furthermore, ^3He - and α -particle induced reactions are also useful. For example, ^{75}Br was often produced via the $^{75}\text{As}(^3\text{He},3n)$ process.

Out of all the positron emitters listed in [Table 39.3](#), five radionuclides, namely ^{64}Cu , ^{73}Se , ^{76}Br , ^{124}I , and ^{120}gI have attracted considerable interest in recent years, though as yet some of them have not been applied in investigations on humans. The radionuclide ^{64}Cu emits low-energy positrons and has a suitable half-life for slow metabolic studies. It was produced previously via the $^{63}\text{Cu}(n,\gamma)^{64}\text{Cu}$ reaction. Due to the rather low specific activity of the product, the $^{64}\text{Ni}(p,n)^{64}\text{Cu}$ reaction was suggested as an alternative route (Szelecsényi et al. 1993) that can be used at a small cyclotron. Production via this route has been successfully developed, including an efficient recovery of the highly enriched target material (cf. McCarthy et al. 1997). It is now extensively used in radioimmunotherapy.

The radionuclide ^{73}Se is a S-analog. It has been under study for about 3 decades, and several methods have been suggested for its production. The most suitable, however, is the $^{75}\text{As}(p,3n)^{73}\text{Se}$ reaction (cf. Mushtaq et al. 1988). The target material used is of natural isotopic composition, but the process demands a medium-sized cyclotron. Several chemical processing methods have been developed (cf. Mushtaq et al. 1988; Plenevaux et al. 1990) among which thermochromatographic separation of radio-selenium from an irradiated Cu_3As alloy appears to be very promising (Blessing et al. 1994, see also discussion above under [Sect. 39.2.5](#)). The availability and application of this radionuclide are expected to increase.

The radionuclide ^{76}Br has been under discussion for some time, first as an undesirable impurity in ^{75}Br , but lately as a useful longer-lived radionuclide for brominating organic compounds. For its production, originally the $^{75}\text{As}(^3\text{He},2n)^{76}\text{Br}$ reaction was suggested (cf. Qaim 1986; Ločh et al. 1994), and the method is still used in some laboratories, but the reaction $^{76}\text{Se}(p,n)^{76}\text{Br}$ (cf. Kovács et al. 1985; Hassan et al. 2004) appears to be more promising as it can be employed at a small cyclotron. The method has been technically developed (Tolmachev et al. 1998) and is an improved form of a previously reported procedure in connection with the production of ^{75}Br (Vaalburg et al. 1985). It utilizes enriched ^{76}Se in the form of $\text{Cu}_2^{76}\text{Se}$ alloy and the separation of radiobromine is effected via thermochromatography. The yield of ^{76}Br is sufficient for the desired applications.

The radionuclide ^{124}I has also been under discussion for about 30 years, initially as a very disturbing impurity in SPECT investigations with ^{123}I . It was mainly due to this impurity that the very expensive but superior route of ^{123}I production, namely the $^{124}\text{Xe}(p,x)^{123}\text{I}$ process was developed (see below under [Sect. 39.4](#)). About 2 decades ago, however, it was shown that ^{124}I could be advantageously used in slow metabolic and therapeutic studies (Bakir et al. 1990). Since then, its demand has been increasing and hence several production methods have been investigated. Originally, the $^{124}\text{Te}(d,2n)^{124}\text{I}$ reaction was employed (Lambrecht et al. 1988; Sharma et al. 1988; Weinreich and Knust 1996; Knust et al. 2000), but after careful studies of Scholten et al (1995) on the $^{124}\text{Te}(p,n)^{124}\text{I}$ reaction, that reaction is becoming the method of choice for the production of ^{124}I (cf. Sheh et al. 2000; Qaim et al. 2003). Recently, the $^{125}\text{Te}(p,2n)^{124}\text{I}$ process was also studied and it appears to be very promising (Hohn et al. 2001). A summary of the three production routes is given in [Table 39.4](#). The suitable energy ranges, the thick target yields and the impurity levels were deduced from the measured excitation functions (cf. Scholten et al. 1995; Bastian et al. 2001; Hohn et al. 2001). The best route appears to be the $^{124}\text{Te}(p,n)^{124}\text{I}$ process as it can be carried out at a low energy cyclotron and the level of the long-lived ^{125}I impurity is very low. The $^{125}\text{Te}(p,2n)^{124}\text{I}$ reaction, on the other hand, gives

■ Table 39.4

Comparison of production routes of ^{124}I

Nuclear reaction	Suitable energy range [MeV]	Thick target yield of ^{124}I [$\text{MBq}\mu\text{A}^{-1}\text{h}^{-1}$]	Impurity [%]	
			^{123}I	^{125}I
$^{124}\text{Te}(\text{p},\text{n})$	$12 \rightarrow 8$	16	1.0	<0.1
$^{124}\text{Te}(\text{d},2\text{n})$	$14 \rightarrow 10$	17.5	–	1.7
$^{125}\text{Te}(\text{p},2\text{n})$	$21 \rightarrow 15$	81	7.4	0.9

a much higher ^{124}I yield but the ^{125}I impurity level is higher than in the (p,n) reaction. Furthermore, the process demands a medium-sized cyclotron. The final choice of the production process will depend on the tolerable level of the ^{125}I impurity.

The targetry and radiochemical separation related to ^{124}I production (cf. ▶ Sect. 39.2.5 above) are based on established technology for dry distillation of radioiodine from $^{124}\text{TeO}_2$ target (cf. Van den Bosch et al. 1977; Michael et al. 1981). The separated product is either directly led to a 0.01 M solution of NaOH or is first adsorbed on a column and subsequently eluted with dilute NaOH. The final product exists $>98\%$ as iodide and is very suitable for subsequent labeling work.

The batch yield of ^{124}I via the $^{124}\text{Te}(\text{p},\text{n})$ process generally amounts to about 500 MBq; in exceptional cases, yields of about 2 GBq have been reported. These yields are sufficient for local medical use, but not for wide distribution. The increasing demands for this radionuclide call for more development efforts and the production route is now being commercialized.

The radionuclide $^{120\text{g}}\text{I}$ is a recent addition to the list of potentially useful radioisotopes of iodine for tracer applications. It is a positron emitter of suitable half-life. Its positron end-point energy is rather high but PET phantom measurements have shown that it can be used for tomographic studies in man. It can be produced via either the $^{120}\text{Te}(\text{p},\text{n})^{120\text{g}}\text{I}$ or the $^{122}\text{Te}(\text{p},3\text{n})^{120\text{g}}\text{I}$ reaction, but the former route is preferred as it can be used at a low-energy cyclotron and the level of the isomeric impurity is low (Hohn et al. 1998a, b). The major drawback is the high cost of the enriched material. On the other hand, as targetry has been well developed in connection with the production of other radioisotopes of iodine (see above), the expensive target material can be safely handled. A production procedure similar to that for ^{124}I has been developed (Qaim et al. 2003). With the use of a thin target, the batch yield of $^{120\text{g}}\text{I}$ achieved so far has been 750 MBq; with thicker targets, higher yields are expected.

39.3.2.3 Positron Emitting Analogs of SPECT and Therapeutic Radionuclides

A β^+ -emitting analog could be applied for quantification of a SPECT radiopharmaceutical. Similarly, in endotherapy with β^- -emitting particles, therapy planning and dosimetric calculations could be done advantageously using a β^+ -emitting analog.

Some of the important radionuclides that have been developed and used to date under the analog approach are listed in ▶ Table 39.5. In part (A), the β^+ -emitting analogs of the most commonly used SPECT-radionuclides are given and in part (B), the analogs of therapeutic radionuclides. Their commonly used production routes are mentioned. The production

Table 39.5

Positron emitting radionuclides for applying the analog approach

Commonly used radionuclide ($T_{1/2}$)	Analog radionuclide				
	Radionuclide ($T_{1/2}$)	Positron ^a branching [%]	E_{max} of positron [MeV]	Nuclear reaction	Energy range of interest for production [MeV]
A. Analogs of commonly used SPECT radionuclides					
⁶⁷ Ga (78.3 h)	⁶⁶ Ga (9.4 h)	57	4.15	⁶⁶ Zn(p,n)	5–20
^{99m} Tc (6.0 h)	^{94m} Tc (52 min)	70	2.47	⁹⁴ Mo(p,n)	5–20
¹¹¹ In (2.8 days)	^{110m} In (69 min)	62	2.25	¹⁰⁹ Ag(³ He,2n)	15–30
¹²³ I (13.2 h)	^{120g} I (1.3 h)	56	4.00	¹²⁰ Te(p,n)	10–20

				⁸⁵ Rb(p,3n)	20–50
⁹⁰ Y (2.7 days)	⁸⁶ Y (14.7 h)	33	1.96	⁸⁶ Sr(p,n)	5–20
¹³¹ I (8.0 days)	¹²⁴ I (4.2 days) ^b	22	2.13	¹²⁴ Te(p,n)	5–20

^a Decay data mostly from Browne and Firestone (1986).
^b ¹²⁴I may also be used as a β⁺-emitting analog of the SPECT nuclide ¹²³I, although the half-life of ¹²⁴I is rather long.

methods of ^{120g}I and ¹²⁴I have been given in detail under ▶ Sect. 39.3.2.2. The radionuclides ^{94m}Tc and ⁸⁶Y are drawing considerable interest, and technical efforts are under way to increase their production yields.

The production of ^{94m}Tc has been studied in detail (for a review cf. Qaim 2000). An enriched ⁹⁴MoO₃ target is irradiated with 15 MeV protons in a target assembly similar to that shown in ▶ Fig. 39.1, and ^{94m}Tc formed via the ⁹⁴Mo(p,n) reaction is separated via thermochromatography using moist air as carrier gas (cf. Rösch et al. 1994). Further purification of the product is done using an Al₂O₃ column. The major radionuclidic impurity is ^{94g}Tc ($T_{1/2}$ = 4.9 h) at a level of about 7%. The radionuclide ^{94m}Tc is available in quantities of 5 GBq and is utilized in quantification of new ^{99m}Tc SPECT agents.

The production of ⁸⁶Y was also investigated in detail and the reaction ⁸⁶Sr(p,n)⁸⁶Y was found to be the most suitable (Rösch et al. 1993a). In this case, an enriched ⁸⁶SrCO₃ target is irradiated with 15 MeV protons, and the radioyttrium is separated via one of the wet chemical processes. The separation is done via coprecipitation followed by ion-exchange (Rösch et al. 1993b) or HPLC (Kettern et al. 2002), or separation via electrolysis (Reischl et al. 2002) or chromatography (Gamestani et al. 2002). The radionuclidic purity of ⁸⁶Y is about 97% and its batch yield amounts to about 2 GBq. The radionuclide ⁸⁶Y has become the most suitable β⁺ emitter for quantification of radiation dosimetry of ⁹⁰Y-labeled radiotherapeutics.

39.4 Production of Photon Emitters

A large number of γ-ray emitting radionuclides have found application in diagnostic nuclear medicine using either γ-cameras or, in recent years, mainly SPECT. The most commonly used SPECT radionuclide ^{99m}Tc ($T_{1/2}$ = 6.0 h) is commercially available on a routine basis via the

$^{99}\text{Mo}/^{99\text{m}}\text{Tc}$ generator, the ^{99}Mo being produced using a nuclear reactor; the details are given elsewhere in this Volume. The four major SPECT radionuclides produced at a cyclotron are listed in ▶ [Table 39.6](#). All of them need a medium-sized cyclotron although, in some cases (e.g., ^{67}Ga , ^{111}In and ^{123}I), low-energy machines capable of inducing (p,n) reactions have also been used for producing these radionuclides for local use. For a comprehensive discussion of the $^{99\text{m}}\text{Tc}$ - and ^{123}I -labeling chemistry and labeled compounds see ▶ [Chaps. 43](#) and ▶ [44](#) in this Volume. Similar aspects for ^{111}In are illustrated in ▶ [Chap. 45](#) in this Volume.

The nuclear reaction cross section data for most of the processes are known and have been recently evaluated, using both nuclear model calculations and fitting methods (cf. Hermanne et al. 2001). Surprisingly, the data for the commonly employed $^{124}\text{Xe}(\text{p},\text{x})$ -process for the production of ^{123}I , a widely used SPECT radionuclide, are still somewhat discrepant (cf. Kurenkov et al. 1989; Tárkányi et al. 1991). In recent years, very high intensity medium-sized cyclotrons have been developed with the specific aim of producing medical radioisotopes. Extracted beams of about 0.5 mA are available: they fall slantingly on solid targets (see ▶ [Sect. 39.2.3](#)). Such cyclotrons are now commercially available and allow the production of several SPECT-radionuclides in large quantities.

The metallic radionuclides ^{67}Ga and ^{111}In form strong metal complexes and are of considerable medical interest. Both are produced via (p,2n) reactions, the former on ^{68}Zn and the latter on ^{112}Cd . Targetry and chemical processing problems have been well studied. The medical applications are well documented. For production on a smaller scale, the (p,n) reactions on ^{67}Zn and ^{111}Cd have also been utilized (cf. Tárkányi et al. 1990, 1994).

■ **Table 39.6**

Routine methods of production of some commonly used photon emitters at a cyclotron

Radio-nuclide	$T_{1/2}$	Mode of decay [%]	Main γ -ray energy in keV [%]	Production data		
				Nuclear reaction ^a	Energy range [MeV]	Thick target yield [MBq $\mu\text{A}^{-1} \text{h}^{-1}$]
^{67}Ga	3.26 days	EC (100)	93 (37)	$^{68}\text{Zn}(\text{p},2\text{n})$	26 \rightarrow 18	185
^{111}In	2.8 days	EC (100)	173 (91)	$^{112}\text{Cd}(\text{p},2\text{n})$	25 \rightarrow 18	166
^{123}I	13.2 h	EC (100)	159 (83)	$^{123}\text{Te}(\text{p},\text{n})$	14 \rightarrow 10	130
				$^{124}\text{Te}(\text{p},2\text{n})$	26 \rightarrow 23	392
				$^{127}\text{I}(\text{p},5\text{n})^{123}\text{Xe}^{\text{b}}$	65 \rightarrow 45	777 ^c
				$^{124}\text{Xe}(\text{p},\text{x})^{123}\text{Xe}^{\text{b}}$	29 \rightarrow 23	414 ^c
^{201}Tl	3.06 days	EC (100)	69–82 (X-rays) 166 (10.2)	$^{201}\text{Tl}(\text{p},3\text{n})^{201}\text{Pb}^{\text{d}}$	28 \rightarrow 20	18 ^e

^aEvaluated excitation functions of all the reactions listed here are available (cf. Hermanne et al. 2001).

^b ^{123}Xe decays by EC (87%) and β^+ emission (13%) to ^{123}I .

^cThis is ^{123}I yield expected from the decay of ^{123}Xe over an optimum time of about 7 h.

^d ^{201}Pb decays by EC (100%) to ^{201}Tl .

^eThis is ^{201}Tl yield, expected from the decay of ^{201}Pb over an optimum time of 32 h.

The radionuclide ^{123}I is a very useful analog label for producing radiotracers. Its nuclear properties are also almost ideal for SPECT studies. The radionuclide ^{201}Tl is very broadly used for myocardial blood flow measurements and has a relatively long shelf-life. The production methods of these two important radionuclides are discussed in some detail.

For the production of ^{123}I , about 25 nuclear processes have been investigated. Among them, only the four listed in [Table 39.6](#) are of significance. At low energy cyclotrons, the ^{123}Te (p,n) reaction over $E_p = 14.5 \rightarrow 10$ MeV is applied (cf. Scholten et al. 1989; Hermanne et al. 2001), and at medium energy cyclotrons, the ^{124}Te (p,2n) process over $E_p = 26 \rightarrow 23$ MeV (cf. Kondo et al. 1977; Van den Bosch et al. 1977; Scholten et al. 1995; Hermanne et al. 2001). In either case, highly enriched target material is used. The recovery of ^{123}I is carried out via dry distillation as described above for ^{124}I . The disadvantages of the (p,n) process are the low ^{123}I yield and the relatively high ^{124}I impurity, especially if ^{123}Te of low enrichment is used. The ^{124}I impurity level is still higher in the case of the (p,2n) route.

The third route of ^{123}I -production consists of the ^{127}I (p,5n) ^{123}Xe (EC, $\beta^+/T_{1/2} = 2.1$ h) ^{123}I process (for references cf. Hermanne et al. 2001). The optimum energy range for the process is $E_p = 65 \rightarrow 45$ MeV. Thus it needs a higher energy cyclotron. The removal of radioxenon from the irradiated NaI target is done either on-line, i.e., during the irradiation in a flow system, or off-line, i.e., after the end of the irradiation in a batch mode. The collected radioxenon is allowed to decay for about 7 h during which period the maximum growth of ^{123}I occurs. Thereafter, ^{123}I is removed from the vessel containing radioxenon. This is a relatively high yield process, and the only impurity observed is ^{125}I ($\sim 0.25\%$).

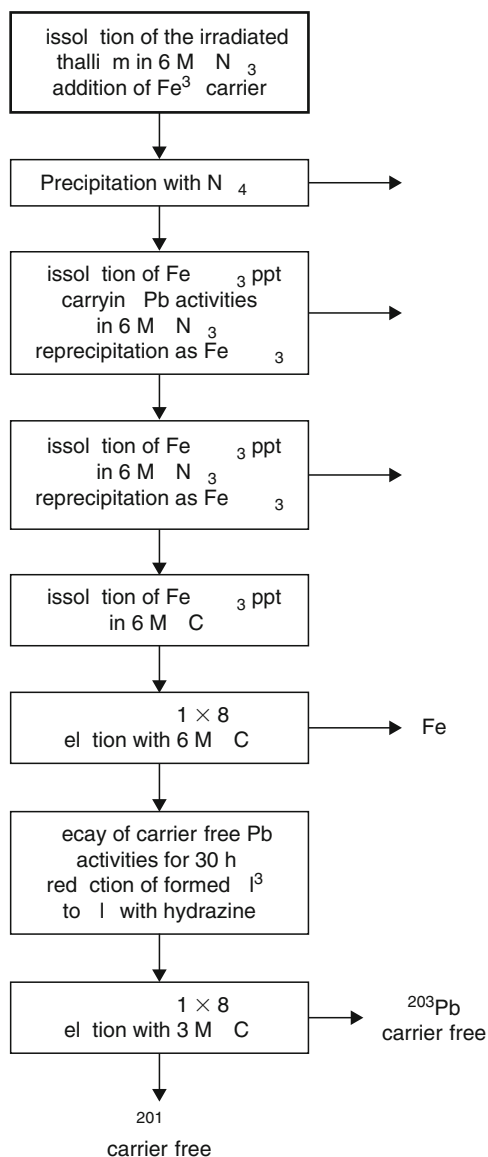

The fourth route of ^{123}I -production consists of the ^{124}Xe (p,x)-process. It involves the use of highly enriched ^{124}Xe , but requires only a medium-sized cyclotron. The development of this process clearly demonstrates the changing demands on the quality of the medically important radionuclides. In contrast to the above mentioned three routes, this process leads to ^{123}I of the highest purity. The natural abundance of ^{124}Xe is only 0.1%; consequently, the highly enriched ^{124}Xe is very expensive. The production method has been well developed. It involves a somewhat similar but more sophisticated target technology than that shown in [Fig. 39.8](#), in particular, checks to avoid loss of the enriched gas. The technology is now commercially available.

For the production of ^{201}Tl also, several methods have been investigated. The most common route, however, consists of the ^{203}Tl (p,3n) ^{201}Pb (EC/ $T_{1/2} = 9.4$ h) ^{201}Tl process. Extensive studies on this route have been done in several laboratories. The optimum energy range for production is $E_p = 28 \rightarrow 20$ MeV (cf. Lagunas-Solar et al. 1978; Qaim et al. 1979). Thus, in this case also, a medium-energy cyclotron is required.

The production of no-carrier-added ^{201}Tl via irradiation of ^{203}Tl or $^{\text{nat}}\text{Tl}$ involves a two step procedure and elaborate wet chemical processing. At first, ^{201}Pb is separated from the matrix activity and inactive Tl. Thereafter, it is allowed to decay for an optimum time of 32 h (cf. Qaim et al. 1979) whereby ^{201}Tl grows in. The removal of the daughter is then effected via anion-exchange chromatography. A flowsheet of the separation procedure is given in [Fig. 39.9](#). In a slightly modified form, it is used for commercial production. Thus, even classical separation methods such as coprecipitation and ion-exchange occasionally find widespread application. It should be mentioned that Tl itself is a toxic heavy metal. The final no-carrier-added ^{201}Tl , therefore, should not contain any measurable quantities of the target material. Furthermore, for medical application, only the product $^{201}\text{Tl}^+$ is of interest. The demands on the chemical, radiochemical and radionuclidic purity of the final product are thus rather stringent.

■ Fig. 39.9

Flow sheet of the separation procedure for the $^{203}\text{Tl}(p,3n)^{201}\text{Pb} \rightarrow ^{201}\text{Tl}$ production process (after Qaim et al. 1979)

Finally, it should be added that a generator system $^{81}\text{Rb}/^{81\text{m}}\text{Kr}$ delivers the short-lived γ -emitter $^{81\text{m}}\text{Kr}$ ($T_{1/2} = 13.1$ s, $E_\gamma = 190$ keV, $I_\gamma = 67\%$), which has found application in lung ventilation studies. The production of the parent cyclotron nuclide ^{81}Rb has been described above. The preparation of the generator is described in [Chap. 40](#) of this Volume.

39.5 Production of Therapeutic Radionuclides

Therapy-related radionuclides are generally produced in a nuclear reactor. The status of nuclear data was recently reviewed (Qaim 2001b). The production technology involved in nuclear reactors is treated elsewhere in this Volume. In recent years, cyclotrons have also been increasingly used to produce some therapeutic radionuclides. The labeling chemistry of the metallic therapeutic radionuclides as well as the aspects relevant to their therapeutic potential are described in detail in ► Chap. 46 in this Volume.

The cyclotron-produced radionuclides ^{64}Cu , ^{124}I , ^{67}Ga , and ^{111}In are diagnostic radioisotopes, but they might also act as therapeutic radionuclides if applied in high activity. The therapeutic use in the first two cases combines PET and low-energy beta particle therapy, and in the case of the next two, SPECT and Auger electron therapy. Their methods of production have been mentioned above (see ► Sects. 39.3.2 and ► 39.4, respectively). Similarly the positron emitters ^{83}Sr and ^{86}Y , which are analogs of the pure β^- -emitting therapeutic radioisotopes ^{89}Sr and ^{90}Y , respectively, are also produced well at cyclotrons and the methods are given above (see ► Sect. 39.3.2.3). The commonly used cyclotron-produced therapeutic radionuclides are given in ► Table 39.7 together with their major production routes. These radionuclides include β^- , α , and Auger electron emitters.

The radionuclide ^{67}Cu emits β^- -particles of ideally suitable energy. It is occasionally produced via the spallation process, but more commonly via the $^{68}\text{Zn}(p,2p)^{67}\text{Cu}$ reaction with protons of energies above 50 MeV. (Mirzadeh et al. 1986; Schwarzbach et al. 1995; Stoll et al. 2002). A recently reported method of production makes use of the $^{70}\text{Zn}(p,\alpha)^{67}\text{Cu}$ reaction over the energy range of 12 to 21 MeV. If highly enriched target material is used, the resulting ^{67}Cu is very pure (Kastleiner et al. 1999).

The calculated integral yields for the latter two processes are given in ► Fig. 39.10a. The targetry with enriched ^{68}Zn or ^{70}Zn is similar to that for production of ^{67}Ga from ^{68}Zn , and so it is well established. The chemical separation of radiocopper is based on a combination of solvent extraction and ion-exchange processes. So far the achievable batch yields of ^{67}Cu , mostly via the $^{68}\text{Zn}(p,2p)$ process, have been limited to about 1 GBq.

The radionuclide ^{103}Pd is almost a pure X-ray and Auger electron emitter. It is being increasingly used in the treatment of prostate cancer, and is therefore in great demand. For its production in a no-carrier-added form, several reactions have been investigated. Their cross section data have been recently reviewed (cf. Hussain et al. 2009). The $^{103}\text{Rh}(p,n)$ reaction is routinely used, the production cross sections of which were measured most accurately by Sudàr et al. (2002). The calculated thick target yield is given in ► Fig. 39.10b. As the target material Rh is rather expensive, a good separation of ^{103}Pd and recovery of Rh are desired. Several methods based on solvent extraction have been worked out. On the other hand, in many cases, ^{103}Pd is not separated. The irradiated Rh in the form of very thin seeds is introduced into the prostate, and the therapy effect is achieved through the X-rays coming out of the seed. In this case, however, it is mandatory that the proton energy does not exceed 13 MeV, so that the reaction $^{103}\text{Rh}(p,pn)^{102}\text{Rh}$ is not induced and the long-lived impurity ^{102}Rh ($T_{1/2} = 207$ days) is avoided. Using slanting beam targets and high current irradiations, batch yields of ^{103}Pd amounting up to 10 GBq have been achieved.

The radionuclide ^{186}Re emits low energy β^- -particles and forms very stable co-ordination compounds (higher homologue of technetium). Therefore, it has great therapeutic potential. Parallel to its production via the $^{185}\text{Re}(n,\gamma)$ process in a nuclear reactor, a cyclotron route,

namely $^{186}\text{W}(\text{p},\text{n})^{186}\text{Re}$, has been suggested (cf. Shigeta et al. 1996). The cross sections for this process were measured (cf. Szelecsényi et al. 1999; Zhang et al. 1999). Szelecsényi et al. (1999) and Zhang et al. (2001) also studied the $^{186}\text{W}(\text{d},2\text{n})^{186}\text{Re}$ reaction. The cross section data of both the (p,n) and the (d,2n) processes have been recently reviewed (cf. Qaim et al. 2008). The yields for the two reactions are shown in [Fig. 39.10c](#). Evidently, above 12 MeV, the yield of ^{186}Re via the (d,2n) reaction is significantly higher than via the (p,n) reaction. Nevertheless, in practice, the (p,n) reaction is preferred for production purposes as the available proton beams are generally of much higher intensity than the deuteron beams. The chemical separation is based on a combination of solvent extraction and ion-exchange processes (cf. Shigeta et al. 1996; Zhang et al. 1999).

The last two radionuclides listed in [Table 39.7](#), i.e., ^{211}At and ^{225}Ac are α -emitters. ^{211}At has been in use in endoradiotherapy for about 30 years but, in recent years, with enhanced progress in tumor targeting, the interest in this radionuclide has greatly increased. It is produced via the $^{209}\text{Bi}(\alpha,2\text{n})^{211}\text{At}$ reaction, and the cross sections are known well (cf. Lambrecht and Mirzadeh 1985). The optimum proton energy incident on the target is 28.0 MeV and it must be carefully controlled. At higher energies, the $^{209}\text{Bi}(\alpha,3\text{n})^{210}\text{At}$ reaction occurs, whose decay product leads to the α -emitting ^{210}Po ($T_{1/2} = 138.4$ days) of high radio-toxicity. In general, thin Bi targets for slanting beams are used. The separation of radioastatine is done mostly by distillation techniques, and the radionuclide is achieved in amounts of about 5 GBq.

The radionuclide ^{225}Ac is very promising, both in itself and as generator for ^{213}Bi . It is generally produced from the nuclear waste via an elaborate chemical processing. An interesting new production route is the $^{226}\text{Ra}(\text{p},2\text{n})^{225}\text{Ac}$ reaction. ^{225}Ac is already produced in reasonable quantities at medium-sized cyclotrons.

Table 39.7

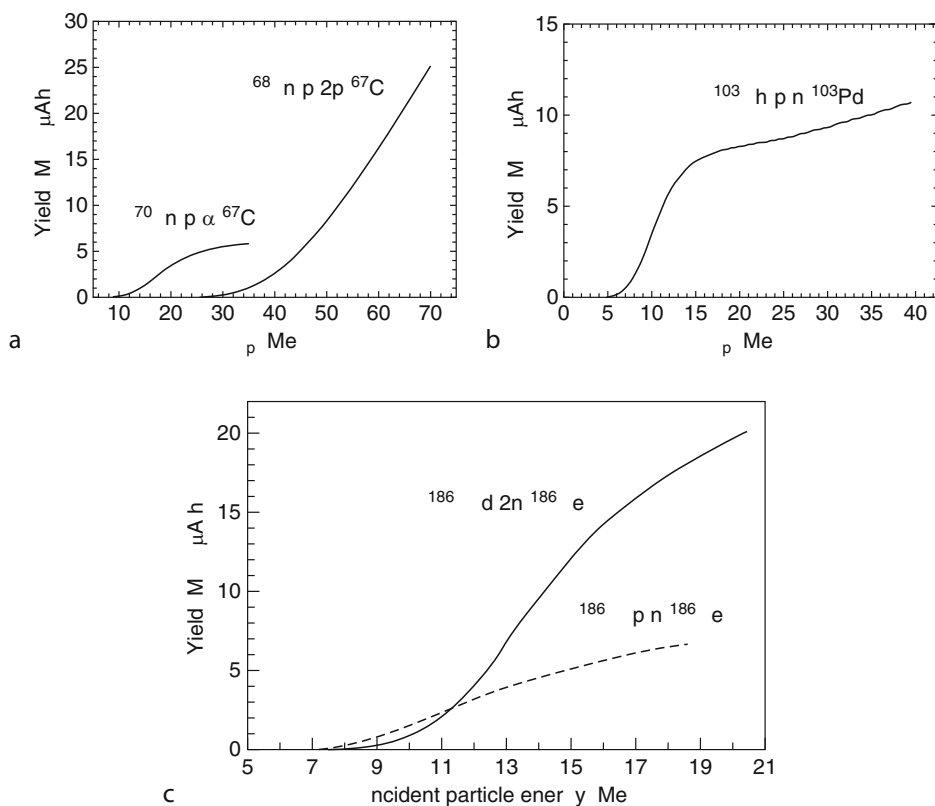

Some therapeutic radionuclides produced at a cyclotron

Radionuclide	$T_{1/2}$	Energy of emitted particle [MeV]	E_{γ} [keV] (I_{γ} in%)	Production route	
				Nuclear reaction	Energy range of interest [MeV]
^{67}Cu	2.6 days	0.6 (β^{-}) ^a	185 (45)	RbBr(p,spall)	800
				$^{68}\text{Zn}(\text{p},2\text{p})$	50–150
				$^{70}\text{Zn}(\text{p},\alpha)$	10–25
^{103}Pd	17.0 days	Auger electrons		$^{103}\text{Rh}(\text{p},\text{n})$	5–15
^{186}Re	3.8 days	1.1 (β^{-}) ^a	137 (8.5)	$^{186}\text{W}(\text{p},\text{n})$	10–20
				$^{186}\text{W}(\text{d},2\text{n})$	10–20
^{211}At (^{211}Po)	7.2 h (0.5 s)	5.9 (α) 7.5 (α)		$^{211}\text{Bi}(\alpha,2\text{n})$	20–28
^{225}Ac	10.0 days	5.8 (α)	100 (1.7)	$^{226}\text{Ra}(\text{p},2\text{n})$ ($T_{1/2} = 1,600$ a)	15–30

^a E_{max} of β^{-} -particle.

■ Fig. 39.10

Integral yields of some therapeutic radionuclides in various nuclear reactions shown as a function of projectile energy: (a) ^{67}Cu , (b) ^{103}Pd , (c) ^{186}Re . The curves for ^{67}Cu were calculated from the excitation functions reported by Kastleiner et al. (1999) and Stoll et al. (2002), and that for ^{103}Pd from the data of Sudàr et al. (2002). The results for ^{186}Re are from Szelecsényi et al. (1999)

In addition to the above mentioned radioisotopes, several other cyclotron-produced, useful or potentially useful, therapeutic radionuclides, e.g., ^{146}Tb ($T_{1/2} = 4.1$ h; $E_{\alpha} = 3.97$ MeV), ^{140}Nd ($T_{1/2} = 3.4$ days, Auger electrons), $^{193\text{m}}\text{Pt}$ ($T_{1/2} = 4.3$ days, Auger electrons), etc., are also receiving attention.

39.6 Conclusions and Perspectives

Radionuclide production technology at cyclotrons has been well developed, especially for short-lived organic positron emitters, commonly used SPECT radionuclides, and a few therapeutic radioisotopes. In this regard, all components of the technology, i.e., special purpose cyclotrons, high current irradiation targets, and automated or remotely controlled chemical processing units can now be purchased. Furthermore, four commonly used cyclotron produced SPECT radionuclides, namely ^{67}Ga , ^{111}In , ^{123}I , and ^{201}Tl , and the generator $^{81}\text{Rb}/^{81\text{m}}\text{Kr}$

are commercially available. Also, the PET radionuclide ^{18}F and the therapeutic radionuclide ^{103}Pd are commercially available in many regions. Some generator systems, which make use of long-lived parents (e.g., $^{68}\text{Ge}/^{68}\text{Ga}$, $^{82}\text{Sr}/^{82}\text{Rb}$), are supplied by several companies, though the parent nuclides are generally produced via intermediate energy nuclear reactions only at a few large research centers.

In contrast to the commonly used radionuclides, a few isotopes that have passed the stage of evaluation and are now in great demand, are not easily available. A few examples are ^{64}Cu , ^{67}Cu , ^{86}Y , ^{124}I , ^{211}At , and ^{225}Ac . Efforts are underway in commercially oriented laboratories to increase the production yields of these radionuclides and thus to ensure their availability on a broader scale.

The number of radionuclides of potential interest for medical applications is relatively large. They are research type radionuclides and the development work needed is rather heavy, calling for investigations in many directions, starting from nuclear data measurements, proceeding via high current target construction and chemical separation, and leading up to quality control and suitability tests for the desired applications. Although in many cases a combination of isotopically enriched target material and a small-sized cyclotron may be sufficient, for production of many new radionuclides, the necessity of an intermediate energy cyclotron may be inevitable. In general, it is concluded that the field of cyclotron production of medical radionuclides is flourishing, and many new impulses are expected within the next few years, especially with regard to new β^+ emitters and therapeutic radionuclides.

Acknowledgments

The author is indebted to many of his colleagues and co-workers for their fruitful co-operation over the years and to Prof. H. H. Coenen for the stimulating discussions.

Abstract: Radionuclide generator systems continue to play a key role in providing both diagnostic and therapeutic radionuclides for various applications in nuclear medicine, oncology, and interventional cardiology. Although many parent/daughter pairs have been evaluated as radionuclide generator systems, there are a relatively small number of generators, which are currently in routine clinical and research use. Essentially every conceivable approach has been used for parent/separation strategies, including sublimation, thermochromatographic separation, solvent extraction, and adsorptive column chromatography. The most widely used radionuclide generator for clinical applications is the $^{99}\text{Mo}/^{99\text{m}}\text{Tc}$ generator system, but recent years have seen an enormous increase in the use of generators to provide therapeutic radionuclides, which has paralleled the development of complementary technologies for targeting agents for therapy and in the general increased interest in the use of unsealed therapeutic radioactive sources. More recently, use of the $^{68}\text{Ge}/^{68}\text{Ga}$ generator is showing great potential as a source of positron-emitting ^{68}Ga for positron emission tomography (PET)/CT imaging. Key advantages for the use of radionuclide generators include reasonable costs, the convenience of obtaining the desired daughter radionuclide on demand, and availability of the daughter radionuclide in high specific activity, no-carrier added form.

40.1 Introduction

40.1.1 Historical Perspective

A radionuclide generator is a concept defined as an effective radiochemical separation of decaying parent and daughter radionuclides such that the daughter is obtained in a pure radionuclidic and radiochemical form. Radionuclide generators were historically called “cows” since the daughter radioactivity was “milked” (i.e., removed) from its precursor and the parent then generated a fresh supply of the daughter.

Generator parent radionuclides are obtained from uranium fission products (i.e., ^{99}Mo and ^{90}Sr) or as decay products from ^{233}U ($^{229}\text{Th}/^{225}\text{Ac}$), or are produced directly in nuclear reactors (^{188}W , etc.) or at accelerators (^{82}Rb , ^{62}Zn , etc.).

Compared to in-house radionuclide production facilities such as accelerators or nuclear reactors, the availability of short-lived radionuclides from radionuclide generators provides an inexpensive and convenient alternative. The development of radionuclide generators over the past 3 decades was primarily motivated by the increasing spectrum of applications of radionuclides and labeled compounds in the life sciences, in particular for diagnostic applications in nuclear medicine. In the last years, however, promising applications of generator-derived therapeutic radionuclides have been developed in the fields of nuclear medicine, oncology, and interventions cardiology. This increasing importance of radionuclide generators has initiated a broad development for radionuclide production of the generator parent radionuclide, for sophisticated radiochemical separations as well as reliable technical design of the generator systems.

The first generator for life sciences application was developed in 1920, providing ^{222}Rn ($T_{1/2} = 3.825$ d) to obtain radon seeds for radiation therapy as a daughter of ^{226}Ra ($T_{1/2} = 1.60 \times 10^3$ a) (Failla 1920). However, practical importance of radionuclide generators was achieved in 1951 by the ^{132}Te ($T_{1/2} = 3.26$ d)/ ^{132}I ($T_{1/2} = 1.39$ h) generator (Winsche et al. 1951), and, much more, in 1957 by the pioneering development of the $^{99}\text{Mo}/^{99\text{m}}\text{Tc}$ generator at

Brookhaven National Laboratory (BNL) (Stang et al. 1954, 1957). The technetium daughter radionuclide was soon envisioned for medical use (1960), and indeed its first clinical application was reported in 1961 (Richards 1960; Harper et al. 1962) and has revolutionized radio-pharmaceutical chemistry and nuclear medicine. Since that time, various other generator systems have been developed, and some of them received significant practical application.

The broad use of the $^{99}\text{Mo}/^{99\text{m}}\text{Tc}$ generator system in nuclear medicine is a key example, which has been crucial for more than 2 decades for the hospital or central radiopharmacy preparation of a wide variety of diagnostic agents for applications in nuclear medicine and oncology. Over 35,000 diagnostic procedures are estimated to be currently conducted daily in the USA. (>16 million studies per year) with $^{99\text{m}}\text{Tc}$. This reliance on the availability of $^{99\text{m}}\text{Tc}$ clearly underscores the crucial importance of the continued and reliable ^{99}Mo production and processing facilities to ensure the uninterrupted supply of the generator parent radionuclide required for fabrication of these generator systems.

These developments have been reviewed (Brucer 1965; Stang 1969; Lebowitz and Richards 1974; Lieser 1976; Yano 1978; Boyd et al. 1984; Paras and Thiessen 1985; Boyd 1986; Mani 1987; Lambrecht and Sajjad 1988; Ruth et al. 1989; Knapp et al. 1992; Knapp and Mirzadeh 1994; Mirzadeh and Knapp 1996; Lambrecht et al. 1997). Detailed reviews have addressed the following topics: parent–daughter half-lives (Finn et al. 1983), reactor-produced generators (Mani 1987), accelerator-produced generators (Lambrecht 1983), cyclotron production of generator parent nuclides (Qaim 1987), ultra short-lived generator-produced radionuclides (Guillaume and Brihaye 1986, 1987), generator-derived positron-emitting radionuclides (Knapp et al. 1992), and clinical applications (Knapp and Butler 1984; Knapp and Mirzadeh 1994). In addition to the generators discussed here in a clinical context, a significant number of other generator pairs exist. Many of those cases have been identified by Lieser (1976) for example, but there still may be other parent/daughter radionuclide pairs whose potential feasibility for generators has not yet been considered.

40.1.2 Equations of Radioactive Decay and Growth

The exponential laws of radioactive-series decay and growth of radionuclides were first formulated by Rutherford and Soddy in 1902, to explain their results (Rutherford and Soddy 1902, 1903) on the thorium series of radionuclides. In 1910, Bateman (Bateman 1910) derived generalized mathematical expressions that were used to describe the decay and growth of the naturally occurring actinium, uranium, and thorium series until the discovery of nuclear fission and other new radioactive decay series were found in the 1940s. For the description of half-lives and decay constants, activities and number of radionuclides involved in the decay of two radionuclides, Friedlander et al. (1981) have given a representative overview (see also ► Chap. 5 in Vol. 1).

A radioactive nuclide decays according to an exponential law:

$$N = N_0 e^{-\lambda t} \text{ or } A = A_0 e^{-\lambda t} \quad (40.1)$$

where N and A represent the number of atoms and the activity, respectively, at time t , and N_0 and A_0 the corresponding quantities when $t = 0$, and λ is the decay constant for the radionuclide. The half-life $T_{1/2}$ is related to the decay constant

$$T_{1/2} = \frac{\ln 2}{\lambda} \approx \frac{0.69315}{\lambda}. \quad (40.2)$$

The general case for the generation of a second radioactive nuclide from the decay of a first one must consider the decay parameters of the first radioactive nuclide, denoted by subscript 1 (parent), as well as the parameters of the produced second radioactive nuclide, denoted by subscript 2 (daughter). The behavior of N_1 is

$$-(dN_1/dt) = \lambda_1 N_1, \text{ and } N_1 = N_1^0 e^{-\lambda_1 t} \quad (40.3)$$

where N_1^0 represents the value of N_1 at $t = 0$. The second radionuclide is formed at the rate at which the first decays, $\lambda_1 N_1$, and itself decays at the rate $\lambda_2 N_2$:

$$\frac{dN_2}{dt} = \lambda_1 N_1 - \lambda_2 N_2 \quad (40.4)$$

or

$$\frac{dN_2}{dt} = \lambda_2 N_2 - \lambda_1 N_1^0 e^{-\lambda_1 t} = 0. \quad (40.5)$$

► Equations (40.4) and ► (40.5) represent linear differential equations of the first order and solutions obtained by standard methods lead to

$$N_2 = \frac{\lambda_1}{\lambda_2 - \lambda_1} N_1^0 (e^{-\lambda_1 t} - e^{-\lambda_2 t}) + N_2^0 e^{-\lambda_2 t} \quad (40.6)$$

where N_2^0 is the value of N_2 at $t = 0$. The first group of terms reflects the growth of a “daughter” radionuclide 2 from a “parent” radionuclide 1 and the decay of these “daughter” radionuclides, while the second term gives the contribution at any time from the “daughter” radionuclides initially present.

Radionuclide generations are distinguished according to the half-lives of the parent and daughter radionuclides. Depending on which of the two radionuclides has the longer half-life, three principal cases occur: (1) parent is longer-lived, but not more than by a factor of about 100, i.e., $T_{1/2,2} < T_{1/2,1} < 100 T_{1/2,2}$, *transient equilibrium*, (2) parent is much longer-lived than the daughter ($T_{1/2,1} \gg T_{1/2,2}$, i.e., $\lambda_1 \ll \lambda_2$), *secular equilibrium*, (3) parent is shorter-lived than the daughter ($T_{1/2,1} < T_{1/2,2}$, i.e., $\lambda_1 > \lambda_2$), *no equilibrium*.

Because in some cases daughter radionuclides are relevant, which are generated via one or more intermediate radionuclides from an original parent, also decay chains must be considered.

40.1.2.1 Transient Equilibrium

Suppose the parent is longer-lived than the daughter ($T_{1/2,1} > T_{1/2,2}$, i.e., $\lambda_1 < \lambda_2$), ► Eq. (40.6) reaches the form of ► Eq. (40.7)

$$N_2 = \frac{\lambda_1}{\lambda_2 - \lambda_1} N_1^0 e^{-\lambda_1 t} \quad (40.7)$$

($e^{-\lambda_2 t}$ is negligible compared with $e^{-\lambda_1 t}$ after t becomes sufficiently large, and $N_2^0 e^{-\lambda_2 t}$ also becomes negligible). Since $N_1 = N_1^0 e^{-\lambda_1 t}$, the ratio of the numbers of the two radionuclides is

$$\frac{N_1}{N_2} = \frac{\lambda_2 - \lambda_1}{\lambda_1}, \quad (40.8)$$

and, consequently, the ratio of the absolute activities of the two radionuclides is

$$\frac{A_1}{A_2} = \frac{(\lambda_2 - \lambda_1)}{\lambda_2} = 1 - \frac{\lambda_1}{\lambda_2}. \quad (40.9)$$

This ratio of the two activities may thus have any value between 0 and 1, depending on the ratio of λ_1 to λ_2 . Consequently, in equilibrium the daughter activity will be greater than the parent activity by the factor $\lambda_2/(\lambda_2 - \lambda_1)$. Starting with an initially pure parent fraction, the sum of the parent and daughter disintegration rates goes through a maximum before transient equilibrium is achieved. In equilibrium, both activities decay with the parent's half-life. The corresponding kinetics are illustrated in ▶ Fig. 40.1, giving an example of the transient equilibrium for the most prominent medical radionuclide generator ^{99}Mo ($T_{1/2} = 65.945 \text{ h}$)/ $^{99\text{m}}\text{Tc}$ ($T_{1/2} = 6.006 \text{ h}$). The ratio between the half-lives is 11. The curves represent variations with time of the parent activity and the activity of a freshly isolated daughter fraction, the growth of daughter activity in a freshly purified parent fraction, and other relations (▶ Fig. 40.2). ▶ Figure 40.2 illustrates the general regime of subsequent separations of the daughter nuclide and shows the ingrowth of the daughter activity within the generators systems after each separation cycle.

40.1.2.2 Secular Equilibrium

The limiting case of radioactive equilibrium at $\lambda_1 \ll \lambda_2$ is called secular equilibrium. In this case, the parent activity does not decrease measurably during many daughter half-lives.

■ Fig. 40.1

Transient radionuclide generator kinetics for the system $^{99}\text{Mo}/^{99\text{m}}\text{Tc}$. A, independent activity of the parent nuclide; B, growth of cumulative parent and daughter activity in a pure parent fraction; C, growth of daughter activity in a pure parent fraction; D, independent decay of the separated pure daughter fraction at maximum of generated activity

► Equations (40.8) and ► (40.9) reduce to $N_1/N_2 = \lambda_2/\lambda_1$ and $A_1 = A_2$. In these equilibria, the daughter activity will not exceed the parent activity. This characteristic, different from the transient equilibrium shown in ► Fig. 40.1, is illustrated for the $^{68}\text{Ge}/^{68}\text{Ga}$ radionuclide generator in ► Fig. 40.3. The ratio between the mother and daughter half-lives in this case is $270.8 \times 24 \text{ h}/1.135 \text{ h} = 5726$.

■ Fig. 40.2

Illustration of daughter (A_2) in growth and parent (A_1) decay for four successive elution cycles

■ Fig. 40.3

Secular radionuclide generator kinetics for the system $^{68}\text{Ge}/^{68}\text{Ga}$. A, independent activity of the parent nuclide; B, growth of cumulative parent and daughter activity in a pure parent fraction; C, growth of daughter activity in a pure parent fraction; D, independent decay of the separated pure daughter fraction at maximum of generated activity

In the case of $T_{1/2,1} \gg T_{1/2,2}$ the maximum activity of the daughter occurs at the time, t , which is calculated by ▶ Eq. (40.10):

$$t = \frac{1}{\lambda_2 - \lambda_1} \ln \frac{\lambda_2}{\lambda_1}. \quad (40.10)$$

With the $^{68}\text{Ge}/^{68}\text{Ga}$ system, the theoretical maximum of generated activity is reached after 14.1 h. However, in the case of secular equilibria cyclic separations are performed much more frequently than that, e.g., after three half-lives of ^{68}Ga already (i.e., about 3.4 h after the preceding elution), when about 90% of the theoretical maximum is generated. In a clinical context, this may allow three individual elutions per day.

40.1.2.3 No Equilibrium

If the parent is shorter-lived than the daughter ($T_{1/2,1} < T_{1/2,2}$, i.e., $\lambda_1 > \lambda_2$), it is evident that no equilibrium is attained at any time. If the parent is made initially free of the daughter, then as the parent decays the amount of daughter will rise, pass through a maximum, and eventually decay with the characteristic half-life of the daughter.

40.1.2.4 Decay Chains: Many Successive Decays

The radionuclide of interest might not be produced by a direct generation from a parent radionuclide exclusively. Instead, it might be a product of a decay chain involving more than one parent radionuclide. If a chain of three or more radioactive products needs to be considered, the equations derived for N_1 and N_2 as functions of time are valid as well, and N_3 for example may be found by solving a new differential equation:

$$\frac{dN_3}{dt} = \lambda_2 N_2 - \lambda_3 N_3. \quad (40.11)$$

Mathematical treatments of this equation and for $n \geq 4$ members of a decay chain were developed (Bateman 1910). Moreover, for many decay chains, the case of branching decay needs to be considered. When a nuclide A can decay by more than one mode (e.g., by β^- decay generating the radionuclide B and by α decay generating the radionuclide C) the two partial decay constants λ_B and λ_C must be considered, cf. the generator systems with the ^{213}Bi parent. The considerations for branching decay, of course, are valid as well for a single, i.e., non-decay-chain decay.

40.1.3 Classifications

Generally, the decay of a radioactive nuclide results in a longer-lived or even stable daughter nuclide. In this respect, radionuclide generator systems where the daughter nuclide presents a shorter half-life are a welcome exception from the general properties of β decay. In particular, for a clinical application, a state of a “radioactive equilibrium” is mandatory. Thus, mainly the transient and secular equilibria of radionuclide generations are relevant for

application of the radionuclide pairs discussed in this chapter. There appears to be some relevancy for application of so-called *in vivo* radionuclide generator, which will be discussed as well.

There is another unique property of a “medical” radionuclide generator: The daughter nuclide is generated at a no-carrier-added concentration. It thus ideally meets the criteria of Hevesy’s tracer concept, which entail the application of labeled compounds at almost negligible concentrations, completely irrelevant for pharmacodynamic interactions with the human body.

In addition, radionuclide generators intended for applications in life science, in particular in the context of routine clinical use, must meet strict regulatory and quality control requirements. The production of the radionuclide generator parent, its separation from the target material, the chemical and technical construction of the separation of the radionuclide generator daughter are factors, which in totality shall finally result in an efficient and easy handling. They are discussed below.

1. The production of the radionuclide generator parent: This includes the route of parent nuclide availability, i.e., reactor or accelerator production or usage of decay chains of “naturally” occurring radioisotopes or of reactor-generated ones; the investigation of precise nuclear data, which is mandatory for optimum production parameters providing the corresponding thick target yields and radionuclidic purities; high-flux irradiations with sophisticated target design at adequate irradiation facilities (including cost of irradiations); costs of target materials and if the use of enriched target material is required; specific activity of the parent isotope (no-carrier-added vs. carrier-added). Reactor and cyclotron-based production of the parent nuclides is discussed in detail in [Chaps. 38 and 39](#) of this Volume.
2. The selection of a separation method of the parent nuclide from the target material: Investigation of the optimum chemical form of the target material and the principal separation methods (ion exchange, extraction, volatilization, precipitation, etc.) allowing high chemical yields of the parent nuclide; recovery of enriched target materials, etc.
3. The chemical and technical concept of the separation of the radionuclide generator daughter: Development of the optimum separation method (most often ion exchange or extraction; for in-house use ion exchange chromatography almost exclusively) providing high yield of the daughter nuclide in minimum volumes and highest radionuclidic purity (i.e., lowest breakthrough of parent nuclide); selection of solutions used, etc.
4. The efficient and easy handling: Experimental vs. routine build-up of the final generator, consideration of the activity scale with regard to radiation stability (radiolysis) and radiation safety; regulatory requirements and commercial logistics; eventual recovery of the parent nuclide, etc.

A significant number of generator radionuclide pairs have been discussed over the last decades, most of which are summarized in [Table 40.1](#). This table also indicates the main production route of the parent radionuclide, i.e., whether the parent nuclide is accelerator or reactor produced or is made available via nuclear decay chains. According to their application for PET imaging, single photon emission computer tomography (SPECT), and photon imaging or for therapy, for various individual generators a short review is provided on the medical potential of the generator, the production routes of the parent nuclide, the chemical concepts of generator pair separations, and on some examples of state-of-the-art application of the daughter nuclide.

40.2 Generator-Produced Positron Emitters

40.2.1 Overview

Among the generator pairs relevant for quantitative PET (➔ Table 40.2), all parent nuclides are neutron deficient and are thus produced at accelerators. All daughter nuclides are positron emitters and provide a significant positron branching, although in some cases the decay is accompanied by high-energy photons, which might require careful adoption of PET scanners.

The generators can be categorized according to the half-life of the daughter nuclide. The short-lived daughters cover half-lives of a few minutes. As the short half-lives do not allow radiochemical synthesis, these systems are relevant for perfusion imaging exclusively. The generator design must allow for direct application of the separated daughter for human use.

The longer-lived daughter nuclides, on the other hand, provide a potential for the development of labeled radiopharmaceuticals. However, due to the long half-life and the low cross sections, in particular for the parent nuclides ^{44}Ti , ^{68}Ga , and ^{82}Sr , the production rates are relatively low and require long high-current irradiations. Although this results in rather high cost per generator, the number of PET scans achievable lowers the costs per individual patient investigation.

40.2.2 Generators with Potential Medical Application

Some generator pairs have been proposed decades ago and have continuously been improved radiochemically. In many cases, however, there was no parallel development of medical

■ Table 40.2

*Mean value of most recent various literature data.

application of the generator daughter nuclides due to various reasons, which might have led to a current routine application of the generator. On the other hand, although not yet accepted for routine clinical use, some generator pairs offer a significant potential for application in diagnostic nuclear medicine using PET due to the promising nuclear data of both the parent and daughter.

^{44}Ti ($T_{1/2} = 60 \text{ a}$)/ ^{44}Sc ($T_{1/2} = 3.927 \text{ h}$). Compared to the chemically similar system $^{68}\text{Ge}/^{68}\text{Ga}$, this generator provides a much longer-lived daughter for extended PET/CT measurements. Also for the mother nuclide, the half-life is even longer than for ^{68}Ge . Although ^{44}Ti half-life values found in the literature vary significantly, most recent values average 60 ± 3 years. ^{44}Ti is produced by the $^{45}\text{Sc}(p,2n)$ reaction and by proton-induced spallation on V or Cr targets (Lambrecht and Lynn 1976; Sajjad and Lambrecht 1986; Zaitseva et al. 1994). The production rates are low and require long high-current irradiations. Dowex-1 and 0.1 M oxalic acid in 0.2 M HCl (Greene and Hillman 1967) provided a 60–70% radiochemical yield of ^{44}Sc in 30–50 mL of eluent, while the initial breakthrough of $10^{-3}\%$ increased to $10^{-1}\%$ after eluent volume of up to 2 L. With zirconium oxide as an analogue of Ti(IV) used as the support, and 0.01 M HCl as eluent, Seidl and Lieser (1973) reported a 42–46% radiochemical yield and a decontamination factor of 5×10^4 . A solvent extraction technique with an organic phase of 1% 1-phenyl-3-methyl-4-capryl-pyrazolone-5 in methyl isobutyl ketone led to >90% recovery of Sc in <10 mL with a Ti contamination of $<10^{-6}$ (Mirza and Aziz 1969).

The first 5 mCi high activity level generator was described recently (Filosofov et al. 2010). $^{44}\text{Ti}/^{44}\text{Sc}$ radionuclide generators are of interest for molecular imaging. In this study, 185 MBq of ^{44}Ti were obtained via the $\text{Sc}(p,2n)$ nuclear reaction. The separation of microscopic levels of ^{44}Ti from the macroscopic levels of scandium represents a significant challenge. The ^{44}Ti was separated from 1.5 g of massive scandium targets in multi-step procedures, including exchange chromatography on a cation column (AG 50W-X8, 200–400 mesh, H^+ -form). In order to design a robust $^{44}\text{Ti}/^{44}\text{Sc}$ generator concept, distribution coefficients of Ti(IV) and Sc(III) on both AG 1-X8 (200–400 mesh, Cl^- -form) and AG 50W-X8 (200–400 mesh, H^+ -form) resins eluted with HCl and $\text{HCl}/\text{H}_2\text{C}_2\text{O}_4$ solution of various concentrations were investigated systematically. Optimal conditions for efficient separations of both radionuclides have been determined for AG 1-X8 resin and mixtures of 0.07 M HCl and 0.005 M $\text{H}_2\text{C}_2\text{O}_4$. The 5 mCi generator was prepared on a column ($H = 150 \text{ mm}$, $D = 3 \text{ mm}$, $V_0 = 0.55 \text{ mL}$) made of radiation resistant PEEK polymer (polyetheretherketone). The system achieved elution of 180 MBq ^{44}Sc in 20 mL of eluate solution. The breakthrough of ^{44}Ti was 90 Bq. This corresponds to an excellent separation factor of 2×10^6 . In the context of long-term stability of $^{44}\text{Ti}/^{44}\text{Sc}$ generators, a “reverse” type of washing steps after each elution using 0.07 M HCl/0.005 M $\text{H}_2\text{C}_2\text{O}_4$ mixtures appeared to be essential. To allow efficient ^{44}Sc labeling, a post-elution processing of initial ^{44}Sc generator eluates was investigated in order to reduce its volume, for HCl concentration and to remove the oxalate anions (Pruszyński et al. 2010). The online adsorption of ^{44}Sc on cationic resin AG 50W-X8 (200–400 mesh, H^+ -form) is achieved with >98% efficacy. Subsequently, the purified ^{44}Sc is desorbed by using 3 mL of 0.25 M ammonium acetate ($\text{pH} = 4.0$). The post-processing requires only 10 min. The overall yield of the post-processing reached 90% of the ^{44}Sc obtained from the $^{44}\text{Ti}/^{44}\text{Sc}$ generator. In addition to the chemical purification, the content of ^{44}Ti breakthrough was further reduced by one order of magnitude. The generator finally provides 150 MBq of ^{44}Sc containing <10 Bq of ^{44}Ti ready for radiolabeling chemistry.

Syed and Hosain (1975) proposed ^{44}Sc as a positron-emitting radionuclide for studying bone disease with positron emission tomography. Due to the increasing medical applications

of trivalent radiometals in diagnosis and therapy, the generator could possibly provide an interesting route for PET-imaging using ^{44}Sc -labeled analogues. As a proof-of-principle, ^{44}Sc -DOTA-TOC was synthesized and somatostatin G-protein coupled receptor (GPCR) localization was verified in patient studies (Rösch and Baum 2009, unpublished data). High-quality PET/CT images have been recorded even 18 h post injection. The unique application will focus on the quantitative measurement of uptake kinetics of, e.g., ^{44}Sc -DOTA-TOC in primary and metastatic neuroendocrine tumors in order to estimate the optimum radiation dose the individual patient will receive in a subsequent therapeutic application of biologically and chemically analogue compounds, e.g., ^{90}Y -DOTA-TOC or ^{177}Lu -DOTA-TOC.

^{52}Fe ($T_{1/2} = 8.28\text{ h}$)/ $^{52\text{m}}\text{Mn}$ ($T_{1/2} = 21.1\text{ min}$). Lyster et al. (1982) and Tendov et al. (1988) have reviewed the production and purification of ^{52}Fe by the $^{50}\text{Cr}(\text{}^4\text{He}, 2\text{n})$, $^{52}\text{Cr}(\text{}^3\text{He}, 3\text{n})$, $^{55}\text{Mn}(\text{p}, 4\text{n})$, $^{54}\text{Fe}(\gamma, 2\text{n})$, and $\text{Ni}(\text{p}, \text{s})$ reactions. Experimental thick target yields for the $^{52}\text{Cr}(\text{}^3\text{He}, 3\text{n})$ and the $^{55}\text{Mn}(\text{p}, 4\text{n})$ reactions are 1.85 and $3.6\text{ MBq } \mu\text{A}^{-1}\text{ h}^{-1}$, respectively, while the proton-induced spallation reaction $\text{Ni}(\text{p}, 3\text{pxn})$ provides $24\text{ MBq } \mu\text{A}^{-1}\text{ h}^{-1}$. A projected half-saturation yield of 307 GBq (end of bombardment, EOB) was considered (Grant et al. 1979), and Ku et al. (1979a) reported a yield of 2.6 GBq (EOB) following irradiation of 0.45 g cm^{-2} of Ni at 200 MeV with $70\text{ } \mu\text{A}$ for 15 h . Recent studies thus concentrated on the latter process, also showing lower ^{55}Fe ($T_{1/2} = 2.6\text{ a}$) impurities. Although providing lower yields of 3.7 MBq h^{-1} at $5\text{ } \mu\text{A}$ beam, 0.008% ^{55}Fe and $1.67\text{ MBq } \mu\text{A}^{-1}\text{ h}^{-1}$, the $^{52}\text{Cr}(\text{}^3\text{He}, 3\text{n})$ (Fessler et al. 1994), and $^{50}\text{Cr}(\alpha, 2\text{n})$ processes on enriched chromium targets (Zweit et al. 1988) could be an alternative concerning the radionuclidic impurity of ^{52}Fe . Conventional anion exchange chromatography using 8 M HCl was applied for the isolation of the short-lived daughter onto Dowex 1 columns (Atcher et al. 1978, 1980) or AGI-X8 (Ku et al. 1979b). To avoid hydrochloric solutions either 2 M tartrate solutions were used to eluate $^{52\text{m}}\text{Mn}$ (Schwarzbach et al. 1991) or a 5% glucose solution (Bläuenstein et al. 1997) from Dowex 1, the later approach providing 90% elution yields with a $<0.3\%$ ^{52}Fe contamination. A hydroxamate resin allowed elution of $^{52\text{m}}\text{Mn}$ with acetate buffer or physiological saline (Herscheid et al. 1983). Based on early tissue distribution studies with $^{54}\text{Mn}^{2+}$ (Chauncey et al. 1977), this generator had received some attention because of the high heart uptake of Mn, and the possibility of using $^{52\text{m}}\text{Mn}$ or ^{51}Mn in combination with positron emission tomography for evaluation of myocardial perfusion (Lambrecht and Wolf 1970; Atkins et al. 1979; Atcher et al. 1980).

^{72}Se ($T_{1/2} = 8.4\text{ d}$)/ ^{72}As ($T_{1/2} = 1.083\text{ d}$). This generator could provide a long-lived positron emitter with significant (88%) positron branching. Both deuteron- or proton-induced reactions on arsenic targets and α - or ^3He -induced reaction on germanium targets have been investigated, mainly in the context of ^{73}Se production (Nozaki et al. 1979; Mushtaq et al. 1988; Mushtaq and Qaim 1990). Alternatively, ^{72}Se was obtained via proton-induced spallation of RbBr. Al-Kouraihi and Boswell (1978) were able to obtain a 70% elution yield of ^{72}As from a coagulated form of carrier-added ^{72}Se on a Dowex 50 column in 15 mL of water. Electrolytic generators based on ^{72}Se deposited on Pt electrodes as Cu^{72}Se were reported (Phillips and Nix 1989). Another process using addition of selenium carrier consists of cyclic reduction of selenium to Se^0 and a separation of ^{72}As by filtration with subsequent oxidative dissolution of Se^0 using H_2O_2 . For generators using no-carrier-added ^{72}Se , Novgorodov et al. (2001) described the distillation of AsCl_3 , while Se remains in nonvolatile compounds in the residue. Jennewein et al. (2004) developed a solid phase extraction system with ^{72}Se fixed as metallic Se; the daughter ^{72}As is eluted by protic solvents. Systematic chemical investigations on the labeling chemistry of no-carrier-added radioarsenic, however, are required prior to the application of ^{72}As labeled compounds (Brockmann et al. 1999a, b). In this context, a new method

was developed (Jennewein et al. 2006) for labeling monoclonal antibodies, i.e., proteins, with radioactive arsenic isotopes via the labeling synthon [*As]AsI₃. Arsenic has a high affinity to sulfur and [*As]AsI₃ is able to bind covalently to sulfhydryl groups. In antibodies, the sulfur moieties are mainly associated with dithiol bridges. To increase the number of free thiols, the antibodies were modified with SATA (*N*-succinimidyl S-acetylthioacetate). At least for the mAb (monoclonal antibody) used in this work, this route of radioarsenic labeling does not affect the immunoreactivity of the product. The arsenic label was stable for up to 72 h at the molecular mass of the monoclonal antibody, which is particularly relevant because of the molecular imaging strategy, namely to follow the pharmacology and pharmacokinetics of the labeled mAb for several days. TarvacinTM, a chimeric monoclonal antibody that binds anionic phospholipids in the presence of serum or β 2-glycoprotein 1, was labeled using trivalent radioarsenic and tested for its ability to image Dunning prostate R3227–AT1 tumors growing subcutaneously in rats (Jennewein et al. 2008). [$^{72,74}As$]TarvacinTM localized specifically to tumor vascular endothelial cells after injection into tumor-bearing rats. Clear images of the tumors were obtained using planar γ -scintigraphy and positron emission tomography, confirming the utility of the arsenic radioisotopes for molecular imaging. Biodistribution studies confirmed the specific localization of [$^{72,74}As$]TarvacinTM to the tumors. The tumor-to-liver ratio 72 h after injection was 22 for [$^{72,74}As$]TarvacinTM as compared with 1.5 for an isotype-matched control chimeric antibody of irrelevant specificity, demonstrating the potential merits of this promising approach.

^{110}Sn ($T_{1/2} = 4.1$ h)/ ^{110m}In ($T_{1/2} = 1.15$ h). Positron-emitting ^{110m}In could be a choice for quantitative imaging of analogous ^{111}In SPECT compounds (Tsai et al. 1997, Lubberink et al. 2002b). The direct production of ^{110m}In via $^{110}Cd(p,n)$ -, $^{107}Ag(\alpha,n)$ -, and $^{109}Ag(^3He,2n)$ -processes, however, leads to the co-formation of the ground state isomer ^{110g}In ($T_{1/2} = 4.9$ h). Isotopically pure ^{110m}In could only be prepared via the generator system $^{110}Sn/^{110m}In$ (Tsai et al. 1997). ^{110}Sn was produced via the $^{110}Cd(^3He,3n)$ reaction with $36 \rightarrow 25$ MeV 3He particles and $^{110}SnCl_4$ was isolated thermochromatographically from the enriched target material. The generator itself was designed by adsorption of ^{110}Sn on a small Kieselgel 40 column and ^{110m}In was eluted quantitatively within 1 mL 0.02 M HCl. However, the short half-life of ^{110}Sn resulting in short useful generator shelf life would possibly limit a wide application of the generator system.

^{118}Te ($T_{1/2} = 6.00$ d)/ ^{118}Sb ($T_{1/2} = 3.6$ min). The production of ^{118}Te via $^{123}Sb(p,6n)$ - and $^{121}Sb(p,4n)$ -processes was initially reported by Lindner and Perlman (1950) and Fink et al. (1961), while excitation functions were measured by Lagunas-Solar et al. (1990). Batch yields of ^{118}Te in a Ci-scale, however, would be accompanied by significant $^{119m,g}Te$ impurities resulting in ^{119}Sb ($T_{1/2} = 38.1$ h) impurities. Alternatively, the $^{116}Sn(\alpha,2n)$ reaction holds promise for the production of isotopically more pure ^{118}Te if an enriched ^{116}Sn target would be used (Yano et al. 1989). These authors used SnO_2 and Al_2O_3 type generators to elute ^{118}Sb with tartrate and citrate solutions.

^{122}Xe ($T_{1/2} = 20.1$ h)/ ^{122}I ($T_{1/2} = 3.6$ min). Various positron-emitting nuclides of iodine have been proposed to obtain more precise data on localization, quantification, and dosimetry of these compounds using PET. ^{122}I represents one important example providing a 77% β^+ branching. The availability via the generator was investigated as a by-product during the production of the $^{123}Xe/^{123}I$ generator by the $^{127}I(p,6n)^{122}Xe$ reaction with 70 MeV protons (Diksic and Yaffe 1977; Richards and Ku 1979; Mathis et al. 1986; Lagunas-Solar et al. 1986) or analogously via the (d,7n) channel (Weinreich et al. 1974) and the $^{124}Xe(p,3n)$ process

(Tárkányi et al. 1991). Amphetamine analogues and iodoperidol were successfully labeled with ^{122}I to measure brain blood flow with PET (Braun et al. 1978; Mathis et al. 1985; Moerlein et al. 1987). Not only rapid iodination chemistry is required to make use of the short-lived iodine positron emitter, but also the short physical half-life might not correspond to longer-lasting physiological requirements.

^{128}Ba ($T_{1/2} = 2.43\text{ d}$)/ ^{128}Cs ($T_{1/2} = 3.62\text{ min}$). The accelerator production of ^{128}Ba has been evaluated with the $^{133}\text{Cs}(\text{p},\text{xn})$ reactions at $E_p = 67 \rightarrow 54\text{ MeV}$ (Lagunas-Solar et al. 1982), and 111 MBq $\mu\text{A}^{-1}\text{ h}^{-1}$ experimental thick target yields were reported. The $\text{Xe}(\alpha,\text{xn})$ reactions seem to be possible as well. Elution yields of ^{128}Cs from a Chelex 100 column ranging from 60–80% were obtained with 5–10 mL of 0.9% NaCl pH 9 solutions. Bievelez and Jacquemin (1982) loaded $^{128}\text{Ba}^{2+}$ onto Chelex 100 from a solution of NH_4OH (pH 9.25–9.3) in a buffer of 0.1 M NH_4Cl . Transition between the buffer and an elution medium of 0.1 M NH_4OH and 0.06 M NaCl/HCl at pH 10 was done by successive washings, which resulted in <0.5% loss of the initial ^{128}Ba . ^{128}Cs yields of 75 and 90% were obtained and the breakthrough was $1.1 \times 10^{-3}\%$ per mL. The $^{128}\text{Ba}/^{128}\text{Cs}$ generator is of medical interest, since ^{128}Cs might be applied to blood flow measurements. Bievelez and Jacquemin (1982) attempted to image the heart of rabbits and dogs, but concluded that ^{128}Cs is not compatible with the relatively slow muscle absorption kinetics of Cs.

^{134}Ce ($T_{1/2} = 3.16\text{ d}$)/ ^{134}La ($T_{1/2} = 6.4\text{ min}$). ^{134}Ce is produced via the $^{139}\text{La}(\text{p},6\text{n})$ route within an optimum energy of $61 \rightarrow 53\text{ MeV}$ resulting in a thick target yield of 85 MBq $\mu\text{A}^{-1}\text{ h}^{-1}$. Of several inorganic materials tested, manganese dioxide provided the best adsorption for ^{134}Ce , and ^{134}La was eluted with 85% yield in 1.6 mL of 0.5 M NaCl (Lubberink et al. 2002a). The ^{134}La was proposed as PET perfusion imaging (Zweit et al. 1994). The generator may have, in addition, potential for in vivo application with ^{134}Ce -labeled radiopharmaceuticals.

^{140}Nd ($T_{1/2} = 3.37\text{ d}$)/ ^{140}Pr ($T_{1/2} = 3.39\text{ min}$). This generator also provides a short-lived positron-emitting radiolanthanide nuclide and could have some potential as an in vivo generator. The parent nuclide is produced via the $^{140}\text{Ce}(\alpha,2\text{n})$ or $(^3\text{He},3\text{n})$ reactions (Rösch et al. 1999, 2000) but also via the $^{140}\text{Pr}(\text{p},2\text{n})$ reaction (Zeisler and Becker 1999). The parent nuclide is radiochemically isolated from the target materials by ion exchange chromatography. Chemical isolation of $^{140}\text{Nd}(\text{III})$ from macro amounts of $\text{Ce}(\text{III})$ was performed by cation exchanger chromatography (two purification steps) with an overall separation yield of > 95% ^{140}Nd , overall decontamination factor for cerium of $\sim 10^8$ and with reduction of contaminations of coproduced $\text{Pr}(\text{III})$ isotopes of up to 0.5% (Rösch et al. 2003).

The radiochemical principle of separation of the generator mother and daughter nuclides is based on physical–chemical transitions of ^{140}Pr following the electron capture process. A significant separation effect was observed when the parent nuclide ^{140}Nd was coordinated to a DOTA-conjugated peptide or octylamine, which were absorbed on resins. The thermodynamically and kinetically stable complex binds ^{140}Nd while the released ^{140}Pr is kinetically hindered to form similar complexes with the macrocyclic ligand. The ^{140}Nd -DOTA absorption on the solid phase remains stable within at least three half-lives of ^{140}Nd . ^{140}Pr is eluted with a yield >93% if optimized eluent systems such as 10^{-3} M DTPA are applied with negligible levels of ^{140}Nd breakthrough. For 100 MBq of ^{140}Nd -DOTA-like activity and 0.5 h between two subsequent elutions (half an hour is enough for the accumulation of 100% of ^{140}Pr activity), a breakthrough of about 25 kBq of ^{140}Nd ($\sim 0.025\%$) could be expected (Zhernosekov et al. 2007b).

40.2.3 Key Examples of Generator-Derived Positron-Emitting Radionuclides

^{62}Zn ($T_{1/2} = 9.26\text{ h}$)/ ^{62}Cu ($T_{1/2} = 9.74\text{ min}$). The parent ^{62}Zn can be produced with a significant thick-target yield via the (p,2n) reaction on ^{63}Cu (Robinson et al. 1980) or via the $^{60}\text{Ni}(\alpha,2\text{n})$ process (Neirinckx 1977; Zweit et al. 1992). Anion exchange chromatography is clearly the method of choice for this generator system. To adsorb no-carrier-added $^{62}\text{Zn}^{2+}$, Dowex 1 was used and Cu^{2+} is eluted with hydrochloric acid (Yagi and Kondo 1979; Fujibayashi et al. 1989; Green et al. 1990). CG-120 Amberlite resin provided an elution of ^{62}Cu in 70% yield with a glycine solution (Fujibayashi et al. 1989) allowing subsequent ligand exchange reactions. For elution, other ligands (Okazawa et al. 1994) or HCl/ethanol (Zweit et al. 1992) solutions were also introduced. The ^{62}Cu was chelated to human serum albumin (HSA) (Fujibayashi et al. 1990) and benzyl-TETA-HSA (Mathias et al. 1991b) used for blood pool imaging (Herrero et al. 1996). Several hypoxia and perfusion ^{62}Cu -complexes have been developed and applied for PET studies such as [^{62}Cu]ATSM (diacetyl-bis(N^4 -methylthiosemicarbazone)) (Fujibayashi et al. 1997) and [^{62}Cu]PTSM (pyruvaldehyde bis(N^4 -methylthiosemicarbazone)) (see, e.g., Green et al. 1990; Mathias et al. 1990; Shelton et al. 1989, 1990; Bormans et al. 1992; Taniuchi et al. 1997). Human biodistribution and dosimetry studies of the perfusion agent [^{62}Cu]PTSM were investigated and this tracer was recommended for repeated studies of myocardial imaging in the same patient (Wallhaus et al. 1998) as well as for quantification of the cerebral blood flow (Okazawa et al. 1994). The clinical performance of the $^{62}\text{Zn}/^{62}\text{Cu}$ generator and results of initial evaluation of [^{62}Cu]PTSM in 68 patients have been described (Haynes et al. 2000), and demonstrated that this generator system is easily manufactured and transported, and is an inexpensive source of the ^{62}Cu positron-emitter for in-house radio-pharmaceutical preparation. The compound was also applied for the assessment of angiotensin II-induced blood flow changes in patients with colorectal liver metastases (Flower et al. 2001). The detection of coronary artery disease with [^{62}Cu]PTSM has been reported in 47 patients (Wallhaus et al. 2001). In addition, the successful use of ^{62}Cu liquid-filled angioplasty balloons for the inhibition of coronary restenosis has been reported in a swine coronary overstretch model (Chan et al. 2001). A recent publication (Fukumura et al. 2006), described further refinement of this generator, and focused on high activity (1.8–3.5 GBq) loading of the $^{62}\text{Zn}^{2+}$ on a Sep-Pak™ “plus” CM weak acidic cation exchanger column with a high ^{62}Cu elution yield of ~96% with a low 3 mL volume of 200 mM glycine solution. The Zn parent breakthrough is <0.1%. Semi-automated syringe pump systems were designed for separated hot cell separation system and dispensing systems.

^{68}Ge ($T_{1/2} = 270.8\text{ d}$)/ ^{68}Ga ($T_{1/2} = 68\text{ min}$). The first compilation of the data relevant to $^{68}\text{Ge}/^{68}\text{Ga}$ generator systems was published in 1996 (Mirzadeh and Lambrecht, 1996). The IAEA has recently initiated comprehensive review of the production of several generator mother nuclides including a chapter on ^{68}Ge (Rösch and Filosofov 2009).

Integral ^{68}Ge thick targets yields have been calculated (Horiguchi et al. 1982) for accelerator-based nuclear reactions on natural metallic germanium and zinc, and Ga_2O_3 targets. The yields for the proton-induced reactions on Ga are larger than those on Ge in the region lower than 60 MeV, although the latter become larger above 60 MeV. The thick target yields for the Ga (p,2n) reactions have been recently validated (IAEA 2001). The (p,2n) reaction on gallium targets (Ga_2O_3 or Ga_4Ni) provides significant cross sections. Experimental thick-target yields – calculated for a 1 h irradiation as well as for saturation – amount to 0.96/0.53 MBq $\mu\text{A}^{-1}\text{ h}^{-1}$

at this energy, but reach values of $>2/>1$ MBq $\mu\text{A}^{-1} \text{h}^{-1}$ already at 25 MeV, respectively. Proton-induced spallation reactions on Rb, Br, or As target materials give about one tenth of that yield. The $^{\text{nat}}\text{Zn}(\alpha, \text{xn})$ reactions show similar low cross sections (Hagebo et al. 1984). Due to the long half-life of ^{68}Ge , high-current accelerators are required for sufficient (about 3.7 GBq batch yields) of the parent nuclide. Routine production is established at Brookhaven National Laboratory (BNL) and Los Alamos National Laboratory (LANL), USA, iThemba Laboratories/NAC, Faure, Republic of South Africa, and Obninsk, Russian Federation. These production centers report on production capacities of about 18.5 to 74 GBq (0.5 to 2 Ci) ^{68}Ge per batch. At the Cyclotron Co., Ltd., Obninsk, Russian Federation, gallium–nickel alloys are used as target material, prepared on copper backings. Irradiations are performed at rather high proton beam intensity of several hundred μA at 23 MeV proton energy. ^{68}Ge of high specific activity of >74 GBq (>2 Ci)/mg and 99.8% radionuclidic purity is obtained (Razbash et al. 2005).

Early attempts to adopt liquid–liquid extraction chemistry for the routine generator use were not sustainable (Gleason 1960; Erhardt and Welch 1978). The first column-based generator systems separated ^{68}Ga using 0.005 N EDTA from ^{68}Ge , absorbed on alumina or zirconium oxides (Greene and Tucker 1961; Yano and Anger 1964) and this neutral $[\text{}^{68}\text{Ga}]\text{EDTA}$ solution was directly used in an attempt to image tumors. Analogously, ^{68}Ge was retained on antimony oxide Sb_2O_5 and ^{68}Ga was eluted with oxalate solutions (Arino et al. 1978). Anion exchange resins using dilute hydrofluoric acid solutions as eluents allowed high-purity separations due to the significant differences of distribution coefficients of the elements (Neirinckx and Davis 1980). The breakthrough of ^{68}Ge was $<10^{-4}$ for up to 600 elutions, and the ^{68}Ga yield $>90\%$. In all these cases, however, further application of the generator eluate for ^{68}Ga labeling reactions was not possible.

Consequently, $^{68}\text{Ge}/^{68}\text{Ga}$ generators were developed to avoid the formation of stable ^{68}Ga -ligand complex in the eluate system. This strategy is achieved for eluates providing both $^{68}\text{Ga}(\text{OH})_4^-$ and $^{68}\text{Ga}^{3+}$. Indeed, ^{68}Ga has been eluted in 0.1 M NaOH solution as gallate anion from alumina columns (Lewis and Camin 1960). A comparison of performances of alumina/EDTA, alumina/NaOH, and tin oxide/HCl generators (McElvany et al. 1984), however, indicated superior characteristics for the latter system in terms of ^{68}Ge breakthrough (10^{-6} – $10^{-5}\%$ per bolus) and $^{68}\text{Ga}^{3+}$ elution (70–80%) in 1 M hydrochloric acid (Loc'h et al. 1980). In other cases, ^{68}Ge was absorbed on inorganic matrices such as alumina, $\text{Al}(\text{OH})_3$, and $\text{Fe}(\text{OH})_3$ (Kopecky et al. 1973; Kopecky and Mudrova 1974), SnO_2 , ZrO_2 , TiO_2 (Malyshev and Smirnov 1975), and CeO_2 (Ambe 1988; Bao and Song 1996).

As $\text{Ge}(\text{IV})$ is known to form very stable complexes with phenolic groups (Kurnevich et al. 1974), its adsorption on a 1,2,3-trihydroxybenzene (pyrogallol)-formaldehyde resin was utilized (Schumacher and Maier-Borst 1981; Neirinckx et al. 1982). Average yields of ^{68}Ga of 75% during a period of 250 days were reported (Schumacher and Maier-Borst, 1981). The Ge breakthrough was <0.5 ppm with no detectable radiolytic by-products for a 370 MBq (10 mCi) generator. The pyrogallol-formaldehyde resin was found to be resistant to dissociation from radiation. An organic macroporous styrene-divinylbenzene copolymer containing *N*-methylglucamine groups was developed to provide ^{68}Ga with a solution of a low-affinity gallium-chelating ligand such as citric acid or phosphoric acid. The ^{68}Ge breakthrough was less than 0.0004% of the ^{68}Ge adsorbed on the resin (Nakayama et al. 2003).

For commercial generator productions, however, $\text{Me}(\text{IV})$ -oxide-based matrices were preferred. A modified TiO_2 phase has been used by the pioneers in this field at the Cyclotron Ltd., Obninsk, Russian Federation, since about 2000 (Razbash et al. 2005). These generators are

eluted with 0.1 N HCl and show initial ^{68}Ga elution yields of about 80% with ^{68}Ge breakthrough of about $1 \times 10^{-3}\%$. These values decrease over time (e.g., after about 1 year) or with increasing number of elutions (e.g., 200), approaching values of about 50% of ^{68}Ga elution and about $10^{-2}\%$ of ^{68}Ge breakthrough. A similar generator is available as “IGG 100” providing improved elution characteristics. Another system is produced at iThemba Laboratories, Republic South Africa, using a SnO_2 -based solid phase. Optimum ^{68}Ge elution efficacy is reported at 0.6 N HCl, decreasing at lower HCl concentration.

However, all commercially available generators need further improvement to be acceptable for regulatory approval for routine medical use (Breeman and Verbruggen 2007). The $^{68}\text{Ge}/^{68}\text{Ga}$ radionuclide generator systems used today are not necessarily optimally designed for direct syntheses of radiopharmaceuticals for human use. The eluates still contain measurable activities of long-lived ^{68}Ge . In addition, the rather large volume and the relatively high concentration of hydrochloric acid in many cases prevent the direct use for labeling reactions. Furthermore, labeling yields and specific activities might not reach maximum values due to the presence of metallic impurities. For example, significant amounts of Zn(II) are generated from the decay of ^{68}Ga . For a “fresh” 1110 MBq ^{68}Ge generator, the number of stable ^{68}Zn atoms generated within 1 day after an elution amounts to 9×10^{13} (i.e., 10 ng of Zn(II)) as compared to about 5×10^{12} atoms of ^{68}Ga in 800 MBq of the ^{68}Ga eluted. In the case of “fresh” generators, amounts of stable ^{71}Ga as generated from the ^{71}Ge decay may be one order of magnitude higher than those of stable ^{68}Zn . In addition, Ti(IV) or other residuals from the generator column material and Fe(III) are present in the eluate. All these metallic impurities will adversely affect the ^{68}Ga -labeling yields as well as the specific activity of the labeled product. Thus, dedicated procedures to process the eluate from the radionuclide generator, ideally including labeling and purification of ^{68}Ga radiopharmaceuticals need to be developed.

Anion exchange chromatography: Following the concept of Schumacher and Maier-Borst (1981) of processing 1 N HCl eluates (Meyer et al. 2004) adopted this approach for 0.1 N HCl eluates. The initial volume of 10 mL of the 0.1 N HCl eluate is transferred to a vial containing 15 mL of 9.5 N HCl to obtain a final hydrochloric acid concentration of 5.5 M. Under these conditions ^{68}Ga can be adsorbed on a strong anion exchanger as anionic chloro complexes of $^{68}\text{Ga}(\text{III})$. Following a washing step with 1 mL of 5.5 N HCl, the resin is flushed with a stream of nitrogen and then ^{68}Ga is eluted with H_2O in small volumes. This strategy separates ^{68}Ge , but does not allow *direct* loading of $^{68}\text{Ga}(\text{III})$ on the anion exchange resin from 0.1 N HCl and does not purify Ga(III) from Zn(II) and Fe(III) impurities either. A final yield of $46 \pm 5\%$ for the ^{68}Ga -labeled DOTA-conjugated octreotide is reported (Meyer et al. 2004; Velikyan et al. 2004; Meyer et al. 2005; Decristoforo et al. 2005).

Fractionation (Breeman et al. 2005): The concept utilizes the fact that the eluted ^{68}Ga activity peaks within $\sim 1\text{--}2$ mL, representing about $2/3$ of the total activity. If this fraction is isolated from the eluate, the contents of ^{68}Ge and metallic impurities are lowered because of the lower eluate volume used. When synthesizing ^{68}Ga -labeled compounds, decay-corrected yields of ^{68}Ga radiopharmaceuticals cannot exceed 60–70% and effective yields of labeled DOTA-conjugated peptides like ^{68}Ga -DOTATOC amount to about 50% (Decristoforo et al. 2005).

Cation exchange chromatography: The key step in this procedure is the direct transfer of the initial 0.1 N HCl ^{68}Ga eluate to a cation exchanger. Due to high distribution coefficients, ^{68}Ga is quantitatively adsorbed on only about 50 mg of the resin directly from the generator eluate. This effect also occurs with higher concentrations of HCl, e.g., 0.6 N HCl, as used for SnO_2 -based $^{68}\text{Ge}/^{68}\text{Ga}$ generators. Low volumes of 0.4–1.0 mL of hydrochloric acid/acetone mixtures

are applied to purify ^{68}Ga from Ge(IV) , Ti(IV) , Zn(II) , and Fe(III) . This procedure leads to almost complete removal of metallic impurities including ^{68}Ge breakthrough, thus providing the purified ^{68}Ga in a form useful for direct labeling with acceptable pH, volume, and purity. The post-processing takes 4 min with overall ^{68}Ga recovery yields of $97 \pm 2\%$ (Zhernosekov et al. 2007; Asti et al. 2008). The above method is adapted for the preparation of a chemistry module, which is commercially used for the preparation of injectable ^{68}Ga -labeled radiopharmaceuticals.

^{68}Ga had some earlier application as [^{68}Ga]BAT-TECH agent for myocardial perfusion (Mathias et al. 1991a), but significant potential has been developed since about 2000 for imaging neuroendocrine tumors using [^{68}Ga]DOTA-DPhe¹-Tyr³-octreotide ([^{68}Ga]DOTATOC) and PET (Hofmann et al. 2001). This octapeptide shows high affinity to the sstr2 subtype of somatostatin receptor expressing tumors, and the conjugated macrocyclic bifunctional chelator DOTA binds the trivalent $^{68}\text{Ga}^{3+}$ with high thermodynamic and kinetic stability. Despite the short ^{68}Ga half-life, this tracer allows excellent visualization of tumors and small metastases (Al-Nahhas et al. 2007; Decristoforo et al. 2007; Dimitrakopoulou-Strauss et al. 2006; von Falck et al. 2007; Gabriel et al. 2007, 2009; Henze et al. 2004, 2005; Khan et al. 2009; Koukouraki et al. 2006a, b; Lopci et al. 2008; Luboldt et al. 2010; Maecke et al. 2005; Milker-Zabel et al. 2006; Nyuki et al. 2010; Putzer et al. 2009; Win et al. 2007). This diagnosis, in particular if carried out using PET/CT imaging, is superior to any other imaging approach (► Fig. 40.4). Systematic

[^{68}Ga]DOTA-DPhe¹-Tyr³-octreotide imaging of neuroendocrine tumors using PET/CT (right) compared to ^{111}In -octreoscan SPECT (middle) and ^{18}F -FDG PET (left) (Courtesy of H. Bihl, Stuttgart)

research continues to develop new ^{68}Ga radiopharmaceuticals. For recent reviews cf. Fani et al. (2008), Rösch and Riss (2010).

Another interesting and potentially important application of ^{68}Ga is the use of ^{68}Ga liquid-filled angioplasty balloons for the inhibition of arterial restenosis following coronary angioplasty (Stoll et al. 2001). This technique with a high-energy positron emitter is similar to the techniques demonstrated using balloons filled with ^{188}Re and other medium and high-energy β emitters (Knapp et al. 2001).

^{82}Sr ($T_{1/2} = 25.6\text{ d}$)/ ^{82}Rb ($T_{1/2} = 1.273\text{ min}$). The ^{82}Rb positron emitter was recognized as a potential PET nuclide due to its analogy to the physiological monovalent potassium cation, which is transported across the cell membrane via the sodium-potassium ATP ion exchange pathway. ^{82}Rb is partially extracted by the myocardium during a single capillary pass. The development of this generator has taken place over the past 25 years and has been intensively discussed in numerous reviews (Waters and Coursey 1987; Vereschchagin et al. 1993). Production routes for ^{82}Sr include $^{85}\text{Rb}(p,4n)$ (Horiguchi et al. 1980; Kastleiner et al. 2002), $^{82}\text{Kr}(^3\text{He},3n)$ (Tárkányi et al. 1988, 1990), and proton-induced spallation processes on Rb, Mo, or Y targets (Erdal et al. 1975; Grütter 1982; Grant et al. 1982). The most common production route is the Mo(p,spall) process (Horlock et al. 1981; Thomas and Barness 1984). The requirement for 600–800 MeV protons, however, limits the production capacities of the generator. As ^{82}Rb is injected intravenously directly from the generator, ^{82}Rb must be obtained from the generator in a sterile pyrogen-free physiological medium. Synthetic resins such as BioRex-70 (Yano and Anger 1968; Yano et al. 1977) and Chelex (Grant et al. 1977; Krizek et al. 1977; Grant et al. 1978) and inorganic ion exchangers such as ZrO_2 (Brihaye et al. 1981) and Al_2O_3 (Neirincx et al. 1982) were developed, with ^{82}Rb eluted with 2% NaCl solutions. Other systems utilize $\alpha\text{-SnO}_2$ (Neirincx et al., 1982), with ^{82}Rb eluted with physiological NaCl solution used either for bolus (Gennaro et al. 1984) or continuous infusion (Brihaye et al. 1987). Commercial generators with up to 3.7 GBq (100 mCi) are available. Corresponding to the flow rate, ^{82}Rb yields range from 10–40%, while the ^{82}Sr breakthrough is in the order of $10^{-6}\%$ per mL (Brihaye et al. 1987).

The automated elution system (Gennaro et al. 1984; Knapp and Butler 1984) provides ^{82}Rb for direct intravenous bolus injection, with an average dose of about 1.9 GBq ($\sim 50\text{ mCi}$) for cardiac PET and sequential rest versus stress studies, is used to identify normal versus abnormal myocardium in patients with suspected myocardial infarction, as well as for the assessment of coronary blood flow, degree of stenosis, viability assessment, and to monitor recovery and maintenance. The generator is routinely used in clinical practice (e.g., Williams et al. 1994; Alvarez-Diez et al. 1999). ^{82}Rb infusion systems for quantitative perfusion imaging were developed (Epstein et al. 2004; Klein et al. 2007).

With commercial generators available, there is a continuous effort to improve its performance concerning PET protocols. A two-dimensional vs. three-dimensional scanning was compared (Votaw and White 2001) and wavelet-based noise reduction (Lin et al. 2001) could assess myocardial flow in humans in regions smaller than 1 cm^3 to the accuracy of that achieved with H_2^{15}O . The use of rubidium-82 for PET evaluation of myocardial perfusion has witnessed continued growth and typical studies involve gated PET for myocardial imaging (Anagnostopoulos et al. 2008; Bateman et al. 2006; Brown et al. 2008; Chander et al. 2008; Chow et al. 2005; Dorbala et al. 2007, 2009; Dorbaia et al. 2009; Eisner and Patterson 2007; El Fakhri et al. 2005; Gibbons and Chareonthaitawee 2009; Javadi et al. 2008; Knesaurek et al. 2003, 2007, 2009; Lertsburapa et al. 2008; Lodge et al. 2005; Lortie et al. 2007; Manabe et al. 2009; Nye et al. 2007; Schuster et al. 2008; Shi et al. 2007; Slomka et al. 2008;

Yoshinaga et al. 2006; Tang et al. 2009; Rahmim et al., 2008; Smith 2008; Schleipman et al. 2006; Parkash et al. 2004; Rosman et al. 2005; Tang et al. 2009).

40.3 Generator-Produced Photon Emitters

40.3.1 Overview

Although the use of ultra short-lived generator-derived radionuclides for first-pass radionuclide angiography (FPRNA) for evaluation of ventricular function (wall motion) is not currently widely practiced, the development and use of generator systems for evaluation of pulmonary ventilation and cardiac function was a major research area in the 1970s and 1980s (see, e.g., Paras and Thiessen (1985)). High count-rate imaging systems and advanced computer technology are required for data acquisition, storage, and analysis. High levels of activity are required for FPRNA, but the short half-lives permit rapid, repeat studies, since the vascular recirculation time is longer than the radionuclide physical half-life. The short radionuclide physical half-lives also ensure greatly reduced radiation burden to both personnel and patients. Generators that provide ultra short-lived daughter radionuclides ($T_{1/2} < 1\text{--}2$ min) for FPRNA include the $^{195\text{m}}\text{Hg}/^{195\text{m}}\text{Au}$ ($T_{1/2} = 30.5$ s) and $^{191}\text{Os}/^{191\text{m}}\text{Ir}$ ($T_{1/2} = 4.94$ s) systems. More recently, the $^{178}\text{W}/^{178\text{m}}\text{Ta}$ ($T_{1/2} = 9.31$ min) generator has been introduced. For pulmonary ventilation studies and evaluation of the right ventricular chamber, the $^{81}\text{Rb}/^{81\text{m}}\text{Kr}$ generator is commercially available and approved for human use in Europe.

Several other generator systems have been developed providing photon-emitting daughter nuclides, but did not receive adequate medical attention. Others were proposed for basic radiochemical and radiopharmaceutical studies rather than for a direct application of the daughter nuclide in nuclear medicine.

^{77}Br ($T_{1/2} = 2.377$ d)/ $^{77\text{m}}\text{Se}$ ($T_{1/2} = 17.4$ s). $^{77\text{m}}\text{Se}$ decays by isomeric transition with the emission of 162 keV photons in 50% abundance and appeared ideal for radionuclide angiocardiology and to study the effects of exercise and pharmaceuticals on hemodynamics (Lambrecht et al. 1977; Norton et al. 1978; Madhusudhan et al. 1979).

^{109}Cd ($T_{1/2} = 1.267$ a)/ $^{109\text{m}}\text{Ag}$ ($T_{1/2} = 39.6$ s). This generator was suggested for FPRNA, although the 88 keV photon emission of $^{109\text{m}}\text{Ag}$ shows a rather low abundance of 3.73% of the ^{109}Cd decay (Steinkruger et al., 1986). While Bartos and Bilewicz (1995) used crystalline antimony acid as absorbent yielding increasing ^{109}Cd breakthrough, Mansur et al. (1995) used cation exchange chromatography, but needed a scavenger column to reduce the ^{109}Cd breakthrough of $10^{-4}\%$.

^{113}Sn ($T_{1/2} = 115.09$ d)/ $^{113\text{m}}\text{In}$ ($T_{1/2} = 1.658$ h). Because of its long shelf life, the $^{113}\text{Sn}/^{113\text{m}}\text{In}$ generator has been proposed for labeling and evaluation of various radiopharmaceuticals with the 392 keV photon-emitting $^{113\text{m}}\text{In}$ as an analogue of ^{111}In (Liu et al. 1989). ^{113}Sn production (Qaim and Döhler 1984) and generators were described (Seidl and Lieser 1973; Rao et al. 1976, 1977; Camin 1977; Al-Janabi and Al-Hashini 1979; Lin et al. 1982).

^{115}Cd ($T_{1/2} = 2.228$ d)/ $^{115\text{m}}\text{In}$ ($T_{1/2} = 4.486$ h). This generator has been considered as an alternative to the $^{113}\text{Sn}/^{113\text{m}}\text{In}$ system. Parent radionuclide production and generator design (Ramamoorthy and Mani 1976; Bhattacharya and Basu, 1979; Erhardt et al. 1981; Yagi et al. 1982) were investigated.

Several radiolanthanides such as $^{140}\text{Ba}/^{140}\text{La}$ (Sakar and Bhattacharya, 1979; Das and Bhattacharya 1982), $^{144}\text{Ce}/^{144}\text{Pr}$ (Skraba et al. 1978), and $^{172}\text{Hf}/^{172}\text{Lu}$ (Daniels et al. 1978, 1987;

Grant et al. 1981, 1985; Thomas 1983; Lebedev et al. 1984; Organessiant et al. 1992; Das et al. 1996; Kueppers, 1999; Novgorodov et al. 2002) are available via generator systems as surrogates for various “medical” radiolanthanides. Some other metallic nuclides are available via generator systems as surrogates for $^{89,90}\text{Sr}$ or ^{90}Nb , for example: $^{87}\text{Y}/^{87\text{m}}\text{Sr}$ (Jannsen et al., 1986) and $^{97}\text{Zr}/^{97}\text{Nb}$ (Bhattacharya and Basu 1979; Das et al. 1993).

40.3.2 Key Examples of Generator-Produced Photon Emitters with Proven Medical Applications

^{81}Rb ($T_{1/2} = 4.58\text{ h}$)/ $^{81\text{m}}\text{Kr}$ ($T_{1/2} = 13\text{ s}$). This generator was introduced in the late 1960s (Yano and Anger 1968; Jones and Clark 1969; Jones et al. 1970; Yano et al. 1970; Colombetti et al. 1974) and was soon made available on a routine scale for clinical use (Clark et al. 1976; Ruth et al. 1980; Finn et al. 1982; Guillaume et al. 1983) for continuous inhalation or infusion studies on regional pulmonary ventilation and perfusion. The short half-life of $^{81\text{m}}\text{Kr}$ and continuous administration enables imaging at high count rates, which results in low patient radiation dose. The common method of production of ^{81}Rb is the $^{82}\text{Kr}(p,2n)$ route on isotopically enriched ^{82}Kr gas targets (Ruth et al. 1980; Acerbi et al. 1981; Kovács et al. 1991; Steyn et al. 1991; Uhlir et al. 1996). ^{81}Rb is typically adsorbed on cation exchange resins such as AG 50W-X8 or BioRad AG MP50. Alternatively, ZrPO_4 has been used as the generator support (Clark et al. 1976; Ruth et al. 1980). $^{81\text{m}}\text{Kr}$ is isolated by either purging the generator with air or oxygen (gas generator, for ventilation studies), or by eluting with normal saline or 5% glucose (solution generator, for perfusion studies). A typical generator consists of a small glass column (4 mm I.D.) filled with resin to the height of 15–20 mm (about 200 mg of resin) and washed with distilled water. A moveable shield with infrared air pump assembly is also available for easy handling. One recent study (Rizzo-Padoni et al., 2001) has reported that the use of the commercial Kryptoscan[®] generator for localization of pulmonary emboli is cost effective and that the cost varied based on the number of patients evaluated with each generator. Bubble type generators were proposed for parallel gas and solution separation (Jannsen et al. 1990, 1992). An online mass separator facility was used to separate ^{81}Rb following $\text{Nb}(p,\text{spall})$ processes at $E_p = 600\text{ MeV}$ with a 2-min collection period providing 0.84 GBq of the parent nuclide. Subsequently, a generator was constructed as Mylar foils implanted with 2×10^{13} atoms of ^{81}Rb (Hanser et al. 1986; Beyer et al. 1991). Although krypton-81m is not widely used currently, some investigators still believe this is an excellent approach for the evaluation of pulmonary perfusion and one recent study described its unique role for lung ventilation scanning in critically ill children on long-term mechanical ventilation (Sundariya et al. 2007).

^{99}Mo ($T_{1/2} = 2.7477\text{ d}$)/ $^{99\text{m}}\text{Tc}$ ($T_{1/2} = 6.006\text{ h}$). This handbook describes in detail the reactor production of ^{99}Mo (► Chap. 1), the radiochemistry of this man-made element and the state-of-the-art of $^{99\text{m}}\text{Tc}$ -radiopharmaceutical chemistry (► Chap. 6). Because of the shortage of fission-produced ^{99}Mo resulting from the undetermined length of the recent NRU reactor shutdown in Canada and the long maintenance outages of other reactors in Europe, the continued availability of ^{99}Mo worldwide for fabrication of the widely used $^{99}\text{Mo}/^{99\text{m}}\text{Tc}$ generators is a major topic of discussion. Several strategies are being discussed to move forward with alternatives to traditional research reactor fission production of ^{99}Mo by irradiation of uranium-235 targets. These strategies include the traditional current fission of ^{235}U targets in research reactors, the use of the *Aqueous Homogeneous Reactor* (AHR) technology originally demonstrated by Enrico Fermi, and the use of high energy accelerators for the $^{238}\text{U}(n,f)\text{ }^{99}\text{Mo}$

and $^{100}\text{Mo}(\gamma, n) ^{99}\text{Mo}$ routes. The AHR technology involves operation of a system where the aqueous ^{235}U salt solution (nitrate or sulfate), which is continuously fissioned, and recycled to remove the ^{99}Mo and off-line separation of other fission products. The advantages of such a system are the low operating temperature, more controlled safety envelope, and compact design, which does not require any specialized/sophisticated cooling or control systems. The expected time is 4–5 years until the new production facility would operate. The regulatory and licensing issues are under discussion and have to be addressed, but such AHR units would presumably not be subject to the complex safety and operational issues that are encountered by traditional research reactors. It is not yet clear which ^{99}Mo production strategy would overcome the recurring severe supply shortages of ^{99}Mo .

The $^{99}\text{Mo}/^{99\text{m}}\text{Tc}$ generator has been described in previous reviews (Boyd 1982; Boyd et al. 1982, 1986). Technetium-99m continues to be the most widely used diagnostic radionuclide in nuclear medicine, and $^{99\text{m}}\text{Tc}$ -labeled tissue-specific radiopharmaceuticals are available for diagnostic studies of essentially all major organs, and represent an estimated 90% of all diagnostic procedures. The widely used chromatographic-type $^{99}\text{Mo}/^{99\text{m}}\text{Tc}$ generator system provides sodium pertechnetate ($\text{Na}^{99\text{m}}\text{TcO}_4$) by elution with saline and uses very high specific activity no-carrier-added ^{99}Mo , produced by the $^{235}\text{U}(\text{n}, \text{fission})^{99}\text{Mo}$ process, which is adsorbed on aluminum oxide. In addition to the chromatographic-type generators, “batch” preparation of $^{99\text{m}}\text{Tc}$ involves solvent extraction (Evans et al. 1982), for instance with methyl ethyl ketone, or sublimation of the low specific activity ^{99}Mo , which can be reactor produced by neutron activation of enriched ^{98}Mo . The latter approach may become more attractive in the future as radioactive waste disposal issues become more crucial.

Two options using low specific activity ^{99}Mo produced by the $^{98}\text{Mo}(\text{n}, \gamma)^{99}\text{Mo}$ for generator fabrication involve the “gel-type” generator or post-elution concentration strategies. The “gel-type” generator approach (Boyd 1982) involves preparation of a molybdenum–zirconium gel. Even if the “gel-type” generator system is used, the specific concentration of the $^{99\text{m}}\text{Tc}$ may be too low for practical use. A useful alternative involves post-elution concentration of $^{99\text{m}}\text{Tc}$ on an anion-exchange column in tandem with the Al_2O_3 generator column, similar to that developed for the $^{188}\text{W}/^{188}\text{Re}$ generator (Knapp et al. 1998a; Guhlke et al. 2000; Sarkar et al. 2001). Although the chromatographic alumina generator is generally considered impractical for use with low specific activity ^{99}Mo because of the significantly larger amounts of alumina adsorbent that are required, the post-elution concentration of the initial low specific volume $^{99\text{m}}\text{Tc}$ provides sufficiently high specific volume activity solutions for labeling.

^{178}W ($T_{1/2} = 21.5 \text{ d}$)/ $^{178\text{m}}\text{Ta}$ ($T_{1/2} = 9.31 \text{ min}$). $^{178\text{m}}\text{Ta}$ decays with the emission of X-rays with energies of 55 keV (K_α , 67.4%) and 64 keV (K_β , 17.7%). The relatively long-lived parent ^{178}W can be produced with the $^{181}\text{Ta}(\text{p}, 4\text{n})^{178}\text{W}$ reaction with yields of $2 \text{ MBq } \mu\text{A}^{-1} \text{ h}^{-1}$ at $40 \rightarrow 32 \text{ MeV}$ proton energy (Neirinckx et al. 1978, 1979; Holman et al. 1978). Neirinckx et al. (1981) evaluated AGI-X8 as the support, and concluded that the generator can operate satisfactorily when eluted with 0.1–0.15 M HCl containing 0.1% H_2O_2 . The ^{178}W breakthrough initially was $10^{-3}\%$, increasing, however, after 100 elutions. The current generator uses a Dowex AG 1-X8 anion exchange column (Lacy et al. 1988a). Elution with 0.03 M HCl provides reproducible $^{178\text{m}}\text{Ta}$ yields with consistently low ^{178}W parent breakthrough.

Preliminary studies explored preparation of $^{178\text{m}}\text{Ta}$ -labeled myocardial perfusion agents (Holman et al. 1979; Layne et al. 1991) and also applications for lung and liver imaging (Neirinckx et al. 1979). High resolution and statistical quality FPRNA studies of ventricular performance were demonstrated in a group of 38 patients in comparison with the traditional $^{99\text{m}}\text{Tc}$ methods (Lacy et al. 1991). Verani et al. (1992a) demonstrated the usefulness of this

system for evaluation of systolic and diastolic left ventricular function in 46 patients undergoing coronary balloon angioplasty. Verani et al. (1992b) reported evaluation of right ventricular performance in 46 patients. The $^{178}\text{W}/^{178\text{m}}\text{Ta}$ generator in combination with a portable multiwire proportional counter gamma camera (MWGC) has recently been shown to be an excellent source of $^{178\text{m}}\text{Ta}$ for the evaluation of ventricular performance (Lacy et al. 2001). These studies clearly demonstrate that the $^{178}\text{W}/^{178\text{m}}\text{Ta}$ generator is the only current system providing a short-lived daughter for the evaluation of FPRNA. In spite of the fact that first-pass ventriculography with ultra-short lived radioisotopes is not currently widely practiced, a recent study described the advantages for the assessment of left ventricular function during upright treadmill exercise using a multiwire gamma camera (Heo et al. 2005).

^{191}Os ($T_{1/2} = 15.4 \text{ d}$)/ $^{191\text{m}}\text{Ir}$ ($T_{1/2} = 4.94 \text{ s}$). The ^{191}Os is produced via the $^{190}\text{Os}(n,\gamma)$ reaction. Radiochemical separations of the generator system were based on ion exchange chromatography (Yano and Anger 1968; Campell and Nelson 1956; Hnatowich 1977; Hnatowich et al. 1977). More recent systems used absorption of $\text{K}_2/^{191}\text{OsO}_2\text{Cl}_4$ or $\text{K}_2/^{191}\text{OsO}_2(\text{OH})_2\text{Cl}_2$ on AGMP-1 anion exchange resin. A second column was required to guaranty radionuclidic purities with a breakthrough of $<10^{-2}\%$ ^{191}Os , while the overall separation yield of $^{191\text{m}}\text{Ir}$ remained relatively low ($<10\%$) (Cheng et al. 1980, 1982). More than 100 patients received injections of $^{191\text{m}}\text{Ir}$ in isotonic saline Na_2HPO_4 buffers. Another system used Os(VI) bound to silica gel impregnated with tridodecylmethylammonium chloride (SG-TDMAC) (Issacher et al. 1989; Hellmann et al. 1989) and provided $^{191\text{m}}\text{Ir}$ in 21–33% yield by elution with acidic (HCl) saline at pH 1 with the final eluate buffered with 1 M succinate solution to pH 9. An activated carbon “scavenger” column was used in tandem with the SG-TDMAC column to remove ^{191}Os parent breakthrough before the eluant is rapidly buffered. Another generator system was also developed for angiocardiology in children which utilized a potassium Os(VI)oxalate species adsorbed on AGMP-1 anion exchange resin (Packard et al. 1986, 1987), which did not require a “scavenger” column. Elution with pH 1 0.9% saline solution provided $^{191\text{m}}\text{Ir}$ in good yields (10% per mL) with low ^{191}Os parent breakthrough ($3 \times 10^{-4}\%$). The use of $^{191}\text{Os(IV)}$ species bound on heat-activated carbon eluted with 0.9% saline at pH 2 containing 0.025% KI was also developed and represented an excellent generator system, providing the daughter nuclide in 16–18% yields with correspondingly low ^{191}Os parent breakthrough ($2\text{--}3 \times 10^{-4}\%$ per bolus). For patient studies, the low-pH bolus was neutralized with 0.13 M TRIS, followed by rapid intravenous administration of the neutralized bolus with physiological saline (Franken et al. 1989, 1991), using a microprocessor-controlled automated elution/injection system.

$^{191\text{m}}\text{Ir}$ was proposed for the evaluation of heart disease and blood flow for various organs (Yano and Anger 1968; Treves et al. 1976, 1980; Thiesson et al. 1983). This first generator provided $^{191\text{m}}\text{Ir}$ for intravenous administration (Yano et al. 1968) and another system was used for quantification of cardiac shunts in children (Treves et al. 1976, 1980) and evaluation of ventricular function in adults (Heller et al. 1986). Studies by Franken et al. (1989, 1991) described rapid sequential multiple view FPRNA for the evaluation of left ventricular ejection fraction and regional wall motion studies in over 600 patients. More recent studies have described the use of $^{191\text{m}}\text{Ir}$ in rabbits via dynamic studies (Kariemo et al. 1994) for renal radionuclide angiograms and continuous infusion for the rapid renal single-photon emission tomographic evaluation of renal blood flow (Treves et al. 1999).

$^{195\text{m}}\text{Hg}$ ($T_{1/2} = 1.73 \text{ d}$)/ $^{195\text{m}}\text{Au}$ ($T_{1/2} = 30.5 \text{ s}$). Like $^{191\text{m}}\text{Ir}$, the short-lived $^{195\text{m}}\text{Au}$ was of interest for first-pass radionuclide angiography (Thiesson and Paras 1983). The parent nuclide

is produced via the $^{197}\text{Au}(p,3n)$ reaction at $34 \rightarrow 26$ MeV proton energies with relatively high thick target yields of $170 \text{ MBq } \mu\text{A}^{-1} \text{ h}^{-1}$ (Birattari and Bonardi 1982; Panek et al. 1985; Guillaume and Brihaye 1986). The $^{195\text{m}}\text{Hg}$ was separated either by solvent extraction (Bett et al. 1981, 1983) or by distillation (Guillaume and Brihaye 1986). Dithiocellulose adsorbents were used showing 1–2% breakthrough of $^{195\text{m}}\text{Hg}$ and 10–20% elution yield of $^{195\text{m}}\text{Au}$ using 10 mM NaCN solution (Bett et al. 1983), while silica gel coated with ZnS showed better retention of the parent nuclide and higher elution yield of 28–30% using $\text{Na}_2\text{S}_2\text{O}_3/\text{NaNO}_3$ solutions (Panek et al. 1984, 1985). For bolus injections, ^{195}Hg was loaded onto a Chelex 100 column, while $^{195\text{m}}\text{Au}$ was eluted with 5% glucose solutions with about 20% yield in mainly ionic form; the ^{195}Hg breakthrough being about $10^{-3}\%$ (Garcia et al. 1981; Brihaye et al. 1982). Some limitations concern the formation of ^{195}Au by isomeric transition of $^{195\text{m}}\text{Au}$, resulting in an increasing absorbed radiation dose. Nevertheless, both cardiac metabolism and function studies have been performed comparing $^{195\text{m}}\text{Au}$ with ^{201}Tl (Mena 1985) and $[^{123}\text{I}]\text{IPPA}$ (Wagner et al. 1990).

40.4 Generator-Produced Particle Emitters for Therapy

40.4.1 Overview

During the last decade there has been a tremendous increase in the development and use of new therapeutic radiopharmaceuticals radiolabeled with radionuclides, which are available from radionuclide generator systems. The availability of generator-derived therapeutic radionuclides is necessary for the development and testing and commercialization of agents with potential for endoradiotherapy (ERT). Just as availability of $^{99\text{m}}\text{Tc}$ from the $^{99}\text{Mo}/^{99\text{m}}\text{Tc}$ has played such a key role in the development of a wide variety of $^{99\text{m}}\text{Tc}$ -labeled radiopharmaceuticals, the availability of generator-derived radionuclides has stimulated the development of an increasing spectrum of therapeutic tracers. It is important to note that in most cases, increased need for and further development of generators, which provide therapeutic radionuclides has been driven by the success in the development of the targeting agents or vectors.

Generator-derived therapeutic radionuclides have a number of characteristic decay processes, and can emit β particles, Auger electrons, low-energy photons, and α particles. Since many therapeutic radionuclides are characterized by β decay, they are often directly produced in a nuclear reactor, since neutron capture by the target nuclide forms a radioactive or unstable product that decays by β emission. Key examples of therapeutic radionuclides obtained from reactor-produced parent radionuclides include ^{166}Ho – from the $^{166}\text{Dy}/^{166}\text{Ho}$ generator, and ^{188}Re – from the $^{188}\text{W}/^{188}\text{Re}$ generator.

Another important source of generator parent radionuclides is recovery of generator parent radionuclides that are produced during nuclear fission. Strontium-90 is the parent for the $^{90}\text{Sr}/^{90}\text{Y}$ generator system and is isolated from fission products. The recent approval by the US Food and Drug Administration (FDA) on February 19, 2002, for “Zevalin” (Ibritumomab tiuxetan) – a ^{90}Y -labeled murine anti CD20 antibody – for the treatment of patients with low grade, follicular, or transformed non-Hodgkin’s lymphoma, represents the first antibody radiolabeled with a therapeutic, generator-derived radionuclide, and would be expected to represent the first of many new therapeutic radiopharmaceuticals for oncologic applications.

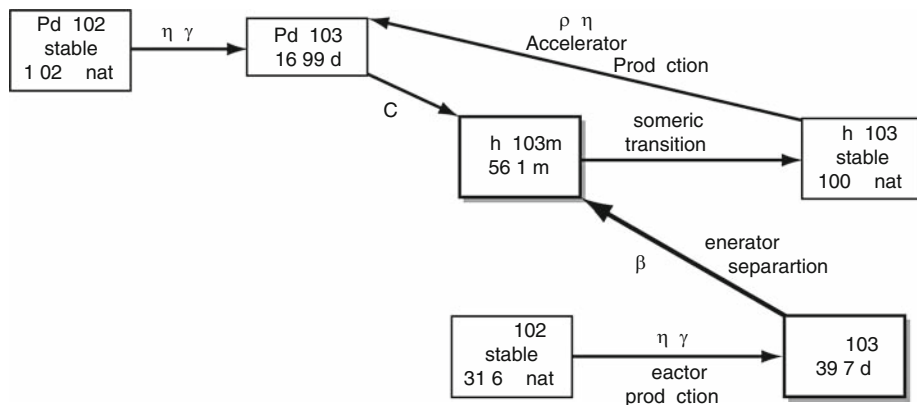

A third source for radionuclide generator systems is the recovery of radioactive parents from “extinct” radioactive decay processes, such as ^{229}Th , which is recovered from ^{233}U decay products. The ^{229}Th represents a convenient, long-lived ($T_{1/2} = 7,340$ years) source from which ^{225}Ac is recovered, which is the parent of the $^{225}\text{Ac}/^{213}\text{Bi}$ generator system.

The α -emitter ^{211}At has great potential for labeling compounds of potential interest in cell biology and endoradiotherapy. Although it is produced mainly via the direct $^{209}\text{Bi}(\alpha, 2n)$ route, it can be produced through the decay of 14.6 h ^{211}Rn (Vachtel et al. 1976; Visser et al. 1979; Mirzadeh and Lambrecht 1980).

^{103}Ru ($T_{1/2} = 39.25$ h)/ $^{103\text{m}}\text{Rh}$ ($T_{1/2} = 56.12$ min). Rhodium-103m is a key example of an Auger-emitting candidate, which can be obtained from decay of reactor-produced ^{103}Ru . Interest for use of $^{103\text{m}}\text{Rh}$ in radioimmunotherapy and other strategies for targeted therapy results from its attractive decay properties (see [Table 40.1](#)) and potential availability from a $^{103}\text{Ru}/^{103\text{m}}\text{Rh}$ generator system for targeted radiotherapy (Bernhard et al. 2001). The 40 keV isomeric decay energy is totally converted in the electronic shells of the stable ^{103}Rh daughter with no measurable γ -rays and results in a “shower” of low-energy electrons and X-rays. Daily elution of equilibrium levels of $^{103\text{m}}\text{Rh}$ is possible from the $^{103}\text{Ru}/^{103\text{m}}\text{Rh}$ generator. Rhodium-103m is expected to exhibit high cytotoxicity resulting from its decay by highly converted isomeric transition and emission of Auger electrons. Availability of a $^{103}\text{Ru}/^{103\text{m}}\text{Rh}$ generator system would offer an opportunity to provide carrier-free $^{103\text{m}}\text{Rh}$ on a routine basis for the assessment of its potential for Auger therapy. Either fission- or reactor-produced ^{103}Ru could be used for the generator system. Although the 3% fission yield of ^{103}Ru from ^{235}U is quite high, fission products are not routinely available. The availability of lower specific-activity ^{103}Ru from reactor irradiation of enriched ^{102}Ru production with sufficient specific activity in many research reactors on an international basis would be expected to be reliable routine source of ^{103}Ru for fabrication of the $^{103}\text{Ru}/^{103\text{m}}\text{Rh}$ generator system. Rhodium-103m can also be obtained by the decay of ^{103}Pd ([Fig. 40.5](#)), and the use of the $^{103}\text{Pd}/^{103\text{m}}\text{Rh}$ in vivo generator has been proposed (Van Rooyen et al. 2008), which may suggest that a $^{103}\text{Pd}/^{103\text{m}}\text{Rh}$ generator for routine availability of $^{103\text{m}}\text{Rh}$ may be feasible. Development of a chromatographic-type $^{103}\text{Ru}/^{103\text{m}}\text{Rh}$ generator would be expected to provide $^{103\text{m}}\text{Rh}$ from

Fig. 40.5

Availability of $^{103\text{m}}\text{Rh}$ from reactor-produced long-lived ^{103}Ru and from decay of ^{103}Pd

separation of Rh from Ru compared to Rh from Pd. In addition, the very low 1.02% natural abundance of ^{102}Pd , coupled with the high costs of enrichment for reactor production of ^{103}Pd , the high costs of accelerator-production of ^{103}Pd from $^{103}\text{Ru}(\text{p},\text{n})$ and the shorter physical half-life of ^{103}Pd compared to ^{103}Ru are other issues.

The separation of Rh from Ru had been described some years ago by solvent extraction techniques (Chiu et al. 1978; Epperson et al. 1976), and these methods with carbon tetrachloride extraction for RuO_4 from Ru/Rh mixtures in HCl have served as the basis for the more recent interest in the availability of $^{103\text{m}}\text{Rh}$. A recent solvent-extraction type $^{103}\text{Ru}/^{103\text{m}}\text{Rh}$ generator, which is based on the earlier extraction work of Epperson et al. (1976) and Chiu et al. (1978), has recently been reassessed (Bartos et al. 2007, 2009; Skarnemark et al. 2009). Recent studies have used both fission- and reactor-produced Ru for these studies (Bartos et al. 2009). The use of batch liquid extraction/post processing of Rh from Ru by liquid extraction technology to routinely provide $^{103\text{m}}\text{Rh}$ may be impractical and could be expected to be primarily centered at a central processing site and not accessible in most research centers. Use of a chromatographic-type generator would be expected to be much more practical and accessible on a routine institutional basis to provide the $^{103\text{m}}\text{Rh}$ Auger emitter for widespread research use.

40.4.2 Key Examples of Generator-Derived Therapeutic Radionuclides with Proven Medical Applications

^{90}Sr ($T_{1/2} = 28.6\text{ a}$)/ ^{90}Y ($T_{1/2} = 64.1\text{ h}$). Yttrium-90 decays with the emission of a high-energy β particle ($E_{\text{max}} = 2.3\text{ MeV}$) and is of broad interest for therapy of solid tumors where deep penetration of radiation is important for cross-fire (cf. [Chaps. 45](#) and [46](#) of this Volume). Although various forms of the $^{90}\text{Sr}/^{90}\text{Y}$ generators have been available for a number of years, broad interest in clinical therapeutic applications of ^{90}Y was stimulated by the development of methods of radiation synovectomy of large synovial joints, and more recently, the development of bifunctional chelating groups that strongly bind the Y^{3+} cation, since the skeletal localization of free trivalent yttrium species would result in significant marrow suppression. The availability of DOTA and the CHX-substituted DTPA chelates provides an opportunity to use ^{90}Y in a predictably safe manner. The availability of the chelates in consort with vectors having very specific cellular targeting, such as the DOTATOC octreotide agent, which binds with high specificity to the somatostatin receptors, provided important agents for the treatment of a wide variety of tumors. Because of the safety issues associated with the use and handling of ^{90}Y and ^{90}Sr , these high-level generators are typically installed in a centralized processing area for preparation of the no-carrier-added ^{90}Y by batch solvent extraction techniques and distribution of the highly purified ^{90}Y product. One method (Bray and Wester, 1996) involves freshly purified HDEHP extraction of ^{90}Y from a nitric acid solution of the purified $^{90}\text{Sr}/^{90}\text{Y}$ mixture. The final $^{90}\text{Y}/^{90}\text{Sr}$ activity ratio of the purified ^{90}Y is $<10^{-7}$ with a concentration of metal impurities of $<10\text{ ppm}$ per Ci ^{90}Y . A generator system has also been described for the separation of ^{90}Y from ^{90}Sr and involves the use of strongly acidic Dowex exchange resin (Chinol and Hnatowich, 1987).

A comparison of solvent extraction, ion exchange, and other radiochemical separation techniques applied to this generator was made by Chuang and Lo (1988). Ion exchange based generators utilize various organic cation exchange resins, but also inorganic compounds, with a particular focus on high radiation resistance (Hsieh et al. 1991; Bielewicz, 1995; Chinol et al. 1996;

Bläuenstein et al. 1996). Because of the limited availability, significant costs of high purity ^{90}Sr and the potential dangers in handling ^{90}Sr , installation of this generator in a hospital-based nuclear pharmacy or a central radiopharmacy is unusual, and high purity ^{90}Y is generally obtained from a central processing approved GMP facility providing both research-grade and sterile, pyrogen-free ^{90}Y for human studies.

^{166}Dy ($T_{1/2} = 3.4\text{ d}$)/ ^{166}Ho ($T_{1/2} = 1.117\text{ d}$). Although ^{166}Ho can be produced with a specific activity of only 8–9 Ci mg^{-1} ($\sim 300\text{ GBq mg}^{-1}$) ^{165}Ho by the $^{165}\text{Ho}(\text{n},\gamma)^{166}\text{Ho}$ reaction even at saturation in a high thermal flux of $2.5 \times 10^{15}\text{ n cm}^{-2}\text{ s}^{-1}$, no-carrier-added ^{166}Ho with a theoretical specific activity of about 700 Ci mg^{-1} ($\sim 26\text{ TBq mg}^{-1}$) is obtained by decay of ^{166}Dy . The ^{166}Dy is reactor produced by the $^{164}\text{Dy}(\text{n},\gamma)^{165}\text{Dy}(\text{n},\gamma)^{166}\text{Dy}$ reaction series. Separation of ^{166}Ho from ^{166}Dy has traditionally been a challenge. Although not a true generator system – since the ^{166}Dy parent is also recovered and requires column reloading for subsequent $^{166}\text{Ho}/^{166}\text{Dy}$ separations following adequate ^{166}Ho in-growth – a method has been described for successful $^{166}\text{Ho}/^{166}\text{Dy}$ separation, which uses an HPLC reversed phase ion-exchange chromatographic method utilizing Dowex AG 50WX12 or Aminex A5 cation exchangers by elution with α -hydroxy-isobutyric acid (α -HIB) of 0.085 M at pH 4.3. This approach provides a Dy/Ho separation factor of approximately 10^3 , with subsequent purification of the $^{166}\text{Ho}^{3+}$ by cation-exchange column chromatography after acid decomposition of the Ho- α -HIB complex (Dadachova et al. 1995a, b). More recently, an apparently simple and efficient method has described separation on the Eichrome Ln resin by elution with dilute nitric acid (Ketrings et al. 2002).

Although ^{166}Ho has attractive radionuclidic properties as a lanthanide for various vector labeling and therapeutic strategies, it has not yet been widely used. Examples are studies of protein labeling with the CHX-B-DTPA ligand system (Dadachova et al. 1997). Animal studies demonstrated that no translocation of the ^{166}Ho daughter radionuclide occurred when the [^{166}Ho]DTPA complex was administered to rats (Smith et al. 1995). The results of these studies may suggest that the $^{166}\text{Dy}/^{166}\text{Ho}$ system may have some promise as an in vivo generator. Clinical applications that have been recently reported include radiation synovectomy with ^{166}Ho -ferric hydroxide (Ofluoglu et al. 2002), the use of [^{166}Ho]DTPA liquid-filled balloons for the inhibition of restenosis following coronary angioplasty (Hong et al. 2002), and use of [^{166}Ho]DOTMP for myeloablative therapy of multiple myeloma (Rajendran et al. 2002). If the availability of no-carrier-added ^{166}Ho becomes a reality, use of this generator system may be a source for these and other applications.

^{188}W ($T_{1/2} = 69\text{ d}$)/ ^{188}Re ($T_{1/2} = 16.9\text{ h}$). Rhenium-188 is currently of broad interest for the development of a wide variety of new therapeutic approaches for applications in nuclear medicine, oncology, and even interventional cardiology, because of the benefits, advantages, and significantly reduced expense of using ^{188}Re in comparison to many other therapeutic radionuclides (Knapp et al. 1997, 1998a, b). There are currently a large number of physician-sponsored clinical protocols in progress. Tungsten-188 is reactor produced by double neutron capture of enriched ^{186}W by the $^{186}\text{W}(\text{n},\gamma)^{187}\text{W}(\text{n},\gamma)^{188}\text{W}$ route. Since the production yield is a function of the square of the thermal neutron flux, even at high thermal neutron flux ($> 2 \times 10^{15}\text{ n cm}^{-2}\text{ s}^{-1}$) ^{188}W is produced with only modest specific activity of 4–5 Ci g^{-1} ($\sim 180\text{ GBq g}^{-1}$) per cycle (Knapp et al. 1994). This is due to the modest neutron capture cross sections and burnup of the ^{188}W product (Mirzadeh et al. 1997). Although the first prototype $^{188}\text{W}/^{188}\text{Re}$ generators were described as early as 1966 using zirconium oxide (Lewis and Eldridge, 1966) and with aluminum oxide in 1972 (Mikheev et al. 1972), in spite of the excellent radionuclidic properties of ^{188}Re , there was no practical use of this therapeutic

radionuclide until nearly 25 years later, when appropriate carrier molecules and targeting agents became available (Knapp et al. 1997, 1998a, b).

The $^{188}\text{W}/^{188}\text{Re}$ generator systems today are mainly based on separation chemistry similar to that used for the $^{99}\text{Mo}/^{99\text{m}}\text{Tc}$ generator, which includes the adsorption of tungstic acid in the alumina-based generator (Mikheev et al. 1972; Callahan et al. 1989; Knapp et al. 1994) (► Fig. 40.6). In addition to the adsorption column chromatographic separation on alumina, zirconium oxide (Dadachova et al. 1994) and gel-type generators (Erhardt et al., 1992) have been reported. For batch separation of ^{188}Re a thermochromatographic technique was described (Novgorodov et al. 2000).

The adsorption type generator is most practical, since it is easy to prepare, has long-term stability with high ^{188}Re yields and consistently low ^{188}W breakthrough. The availability of effective and inexpensive post-elution tandem column-based concentration systems (Guhlke et al. 2000; Knapp et al. 1997, 1998a) provides a useful method for ^{188}Re concentration to very high specific volumes (<1 mL total volume).

There are presently a large number of physician-sponsored clinical trials in progress using the Oak Ridge National Laboratory (ORNL) alumina-based $^{188}\text{W}/^{188}\text{Re}$ generator system. ^{188}Re -labeled HEDP (Palmedo et al. 2000; Savio, et al. 2001) and DMSA (Blower et al. 2000) have proven to be effective agents for the palliative relief of bone pain from skeletal metastases in patients with prostatic carcinoma, and may represent a more cost-effective alternative to

■ Fig. 40.6

Scheme of the $^{188}\text{W}/^{188}\text{Re}$ generator. Post-elution concentration after saline elution of the alumina-based $^{188}\text{W}/^{188}\text{Re}$ generator system conveniently provides high specific volume ^{188}Re perrhenate solutions. The generator is eluted with physiological saline (for instance, 25–50 mL) at a flow-rate of 1–2 mL min⁻¹ through the disposable, one time use tandem cation/anion exchange system, with stopcocks (SC) 1 and 2 in the following positions: SC 1, position b–c and SC 2, position a–b. After generator elution, the ^{188}Re perrhenate trapped on the QMA anion column is then eluted with a small volume (1–2 mL) of saline with SC 1, in position a–c and SC 2, in position a–c

other radionuclides used for this application. In addition, the use of liquid-filled angioplasty balloons for the inhibition of hyperplastic restenosis after coronary balloon angioplasty using ^{188}Re -perrhenate (Hoeher et al. 2000; Kotzerke et al. 2000; Makkar et al. 2000; Schuelen et al. 2001; Kropp et al. 2002), ^{188}Re -MAG3 (Weinberger and Knapp 1999; Weinberger et al. 1999; Park et al. 2001) and [^{188}Re]DTPA (Hong et al. 2002) are in progress, and the use of the ^{188}Re -labeled anti-CD66 has also been reported (Nowak et al. 2001). The use of the ^{188}Re -labeled anti-CD66 antibody (anti-NCA95) has been found to be a useful new method for marrow ablation using combinational preconditioning in leukemia patients (Bunjes et al. 2000; Reske et al. 2001; Buchman et al. 2002). The use of the $^{188}\text{W}/^{188}\text{Re}$ generator in developing regions has been demonstrated to be of particular usefulness because of its cost-effectiveness, and multi-center trials supported by the International Atomic Energy Agency are in progress for restenosis therapy with ^{188}Re -perrhenate and for the treatment of liver cancer (Sundram et al. 2002) with ^{188}Re -labeled lipiodol analogues (Jeong et al. 2001a, b). A ^{188}Re -labeled antibody has been used for treatment of bladder cancer (Murray et al. 2001) and use of the ^{188}Re -labeled P2045sstr-targeting peptide for the treatment of lung cancer has also been reported (Bugai et al. 2002) and is now in clinical trials in the USA.

Several new generator prototypes for the separation of nca ^{188}Re from ^{188}W have been recently described, which use a new high-capacity adsorbent consisting of synthetic alumina functionalized with sulfate moieties prepared from a sol-gel process (Lee et al. 2009). This material is reported to have a tungsten loading capacity of >450 mg/g, allowing preparation of a 3 Ci generator using only 1 g of adsorbent, which is a much higher loading capacity than reported for acid-washed alumina. Elution with 5 mL of saline at 1 mL/min results in ^{188}Re yields of 70–90%. In this manner, a 1 Ci generator can provide ^{188}Re solutions with a specific volume of >200 mCi/mL saline. In addition, a simple electrochemical separation technique has been reported using platinum electrodes immersed in $^{188}\text{W}/^{188}\text{Re}$ equilibrium mixture by applying a constant 7 V potential difference at 80°C for 60 min. The ^{188}Re is stripped as perrhenic acid from the platinum cathode with warm 0.1 N HCl (Chakravarty et al. 2009). Decay-corrected ^{188}Re yields of $>70\%$ have been reported in preliminary studies using 30 mCi of ^{188}W . There are several examples of recent clinical applications with ^{188}Re which include use of the ORNL $^{188}\text{W}/^{188}\text{Re}$ generator for preparation of the HDD agent for liver cancer therapy (Jeong and Knapp 2008). Results of the recent multicenter clinical trial with this agent coordinated through the IAEA have demonstrated the efficacy of ^{188}Re -labeled HDD/Lipiodol for the transarterial palliative treatment in patients with non-resectable/non-transplantable liver tumors (Padhy et al. 2008). Further assessment of the initial use of ^{188}Re liquid-filled angioplasty balloons for the inhibition of hyperplasia following PCTA of the coronaries has now been demonstrated for the peripheral arteries (Wohlgemuth et al. 2008).

^{225}Ac ($T_{1/2} = 10$ d)/ ^{213}Bi ($T_{1/2} = 45.6$ min). Because of the very high linear energy transfer (LET) in the 50–90 μm range, α particles are very suitable for therapy of microscopic or subclinical disease, such as for the treatment of micrometastatic disease (cf. [▶ Chap. 46](#) of this Volume). The attachment of α emitters to cellular-targeted carrier molecules such as antibodies or peptides is the most common approach. For this reason, interest in the $^{225}\text{Ac}/^{213}\text{Bi}$ generator system has rapidly increased in the last few years. The ^{225}Ac is generally obtained as a decay product of ^{229}Th , which is extracted as a radioactive decay product of the ^{233}U , a member of the “extinct” ^{237}Np decay chain (see [▶ Fig. 5.5 in Chap. 5, Vol. 1](#)). Production has also been proposed via accelerators, as an example, by the $^{226}\text{Ra}(\text{p},\text{n})^{225}\text{Ac}$ reaction. The ^{229}Th can be obtained from processing of the ^{233}U stockpile, which had originally been produced in a proposed molten salt breeder reactor program at ORNL. From a complex series of

ion-exchange and extraction chromatographic steps for recycling of $^{229}\text{Th}(\text{IV})$, the $\text{Ra}(\text{II})$ decay product is separated at optimal timing, and the ^{225}Ac then separated. A variety of chromatographic-type $^{225}\text{Ac}/^{213}\text{Bi}$ generators have been described (Geerlings et al. 1993; Lambrecht et al. 1997; Wu et al. 1997; Boll et al. 1997; Mirzadeh 1998; Hassfjell and Brechbiel 2001).

At ORNL, the ^{225}Ac in 1 M HNO_3 solution is provided to investigators with generator components for on-site generator loading, to minimize the effects of radiolysis. This solution is loaded onto a small AG 50W-X4 strong cation exchange resin with elution of the ^{213}Bi daughter with 0.15 M HI solution. Several other $^{225}\text{Ac}/^{213}\text{Bi}$ generator systems have also been described. One example (Geerlings et al. 1993) used two successive Dowex 50W-X8 cation exchange columns, with initial separation of ^{225}Ac from $^{224/225}\text{Ra}$ with subsequent separation of the desired ^{213}Bi from the ^{225}Ac formed from radon decay. Wu et al. (1997) reported a generator using the inorganic AC-Resin ion exchanger. The ^{213}Bi was eluted with 1 M HCl in a continuous elution mode, diluted to 0.2 M HCl and then loaded on a second small AGMP-50 cation exchange resin and eluted with 0.1 M HI. A similar column is being used (McDevitt et al. 1999a) where ^{213}Bi is being applied for the clinical treatment of acute myeloid leukemia (AML) under physician-sponsored protocols (McDevitt et al. 1999b; Sgoruos et al. 1999; Jurciv et al. 2002). Another variation proposed by Bray et al. (1999) passes a ^{225}Ac solution through a disc containing a thin film of the Anex (3M Company) strong anion-exchange resin that binds the ^{213}Bi , which is subsequently eluted with pH 5.5 solution of 0.05 M NaOAc.

As discussed later in the *in vivo* generator section, in addition to its utilization in a generator system to provide ^{213}Bi for α -targeted therapy, interest is increasing in using the ^{225}Ac parent for targeted therapy, because of the emission of four α particles and the long half-life (Chang et al. 2008; Miederer et al. 2008; Sofou et al. 2007; Antczak et al. 2006). The current major clinical application of bismuth-213 is for treatment of myelogenous leukemia and use of actinium-225 is gaining interest for α therapy because of the longer physical half-life (McDevitt et al. 2001).

^{224}Ra ($T_{1/2} = 3.66\text{ d}$)/ ^{212}Pb ($T_{1/2} = 10.64\text{ h}$)/ ^{212}Bi ($T_{1/2} = 1.01\text{ h}$). Bismuth-212 has been of interest for some time and is available from decay of ^{212}Pb . The traditional generator involves loading a cation exchange resin with ^{224}Ra with subsequent elution of the ^{212}Bi with HCl or HI (Atcher et al. 1988), which requires replacement of the generator every 3–6 days. More recently, a generator based on gaseous ^{222}Ra emanating from thin films of ^{228}Th barium stearate has been described (Hassfjell and Brechbiel 2001), which involves collecting the gaseous ^{224}Ra in a trap containing an organic solvent such as methanol or hexane or a methanol/hexane mixture, at temperatures lower than -72°C . The ^{212}Pb decay product can be obtained in about 70% yield and this system has the advantage of an indefinite shelf life of the long-lived ^{228}Th ($T_{1/2} = 1.913\text{ a}$) source.

^{227}Ac ($T_{1/2} = 21.77\text{ d}$)/ ^{223}Ra ($T_{1/2} = 11.43\text{ d}$). Because of availability from decay of ^{227}Ac , localization of ionic radium in growing bone and the high LET, radium-223 has emerged as a promising new candidate for routine use for palliative treatment of bone pain from tumor metastases to the skeleton (Bruland et al. 2008; Nilsson et al. 2005, 2007). Radium-223 can be conveniently repeatedly obtained from separation from the ^{227}Ac parent. The ^{227}Ac is obtained from decay of ^{235}U and decays to ^{227}Ac through ^{227}Th , or can be reactor produced by neutron irradiation of ^{226}Ra (Larsen et al. 2007) or from α irradiation of protactinium-231 targets. The availability of beryllium/actinium neutron sources often used for well logging can provide a ready source of ^{227}Ac . The purified $^{227}\text{Ac}/^{227}\text{Th}$, purified by traditional ion exchange methods, can be adsorbed on 1 M HCl preconditioned P,P' -di(2-ethylhexyl)

methanediphosphonic acid/silica (Dipex-2) extraction resin (Hendricksen et al. 2001). The ²²³Ra then eluted with 1 M HCl or HNO₃. Further purification of the ²²³Ra is accomplished using a small AG 50W-X12 cation resin by elution with 1 M nitric acid. Although there are no practical complexing/chelating agents for ionic radium, the targeting of Ra²⁺ to metabolically active bone, allows the simple administration of radium chloride. In this manner, the generator can be eluted, the ²²³Ra eluant evaporated, then dissolved in saline/sodium citrate buffer, and dispensed by sterile filtration. It is then ready for administration precluding any complex radiolabeling and purification procedures normally encountered for radiopharmaceutical administration.

40.5 In Vivo Generators

40.5.1 Concept

A relatively recent and potentially useful approach is based on the concept of an in vivo generator (Mausner et al. 1989). The concept involves labeling of various molecular carriers (complexes, peptides, mcAb, mcAb-fragments, etc.) with intermediate half-life generator parents, which after accumulation in the desired tissue generate much shorter half-life daughter radionuclides (Table 40.3). These in vivo generated daughter radionuclides can act either as imaging agent (if decaying via single-photon or positron emission) or as therapeutic agent (if decaying via α, β[−], or Auger electron emission). In particular, for therapy, since the daughter will be in equilibrium in vivo with the parent, formation of the particle-emitting daughter will add in situ a significant radiation dose. This concept of targeting the parent radionuclide will

Table 40.3

Potential parent/daughter pairs for the in vivo generator concept

Generator system	Parent		Daughter			Application
	T _{1/2}	decay	T _{1/2}	Emission (%)	E _{β/α} (MeV)	
⁶⁶ Ni/ ⁶⁶ Cu	2.275 d	β [−]	5.10 min	γ, β [−]	1.076	ERT
¹¹² Pd/ ¹¹² Ag	21.04 h	β [−]	3.14 h	γ, Auger-e, β [−]	1.380	ERT
¹³⁴ Ce/ ¹³⁴ La	3.16 d	EC	6.45 min	γ, Auger-e, β ⁺ (63%)	0.756	PET
¹⁴⁰ Nd/ ¹⁴⁰ Pr	3.37 d	EC	3.39 min	γ, Auger-e, β ⁺ (51%)	0.544	ERT, PET
¹⁶⁶ Dy/ ¹⁶⁶ Ho	3.400 d	β [−]	1.117 d	γ, Auger-e, β [−]	0.711	ERT
²¹² Pb/ ²¹² Bi	10.64 h	β [−]	1.01 h	γ, Auger-e, α (64%), β [−] (36%)	2.170	ERT
					0.492	
²¹³ Bi/ ²⁰⁹ Pb	45.6 min	β [−] , α	3.253 h	β [−]	0.198	ERT
²²⁵ Ac/chain	10.6 d	α	Various	α	Various	ERT
²²⁷ Th/ ²²³ Ra	18.7 d	α	11.4 d	α	Various	ERT

assist to focus the therapeutic efficacy to the tumor cells, which is of particular importance, since the potential usefulness of radiotherapy is often limited by the irradiation of radiation-sensitive non-target tissues. The in vivo generator is thus a potential alternative to minimize exposure.

However, the concept implies that the chemical binding of the daughter nuclide is analogous to the parent one and the daughter radionuclide is thus not released from the original position. If not, i.e., if released from the targeted tracer due to various factors, which are well known from hot atom chemistry processes, the decay product will be bound in the near surrounding environment of the parent due to other chemical or biochemical binding (such as intracellular trapping effects) or is released from the target site.

40.5.2 Examples of In Vivo Generators

Several generator pairs could potentially be utilized as in vivo systems, presuming the parent nuclide offers the adequate chemical properties for synthesis of labeled compounds and a half-life adequate to the biochemical/physiological process the labeled compound is involved. In this context, stable labeling with ^{66}Ni and ^{112}Pd , for instance, is not yet established, whereas there are reliable bifunctional chelators available to bind trivalent parent nuclides such as ^{134}Ce , ^{140}Nd , ^{166}Ho , and ^{213}Bi . The most intensively studied pair as in vivo generator is $^{166}\text{Ho}/^{166}\text{Dy}$ (Ma et al. 1993; Mirzadeh et al. 1994; Smith et al. 1995). After intravenous injection of [^{166}Dy] DTPA and accumulation of the parent nuclide in bone, no translocation of the daughter ^{166}Ho was observed subsequent to the β^- decay of ^{166}Dy .

Issues related to the possible in vivo use of the ^{103}Pd ($T_{1/2} = 16.99$ d)/ $^{103\text{m}}\text{Rh}$ ($T_{1/2} = 56.1$ min) generator have also recently been discussed on a theoretical basis (Suzcs et al. 2009; Van Rooyen et al. 2008).

Interest in the use of the in vivo generator concept for tumor therapy has reemerged with increased focus on ^{225}Ac ($T_{1/2} = 10$ days), which decays to the ^{213}Bi ($T_{1/2} = 45$ min) daughter. Although the dose rate is much lower, the integrated delivered radiation dose is much higher for administered levels of radioactivity. The use of complexed ^{225}Ac as an in vivo generator has also been evaluated by McDevitt et al. (2001), where it is described as a “nano generator.” Other studies with ^{225}Ac have demonstrated that select carboxylate-derived calixarene agents have an ionophore cavity capable of highly selective complexation of Ac^{3+} in weak acid and neutral solution. Successful functionalization of these molecules may provide other candidate chelate approaches for use of ^{225}Ac for the in vivo generator approach.

The ongoing clinical application of ^{213}Bi -radiotherapeutics themselves may already be considered as a version of an in vivo generator, as the various nuclides of the decay chains

probably stay in the vicinity of the parent nuclide cellular environment and do significantly contribute to an enhanced radiation dose in the target tissue.

However, as investigated for the $^{140}\text{Nd}/^{140}\text{Pr}$ generator system, the daughter (^{140}Pr) may quantitatively be released from initial (^{140}Nd -DOTA) complexes in, e.g., (^{140}Nd)-DOTA-octreotide compounds despite the very high thermodynamic and kinetic stability of the

trivalent lanthanide with the macrocyclic chelator (Zhernosekov et al. 2007b). This dramatic effect – different to the $^{166}\text{Ho}/^{166}\text{Dy}$ system – is explained by the difference in the radioactive decay. The electron capture $^{140}\text{Nd} \rightarrow ^{140}\text{Pr}$, namely, ruptures the initial chemical bonds of the mother radionuclide and releases a daughter atom in situ, which is not able to form complexes with DOTA-like compounds at room temperature. Thus, nuclide pairs connected by EC and ligands involved with kinetically determined complex formation characteristics are not useful as in vivo generators.

In addition, in vivo generators have been discussed in the context of radiation therapy seeds and of diagnostic tests with ultra-short-lived daughters (Lambrecht et al. 1997).

Acknowledgments

The authors thank their many colleagues and collaborators for their support and interest. Research at the Oak Ridge National Laboratory (ORNL) supported by the US Department of Energy (DOE), under contract DE-AC05-00OR22725 with UT-Battelle, LLC.

Abstract: Methods for the synthesis of compounds labeled with the short-lived positron emitting radionuclide ¹¹C are described. Important aspects on how to achieve high specific radioactivity and the need for technical solutions to establish a reproducible routine tracer production are pointed out. Examples of positron emission tomography (PET) as a tool in drug development are also included.

41.1 Introduction

The possibility to quantify in vivo biochemistry noninvasively using compounds labeled with radioactive isotopes is a milestone in medical imaging. The first production of the short-lived positron emitting radionuclide ¹¹C was performed in 1934 (Crane and Lauritsen 1934). It was found that ¹¹C decays with a half-life of 20.4 min by positron emission to the stable nuclide ¹¹B. Due to its favorable decay characteristics (98.1% by β^+ emission, 0.19% by electron capture), it was recognized as a useful tool in medical imaging. The first biological experiment using ¹¹C was performed by Ruben in 1939 who studied the photosynthesis in plants using [¹¹C]carbon dioxide (Ruben et al. 1939). This was followed by Tobias who in 1945 investigated the fixation of [¹¹C]carbon monoxide by red blood cells in humans (Tobias et al. 1945). The possibility to prepare more complex molecules and to choose labeling position has significantly contributed to the versatility of the positron emission tomography (PET) technique. In this chapter, the most important labeling methods are presented with focus on recent improvements. For a comprehensive review with references to the earlier work in this field of research see Fowler and Wolf (1986). A catalog of references to ¹¹C-labeled compounds is available on the Internet (Cyril 2003).

PET has during the last 10 years evolved into a valuable tool in drug development. Compounds labeled with positron emitting radionuclides are currently used in different phases in the drug development process using preclinical methods as well as PET investigations both in animals and in man. One of the major research fields that have contributed to establish PET as a useful and in some cases a necessary tool in drug development is radiochemistry. Especially developments in ¹¹C chemistry have opened up new perspectives for the use of PET in drug development.

41.2 Radiotracer Synthesis

41.2.1 Technical Considerations

A limiting factor that has to be considered when planning syntheses with ¹¹C is the short physical half-life. It is thus important to use rapid synthetic methods and to avoid reaction sequences that may require lengthy purification processes. The short half-life requires high amounts of starting radioactivity in order to obtain a tracer with enough radioactivity for a PET study. Radiation protection and safe handling of radioactive reactants is thus important. Examples of technical approaches that can be applied when working with short-lived radionuclides and high levels of radioactivity are as follows.

Remote or processor-controlled automated device. Remote or processor-controlled automated devices, mainly developed for radiation protection purposes, also have other advantages such as increasing the reproducibility in the tracer production. This also facilitates

development of standardized procedures, which is important with respect to quality assurance and the implementation of Good Manufacturing Practice (GMP) in PET-related work.

One-pot and online procedures. Transfer of small volumes between reaction vessels may reduce the radiochemical yield and increase the risk of introducing carrier carbon. The uses of one-pot and online procedures are thus important means to facilitate the technical handling.

Miniaturization. Miniaturization of synthesis equipment makes it possible to reduce the amounts of reagents. This feature can facilitate purification or even omit the need of a purification step and may increase the specific radioactivity. Especially when working with [^{11}C]carbon dioxide this is important since reduction of the amount of reagent might increase the specific radioactivity by lowering the amount of carrier carbon present. The gas volume in a reaction vial may have some impact on the alkylation yield using [^{11}C]methyl iodide, since a large gas volume together with high temperature will distribute a significant portion of the [^{11}C]methyl iodide to the gas phase and thus lower the reaction yield.

On-column preparations and closed loops. The use of on-column preparations and closed loops as an alternative to reaction vials is another technical solution (Jewett et al. 1985; Iwata et al. 1995). An example of this approach is the synthesis of [^{11}C]cyclohexanecarbonyl chloride where [^{11}C]carbon dioxide is reacted with cyclohexylmagnesium bromide coated on the internal surface of polypropylene tubing, followed by treatment of the complex with thionylchloride (McCarron et al. 1996).

Sonication and microwaves. Sonication (Le Breton et al. 1991) or microwaves (Niisawa et al. 1984; Hwang et al. 1987; Stone-Elander et al. 1994; Thorell et al. 1992) can be used to speed-up a reaction. The selectivity in the reaction may in some cases also change when microwave heating is used (Elander et al. 2000).

Solvation parameters. Increased control of the solvation parameters by performing the synthesis in a supercritical media may also offer advantages such as high reproducibility (Jacobson et al. 1994a, b, 1996).

41.2.2 Synthetic Considerations

For the production of ^{11}C -labeled tracers, four main approaches have been employed: (1) Biosynthetic methods, (2) Recoil labeling, (3) Organic synthetic methods, and (4) Enzyme catalysis.

Biosynthetic methods using plant leaves or algae (Lifton and Welch 1971) and recoil labeling (e.g., via the spallation reaction $^{16}\text{O}(\text{p},3\text{p}3\text{n})^{11}\text{C}$) are today of little importance. Presently, the only labeling methods of practical interest are organic synthesis and enzymatic catalysis.

The requirement for a rapid tracer production means that the synthesis should be designed in such a way that the ^{11}C atom is introduced as late as possible. This approach is exemplified by alkylation of carbon, nitrogen, oxygen, and sulfur nucleophiles with [^{11}C]methyl iodide, a synthetic route that provides a general method for the labeling of many biomedically interesting compounds.

41.2.2.1 Position-Specific Labeling

The development of rapid labeling syntheses is conditioned on the availability of suitable labeled precursors. A few useful target-produced primary precursors are available such as

[¹¹C]carbon dioxide and [¹¹C]methane. Much work has been devoted to the development of methods for the routine production of secondary precursors to be used as building blocks in the production of PET tracers.

Most biomolecules contain several carbon atoms, which opens up the possibility to select the labeling position (i.e., position-specific labeling). Since heteroatom-bound methyl groups are common in many biomolecules and pharmaceuticals, [¹¹C]methyl iodide has, so far, been the most used labeling reagent. Another general synthetic approach that has been adopted is to label in the carbonyl position using [¹¹C]carbon dioxide, [¹¹C]carbon monoxide, or [¹¹C]phosgene. This has a primary value in PET-tracer synthesis since biologically active substances often contain carbonyl groups or functionalities that can be derived from a carbonyl group.

It is important to select a labeling position that does not give rise to labeled metabolites that interfere with the measurement of the process to be studied. It is thus essential to establish synthetic strategies that give access to a variety of labeling positions. This concept is illustrated with the 5-HT_{1A} receptor antagonists WAY100635 (● Fig. 41.1). Labeling in the methoxy position (Mathis et al. 1994) resulted in the formation of the labeled lipophilic metabolite WAY100634 that also penetrated the blood-brain barrier (BBB) and added to the nonspecific binding in the brain (Osman et al. 1996). With the label in the carbonyl group [¹¹C]cyclohexane carboxylic acid was the main labeled metabolite, and since that compound is not transported over the BBB, interpretation of the PET data was simplified.

41.2.2.2 Reaction Kinetics

The kinetic aspect needs special attention when a synthetic strategy is selected. The significance of time as a reaction parameter is of equal importance, as chemical yield has to be considered in the planning of a labeling synthesis. Since the radiochemical yield is a function of chemical yield and radioactive decay, the maximum radiochemical yield is attained before the reaction has proceeded to completion. This relation between time and concentration of reactants with respect to kinetics is described in some of the initial works on ¹¹C-chemistry (Långström and

■ Fig. 41.1

Synthesis of methoxy-¹¹C and cyclohexyl-¹¹C-labeled WAY100635

Bergson 1980; Långström et al. 1981a; Berger et al. 1981). The stoichiometric relationships in labeling synthesis with radionuclides of high specific radioactivity need special attention. The small amounts of labeled compound mean that the ratio between unlabeled precursor and labeled reagent can be very high. This usually increases the conversion rate of the labeled reactant to product to give satisfactory radiochemical yield within 5–10 min. A special case is the aforementioned alkylation of amines with [¹¹C]methyl iodide. Alkylation of amines with methyl iodide in stoichiometric amounts typically results in product mixtures with quarternarized amines as end product. This is due to the increased nucleophilicity from the primary to the secondary and tertiary amines. However, in ¹¹C-labeling synthesis the amount of [¹¹C]methyl iodide is very low and a concentration ratio amine/methyl iodide of 50–500 can be achieved. Due to the resultant change from second-order kinetics to pseudo-first order kinetics, the problem with polyalkylation is minimized and the monoalkylated product is obtained. An example where the large excess of unlabeled reagent is disadvantageous is the synthesis of [1–¹¹C]acetate by the reaction of [¹¹C]carbon dioxide with methylmagnesium bromide. A too high concentration of methylmagnesium bromide results in the formation of labeled acetone and tert-butanol. The use of a solid support for the Grignard reagent instead of performing the reaction in solution is one way of minimizing this problem.

41.2.3 Specific Radioactivity

The theoretical specific radioactivity of ¹¹C is 3.4×10^5 GBq/μmol, a limit that is considerably higher than the 1,500–2,500 GBq/μmol typically obtained at end of radionuclide production (Harada and Hayashi 1993).

41.2.3.1 Isotopic Dilution – Radionuclide Production

It is practically impossible to completely avoid isotopic dilution by stable carbon isotopes from the target material (e.g., nitrogen/oxygen, nitrogen/hydrogen gas mixtures) and target holder, usually aluminum (Heselius et al. 1987). The major isotopic dilution by stable carbon is obtained during the radionuclide production. The amount of carbon isolated in the form of carbon dioxide or methane following radionuclide production is typically in the order of 1–100 nmol.

41.2.3.2 Isotopic Dilution – Labeling Synthesis

The degree of isotopic dilution during production of a PET tracer is also determined by the choice of primary precursor and the quality of the reagents used in the chemical transformations. It is important to remember that products formed from reaction with atmospheric carbon dioxide usually contaminate chemicals such as lithium aluminum hydride and Grignard reagents (Iwata et al. 1988).

In some special cases, an isotopic dilution can occur by exchange (see ► Chap. 15 in Vol. 2) between the labeled reagent and the solvent or reagents used. Dimethyl sulfoxide, a commonly used solvent in alkylation reactions, might react with [¹¹C]methyl iodide to form labeled oxo-trimethyl-sulfonium iodide. This intermediate can transfer any of the three methyl groups to

another nucleophile in the reaction mixture and thus reduce the radiochemical yield and the specific radioactivity (Klein and Holschbach 2001). Other similar problems are the exchange reaction between [¹¹C]cyanide and the cyano group in acetonitrile in the presence of a phase transfer catalyst (Jay et al. 1980) and the transfer of methyl groups in Stille couplings using trimethylstannanes. In spite of all precautions, the amount of carrier carbon introduced during the synthesis is in the range of 10–100 nmol.

41.3 Methods for ¹¹C-Syntheses

41.3.1 Labeled Precursors

41.3.1.1 Primary Precursors – Target Produced One-Carbon Compounds

The limited access to labeled precursors is a restriction in the choice of synthetic route. Development of new precursors for labeling synthesis is thus an important field of research.

Primary precursors are prepared in the target and secondary by further chemical processing of a primary product (usually by online or one-pot procedures). [¹¹C]Carbon dioxide and [¹¹C]methane are the most commonly prepared primary precursors (Bida et al. 1978; Christman et al. 1975). The production method usually employed is the ¹⁴N(p,α)¹¹C reaction. [¹¹C]Carbon monoxide is formed simultaneously with [¹¹C]carbon dioxide but can easily be separated cryogenically from the latter. [¹¹C]Methane is obtained if a nitrogen/hydrogen gas mixture is used. Other precursors available directly in the target are hydrogen [¹¹C]cyanide (Lamb et al. 1971), [¹¹C]cyanamide (Iwata and Ido 1983), [¹¹C]guanidine (Iwata et al. 1981), and [¹¹C]methyl iodide (Wagner et al. 1981).

In conclusion, [¹¹C]carbon dioxide is the most versatile primary precursor with respect to production yield, ease of separation from target gas, and prospect for chemical transformations. Furthermore, of the primary precursors only [¹¹C]carbon dioxide has been used directly as a labeling agent to any greater extent. It can be used as a substitute for phosgene in the formation of ureas (Schirbel et al. 1999) or in reactions with alkyl lithium compounds and Grignard reagents. The latter reaction gives access to important tracers such as acetate (Pike et al. 1982) and palmitate labeled in the carboxylic position. Another possibility is to perform a direct incorporation of [¹¹C]carbon dioxide to produce a label in the *N*-methyl position by reaction with a *N*-trimethylsilyl derivative as shown in ► Fig. 41.2 (Ram et al. 1986; Ram and Spicer 1989).

41.3.1.2 Secondary Precursors

Several reactive molecules have been prepared by simple online or one-pot procedures from [¹¹C]CO₂. Some of the most important secondary precursors obtained from [¹¹C]CO₂ are shown in ► Fig. 41.3. [¹¹C]Methane, the other main primary precursor, is also a useful source for the preparation of more reactive labeling reagents (► Fig. 41.4).

[¹¹C]Methyl iodide (► Fig. 41.5) has been the most versatile of the secondary precursors (Bolton 2001). It can be prepared by reduction of [¹¹C]carbon dioxide with lithium aluminum hydride in tetrahydrofuran or diethyl ether, followed by reaction with hydroiodic acid (Långström and Lundqvist 1976; Crouzel et al. 1987a).

■ Fig. 41.2

Synthesis of [^{11}C]tamoxifen

■ Fig. 41.3

Examples of secondary precursors obtained from [^{11}C]CO $_2$ 

This method is very reliable but suffers from the drawback that the lithium aluminum hydride contains carrier carbon that reduces the specific radioactivity. A solid phase technique has also been reported for the synthesis of [^{11}C]methyl iodide (Sarkadi et al. 1997, 1998). In an alternative method, that gives higher specific radioactivity, [^{11}C]methane undergoes a free radical iodination in a circulating gas phase while the [^{11}C]methyl iodide formed is continuously trapped on a solid phase to prevent further iodination (Larsen et al. 1997).

In order to achieve maximum specific radioactivity, in target production of [^{11}C]methane followed by iodination is the method of choice. Alkylation reactions on oxygen, nitrogen, phosphorus, and sulfur nucleophiles as well as on carbanions indeed cover a large variety of

■ Fig. 41.5

Methods for the synthesis of [^{11}C]methyl iodide

possible reactions with [^{11}C]methyl iodide. Alkylation on ionic nucleophiles, e.g., carboxamide anions and carboxylates, generated by the addition of alkali metal hydroxides are usually accompanied by the formation of [^{11}C]methanol. This can be minimized by isolation of the preformed anionic salt either in the form of a tetrabutylammonium salt or as a benzo-5-crown-5 sodium complex. The latter is exemplified by the synthesis of [^{11}C]diazepam (Sassaman et al. 1999).

The reactivity of [^{11}C]methyl iodide can be increased by conversion to [^{11}C]methyl triflate ([^{11}C]methyl trifluoromethanesulphonate) by an online process (Jewett 1992) using silver triflate absorbed on graphite. Methyl triflate is more reactive than methyl iodide, is less sensitive to excess of metal hydroxides and usually gives higher radiochemical yields (Någren et al. 1995). Furthermore, the use of [^{11}C]methyl triflate increases the selection of solvents suitable for alkylation reactions. An alternative method for [^{11}C]methyl triflate synthesis is from [^{11}C]methyl bromide via [^{11}C]methane (Mock et al. 1999). [^{11}C]Methyl bromide can be prepared either by passing [^{11}C]methane through liquid bromine or by recirculation over pyridiniumtribromide. Use of liquid bromine typically results in a mixture of mono and dibromomethanes. The reported conversion from halomethanes to triflate was higher using [^{11}C]methyl bromide than [^{11}C]methyl iodide (Steel et al. 1998).

The reactivity can be further increased using [^{11}C]methyl nona-fluorobutyl-1-sulfonate (Jolly et al. 2007).

Conversion of the electrophilic methyl iodide to the nucleophilic methyl lithium (Reiffers et al. 1980) and lithium [^{11}C]methyl(2-thienyl)cuprates (Kihlberg et al. 1997) broadens the spectrum of functionalities that may be labeled in a methylation reaction. Transformation of [^{11}C]methyl lithium to trimethylsilyl chloride is a method for labeling of aryl trimethylsilyl

compounds (Roeda et al. 1999). [^{11}C]Diazomethane is a useful but not easily accessible methylating agent (Crouzel et al. 1987b). Other labeling agents that can be prepared from [^{11}C]methyl iodide are Wittig reagents (Kihlberg et al. 1990; Hörnfeldt and Långström 1994a, b, c, see also ▶ Fig. 41.6) useful in alkene syntheses, triphenylarsonium [^{11}C]methylide, used in ring-closure reactions (Zessin et al. 1999), [^{11}C]methylhypofluorite for the formation of enolmethyl ethers (McCarthy et al. 1993) and [^{11}C]methylmagnesium iodide (Elsinga et al. 1995) for Grignard reactions.

A difficulty in the synthesis of the phosphorylide in the Wittig reaction is to add an equimolar amount of base to the alkyl halide. The use of epichlorohydrine, which forms one equivalent of base in situ by the reaction with iodide ions, obtained from the reaction of a ^{11}C -labeled alkyl iodide with triphenyl phosphine is one method to overcome the problem. Some examples of useful precursors prepared from [^{11}C]methyl iodide are shown in ▶ Fig. 41.7.

^{11}C -Labeled ethyl-, allyl-, propyl-, cyclopropyl-, isopropyl-, butyl-, isobutyl-, benzyl-, and some substituted benzyl halides are examples of other alkylating agents prepared from [^{11}C]carbon dioxide and Grignard reagent (Långström et al. 1986; Fasth et al. 1990b; Antoni and Långström 1987a, b, c; Lasne et al. 1991; Luthra et al. 1985) as shown in ▶ Fig. 41.8.

■ Fig. 41.6

Examples of labeled Wittig reagents

■ Fig. 41.7

Examples of precursors obtained from [^{11}C]methyl iodide

These precursors suffer from the typical isotopic dilution problems encountered with the use of Grignard reagents and lithium alkyl compounds. Another problem encountered when reacting high specific activity [^{11}C]carbon dioxide with Grignard reagents is the formation of products from reaction of two or three Grignard reagents per [^{11}C]carbon dioxide molecule. The synthesis of [^{11}C]ethyl iodide from methylmagnesium bromide and [^{11}C]carbon dioxide is an example of that and both methyl and isopropyl iodide are formed in substantial amounts. This is, however, less problematic when longer alkyl chain Grignard reagents are used such as in the synthesis of carboxylic-labeled fatty acids. On the other hand, di-coupling of the Grignard reagent can be an advantage since precursors such as [$2\text{-}^{11}\text{C}$]acetone (Berger et al. 1980a) and [^{11}C]isopropyl iodide (Antoni and Långström 1987c) can be prepared from methylmagnesium bromide. Alkyl lithium reagents can also be used to achieve di-couplings, and acetone and isopropyl iodide are preferentially prepared from these reagents. Difunctional precursors such as 1,2-dibromo[^{11}C]ethane (► Fig. 41.9) and [^{11}C]chloroethyltriflate synthesized from [^{11}C]ethylene obtained via [^{11}C]ethanol (Shah et al. 1994a; Shah et al. 1997; Prenant et al. 1995b) are also interesting as labeling tools.

Nitro[^{11}C]alkanes have been obtained from labeled methyl-, ethyl-, and propyl iodide by reaction with silver nitrite by the online process presented in ► Fig. 41.10 (Schoeps et al. 1989; Schoeps and Halldin 1992).

Nitroalkanes can be reacted with aldehydes in a Knoevenagel-type condensation reaction; amphetamine and phenethylamine are examples of compounds labeled using this methodology (► Fig. 41.11).

■ Fig. 41.9

Synthesis of 1,2-[^{11}C]dibromoethane

■ Fig. 41.10

Synthesis of [^{11}C]nitroalkanes

The products obtained are racemic since the addition of nitromethane is not stereospecific. It is possible to modify the reaction conditions to obtain either the nitroalcohol or the dehydrated product.

Labeling of a carbon in an aromatic ring may give access to useful structural units with the label in a metabolically stable position. The synthesis of some aromatic compounds including heterocycles from ^{11}C nitromethane is shown in ► Fig. 41.12 (Zessin et al. 1999; Mäding et al. 1997; Mäding and Steinbach 1998, 2000; Steinbach et al. 1995).

■ Fig. 41.11

■ Fig. 41.12

^{11}C Labeling of aromatic compounds in the ring structure. The labeled carbon is indicated by an asterisk

Ethyl nitro[2-¹¹C]acetate, obtained from [¹¹C]nitromethane, could potentially be used for labeling of amino acids and heterocycles (Kato et al. 2007).

In the synthesis of sulphonamides and methane sulphonates [¹¹C]methane sulphonyl chloride has been used (McCarron et al. 1999).

[¹¹C]Methyl azide can be used in rapid and mild reactions, i.e., click chemistry, to label peptides containing an ethynyl-terminal (Schirrmacher et al. 2008).

Formaldehyde is a versatile one-carbon precursor and should thus be an attractive tool in labeling chemistry. Due to lack of reliable and simple production method it has not been used to the same degree as [¹¹C]methyl iodide. The main applications have so far been reductive formylations of amines. [¹¹C]Formaldehyde can be obtained by enzymatic catalysis or organic synthetic approaches (Christman et al. 1971; Hughes and Jay 1995). The most applied methods rely on the formation of [¹¹C]methanol from [¹¹C]carbon dioxide, followed by oxidation by silver wool, ferric molybdenum oxide, or xenon difluoride (Marazano et al. 1977; Berger et al. 1980b; Nader et al. 1997). Reduction of [¹¹C]carbon dioxide with metal hydrides at temperatures below -50°C (Nader et al. 1998; Roeda and Crouzel 2001) is another possibility. In the latter method, the low temperature minimized the reduction of formaldehyde to methanol but formic acid has been identified as a by-product. Recently a simple, robust, and high yielding method was developed where [¹¹C]formaldehyde is obtained from [¹¹C]methyl iodide via a reaction with trimethyl amine *N*-oxide (Hooker et al. 2008).

A procedure for ¹¹C-labeling of the 4-imidazolyl group using [¹¹C]formaldehyde is shown in Fig. 41.13. The 4-imidazolyl group is a commonly found structural unit in histamine receptor ligands (Roeda et al. 1997).

Substituted benzaldehydes have been prepared from [¹¹C]carbon dioxide and Grignard reagents via the corresponding carboxylic acids and reduction to the alcohol followed by selective oxidation (Halldin and Långström 1984a; Kutzman et al. 1980).

The carbonyl functionality is a prevalent structure in many biomolecules. Labeling in this position can be achieved by reaction with [¹¹C]phosgene (Roeda et al. 1978; Roeda and Westera 1981; Nishijima et al. 2002, see also Fig. 41.14) and acyl chlorides such as acetyl- (Luthra et al. 1990), cyclohexanecarbonyl-, (McCarron et al. 1996), and furoyl chloride (Ehrin et al. 1988).

Fig. 41.13

Synthesis of 4-imidazolyl derivatives

Fig. 41.14

Synthesis of [¹¹C]phosgene

The specific radioactivity of [^{11}C]phosgene has been relative low, probably due to carrier carbon in the chlorine gas.

Labeling in the carbonyl position can be also accomplished by the use of [^{11}C]propyl ketene (Imahori et al. 1989, 1991) obtained by pyrolytic decomposition of [^{11}C]butyric acid. [^{11}C]methylisocyanate (Bonnot-Lours et al. 1993; Brown et al. 1994; Crouzel et al. 1995) prepared either from [^{11}C]acetyl chloride or [^{11}C]phosgene, and [^{11}C]methylchloroformate (Ravert et al. 1995) synthesized from [^{11}C]methanol and phosgene are other examples of useful reactive precursors (► Fig. 41.15).

Phosgenation of *N,N*-bis(trimethylsilyl)amine is superior to the use of methylamine. The Curtius rearrangement reaction effectively produces the labeled methylisocyanate but is very time consuming and results in a low radiochemical yield.

Reacting [^{11}C]methyl iodide with silver cyanate gives methylisocyanate with the label in the methyl group. Other organo-isocyanates have been synthesized from *N*-sulfinylamines or *N,N'*-organo ureas as shown in ► Fig. 41.16 (Brown et al. 2001). The organosulfinylamines give the highest radiochemical yield.

[^{11}C]Urea has been synthesized by several methods starting either with [^{11}C]cyanide (Emran et al. 1985) or with [^{11}C]carbon dioxide (Chakraborty et al. 1997).

A versatile precursor is hydrogen [^{11}C]cyanide prepared from [^{11}C]methane by a platinum catalyzed reaction with ammonia (Christman et al. 1975; Iwata et al. 1987). Hydrogen [^{11}C]cyanide is obtained with a specific radioactivity higher or similar to that of [^{11}C]methyl iodide prepared by the gas phase method. From [^{11}C]cyanide other labeled reagents can be prepared such as $\text{Cu}[^{11}\text{C}]\text{CN}$ (Ponchant et al. 1997), halonitriles (Hörnfeldt et al. 1992), acrylonitrile (Antoni and Långström 1992), [^{11}C]cyanomethyl pivalate (Thorell et al. 1994), and [^{11}C]trifluoroacetone nitrile (Roeda et al. 1999a) as schematically shown in ► Fig. 41.17.

■ Fig. 41.15

Synthesis of methylisocyanate

■ Fig. 41.16

Synthesis of organo-isocyanates

The multistep synthesis of the putative glycine antagonist Licostinel may serve as an example of the use of [¹¹C]cyanide in labeling synthesis. The synthesis of [¹¹C]diethyloxalate and the following ring closure to produce the [¹¹C]quinoxaline ring structure, is shown in ▶ Fig. 41.18 (Thorell et al. 1993b, 1995, 1998).

In cyanogen bromide, the carbon has reversed polarity as compared with cyanide and is accordingly used as an electrophilic equivalent of the nucleophilic cyanide. This, so-called, “umpolung” offers new alternatives in labeling synthesis for the introduction of a cyano group. [¹¹C]Cyanogen bromide is prepared by reaction of hydrogen [¹¹C]cyanide with bromine or perbromide (Westerberg and Långström 1993, 1997a, b). Some examples of possible synthetic transformations from [¹¹C]cyanogen bromide are shown in ▶ Fig. 41.19 (Westerberg and Långström 1994a).

The influenza virus neuraminidase inhibitor GG167 labeled with ¹¹C in the guanidine group has been synthesized from [¹¹C]cyanogen bromide (Westerberg et al. 1996) as shown in ▶ Fig. 41.20.

[¹¹C]Cyanogen bromide can also be used for unspecific labeling of macromolecules. The reactions can be performed at near physiological conditions, with respect to temperature and pH.

Synthesis of $[^{11}\text{C}]$ GG167

Proteins such as transferrin and albumin as well as the polysaccharide hyaluronan have been labeled by this method (Westerberg and Långström 1994b; Westerberg et al. 1995). The label in the form of a ^{11}CN group is either attached to a free amino group in the protein or to a hydroxyl in a carbohydrate. Other methods used for unspecific labeling of macromolecules include reductive methylation with $[^{11}\text{C}]$ formaldehyde and direct alkylation with methyl iodide (Straatman and Welch 1974; Marche et al. 1975; Turton et al. 1984). Labeling with formaldehyde and methyl iodide suffers from the drawbacks that either a reducing agent or alkaline conditions are needed in the synthesis that may be deleterious to the protein.

$[^{11}\text{C}]$ Carbon monoxide was until recently rarely used as a precursor due to its low reactivity and low solubility in most solvents. It can be prepared by reduction of $[^{11}\text{C}]$ carbon dioxide using Zn (Christman et al. 1975), charcoal (Al-Qahtani and Pike 2000), or molybdenum (Zeisler et al. 1997). The use of solid phase supports for the concentration of $[^{11}\text{C}]$ carbon dioxide and $[^{11}\text{C}]$ carbon monoxide and a micro-autoclave for the transition metal-mediated carbonylation reactions have solved some of the earlier problems that restricted the use of this easily prepared precursor (Kihlberg and Långström 1999; Kihlberg et al. 2001). The earlier discussed problems with low specific radioactivity of alkyl halides prepared from Grignard or alkyllithium reagents may be circumvented by applying a newly presented method where

[¹¹C]ethyl iodide is synthesized with higher specific radioactivity and radiochemical purity from [¹¹C]carbon monoxide by a palladium catalyzed reaction with methyl iodide followed by reduction and iodination (Eriksson and Långström 2001).

41.3.2 ¹¹C–C Bond Formation

In organic chemistry C–C bond formations are among the most essential reactions. In ¹¹C-chemistry, the common method for introduction of the label has been heteroatom alkylations. However, ¹¹C–C bond formations are important complements for compounds lacking a heteroatom-bound alkyl group, or when other labeling positions are needed due to the metabolic fate of the tracer. In tracer synthesis, the following ¹¹C–C bond forming reactions have been applied.

- Alkylation on a stabilized carbanion using a ¹¹C-labeled alkyl iodide (e.g., malonic ester alkylation, see Gee and Långström 1991).
- Carbonation of an organometallic reagent with [¹¹C]carbon dioxide (e.g., [1–¹¹C]acetate, see Pike et al. 1981; Oberdorfer et al. 1992; Iwata et al. 1995).
- Reactions of [¹¹C]cyanide with electrophilic carbons (e.g., [1–¹¹C]glucosamine, see Thorell et al. 1993).
- Reactions with the anion of a ¹¹C-labeled nitroalkane (e.g., [1–¹¹C]norepinephrine, see Schoeps and Halldin 1992).
- Cuprate-mediated coupling reactions using a ¹¹C-labeled alkyl iodide or a ¹¹C-labeled methyl cuprate. (e.g., methyl ¹¹C-labeled fatty acids, ¹¹C-labeled steroids, see Kihlberg and Långström 1994a, b; Lidström et al. 1997; Neu et al. 1998).
- Alkene-synthesis using [¹¹C]methylenetriphenylphosphorane (e.g., ¹¹C-labeled monosaccharides, see Grierson et al. 1993; Ögren et al. 1995b, 1997).

Recently, transition metals and particularly palladium have found an increased use in ¹¹C-synthesis. Reactions such as aromatic cyanation, the Stille-coupling reactions, and palladium-mediated carbonylation reactions using [¹¹C]carbon monoxide are opening up new labeling pathways.

41.3.3 Transition Metal–Mediated Reactions

41.3.3.1 General

Organo transition metallic reagents differ from other organo metallic reagents in several aspects. They are not strongly basic or nucleophilic, they easily coordinate a variety of different compounds and have a low energy barrier between different oxidation states. Thus, mild and selective syntheses can be developed using substrates with relative low reactivity. This is particularly valuable in ¹¹C-labeling synthesis, since it implies that protective groups can be omitted.

In organic chemistry, the reactions are usually performed in a catalytic fashion. In ¹¹C-labeling synthesis, however, all reagents including the transition metals are used in large excess compared to the labeled precursor. For this reason, the term “mediated” is more appropriate than “catalyzed.”

Among the transition metals palladium has been most useful. The organo palladium reagents can be conveniently made in situ, which has a practical value in the context of tracer synthesis. The reactions are very mild and often give high yields using short reaction times. One limitation is encountered with organohalides having β -protons bound to sp^3 -carbons, these usually give low yields due to the competing β -hydride elimination reaction. (Collman et al. 1997; Stille 1986)

Organocuprates are much less prone to β -hydride elimination reaction and rapidly couple with alkyl halides. In this respect, they complement the palladium reagents. A disadvantage is their basicity and that their most common sources are the strongly basic and nucleophilic alkyl lithium and Grignard reagents, which require protection of sensitive functionalities.

41.3.3.2 Cyanations

The ^{11}C -cyano group can be attached to aromatic rings using palladium as exemplified by the labeling of an analogue of the NMDA receptor antagonist MK-801 (3-cyano-MK-801) by cyanation of 3-iodo-MK-801 (Andersson et al. 1998). By the same Pd-mediated cyanation reaction followed by selective hydrolysis to the corresponding amides (Andersson et al. 1994) ^{11}C -benzamides, as potential tracers for poly (ADP-ribose) synthetase, have been obtained.

Attaching the strongly electron-withdrawing group tricarbonylchromium to the aromatic ring can further increase the rate of the cyanation reactions. Thus, also deactivated substrates can be labeled in high radiochemical yield with this method (Balatoni et al. 1989; Andersson and Långström 1994, see also [Fig. 41.21](#)).

41.3.3.3 Cross-Couplings

Palladium(0)-complex can mediate the cross-coupling of organic halides or triflates to organo-metallic reagents with high regio- and stereoselectivity. Due to the possible β -hydride

■ Fig. 41.21

Transition metal-mediated cyanation reactions

undecane (► Fig. 41.24), was prepared for these reasons and used in Stille couplings (Vedejs et al. 1992; Forngren et al. 2001).

The Heck reaction, i.e., the palladium-promoted coupling of organoelectrophiles with alkenes, is another mild and versatile method for C–C bond formations. Its value for ^{11}C -labeling has been investigated using ^{11}C -labeled alkenes obtained via a Wittig reaction from [^{11}C]methyl iodide (Björkman and Långström 2000). This approach permitted the incorporation of ^{11}C into the backbone of carbon structures inaccessible by other methods (► Fig. 41.25).

41.3.3.4 Carbonylations

Insufficient trapping caused by low reaction rates and low solubility has hitherto precluded the practical use of [^{11}C]carbon monoxide in tracer synthesis. Examples of early investigations are the carbonylations of lithium dialkylamides (Kilbourn et al. 1983) and the insertion of [^{11}C]CO into a carbon–boron bond (Tang et al. 1979). There are, however, several principal advantages of using [^{11}C]carbon monoxide in tracer synthesis (Långström et al. 2007).

The rich chemistry of carbonylative coupling, developed through the advent of transition metal reagents, offers pathways to a broad range of carbonyl compounds. (1) Carbonyl groups are common among biologically active compounds. (2) Complex building blocks can be assembled in the carbonylation step to yield the target compound, which means short production times.

The low reactivity and the low concentration of carbon monoxide in the environment make prerequisites for high levels of specific radioactivity.

■ Fig. 41.24

Synthesis of ^{11}C -labeled 1-aza-5-stannabicyclo[3.3.3] undecane

■ Fig. 41.25

^{11}C -Labeling with the Heck reaction

Recent technical innovations, where the $[^{11}\text{C}]$ carbon monoxide is either concentrated and pressurized with the reagent in a micro-autoclave or recycled through the reaction mixture, have greatly diminished the trapping problem (Lidström et al. 1997; Kihlberg and Långström 1999; Burns and Hostetler 2002). The autoclave method gives higher trapping efficiency than the recycling method and allows the use of volatile solvents at high temperature (e.g., THF at 180°C). Another possibility is to trap the $[^{11}\text{C}]$ carbon monoxide as a complex with BH_3 , or a copper(I) scorpionate. This method requires less sophisticated apparatus but is less general and efficient than the autoclave method (Audrain et al. 2004; Long et al. 2008). A microfluidic technology solution is to use a microtube reactor loaded with a silica supported palladium catalyst (Miller et al. 2007).

Compounds where the carbonyl group is bound to carbon have been synthesized using palladium, rhodium, or free radical chemistry and compounds where the carbonyl group is bound to two heteroatoms by using selenium or rhodium (Kihlberg and Långström 1999; Långström et al. 2007; Itsenko 2005; Kihlberg et al. 2002; Doi et al. 2004). The palladium-mediated carbonylations proceed via a palladium acyl complex, which reacts with nucleophiles to form a wide range of carbonyl compounds. Some chemical transformations that have been performed with $[^{11}\text{C}]$ carbon monoxide are shown in Fig. 41.26.

■ Fig. 41.26

Possible chemical transformations using $[^{11}\text{C}]$ carbon monoxide

In most of the palladium-mediated reactions, aryl halides have been used although several other types of electrophiles or alkenes may be employed. Aryl triflates give somewhat lower radiochemical yields and require the presence of lithium bromide. Diaryliodonium salts (e.g., diphenyliodonium bromide) have shown to be an interesting alternative in the synthesis of ^{11}C -labeled ketones (Al-Qahtani and Pike 2000).

The labeling of amides usually runs smoothly and is probably the most useful reaction since amides are common among biologically active compounds (Kihlberg and Långström 1999). In some cases, due to sterical hindrance or weak nucleophilicity, the use of lithium amides is needed, as in the case of the WAY-100635 analogues (► Fig. 41.27). This example shows the convenience by which a large number of derivatives of a lead compound can be labeled using the same carbonylation method. Depending on which part carries the main biological activity, either the organohalide or the nucleophile part is kept unchanged.

The labeling of open esters gives significantly lower yields due to the weaker nucleophilicity of alcohols compared to amines. The yields can be increased up to threefold by employing the acylation catalyst *N,N*-dimethyl amino pyridine (Kihlberg et al. 2001). Aldehydes are efficiently labeled at relatively low temperatures using different hydride donors as the source of nucleophile (Björkman et al. 2000b). Labeled aldehydes and ketones provide another route to obtain functionalized alkenes via the Heck reaction (Björkman et al. 2000b). Flavones and phthalimides can be synthesized by ^{11}C -carbonylations in ring-closure reactions (Kihlberg et al. 1999; Karimi et al. 2001).

The problem with β -hydride elimination that usually precludes the transition metal-mediated labeling of carbonyl groups bound to sp^3 carbons, can be circumvented by the use of free radical chemistry (Itsenko et al. 2004).

^{11}C -labeled carbamoyl compounds can be prepared by using a selenium-mediated reaction with $[^{11}\text{C}]$ carbon monoxide. The urea formation works excellent in the case of cyclizations but in other cases satisfactorily only with primary amines (Kihlberg et al. 2002). Since selenium is practically insoluble in most solvents the use of primary alkyl amines or tetrabutylammonium fluoride is necessary for the formation of soluble and reactive complexes with selenium. Except for ring closures, rhodium-promoted carbonylations are probably more useful than the corresponding selenium reactions (Ohad et al. 2009).

■ Fig. 41.27

Synthesis of ^{11}C -labeled substituted aryl analogues of WAY-100635

The zerovalent cuprates can also be used for synthesis of lithium [^{11}C]methyl(2-thienyl) cuprates from [^{11}C]methyl iodide (Kihlberg et al. 1997). These nucleophilic alkyl reagents have been employed in the synthesis of [21- ^{11}C]progesterone and [1 α -methyl- ^{11}C]mesterolone (► Fig. 41.29) (Lidström et al. 1997; Neu et al. 1998).

* ¹⁴C

41.3.4 Enzymes as Catalysts in ^{11}C -Labeling Synthesis

The use of enzymes in labeling synthesis, either free in solution or immobilized on a solid support, is an efficient way of synthesizing compounds that would otherwise be difficult to label in the desired position. Enzymes usually exhibit high regio-, chemo-, stereo-, and substrate selectivity. Two different types of enzymatic transformations can be distinguished: carbon–carbon bond formations and functional group transfer or transformation. The latter can be exemplified by transaminations or oxidations of amino groups to ketones (Barrio et al. 1982a; Halldin and Långström 1986).

Examples of the use of enzymes in ^{11}C -labeling are given below. Pyruvate and acetyl coenzyme A (acetyl CoA), are two generally useful precursors, available by enzymatic ^{11}C -labeling. Acetyl coenzyme A (Mannens et al. 1988) can be used as a general acetylating agent as is exemplified in the synthesis of $[^{11}\text{C}]$ acetyl-L-serotonin, *N*-acetyl-D- $[^{11}\text{C}]$ glucosamine (Mannens et al. 1990a, b), and acyl-L-carnitines (Spolter et al. 1979; Holsbach et al. 1991; Davenport et al. 1997; Jacobson et al. 1997; Angelini et al. 1999).  Figure 41.30 shows the multi-enzymatic synthesis of acetyl-L-carnitine labeled in two positions. Acetyl-CoA is formed as an intermediary product that is further used in the multienzymatic synthesis to the product, acetyl carnitine.

Pyruvate can be labeled either in the carboxylic (Hwang et al. 1986; Takahashi et al. 1990) or in the 3-position (Bjurling et al. 1988; Ropchan and Barrio 1984; Cohen et al. 1980). Pyruvate is a versatile compound for further transformations to aromatic amino acids and to lactic acid (Kloster and Laufer 1980; Bjurling and Långström 1989; Cohen et al. 1980). Some aliphatic amino acids have been labeled with ^{11}C employing enzymatic and combined chemo-enzymatic methods (Antoni et al. 1997, 2001; Barrio et al. 1982b; Cohen et al. 1982; Kaneko et al. 1999; Svård et al. 1990) as exemplified in  Fig. 41.31 and  41.32.

The chemo-enzymatic syntheses ( Fig. 41.33) of the aromatic amino acids, 3,4-dihydroxy-L-phenylalanine (DOPA), L-tyrosine, L-tryptophan, 5-hydroxy-L-tryptophan (5-HTP), and analogues thereof, ^{11}C -labeled either in the carboxylic- or β -position (Bjurling and Långström 1989; Bjurling et al. 1990a, b; Sasaki et al. 1999; Harada et al. 1999; Ikemoto et al. 1999) are other important achievements.

■ Fig. 41.33

Chemo-enzymatic synthesis of aromatic L-amino acids ^{11}C -labeled in two positions

The importance of the labeling position is shown in ► Fig. 41.34 where DOPA (3,4-dihydroxy-L-phenylalanine) labeled either in the carboxylic position or the β -position is used to visualize endocrine tumors (Bergström et al. 1996).

Some neuroendocrine tumors overexpress the enzyme aromatic amino acid decarboxylase (AADC). This can be used to visualize the tumor and at the same time gain information about the type of tumor. In these tumors L- $[\beta\text{-}^{11}\text{C}]\text{DOPA}$ is converted to $[\text{}^{11}\text{C}]\text{dopamine}$, which is trapped in the tumor whereas L- $[\text{carboxy-}^{11}\text{C}]\text{DOPA}$ gives unlabeled dopamine and $[\text{}^{11}\text{C}]\text{carbon dioxide}$. In ► Fig. 41.34, the tumor is clearly visualized after administration of L- $[\beta\text{-}^{11}\text{C}]\text{DOPA}$ indicating that AADC is overexpressed. Labeled carbon dioxide is washed out from the tumor, which is demonstrated in the right image.

Enzymatic catalysis is also used in the synthesis of 1- ^{11}C -labeled D-fructose and D-glucose from mannitol and glucitol, respectively (Ögren and Långström 1998). The preparation of S-adenosyl-L- $[\text{}^{11}\text{C}]\text{methionine}$ (Guegen et al. 1982), $[\text{}^{11}\text{C}]\text{epinephrine}$ (Soussain et al. 1984), and $[\text{}^{11}\text{C}]\text{daunorubicin}$ (Eriks-Fluks et al. 1998) are other examples of enzyme catalysis. The nucleosides $[\text{}^{11}\text{C}]\text{thymidine}$ and $[\text{}^{11}\text{C}]\text{-2'-arabino-2'-fluoro-}\beta\text{-5-methyl-uridine}$ have been prepared by enzymes immobilized on hollow fiber membranes using $[\text{}^{11}\text{C}]\text{formaldehyde}$ as the labeled precursor (Hughes and Jay 1995).

41.4 Examples of ^{11}C -Labeled Compounds

41.4.1 Amino Acids

The labeling position in the amino acids needs to be considered when designing the synthesis. Different positions may be preferred depending on the intended biological application as shown in ► Fig. 41.34. A complication is the chirality of the amino acids. Three synthetic methods have been used: (1) Establishing the stereochemistry in the precursor and introducing the label in a position that does not involve the chiral center. (2) Performing an asymmetric synthesis. (3) Separating the enantiomers of a racemic synthesis by chromatographic (Washburn et al. 1982) or enzymatic methods (Barrio et al. 1982a).

The main synthetic strategies that can be adopted for the synthesis of ^{11}C -labeled amino acids are (1) Bucherer–Strecker synthesis using $[\text{}^{11}\text{C}]\text{cyanide}$ or $[\text{}^{11}\text{C}]\text{aldehydes}$.

► Fig. 41.34

Positron emission tomography (PET) images over the abdomen in a patient with a neuroendocrine tumor (gastrinoma) after administration of L- $[\beta\text{-}^{11}\text{C}]\text{DOPA}$ (left) and L- $[\text{carboxy-}^{11}\text{C}]\text{DOPA}$ (right)

(2) Carboxylation reactions using [¹¹C]carbon dioxide. (3) Condensation reactions using [¹¹C]aldehydes. (4) Alkylation reactions using [¹¹C]alkyl halides. (5) Enzymatic methods.

In the Bucherer–Strecker synthesis, hydrogen [¹¹C]cyanide is reacted with the bisulfite adduct of an aldehyde (Hayes et al. 1978; Casey et al. 1981; Barrio et al. 1982) to produce neutral amino acids labeled in the carboxylic position. Labeled aromatic aldehydes have also been applied in the Bucherer–Strecker synthesis (Halldin and Långström 1984b) as well as in condensation reactions with oxazolones (Halldin and Långström 1984c, d, 1986) for labeling in the α - or the β -positions, respectively.

Carboxylation of lithiated carbanions of isonitriles with [¹¹C]carbon dioxide (Vaalburg et al. 1976; Bolster et al. 1986a; Hamacher and Hanus 1989) is an alternative synthetic approach to racemic amino acids labeled in the carboxylic position. Labeling in the 3-position (or β in the case of aromatic amino acids) can be achieved by alkylation using aliphatic or aromatic alkyl halides (Långström and Stridsberg 1979; Kilbourn et al. 1984; Antoni and Långström 1987).

This approach has also been applied in asymmetric syntheses of aliphatic [¹¹C]amino acids using different glycine derivatives such as [(+)-2-hydroxypinanyl-3-idene]glycine *tert*-butyl ester (Antoni and Långström 1986, 1987b), the nickel complex of the Schiffs base of (S)-*o*-(*N*-benzylpropyl)amino]benzophenone and glycine (Fasth et al. 1989, 1990a; Fasth and Långström 1990). The enantiomeric purity obtained is 80–98% enantiomeric excess (e.e.). The most promising methods, which give nearly enantiomerically pure [¹¹C]amino acids, used an imidazolidinone derivative (► Fig. 41.35) (Fasth et al. 1995; Plenevaux et al. 1994). These amino acid syntheses utilizing [¹¹C]alkyl halides in alkylation reaction on stabilized carbanions are efficient ways of forming C–¹¹C bonds.

The preparation of L-[¹¹C]methionine (Comar et al. 1976; Långström et al. 1987; Schmitz et al. 1995) and L-[4-¹¹C]ornithine (Ding et al. 1989) from [¹¹C]methyl iodide and hydrogen [¹¹C]cyanide, respectively, are examples of syntheses where the chiral center is established before introduction of the label (► Fig. 41.36).

Labeling of peptides can be accomplished by methylation of the corresponding sulphide anion of a homocysteine residue (Franzén et al. 1987, 1988; Långström et al. 1981b; Någren et al. 1986, 1988) similar to the L-[¹¹C]methionine synthesis. Some dipeptides have also been labeled using a reaction between [1-¹¹C]glycine and the carboxyanhydrides of phenylalanine and leucine (Bolster et al. 1986b).

Some amino acid analogues such as α -[methyl-¹¹C]methylphenylalanine and α -[¹¹C-methyl]methyltyrosine have been synthesized by alkylations of malonic esters (Gee and Långström 1991) as well as α -[methyl-¹¹C]methyltryptophan (Bourne et al. 1991; Pulak et al. 1996). α -aminoisobutyric acid, labeled in either the carboxylic position (Dunzendorfer et al. 1981) or 2-position (Prenant et al. 1995a), or the 3-position (Oberdorfer et al. 1993; Schmall et al. 1996) and β -aminoisobutyric acid (Alauddin et al. 1997) are other examples. Other

■ Fig. 41.36

Methods for the synthesis of L-[methyl- ^{11}C]methionine

non-proteinogenic amino acids that have been prepared are 1-aminocyclopentane carboxylic acid (Hayes et al. 1976; Iwata et al. 1995) and *para*-[^{11}C]boronophenylalanine. The latter was synthesized as a tracer for treatment planning in connection with boron neutron captures therapy (Kabalka et al. 2001).

41.4.2 Carbohydrates, Steroids, Fatty acids and Nucleosides

Labeled carbohydrates such as glucose have been important tools for in vivo studies of energy metabolism. Several methods employing [^{11}C]cyanide, [^{11}C]methyl iodide, or [^{11}C]nitromethane have been developed for the specific labeling of glucose in positions 1 and 6 (Shiue and Wolf 1981; Tada et al. 1989; Schoeps et al. 1991; Grierson et al. 1993; Ögren et al. 1995b; Ögren et al. 1997). ➤ Figure 41.37 shows the synthesis of D-glucose and D-mannose labeled in position 1 using [^{11}C]nitromethane. The two sugars could be separated by HPLC.

Labeled 2-deoxy-glucose was developed to acquire metabolic trapping (Reivich et al. 1998; Padgett et al. 1982a). 2-Deoxy-D-[1- ^{11}C]glucose can, e.g., be obtained by a Wittig reaction followed by a PdCl_2 catalyzed oxidation (Ögren et al. 1997).

Saturated and unsaturated fatty acids have been labeled in the carboxylic position using [^{11}C]carbon dioxide and Grignard reagents (Pike et al. 1981; Padgett et al. 1982b; Piette et al. 1989; Oberdorfer et al. 1992; Channing and Simpson 1993; Ishiwata et al. 1995). Branched fatty acids such as β -[^{11}C]methyl heptadecanoic acid (Livni et al. 1982), 3,3-[^{11}C]dimethyl-heptadecanoic acid (Jones et al. 1988), and other fatty acids that do not participate in the β -oxidation have also been developed. Labeling in the 2-position of some β -methyl fatty acids

■ Fig. 41.37

Synthesis of D-[1- ^{11}C]glucose and D-[1- ^{11}C]mannose

was achieved by alkylation of malonic ester with [^{11}C]methyl iodide (Ogawa et al. 1997). Another example is the synthesis of a ^{11}C -leukotriene derivative, a potent metabolite of arachidonic acid, from acetyl chloride (Oberdorfer et al. 1992). The copper-mediated labeling of fatty acids is presented in ▶ Sect. 41.3.3.5.

The steroid structure is difficult to build up from simple labeled intermediates within the time frame allowed for ^{11}C synthesis. However, some examples of successful ^{11}C -labeling include 17- α -[^{11}C]methyltestosterone (Berger et al. 1981b), 17 α -[^{11}C]methylestradiol, and 11 β -ethyl-17 α -[^{11}C]-methylestradiol (Dence et al. 1994). In these syntheses [^{11}C]methyl iodide was converted to [^{11}C]methyllithium and was further reacted with the carbonyl functionality to give the corresponding alcohols. Examples of different labeling strategies are the syntheses of the adrenocortical steroid, triamcininolone acetone, prepared by reaction with [^{11}C]acetone (Berridge et al. 1994) and [*carbonyl*- ^{11}C]estramustine phosphate (Lidström et al. 1998) synthesized using [^{11}C]phosgene (▶ Fig. 41.38). The copper-mediated synthesis of mestrelone and progesterone are presented in ▶ Sect. 41.3.3.5.

The development of tracers for the study of cell proliferation is an important area of research. The labeling of thymidine in different positions (▶ Fig. 41.39) is such an example (Goethals et al. 1992; Alauddin et al. 1995). The methyl position is not optimal since it gives rise to labeled metabolites interfering with the interpretation of the PET data. Labeling in any of the carbonyl positions may be advantageous since [^{11}C]carbon dioxide is the most prominent labeled metabolite using this labeling position. This has been achieved by using [^{11}C]urea or [^{11}C]phosgene in ring-closure reactions (Labar and Vander Borgh 1991; Borgh et al. 1991; Steel et al. 1993, 1999).

Other potentially useful tracers for the study of cell proliferation are uracil (Chakraborty et al. 1997), the uracil analogue [^{11}C]FMAU (Conti et al. 1995), 6-[methyl- ^{11}C]methyl-2'-deoxyuridine (Goethals et al. 1997), and [*methyl*- ^{11}C] β -pseudothymidine (Grierson et al. 1995). Another nucleoside analogue that was prepared by a ring-closure reaction is 1,3,6-trimethyl [2- ^{11}C]uracil prepared from 1,3-dimethyl [2- ^{11}C]urea (Castro-Ibarra et al. 1997).

41.4.3 Compounds for Study of Enzymes and Receptors

A comprehensive list of synthesized ^{11}C -labeled receptor ligands is outside the scope of this chapter. Most attention has been focused on ligands for the dopamine- D_1 and D_2 receptors.

■ Fig. 41.38

Synthesis of [*carbonyl*- ^{11}C]estramustine phosphate

■ Fig. 41.39

Syntheses of [^{11}C]thymidine

The first example of a dopamine- D_2 antagonist that could visualize striatal dopamine receptors was *N*-[methyl- ^{11}C]methylspiperone (Wagner et al. 1983, see also ▶ Fig. 41.40). This compound also has affinity for the 5-HT $_{\text{A}2}$ receptors. [^{11}C]Raclopride is a more selective (Ehrin et al. 1986) D_2 antagonist and has become the golden standard for the investigation of dopamine D_2 receptors. It has been labeled in the methoxy group or in the *N*-ethyl group (▶ Fig. 41.40). The former labeling position being the preferred. The dopamine transporter has also been studied using, e.g., the cocaine analogue β -CIT-FT (Halldin et al. 1996, see also ▶ Fig. 41.40).

■ Fig. 41.40

Compounds for the dopaminergic system, ^{11}C -labeled raclopride, *N*-methylsipiperone, and β -CIT-FE

■ Fig. 41.41

Synthesis of ^{11}C -labeled OSU6162

The presynaptic dopamine receptor antagonist (–)-OSU6162 has been labeled with ^{11}C and used to investigate the dopaminergic system (Neu et al. 1997b). OSU6162 has been claimed to be a drug that modulates the dopaminergic system in terms of minimizing on/off effect in late Parkinson's disease. ➤ Figure 41.41 shows the synthesis of OSU6162.

Benzodiazepine receptors, both central and peripheral have been investigated using the benzodiazepine receptor antagonists [^{11}C]flumazenil (Samson et al. 1985) and (+)PK11195 (Shah et al. 1994), respectively (➤ Fig. 41.42).

The serotonergic system has been studied using, e.g., the earlier presented $\text{HT}_{1\text{A}}$ antagonist [^{11}C]WAY100635 (McCarron et al. 1996). The selective 5-HT $_{2\text{A}}$ antagonist [^{11}C]MDL100907 (Lundkvist et al. 1996) is an alternative to *N*-methylsipiperone (➤ Fig. 41.43). The labeling position in MDL100907 is of importance. The methoxy group in the 3-position is preferred since the 3-OH analogue (MDL10575) had been identified as a metabolite. Labeling in position 2 should thus give a labeled compound with unknown biological properties that may disturb interpretation of PET data.

■ Fig. 41.42

Examples of ^{11}C -labeled benzodiazepine receptor ligands

■ Fig. 41.43

Synthesis of ^{11}C -labeled MDL100907

$[^{11}\text{C}]$ Nicotine has been used for the study of nicotinic cholinergic receptors. It is not an ideal tracer and other compounds have been used as alternatives such as analogues of the naturally occurring alkaloid epibatidine, a potent nicotine receptor antagonist (Spang et al. 1999, 2000). The muscarinic acetylcholine receptor has been investigated using, e.g., *N*-methyl-4-piperidyl benzilate and the corresponding ethyl- and propyl analogues (Mulholland et al. 1988; Nishiyama et al. 2000).

Some tracers for the different subclasses of opioid receptors are also available such as the μ -selective carfentanil and the nonselective diprenorphine (► Fig. 41.44). The latter is either labeled in the cyclopropyl- (Luthra et al. 1985) or the 6-methoxy group (Luthra et al. 1994).

The monoamine oxidase type B enzyme (MAO-B) has attracted much attention. A double-isotope labeling approach has been employed for the determination of MAO-B concentration in the heart and the brain using $[^{11}\text{C}](\text{--})\alpha,\alpha\text{-dideuterophenylephrine}$ (De Rosario and Wieland 1995) and $\alpha,\alpha\text{-dideutero-L-}[^{11}\text{C}]\text{deprenyl}$, respectively (Fowler et al. 1995). A kinetic isotope effect (KIE) (see ► Chap. 15 in Vol. 2) is observed when the deuterated compounds are used indicating that the C–D bond is involved in the rate limiting step with the enzyme. MAO-B has also been investigated using *N,N*-dimethylphenethylamine labeled either in the methyl or phenethyl group (Halldin et al. 1989).

The acetylcholine esterase inhibitor physostigmine has been labeled from $[^{11}\text{C}]\text{methyl isocyanate}$ (► Fig. 41.45).

Other example of useful acetylcholine esterase inhibitors are *N*-methylpiperidine-4-yl acetate (Iyo et al. 1997) and propionate (Kilbourn et al. 1998).

41.5 PET in Drug Development

41.5.1 General Considerations

The exploration of new chemical entities as potential drug candidates is a very expensive process and the failure rate, as late in the process as in clinical trials, is around 75%. A shift from the present empirical paradigm to a mechanistic one based on in vivo characterization of biochemical and physiological parameters should increase the scientific impact in the drug development process. Thus, to speed up the development process, achieve more accurate information for decision-making, and reduce the cost for the benefit of patients and the society, the noninvasive PET technology in combination with preclinical methods may be used. The use of labeled compounds to evaluate biological properties of new drug candidates early in the process and to select the lead candidates to be further investigated is a key process in drug development. PET is especially useful in the drug development process for the study of the following.

Pharmacokinetics – labeling of a potential drug candidate. This study includes distribution studies of drug passage over the blood-brain barrier and selective accumulation in critical organs. Apart from intravenous administration, oral and nasal administration routes are other important applications employed for quantification of the deposition and disposition of a drug formulation.

Pharmacodynamics – use of a labeled tracer to monitor drug effect. An evaluated tracer can be used in standard dose-response studies, e.g., to measure receptor occupancy as a function of increasing dose or to follow up treatment effects. Especially in cancer treatment is the use of a surrogate marker for tumor metabolism or proliferation rate of great value since other imaging modalities such as computed tomography (CT) and magnetic resonance imaging (MRI) only can distinguish a reduction in size of the tumor, which usually has a time span of several months from start of treatment, whereas a change in metabolism or proliferation may be observed within days or even hours. The use of L-[methyl-¹¹C]methionine for the differential diagnosis between non-responding pituitary tumors and those tumors that show nearly immediate effect on bromocryptine treatment (Bergström and Muhr 1991; Bergström et al. 1992) is a good example of PET in the evaluation of a therapeutic agent.

41.5.2 PET Microdosing

PET microdosing is a concept consisting of a first-time-in-man (FTIM) application of a labeled drug candidate in a PET study (Bergström et al. 2002). This requires high specific radioactivity of the labeled compound to assure that the given dose is in the nanomolar range and that the study is performed at true tracer conditions. Crucial information about distribution and kinetics can be gained from such investigations aiming at an in vivo characterization of biochemical and/or physiological parameters of the new drug candidate. The PET-microdosing concept is based on the use of trace amount of a drug that has been qualified for a FTIM study by a reduced safety toxicology investigation using a preclinical package that includes assessment of the following.

Acute toxicity. One species should be used to study the acute effect of the new drug. If a significant difference of free fraction of the drug in plasma is found between human and animal plasma, the drug dose is modified in accordance with the results from plasma protein

binding. Acute toxic effects are investigated by inspection and histological evaluation of the organs after different intervals from dosing. Acute effects are investigated using a dose that is at least 100 times the expected administered dose in a human PET study.

Primary pharmacology. Information that suggests that the new drug candidate has affinity and some specificity for the target organ or receptor.

Secondary pharmacology. Clinical observation of acute effects in rats after dosing with 100 times of the expected dose in a human PET study followed by a similar study in monkeys.

Genotoxicity. Potential genotoxicity of the new drug is evaluated using classical methods such as AMES test in bacteria and mammalian cells. The amount of drug used is typically much lower than in the standard test methods.

Metabolism. PET can only measure radioactivity and in order to be able to evaluate those PET data, information about the chemical form of the measured radioactivity is important. Determination of the fraction of intact tracer in plasma and in the target organ in animal experiments can give the required information. The occurrence of labeled metabolites should be assessed at different time points in the human microdosing study.

Dose linearity. In a microdosing study, the drug concentration is significantly lower than at the expected therapeutic level. It cannot be taken for granted that metabolic patterns and the biodistribution are similar at these very different conditions. High-affinity binding sites and saturation of transport and enzyme systems at high doses may result in a nonlinear dose-dependent drug distribution. This can be evaluated by a few PET studies in monkeys where different doses of the new drug are given together with the labeled drug.

Plasma protein binding. Plasma protein binding should be assessed in the same species used for acute toxicity and secondary pharmacology. The main objective is to assure that binding is stable and the risk for a sudden concentration rise in plasma due to an unexpected release of bound tracer is unlikely.

Radiotoxicity. Animal ex vivo studies to evaluate the biodistribution of the labeled compound are performed to exclude selective accumulation of radioactivity in organs that could lead to radiation-induced tissue damage.

The information gained from a human PET-microdosing study can be very helpful in deciding whether or not to continue the drug development process. Vital information about drug pharmacokinetics is obtained such as high accumulation in an organ that could give rise to unwanted side effects. The microdosing study can be performed using small amounts of the new drug candidate and a time-consuming and expensive up-scaling of the synthesis is thus not needed.

41.5.3 ¹¹C-Tracers in Drug Development

A smoke cessation device that simulates a cigarette by inhalation of nicotine from a plastic tube containing a porous plug impregnated with nicotine was labeled with S-[¹¹C]nicotine and the deposition pattern and the appearance of nicotine in plasma were investigated (Bergström et al. 1995; Lunell et al. 1996). As a comparison, a cigarette was impregnated with S-[¹¹C]nicotine and the distribution pattern studied. ▶ [Figure 41.46](#) shows the S-[¹¹C]nicotine deposition.

The use of the vaporizer device resulted in high levels of S-[¹¹C]nicotine in the oral cavity, the esophagus, and the stomach. No activity could be detected in the lungs. Smoking a cigarette gave the expected results with high amounts in the lungs. These findings correlate well with the observed slow increase of blood radioactivity from the vaporizer and the very rapid blood

Fig. 41.46

Lung deposition of S -[^{11}C]nicotine in a healthy volunteer after pulmonary inhalation from the device (left). Deposition of S -[^{11}C]nicotine after smoking a cigarette in a normal way (right)

radioactivity increase from the cigarette. The use of the vaporizer is thus unlikely to give the subject a nicotine effect that maintains the addiction.

Another example of an inhalation study is the investigation of pulmonary distribution of the anti-inflammatory steroid triamcinolone acetonide. Drug deposition following inhalation of [^{11}C]triamcinolone using the Azmacort inhaler was investigated with PET (Berridge et al. 2000).

Another educational example is the quantification of the inhibition of the enzyme monoamino oxidase type A (MAO-A) in the brain using PET. A new reversible MAO-A inhibitor, esuprone, was promoted as an antidepressive drug and a correct assignment of treatment regimes such as dosage and dose intervals was evaluated using PET (Bergström et al. 1997). The pharmacodynamic property of the drug was measured as percentage inhibition of MAO-A in the brain. The duration of the inhibition of the enzyme was an important parameter to determine. Several putative MAO-A inhibitors were investigated and [*methyl*- ^{11}C]harmine was found to be a useful tracer for the assessment of the pharmacodynamics of esuprone (Bergström et al. 1997). [Figure 41.47](#) shows the uptake of [^{11}C]harmine in the brain before and after esuprone treatment.

High uptake of [^{11}C]harmine was found in the brain with kinetics indicating trapping of the tracer. After dosing with the study drug, a clear washout was observed. The antidepressant drug esuprone had a half-life of 3.5 h in plasma and 14.8 h at the target enzyme in the brain. The plasma pharmacodynamics was thus significantly different from that on the effector system. This is crucial information with respect to dosing since the drug concentration in plasma is the main input for determining dose and dose interval. The PET data on the other hand give the true drug concentration and enzyme inhibition at the pharmacological target. This information suggests a longer dose interval, which may reduce unwanted side effects from the drug.

41.6 Quality Control of ^{11}C -Compounds

The quality control of radiopharmaceuticals labeled with short-lived radionuclides has to rely on indirect methods for the identification of the compound. Direct methods such as nuclear magnetic resonance (NMR) and infrared spectroscopy cannot be used. Some tests, such as measurement of pH and LC-analysis, can be performed before the radiopharmaceutical is released for use. The radiopharmaceutical is mixed with authentic reference substance and if

■ Fig. 41.47

Brain uptake of [^{11}C]harmine before and after esuprone treatment indicating expression of monoamino oxidase type A (MAO-A) (*upper images*) and after treatment with esuprone a marked inhibition (*lower images*)

identical peak shape and retention times are obtained for the radioactive peak and the response from the mass detector, usually UV-absorbance detector, the identity is verified.

Radiochemical purity is usually determined by a HPLC analysis complemented by another chromatographic method, e.g., TLC. This gives the option of using two distinct chromatographic methods and the risk of coincidental identical retention times is minimized. The recovery of the injected radioactivity from the chromatographic column must be determined in order to validate that the chromatogram obtained is representative of the injected sample.

Liquid chromatography mass spectrometry has evolved as a nearly direct method for the verification of the identity of a labeled compound. A combined $^{11}\text{C}/^{13}\text{C}$ labeling synthesis can be used to further ascertain the identity of the product. After decay of ^{11}C , the ^{13}C -compound is analyzed with NMR and the shift of the ^{13}C -enriched position in the sample can be compared with that of authentic reference substance.

The concept of parametric release has to be adopted since the analyses that are used to ascertain the absence of viable microorganisms or bacterial endotoxins cannot be completed before the radioactivity has decayed. However, it should be emphasized that a strict GMP protocol should be used in routine production of compounds for human use. A validation program should be practiced where randomized sampling of used batches is applied for analysis of presence of microorganisms or endotoxins.

Since most PET radiopharmaceuticals are purified by chromatographic methods using organic solvent, a residual solvent analysis should be performed as a routine validation of a certain number of used batches.

41.7 ¹¹C as a Tool in Chemistry Research

Kinetic isotope effect studies. Kinetic isotope effect (KIE) measurements are a powerful approach for the elucidation of reaction mechanism and the quantification of rate constants. This gives insight into molecular mechanisms and increases one's understanding of molecular interaction. The KIE is dependent on the mass difference between the isotopes and the largest practical value for a carbon KIE ratio is obtained using ¹¹C/¹⁴C (Axelsson et al. 1990; Matsson et al. 1999).

A KIE may occur as a result of an isotopic substitution in a position in the molecule that is involved in a rate-limiting step of the reaction. The magnitude of the effect gives information about the transition state (TS) structure such as if the TS is reactant–product-like or symmetric. KIE can, e.g., be used to determine which step is rate limiting, if the process is stepwise or concerted. The method has been applied to investigate incoming group KIE using [¹¹C]cyanide (Matsson et al. 1996) to study rearrangements in the methyldiene ring system (Axelsson et al. 1990) and enzyme mechanism investigations (Axelsson et al. 1992).

Abstract: Positron emission tomography (PET) is a unique tool for the investigation, localization, and quantification of physiological activities in vivo by tracing the involved or accompanying biochemical processes. Because of its nuclear and chemical properties, fluorine-18, which is commonly produced by a cyclotron using the $^{18}\text{O}(\text{p},\text{n})^{18}\text{F}$ or the $^{20}\text{Ne}(\text{d},\alpha)^{18}\text{F}$ nuclear process, is a nearly ideal positron emitting radionuclide. Its half-life of 109.7 min permits tracer syntheses and imaging protocols extending over hours and allows distribution of ^{18}F -radiopharmaceuticals to hospitals and facilities lacking a cyclotron. The low maximum positron energy of 635 keV results in low radiation doses, short ranges in tissue, and therefore in excellent imaging resolution. Introduction of ^{18}F -fluorine, either via nucleophilic strategies using $[\text{}^{18}\text{F}]\text{F}^-$ or electrophilic routes using molecular $[\text{}^{18}\text{F}]\text{F}_2$, permits the synthesis of a broad spectrum of compounds within a time compatible with the half-life. Although fluorine is only slightly larger than a hydrogen atom, changes in the physiological behavior of bioactive compounds as a result of alteration in metabolic stability, lipophilicity, affinity to the target, or other structures, etc., are often observed even after F-for-H or F-for-OH substitutions. In this chapter, an overview of the scope and limitations of the ^{18}F -chemistry is given. Fluorination strategies, routes, and synthetic aspects are exemplified, as far as possible, by established and selected ^{18}F -radiopharmaceuticals with clinical relevance or with potential for further clinical application.

Further Reading: A review of the clinical use and the potential of ^{18}F -labeled radiopharmaceuticals are by far beyond the scope of this chapter. Excellent reviews have been published, e.g., on PET tracers for mapping cardiac nervous system (Langer and Halldin 2002), on the production (Stöcklin 1995) and future of clinical ^{18}F -labeled radiopharmaceuticals (Stöcklin 1998; Shiue and Welch 2004) for the heart and brain (Stöcklin 1992; Halldin et al. 2001), for the 5-HT system (Crouzel et al. 1992), on targeting peptide receptors by PET (Lundquist and Tolmachev 2002; Okarvi 2001, 2004; Schottelius and Wester 2009; Tolmachev and Stone-Elander 2010) on general aspects in “working against time” during rapid radiotracer synthesis (Fowler and Wolf 1997), on radiotracers for endogenous competition (Laruelle and Huang 2001), on molecular imaging of cancer with PET (Gambhir 2002), on hypoxia PET tracers (Grierson and Patt 1999), on ^{18}F -fluorine chemistry (Lasne et al. 2002; Stöcklin and Pike 1993; Stöcklin 1995; Ametamey et al. 2008; Miller et al. 2008; Cai et al. 2008), on microwave heating (Stone-Elander and Elander 2002), or on fluorinase-based ^{18}F -labeling (Onega et al. 2009), to mention only a few.

42.1 Introduction

Physiological and pathophysiological activities are evolved and are accompanied by biochemical processes and by factors that affect these processes, such as the supply of bioenergetic substrates and enzymes. In 1913, George de Hevesy invented the *tracer principle*, a concept that allows to investigate and to quantify pathways by radiolabeled compounds (*tracer*) (Nobel Prize 1943). On the basis of the coincidence detection of two 511 keV photons, emitted upon positron annihilation in nearly opposite directions, modern *Positron Emission Tomography* permits to measure and quantify the distribution of a tracer labeled with a positron emitting radionuclide noninvasively in living organism with high imaging resolution. PET-radiopharmaceuticals have been developed to quantify molecular processes, e.g., enzyme activities, drug-receptor interactions, energy metabolism or substrate transport, and to

correlate biochemical alterations with the extent of diseases. The choice of the appropriate radionuclide, i.e., its half-life in relation to the kinetics of the process to be monitored, the position of label, the lipophilicity of the tracer, plasma protein binding, clearance kinetics, excretion routes, unspecific uptake in nontarget tissues, affinity to and retention at the locus of interest, and, since PET cannot distinguish between an intact tracer and labeled metabolites, the fate of the label is an aspect among a variety of factors of crucial importance for successful imaging and high target to background ratios.

In contrast to a broad spectrum of drugs with well evaluated and defined in vivo behavior useful for isotopic labeling with ¹¹C, ¹³N, or ¹⁵O (► [Table 42.1](#)), fluorine-containing bioactive probes or drugs are comparatively rare and most of the ¹⁸F-labeled radiopharmaceuticals developed and evaluated so far are non-isotopic analogs of the corresponding drugs or have been designed especially for PET. Even when an ¹⁸F-compound closely resembles the parent structure (e.g., F-for-H or F-for-OH substitutions), alteration of pharmacokinetics and pharmacodynamics cannot be excluded. Thus, an extensive and detailed evaluation process on the characteristics of a new compound using suitable in vitro and in vivo models is generally necessary prior to the first human application. In this chapter, basic aspects of the *¹⁸F-labeling chemistry*, strategies for secondary *precursor synthesis*, and multistep syntheses are summarized, exemplified and discussed.

42.2 Special Characteristics of ¹⁸F-Fluorine

42.2.1 Physical Properties and Production

With regard to its use for PET, the nuclear properties of *fluorine-18* are excellent. The positron energy of $E_{\beta^+ \text{ max}} = 633.5 \text{ keV}$ is the lowest of the commonly used PET nuclides and results in

► **Table 42.1**

Nuclear properties of commonly used positron emitters (Data taken from Brown and Firestone 1986 and from the Brookhaven National Laboratory internet data base, BNL 2003)

Isotope	Half-life	Decay mode	$E_{\beta^+ \text{ avg.}}$ (keV)	Maximum (average) range in H ₂ O (mm)	Maximum specific activity (GBq μmol^{-1})
¹¹ C	20.39 min	β^+ (99.8%)	385	3.8 (1)	3.4×10^5
		EC (0.24%)			
¹³ N	9.965 min	β^+ (99.8%)	491	5 (1.5)	7.0×10^5
		EC (0.2%)			
¹⁵ O	122.24 s	β^+ (99.9%)	735	7.6 (2.7)	3.4×10^6
		EC (0.01%)			
¹⁸ F	109.77 min	β^+ (96.73%)	242	2.2 (0.3)	6.3×10^4
		EC (3.3%)			
⁶⁸ Ga	67.629 min	β^+ (89.1%)	740	13.6 (3.7)	1.0×10^5
		EC (11.0%)			
¹²⁴ I	4.1760 days	β^+ (22.8%)	188	9.7 (3)	1.2×10^3
		EC (11.0%), e^-			

low radiation doses. Furthermore, the short maximum range in tissue of only about 2.2 mm (average range of about 0.3 mm) does not exceed the inherent resolution of state-of-the-art clinical PET scanners (clinical PET: ≥ 4 mm, animal PET: ≥ 1 mm). Compared with ^{11}C ($T_{1/2} = 20.4$ min) the half-life of 109.7 min of ^{18}F allows more flexibility in tracer production (as a rule of thumb < 3 half-lives), transport of tracers to PET facilities without an on-site cyclotron and scanning procedures extending over several hours. ^{18}F -Fluorine can be produced in high yields even with small “baby cyclotrons” (e.g., Qaim and Stöcklin 1983; Guillaume et al. 1991; Stöcklin and Pike 1993; Qaim et al. 1993; cf. also ► Chap. 39 of this Volume) allowing to prepare, e.g., 2- ^{18}F]fluoro-deoxy-D-glucose on the Ci-scale.

Among the four main production routes listed in ► Table 42.2, the $^{18}\text{O}(\text{p},\text{n})^{18}\text{F}$ nuclear process on highly enriched H_2^{18}O is the most effective. This process and the alternative route via $^{16}\text{O}(^3\text{He},\text{n})^{18}\text{F}$ leads to ^{18}F -fluoride ($^{18}\text{F}]\text{F}_{\text{aq}}^-$) suitable for nucleophilic substitutions in high specific activities. To recycle and thus to minimize the quantities of enriched H_2^{18}O to be used and to eliminate cationic impurities from the target material, $^{18}\text{F}]\text{F}_{\text{aq}}^-$ is trapped after irradiation on suitable anion exchange resins (Schlyer et al. 1990; Jewett 1991; Hamacher et al. 1990) and subsequently eluted. $^{18}\text{F}]\text{F}_2$, the corresponding primary species for electrophilic fluorination, can only be obtained in lower specific activities and lower thick target yields. For a detailed discussion about the production of ^{18}F see ► Chap. 39 of this Volume.

42.2.2 Chemical Properties and Fluorine Substituent Effects

- As a substituent, fluorine is never boring, always good for a surprise but often completely unpredictable (Schlosser 1998).

With perhaps the exception of fluorine steric interactions, substituent effects on reactive intermediates that underlie the chemical reactivity of fluorinated compounds are now rather well understood and fairly predictable (see Smart 2001 and references therein). In contrast, *fluorine substituent effects* on the physical properties that can impact pharmacokinetics and pharmacodynamics (e.g., absorption, transport, binding, and pharmacological effect) are often less predictable or at least “always good for a surprise.” The replacement of a hydrogen atom or a hydroxy group by a fluorine atom is not only a strategy used in PET radiotracer development, but also widely used in drug development to alter biological function (Smart 2001; Park et al. 2001;

■ Table 42.2

Production routes to $^{18}\text{F}]\text{fluoride}$ and $^{18}\text{F}]\text{fluorine}$ (Stöcklin 1995; cf. also ► Chap. 39, this volume)

Nuclear reaction	$^{18}\text{O}(\text{p},\text{n})^{18}\text{F}$	$^{16}\text{O}(^3\text{He},\text{n})^{18}\text{F}$	$^{20}\text{Ne}(\text{d},\alpha)^{18}\text{F}$	$^{18}\text{O}(\text{p},\text{n})^{18}\text{F}$
Target	H_2^{18}O	H_2O	Ne (0.1–0.2% F_2 , 18 atm)	$^{18}\text{O}_2$ 20 atm

Specific activity ($\text{GBq } \mu\text{mol}^{-1}$)	40×10^3	40×10^3	0.04–0.4	0.04–2

Müller et al. 2007; Hagmann 2008). The van der Waals radius of fluorine (147 pm) lies between hydrogen (120 pm) and oxygen (152 pm) and thus fluorine appears to have a particular close isosteric relationship to oxygen while being larger than hydrogen. Despite the differences in size, numerous studies have demonstrated that fluorine is a reasonable hydrogen mimic. However, due to their quite different electronic properties, resulting changes in the electron distribution in a molecule by F-for-H replacement can alter the pK_a , the dipole moments, lipophilicity, hydrogen bonding, the chemical reactivity, the oxidative stability, the chemical reactivity of neighboring groups, or metabolic processes (► Table 42.3).

As a rule of thumb, fluorination usually but not always increases lipophilicity. Aromatic fluorination always increases lipophilicity, fluorination adjacent to atoms with π -bonds increases lipophilicity, with exceptions for some fluorinated α -carbonyl compounds (Smart 2001 and references therein). Whereas β -fluorination always increases C–H acidity, α -fluorination is less acidifying than other α -halogenations.

The replacement of a hydroxy group is usually based on the premise that fluorine is a hydrogen bond acceptor in a manner similar to the oxygen of a hydroxy function. Ab initio calculations revealed that the $C(sp^3)$ –F fluorine in fluoromethane is a better hydrogen bond acceptor and can enter into stronger hydrogen bonds (optimum distance: 1.9 Å, 2.38 kcal mol^{−1}) than $C(sp^2)$ –F of fluoroethene (1.48 kcal mol^{−1}). However, the $C(sp^3)$ –F⋯H–O bond is less than half the strength of a C–O⋯H–O bond, conservatively estimated to be about 5 kcal mol^{−1} (Howard et al. 1996).

High in vivo stability against defluorination is obviously a major focus in the development of ¹⁸F-PET tracers. However, fluoride is a good leaving group. This aspect is utilized for pharmaceutical design of “lethal drugs” and “suicide substrates” forming stable covalent bonds with their binding sites, receptors, or enzymes. Thus, a careful selection of the labeling position is imperative. Based on the premise, that the C–F bond is much more resistant to cytochrom P450 attack, alteration of the rate, route, and extent of tracer metabolism can not only be achieved by fluorine substitution at the site of metabolic attack, but also by substitution adjacent to the site of attack (Rietjens et al. 1997). Whereas in simple saturated systems the inductive effect of fluorine should reduce susceptibility of adjacent groups to P450 enzymes, the presence of fluorine *ortho* to a phenolic group might increase its reactivity in methylation and glucuronidation reactions (Park et al. 2001).

■ Table 42.3

Physicochemical data of fluorine compared to other halogens, oxygen, and hydrogen

	Fluorine	Chlorine	Bromine	Iodine	Hydrogen	Oxygen
Ionization enthalpy (kJ mol ^{−1})	1,681	1,251	1,139	1,008	1,312	1,314

42.3 Methods of ^{18}F -Fluorination

42.3.1 Electrophilic ^{18}F -Fluorination

Electrophilic ^{18}F -fluorination is characterized by the reaction of highly polarized fluorine with an electron rich reactant, e.g., an aromatic system, an alkene, or a carbanion. $[^{18}\text{F}]\text{F}_2$, the simplest electrophilic fluoro-species, is obtained directly from the irradiated target. Other reagents have to be prepared in subsequent steps, either from carrier-added (c.a.) $[^{18}\text{F}]\text{F}_2$ or no-carrier-added (n.c.a.) $[^{18}\text{F}]\text{fluoride}$. $[^{18}\text{F}]\text{XeF}_2$ can be obtained in-target via the $^{19}\text{F}(\text{p,pn})^{18}\text{F}$ process on XeF_2 , by the reaction of Xe and $[^{18}\text{F}]\text{F}_2$ or by isotopic exchange of XeF_2 with $[^{18}\text{F}]\text{HF}$. Synthesis of another important reagent, $[^{18}\text{F}]\text{acetylhypofluorite}$ ($[^{18}\text{F}]\text{AcOF}$) can be carried out by passing dilute fluorine-18 gas through a solution of ammonium acetate in glacial acetic acid (Shiue et al. 1982), or via an on-column gas–solid phase reaction by passing F_2 diluted in N_2 through columns containing complexes of alkali metal acetates with acetic acid (Jewett et al. 1984; Ehrenkaufer et al. 1984; Bida et al. 1984).

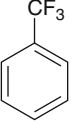

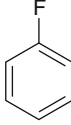

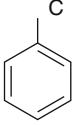

The theoretical maximum radiochemical yield for fluorination with electrophilic reagents is only 50%, because only one of the fluorine atoms in the $[^{18}\text{F}]\text{F}_2$ molecule is labeled and typically only one of them is incorporated. This also applies to all other electrophilic reagents, because they are either produced via $[^{18}\text{F}]\text{F}_2$ or by isotopic exchange. Furthermore, the products are c.a. with maximum specific activities in the range of $0.04\text{--}0.4\text{ GBq }\mu\text{mol}^{-1}$. Consequently, this method is limited to the production of a tracer (a) which competes to a high concentration of endogenous analogs in vivo, e.g., amino acids, or (b) which bind to molecular targets of low saturability, e.g., enzymes or transporter substrates. Nevertheless, the amount of inactive carrier can influence the pharmacokinetics, uptake, and binding to the target. Furthermore, pharmacological or even toxic effects have to be considered.

42.3.1.1 Direct Fluorination

Although the direct electrophilic substitution of electron rich compounds (aryls and alkenes) with $[^{18}\text{F}]\text{F}_2$ is a straightforward method, its major disadvantage is its lack of *regioselectivity* (Coenen et al. 1988, cf. [Fig. 42.1](#)).

■ Fig. 42.1

Selectivity and reactivity of $[^{18}\text{F}]\text{F}_2$ (without brackets) and $[^{18}\text{F}]\text{acetylhypofluorite}$ ($[^{18}\text{F}]\text{AcOF}$) (in brackets) toward monosubstituted benzenes. The radiochemical yields (%) are given for each position

				
		11 10 30 32	15 12 6 3	32 30 05 05
		18 16	58 70	35 39
bstit tion	$^{18}\text{F F}_2$	32 3	34 3	48 2
	$^{18}\text{F Ac F}$	55 2	74 5	85 3

Furthermore, the oxidizing strength of fluorine can lead to the formation of side products. To reduce side reactions, the reactivity of $[^{18}\text{F}]\text{F}_2$ is moderated by dilution with inert gas (neon) at low temperatures (Casella et al. 1980). The solvent has to be inert as well. Freon, trifluoroacetic acid, carbon tetrachloride, and hydrogen fluoride are used.

Cis-addition of $[^{18}\text{F}]\text{F}_2$ on the double bond of 2,4,6-tri-O-acetyl-D-glucal was the first method used for production of 2- $[^{18}\text{F}]$ fluoro-2-deoxy-D-glucose at the Brookhaven National Laboratory (Ido et al. 1978, cf. [Fig. 42.2](#)). Two epimers, 2- $[^{18}\text{F}]$ fluoro-2-deoxy-D-glucose ($[^{18}\text{F}]\text{FDG}$) and 2- $[^{18}\text{F}]$ fluoro-2-deoxy-D-mannose ($[^{18}\text{F}]\text{FDM}$) were formed and separated after hydrolysis ($[^{18}\text{F}]\text{FDG}$: 10% radiochemical yield).

The synthesis was improved (20% yield) by using $[^{18}\text{F}]\text{AcOF}$ instead of $[^{18}\text{F}]\text{F}_2$ (Shiue et al. 1982) and unprotected glucal in water (Ehrenkaufer et al. 1984). Nevertheless, varying amounts of the epimer $[^{18}\text{F}]\text{FDM}$ are formed via the electrophilic route. These disadvantages were overcome by an alternative strategy allowing high-yield production of no-carrier-added $[^{18}\text{F}]\text{FDG}$ with high radiochemical purity via the *nucleophilic substitution* reaction on 1,3,4,6-tetra-O-acetyl-2-triflate- β -D-mannose (Hamacher et al. 1986a). Fowler and Ido (2002) provide a comprehensive overview reflecting the history and different approaches of $[^{18}\text{F}]\text{FDG}$ production.

The addition of elemental $[^{18}\text{F}]$ fluorine to 2-(2-nitro-1[H]-imidazol-1yl)-*N*-(2,3,3-trifluoroallyl)-acetamide in trifluoroacetic acid to form $[^{18}\text{F}]\text{EF}_5$ represents a more recent example of an aliphatic electrophilic fluorination (Dolbier et al. 2001, cf. [Fig. 42.3](#)). EF_5 as well as EF_1 (Kachur et al. 1999) and EF_3 (Josse et al. 2001), which are prepared via nucleophilic routes, have been suggested for PET imaging of tumor hypoxia.

The substitution of hydrogen by ^{18}F -fluorine has also been used for the production of 5- $[^{18}\text{F}]$ fluoro-DOPA (Firnaeu et al. 1973) and 6- $[^{18}\text{F}]$ fluoro-L-DOPA (3,4-di-hydroxy-6- $[^{18}\text{F}]$ fluoro-L-phenylalanine; 6- $[^{18}\text{F}]\text{FDOPA}$) (Garnett et al. 1983a, b; Firnaeu et al. 1980, 1984; Adam et al. 1986; Coenen et al. 1988) (cf. [Fig. 42.4](#)). 6- $[^{18}\text{F}]\text{FDOPA}$ is transported across the blood-brain barrier, where it is decarboxylated to produce 6- $[^{18}\text{F}]$ fluoro-dopamine.

■ Fig. 42.4

Synthesis of [^{18}F]FDOPA by [^{18}F]F₂ in (HF)_x (Firnau et al. 1984)

The rate of uptake reflects decarboxylase activity, suitable to assess presynaptic dopaminergic function (Leenders et al. 1986). Direct fluorination was carried out on protected and unprotected DOPA. Labeling of DOPA ([^{18}F]F₂ in HF) yields the three possible regioisomers: 2-, 5-, and 6-[^{18}F]FDOPA. Both regioselectivity and overall radiochemical yields are strongly dependent on the solvent systems used. Using the same methodology, fluorinated analogs of L-tyrosine and L-phenylalanine were also obtained (for review cf. Lemaire 1993).

In 1999, Chirakal et al. investigated the effect of different acidic solvents on the selectivity and reactivity of the [^{18}F]fluorination of L-DOPA. While the orientation of electrophilic fluorination of L-DOPA in weak acids (trifluoroacetic acid, 10% TFA in glacial HOAc and HCOOH) is influenced by the electron donating OH groups on the ring, the orientation in strong acids (HF and HF/BF₃) is mainly influenced by the side chain.

For imaging and monitoring of new techniques in *gene therapy* 8-[^{18}F]fluoroguanines were prepared. The fluorination of *gancyclovir* with [^{18}F]F₂ was carried out in absolute ethanol in the presence of tetraethylammonium hydroxide at room temperature to give 8-[^{18}F]fluorogancyclovir (► Fig. 42.5a) in about 1% radiochemical yield. Similarly, 8-[^{18}F]fluoropencyclovir (B), 8-[^{18}F]fluoroacyclovir (C), and 8-[^{18}F]fluoroguanosine (D) were synthesized from pencyclovir (Barrio et al. 1996; Namavari et al. 2000).

The cytostatic agent 5-[^{18}F]fluorouracil (5-[^{18}F]FU) has been prepared by electrophilic addition of [^{18}F]F₂ (Fowler et al. 1973) and [^{18}F]AcOF (Fowler et al. 1982; Diksic et al. 1986; Visser et al. 1986) to uracil. Subsequent elimination of the 6-fluoro or 6-acetoxy groups results in high regioselectivity for the five positions (see ► Fig. 42.6). Laborious purification methods to separate 5-[^{18}F]FU from unreacted uracil have been overcome by using a single column method reported by Brown et al. (1993). Radiochemical yields >20% are obtained using this method.

Synthesis of 8-¹⁸F]fluoroguanines for gene therapy monitoring (Namavari et al. 2000)

Fig. 42.6

Synthesis of 5-¹⁸F]fluorouracil (5-¹⁸F]FU) from [¹⁸F]acetyl hypofluorite (X = Na, K, NH₄)

Among a variety of other rarely used reagents suggested for electrophilic fluorinations are [¹⁸F]perchloryl fluoride (Ehrenkauf and McGregor 1983), nitrosyl fluoride, N-fluoro-N-alkylsulfonamides (Satyamurthy et al. 1990), or 2-¹⁸F]fluoro-2-pyridone (Oberdorfer et al. 1988a). Fluorination of carbanions, such as, aryllithium and aryl Grignard reagents can be obtained in 60–70% yields with N-¹⁸F]fluoro-N-alkylsulfonamides (Barnette 1986; Satyamurthy et al. 1984) as a source of “positive” [¹⁸F]fluorine. This labeling reagent is prepared from [¹⁸F]F₂ and N-*endo*-norbornyl(p-tolyl)sulfonamide in up to 45% yield. Similarly, [¹⁸F]fluorobenzene can be obtained in 60% yield using N-¹⁸F]fluoro-2-pyridone, a reagent prepared by reaction of N-trimethylsilylpyridinium triflate and [¹⁸F]F₂ (Oberdorfer et al. 1988b). Starting from methyl lithium (MeLi), [¹⁸F]fluoromethane can be prepared using N-¹⁸F]fluoro-2-pyridone in quantitative yields (10 min, −80°C), thus demonstrating the suitability not only for the synthesis of arylfluorides.

42.3.1.2 ¹⁸F-Fluorodemetallation

¹⁸F-fluorodemetallation is the method of choice to introduce fluorine into a predefined position of an aromatic ring and to avoid formation of possible regioisomers. Here, regioselective electrophilic aromatic substitution is accomplished by displacement of a metallic substituent, e.g., alkylated species of Sn, Hg, Si, or Ge by [¹⁸F]F₂ or [¹⁸F]AcOF. In an early comparative study (Coenen and Moerlein 1987), tin compounds appeared to be better leaving groups than the corresponding Si- and Ge-derivatives (cf. Table 42.4). Whereas no or low yields were observed using hydrogen-containing solvents, e.g., CH₂Cl₂, dimethyl sulfoxide (DMSO), or

Table 42.4

MeCN; satisfactory yields were obtained with perhalogenated methane, e.g., CFC₃. Low yields were also obtained in the presence of electron withdrawing groups (NO₂, CF₃).

For synthesis of 6-[¹⁸F]FDOPA via demetallation, a variety of precursors were studied (Adam et al. 1983; Adam and Jivan 1988; Luxen et al. 1990; Namavari et al. 1992; Szajek et al. 1998; Dollé et al. 1998a; de Vries et al. 1999). 6-[¹⁸F]FDOPA can be prepared by demercuration (Adam et al. 1983; Adam and Jivan 1988; Luxen et al. 1990) in solution and in a solid–liquid phase reaction (precursor on solid support, 23% yield) (Szajek et al. 1998) or via destannylation (Namavari et al. 1992). For destannylation, the use of [¹⁸F]F₂ is preferred (30% yield) (Dollé et al. 1998a; de Vries et al. 1999). Hess et al. (2002) described the synthesis of 2-[¹⁸F]fluoro-L-tyrosine via regiospecific destannylation of O,N-di-Boc-2-trimethylstannyl L-tyrosine ethylester in 42% radiochemical yield (► Fig. 42.7).

The radiolabeled catecholamine tracer 6-[¹⁸F]fluorometaraminol (► Fig. 42.8b) for mapping cardiac sympathetic neurons is another example for the introduction of ¹⁸F-fluorine by demetallation. It has been prepared by fluorination of 6-acetoxymercuro-N-t-BOC-metaraminol with acetyl hypofluorite followed by removal of the BOC group in about 30% radiochemical yield (Mislankar et al. 1988). In 2000, Ermert et al. have used an n.c.a. nucleophilic ¹⁸F-for-N(CH₃)₃ exchange on an N,N-dibenzyl protected α-aminopropiophenone derivative, followed by a stereoselective reduction and deprotection step to prepare 4-[¹⁸F]fluorometaraminol in 15–20% radiochemical yield. Another four-step strategy was described by Langer et al. (2001).

The alternative n.c.a. catecholamine analog (–)-6-[¹⁸F]fluronorepinephrine (► Fig. 42.8a) was synthesized by a nucleophilic aromatic ¹⁸F-for-nitro substitution on a protected benzaldehyde precursor (Ding et al. 1991) followed by a multistep procedure. Three-step syntheses starting with a nucleophilic ¹⁸F-for-N(CH₃)₃ exchange are also required to prepare the guanidine-derived catecholamine analogs 4-[¹⁸F]fluoro-3-iodobenzylguanidine (► Fig. 42.8c) (Vaidyanathan et al. 1994) and 4-[¹⁸F]fluorobenzyl guanidine (► Fig. 42.8d) (Garg et al. 1994) (► Table 42.5).

42.3.1.3 Electrophilic [¹⁸F]F₂ from n.c.a. [¹⁸F]F[–]

In order to improve the specific activity of [¹⁸F]F₂ and thus to exploit the electrophilic fluorination also for the production of neuroreceptor ligands, recent studies have addressed the conversion of [¹⁸F]fluoride to [¹⁸F]F₂ with high specific activity, cf. ► Fig. 42.9.

■ Fig. 42.9

Synthesis of 6- ^{18}F FDOPA (a), ^{18}F CFT (b), ^{18}F oxoquazepam (c), and ^{18}F fluoroatipamezole (d)

In a procedure described by Bergman and Solin (1997), $^{18}\text{F}\text{CH}_3\text{F}$ was synthesized from $^{18}\text{F}\text{F}^-$ in an inert neon matrix. Following atomization in an electric discharge, after which a rearrangement and ^{18}F -for- ^{19}F exchange took place, $^{18}\text{F}\text{F}_2$ was obtained with a specific activity of up to $55\text{ GBq }\mu\text{mol}^{-1}$ (Bergman and Solin 1997). Using the aforementioned methodology, the authors succeeded in the syntheses of 6- ^{18}F FDOPA (● Fig. 42.9a) from N-formyl-3,4-di-*t*-butoxycarbonyloxy-6-(trimethylstannyl)-L-phenylalanine ethyl ester, ^{18}F CFT (B) (a dopamine transport marker) from 2- β -carbomethoxy-3- β -(4-trimethylstannyl-phenyl)tropane, ^{18}F fluoroatipamezole (D) ($\alpha 2$ adrenergic antagonist) from 4-(2-ethyl-2,3-dihydro-5-tributylstannyl-1H-2-indenyl)-1-acetyl-imidazole, and the benzodiazepine ^{18}F fluoro-oxoquazepam (C) from 7-chloro-1-(2,2,2-trifluoroethyl)-1,3-dihydro-5-(2-trimethyl-stannylphenyl)-2H-1,4-benzodiazepine-2-one). The specific activities of the compounds have been about $15\text{ GBq }\mu\text{mol}^{-1}$. All tracers are further examples for the importance of destannylations for the introduction of ^{18}F -fluorine into nonactivated aromatic systems.

42.3.2 Nucleophilic ^{18}F -Fluorination

At present, the aromatic and aliphatic *nucleophilic fluorination* starting with n.c.a., ^{18}F fluoride is the only way suitable for preparing high specific activity ^{18}F -labeled tracers. The ^{18}F fluoride, commonly produced by the $^{18}\text{O}(\text{p},\text{n})^{18}\text{F}$ nuclear reaction on highly enriched $^{18}\text{O}\text{H}_2\text{O}$, is in aqueous solution. Because of the high charge density of the fluoride ion, it is highly solvated in aqueous solution ($^{18}\text{F}\text{F}_{\text{aq}}^-$) and a poor nucleophile. As a strong base, it is

protonated in the presence of acidic protons to form [¹⁸F]HF. Furthermore, n.c.a. [¹⁸F]fluoride has the tendency to adhere or to get absorbed on the reaction vessel walls. Thus, several major aspects have to be considered for successful nucleophilic fluorinations. The fluoride ion has to be activated to increase its nucleophilicity and solubility. Dipolar aprotic solvents are used to avoid protonation. Furthermore, absorption losses may occur when unsuitable reaction vessels are used. High-purity chemicals, precursors, and solvents are strongly recommended and often even small traces of water dramatically impair or even preclude the radiochemical yield.

The reactivity and solubility can be increased by using large and soft cations, such as Rb⁺ and Cs⁺. Although these M[¹⁸F] salts are more soluble in dipolar aprotic solvents than K[¹⁸F], the use of cryptate complexes of potassium or tetraalkylammonium salts as phase transfer catalysts is the method of choice making the fluoride to a “naked” anion with high nucleophilicity. Thus, the *Kryptofix* 2.2.2 (4,7,13,16,21,24-hexaoxa-1,10-diazabicyclo[8.8.8]hexacosane) potassium carbonate system ([K/2.2.2]⁺ carbonate) (Coenen et al. 1986; Block et al. 1986b) has become the most often used phase transfer system in ¹⁸F-fluorination chemistry. For activation, the [¹⁸F]fluoride obtained in [¹⁸O]H₂O from the target is passed through an anion exchange resin. While the [¹⁸F]fluoride is retained, cationic contaminations from the target body are eluted and [¹⁸O]H₂O is recovered. [¹⁸F]Fluoride is then eluted with an aqueous solution of K₂CO₃ and transferred into a vessel. *Kryptofix* 2.2.2 is added, followed by successive azeotropic drying with at least three portions of acetonitrile. In contrast to the less basic carbonate, hydroxide, which is nucleophilic and strongly basic, is also often used as anion with R₄N⁺. If milder conditions are required, substitution of part of the carbonate by the non-nucleophilic and less basic oxalate allows fluorination of base-sensitive compounds. Polymeric-resin bound fluoride was also shown to be an efficient alternative in n.c.a. nucleophilic ¹⁸F-fluorinations. Lemaire et al. (2010) tested a set of strong organic bases, which enabled a sufficient elution of [¹⁸F]fluoride from the exchanger resin with a acetonitrile solution containing 500–10,000 ppm of water. Furthermore, the strong bases allowed effective ¹⁸F-labeling (aliphatic and aromatic) of different tracers directly in the elution volume still containing traces of water.

Nucleophilic ¹⁸F-fluorination has been performed in a variety of solvents. Because of their ability to solubilize the fluoride salts and most of the organic compounds, the dipolar aprotic solvents acetonitrile (MeCN), dimethyl sulfoxide (DMSO), dimethyl formamide (DMF), and dimethyl acetamide (DMAA) are most commonly used. Other solvents successfully used are tetrahydrofuran (THF), *ortho*-dichlorobenzene (DCB), and dichloromethane (DCM). For high temperature reactions, DMSO, DCB, nitrobenzene, or DMAA have been superior in some cases. In some studies, the use of ionic liquids such as [bmim][BF₄] or 1-butyl-3-methylimidazolium trifluoromethanesulfonate (BMI) showed promising results as cosolvents with the major advantages of tolerating the presence of water in the ¹⁸F-labeling step and enhancing the radiochemical yields (Kim et al. 2002; Kim et al. 2004). More recently, an unusual cosolvent of protic tertiary alcohols was found beneficial for ¹⁸F-fluorinations (Kim et al. 2006). The use of tertiary alcohols in a mixture with MeCN was reported to reduce side product formation and to enable higher and very reliable radiochemical yields at lower temperatures and shorter reaction times. Although, the beneficial effect of tertiary alcohol cosolvent system was thought to be limited to aliphatic ¹⁸F-labeling, a first example for an aromatic system was recently reported by Olberg et al. (2010).

As a general aspect of chemistry at the n.c.a. level, the reagents used are added in great excess. When typically 10–100 μmol of reagent are reacted with nmol amounts of the radioactive component, rates of reaction and reaction kinetics can be different from those expected from the “normal” organic chemistry. Although this difference can open routes to tracers not

available in the equimolar range, it also can result in unexpected pitfalls at the n.c.a. level. Thus, surprising results often can be avoided by a careful survey of the proposed reaction mechanism.

42.3.2.1 Nucleophilic Aromatic Substitutions

Finger and Kruse reported the first use of fluoride in *nucleophilic aromatic substitutions* in 1956. Twenty years later this methodology was applied to ¹⁸F-labeling, and introduction of [¹⁸F]fluoride into electron deficient aromatic systems is widely used (Stöcklin 1995; Lasne et al. 2002; Miller et al. 2008; Cai et al. 2008).

A variety of leaving groups, e.g., Y = NO₂, F, Cl, Br, I, (CH₃)₃N⁺, (CH₃)₂S⁺, has been investigated in the presence of activating groups, such as CN, CHO, COR, COOR, and NO₂ in small and complex molecules with different substitution patterns using different phase transfer catalysts and solvents. Radiochemical yields up to 80% are obtained. Variations in temperature, time, solvent, catalyst, and counter ions (for (CH₃)₃N⁺ and (CH₃)₂S⁺) render a direct comparison difficult. High yields are obtained with trimethylammonium salts (preferably triflate) or NO₂ as leaving groups and NO₂, CN, CHO, COR, or COOR as activating groups in *ortho*- or *para*-position (50–85%). Although activation is maximum in *ortho*- and *para*-position, high yields are also observed in some cases in 1,3-disubstituted benzenes, e.g., 3-[¹⁸F]fluoronitrobenzene from 1,3-dinitrobenzene (84%). Although comparable yields are obtained with NO₂ and the cationic leaving group (CH₃)₃N⁺, the latter is superior with respect to precursor separation, both via cartridge systems or HPLC. Demethylation and formation of [¹⁸F]FCH₃ are often reported as limitations when the aromatic system is not sufficiently activated by electron-withdrawing substituents, and indeed, this side reaction was exploited for synthesis of [¹⁸F]fluoromethane. Nevertheless, the high yields for the aromatic nucleophilic substitution reveal that this process can be tolerated.

Fluorine-for-halogen exchange has also been described in DMSO/[K/2.2.2]⁺ systems using 4-haloacetophenones and 4-halobenzonitriles. In both series, ¹⁸F-for-F exchange was the most efficient (70–75%). This process, however, is only suitable when high specific activities are not needed.

Complex molecules have been labeled with [¹⁸F]fluoride by direct aromatic nucleophilic substitution. The serotonin receptor ligands [¹⁸F]altanserin (Lemaire et al. 1991) (► Fig. 42.10a) and the D₂-like receptor ligand N-[¹⁸F]methylspiperone (Hamacher et al. 1986a) were successfully prepared by aromatic ¹⁸F-for-NO₂ and ¹⁸F-for-Cl exchange.

For labeling of the latter compound and other analogs of a series of *butyrophenone neuroleptics* the basicity of the [K/2.2.2]⁺ ¹⁸F[−] was reduced by using the less basic *oxalate* and only traces of carbonate (Hamacher et al. 1986a; Katsifis et al. 1993). Another example for a direct nucleophilic substitution is *p*-[¹⁸F]MPPF (Shiue et al. 1997), a 5-HT_{1A} receptor antagonist (► Fig. 42.10c). [¹⁸F]fluoride-for-bromide displacement on the pyrazole backbone of a CB1 cannabinoid receptor ligand yielded the potential CB1 cannabinoid receptor ligand in only 6% (Katoch-Rouse and Horti 2003) (► Fig. 42.10d).

The new ¹⁸F-labeled phenylthiophenyl derivative, specific for imaging of serotonin reuptake transporters (SERT), was synthesized by ¹⁸F-for-NMe₃ substitution and subsequent combined borane and stannous chloride reduction of the nitro and amido group in the precursor (Oya et al. 2002) (► Fig. 42.10e).

With the aim to obtain 6-[¹⁸F]FDOPA with high specific activity, “nucleophilic” routes were also investigated (Ding et al. 1990; Reddy et al. 1993; Lemaire et al. 1994; Lemaire et al. 2004;

Fig. 42.10

The serotonin receptor ligand [^{18}F]altanserin (**a**), the D_2 -like receptor ligand N-[^{18}F]methylspiperone (**b**), the $5\text{-HT}_{1\text{A}}$ receptor antagonist *p*-[^{18}F]MPPF (**c**), the CB1 cannabinoid receptor ligand (**d**), and a ^{18}F -labeled phenylthiophenyl derivative (**e**), specific for imaging of serotonin reuptake transporters (SERT)

Wagner et al. 2009). [▶ Figure 42.11](#) summarized the asymmetric syntheses of 6-[^{18}F]FDOPA, 2-[^{18}F]fluoro-L-tyrosine, and 4-[^{18}F]fluoro-*meta*-L-tyrosine starting with the nucleophilic aromatic ^{18}F -for- NO_2 -exchange on the aldehydes. Diiodosilane was used to prepare the corresponding benzyl iodides in about 35% radiochemical yield. Alkylation of (S)-1-Boc-2-*tert*-butyl-3-methyl-4-imidazolidinone (S-Boc-BMI) and hydrolysis with hydrogen iodide led to the tracers after purification within about 125 min and 11–16% radiochemical yield (Lemaire 1993).

In an enantioselective multistep approach using asymmetric phase-transfer-catalysts, the radiochemical yield of n.c.a. 6-[^{18}F]FDOPA could be increased to 20–30% and the isolated product was obtained with an enantiomeric excess of $\geq 96\%$ (Lemaire et al. 2004). Recently, a direct precursor for nucleophilic ^{18}F -labeling of 6-[^{18}F]FDOPA by isotopic exchange was developed (Wagner et al. 2009). The ^{18}F -introduction is facilitated by an activating aldehyde function in *para*-position ([▶ Fig. 42.12](#)). After Bayer–Villiger oxidation of the aldehyde and subsequent acid hydrolysis, 6-[^{18}F]FDOPA was achieved in good radiochemical yields of 22% within 105 min.

42.3.2.2 Nucleophilic Aromatic Substitution of Small Synthons

Obviously, one-step fluorinations are not always possible or even rare. For the majority of compounds, competing nucleophilic and acidic groups in a molecule have to be protected. For other compounds, labeling can only be achieved in multistep syntheses starting with small labeled synthons.

■ Fig. 42.11

Multistep synthesis of no-carrier-added (n.c.a.) 2- ^{18}F fluoro-L-tyrosine (^{18}F FTyr), n.c.a. 6- ^{18}F fluoro-L-DOPA (6- ^{18}F FDOPA) and n.c.a. 4- ^{18}F fluoro-meta-L-tyrosine (4- ^{18}F mTyr) (Lemaire 1993). 2- ^{18}F FTyr: $\text{R}_1' = \text{NO}_2$ or $\text{Me}_3\text{N}^+ - \text{SO}_3\text{CF}_3$; $\text{R}_1 = \text{R}_1'' = ^{18}\text{F}$; $\text{R}_2 = \text{R}_2' = \text{OCH}_3$; $\text{R}_2'' = \text{OH}$, $\text{R}_3 = \text{R}_3' = \text{R}'' = \text{H}$ 6- ^{18}F FDOPA: $\text{R}_1' = \text{NO}_2$ or $\text{Me}_3\text{N}^+ - \text{SO}_3\text{CF}_3$; $\text{R}_1 = \text{R}_1'' = ^{18}\text{F}$; $\text{R}_2 = \text{R}_2' = \text{R}_3 = \text{R}_3' = \text{OCH}_3$; $\text{R}_2'' = \text{R}_3'' = \text{OH}$ 4- ^{18}F mTyr: $\text{R}_2' = \text{NO}_2$ or $\text{Me}_3\text{N}^+ - \text{SO}_3\text{CF}_3$; $\text{R}_2 = \text{R}_2'' = ^{18}\text{F}$; $\text{R}_3 = \text{R}_3' = \text{OCH}_3$; $\text{R}_3'' = \text{OH}$, $\text{R}_1 = \text{R}_1' = \text{R}'' = \text{H}$

■ Fig. 42.12

Radiosynthesis of 6- ^{18}F FDOPA by isotopic exchange and subsequent Bayer–Villiger oxidation and acidic hydrolysis (Wagner et al. 2009)

Although most of the precursors in Fig. 42.13 are shown as substituted NO_2 -compounds, the corresponding trimethylammonium salts (triflates and perchlorates) often lead to comparable or even higher yields (see Table 42.6).

Nonactivated ^{18}F -labeled aromatic systems, such as 4- ^{18}F fluorobenzene and 4- ^{18}F fluoroiodobenzene can be prepared in good yields (30–50%) by symmetrically and

Fig. 42.13

unsymmetrically substituted *diaryliodonium salts* (e.g., triflates) (Pike and Aigbirhio 1995; Gail et al. 1997; Shah et al. 1998; Wüst and Knieß 2003, 2004). In addition, diaryliodonium salts were used for the radiofluorination of nonactivated heteroaromatic systems and enabled convenient ¹⁸F-labeling of 3-[¹⁸F]fluoropyridines and 3-[¹⁸F]fluoroquinolines, cf. Table 42.7 (Carroll et al. 2007a). Diaryliodonium salt precursors have been applied to ¹⁸F-labeling in microreactors and yielded various *ortho*-substituted [¹⁸F]fluoroarenes in high yields (Chun et al. 2010). In case of symmetrical diaryliodonium salts, the reaction with [¹⁸F]fluoride yields only one ¹⁸F-labeled product. The unsymmetrical diaryliodonium salts lead generally to two ¹⁸F-arenes with a preference for the less electron-rich system. This fact provides an electronic control of the regioselectivity of this ¹⁸F-labeling procedure. Furthermore, also a steric effect of *ortho*-substituents allows an influence on the direction of the nucleophilic attack (*ortho* effect) (Gail et al. 1997; Shah et al. 1998). The use of a very electron-rich heteroaromatic ring to direct the nucleophilic ¹⁸F-attack exclusively toward the desired ¹⁸F-anisoles was investigated using the 2-thienyl moiety (Ross et al. 2007). No 2-[¹⁸F]fluorothiophene was observed in this study and only ¹⁸F-anisoles were found. However, recent investigations on the (radio)fluorination of 2-thienyl(phenyl)iodonium salts reported the detection of 2-fluorothiophene and the 2-thienyl ring revealed not to be an optimal choice due to the extremely problematic detection, isolation, and characterization of 2-fluorothiophene (Carroll et al. 2007b). Nonetheless, the 2-thienyl group in combination with 4-halobenzene rings gave good radiolabeling yields (50–60%) of the corresponding 4-[¹⁸F]fluorohalobenzenes (Ross et al. 2007). Especially the 4-[¹⁸F]fluoroiodobenzene can further undergo palladium-mediated cross coupling reactions, e.g., Sonogashira, Suzuki, Stille, Hartwig-Buchwald or Heck, and presents an attractive intermediate for multistep syntheses (Wüst and Knieß 2003, 2004; Ermert et al. 2004).

Table 42.7
Radiochemical yields for nucleophilic aromatic substitution of pyridines

Leaving group (LG)	Other substituent's	Yields (%)	Leaving group	Other substituent's	Yields (%)
2-I	3-OR	40	2-I	–	20
2-NO ₂	3-OR	70–80	2-Cl	–	60
2-N(CH ₃) ₃ ⁺	3-OR	80–95	2-Br	–	90
6-I	3-OR	30	2-NO ₂	–	90
6-NO ₂	3-OR	20–30	2-N(CH ₃) ₃ ⁺	–	90–95
6-N(CH ₃) ₃ ⁺	3-OR	40–50	3-I(4-MeOC ₆ H ₄) ⁺	–	55–63
6-Br	3-R	25–35	3-NO ₂	6-CO-NHR	37
6-NO ₂	3-R	10–20	3-I(4-MeOC ₆ H ₄) ⁺	“Quinoline”	22–25
6-N(CH ₃) ₃ ⁺	3-R	70			

Using Pd-catalysis, reaction of RSnBu₃ with 4-[¹⁸F]fluoroiodo- and 4-[¹⁸F]fluorobromobenzene yielded the corresponding alkyl- and aryl- substituted 4-[¹⁸F]fluorobenzenes (Allain-Barbier et al. 1998; Plevenaux et al. 1992). RP62203, a serotonin receptor antagonist, was successfully synthesized by Pd-catalyzed 4-[¹⁸F]fluorophenylation of a piperazine precursor (Marrière et al. 1999). Via the formation of [¹⁸F]fluorophenyllithium from 4-[¹⁸F]fluorobenzene, a variety of other compounds, which do not lend themselves to nucleophilic aromatic substitution, can be obtained (Ludwig et al. 2001; Ermert et al. 2007). Generally, examples for ¹⁸F-labeling of more complex structures by the use of diaryliodonium salts are rare (Hostetler et al. 1999b; Wüst and Knieß 2003). The most successful example of which is the PBR ligand [¹⁸F]DAA1106, which was labeled in radiochemical yields of 46% within 20 min from the corresponding *para*-anisole iodonium tosylate precursor, cf. Fig. 42.14 (Zhang et al. 2007).

[¹⁸F]Fluorobenzaldehyde, another versatile labeled intermediate, is obtained via the NO₂ or trimethylammonium precursors in good to high yields. The aldehyde is transformed to the [¹⁸F]fluorobenzylhalides (Br, Cl, I) either after the reduction to [¹⁸F]fluorobenzyl alcohol and subsequent halogenation or in one step using di-iodosilane (Hatano et al. 1991; Damhaut et al. 1992; Najafi et al. 1993; Mach et al. 1993; Lemaire et al. 1994; Halldin et al. 1994; Dence et al. 1997; Iwata et al. 2000a, b; Hwang et al. 1991).

Although [¹⁸F]fluoroalkoxyphenols can also be obtained by oxidation of the corresponding [¹⁸F]fluorobenzaldehydes (Chakraborty and Kilbourn 1991b), Bayer–Villiger oxidation of [¹⁸F]fluoroaryketones seems to be the most favorable route to more complex molecules (Ekaeva et al. 1995; Ludwig et al. 2002; Stoll et al. 2004). [¹⁸F]fluorobenzaldehyde was also used to prepare ¹⁸F-labeled activated esters for peptide labeling via oxidation to [¹⁸F]fluorobenzoic acid and esterification (Vaidyanathan and Zalutsky 1992), although labeling of nonactivated (ethyl, butyl, anthrylmethyl) esters and subsequent hydrolysis seems to be the most straightforward approach to the acids, acid chlorides, and activated esters (Guhlke et al. 1994a; Wester et al. 1996). [¹⁸F]fluorobenzaldehydes are also important intermediates for the synthesis of [¹⁸F]fluorobenzylamines by reductive amination (Choe et al. 2000).

■ Fig. 42.14

Radiosynthesis of the PBR ligand [^{18}F]DAA1106 via nucleophilic ^{18}F -labeling of a diaryliodonium salt precursor (Zhang et al. 2007)

For synthesis of ^{18}F -labeled deprenyl (MAO inhibitor), 4- ^{18}F -fluorobenzaldehyde was converted to 4- ^{18}F -fluorobenzylmethylketone (Cooke et al. 1982), followed by reductive amination (Plevenaux et al. 1991).

Decarbonylation of 2- ^{18}F -fluorobenzaldehydes has been used to synthesize labeled arenes with nonactivated substituents, e.g., 4-bromo- ^{18}F -fluorobenzene from 3-bromo-6-nitrobenzaldehyde (Chakraborty and Kilbourn 1991a). This methodology was also applied to ^{18}F -fluoroarylketones (Allain-Barbier et al. 1998; Forngren et al. 1998) and to mono- to tetra-methoxy-substituted ^{18}F -fluorobenzenes from the corresponding 2-nitro(methoxy)benzaldehydes (Shen et al. 2009). In the latter study they identified side products, which derived from demethylation of methoxy groups and intramolecular redox processes that reduced the radiochemical yields.

Similar to most of the other aromatic intermediates discussed before, 4- ^{18}F -fluorocyanobenzene can be obtained both by ^{18}F -for- NO_2 or ^{18}F -for- $(\text{CH}_3)_3\text{N}^+$ -exchange in good to high yields. Reduction led to 4- ^{18}F -fluorobenzylamine (Shiue et al. 1989), which was used as an intermediate in the syntheses of prosthetic groups for peptide (4- ^{18}F -fluorophenacyl bromide (Kilbourn et al. 1987), protein (N-(*para*- ^{18}F -fluorophenyl)maleimide, Shiue et al. 1989), and oligonucleotide labeling (Dollé et al. 1997; Kuhnast et al. 2000a, b).

Ortho-, *meta*-, and *para*- ^{18}F -fluoronitrobenzenes are other interesting intermediates. They can be obtained in high yields from the corresponding trimethylammonium nitrobenzenes or dinitrobenzenes. Reduction yields the ^{18}F -fluoroanilines (Feliu 1988; Olma et al. 2006), suitable precursors for labeled piperazines (Collins et al. 1992; Das and Mukherjee 1993; Lasne et al. 1994). Conversion of ^{18}F -fluoroaniline to the diazonium salt opens synthetic routes to 4- ^{18}F -fluorochlorobenzene, 4- ^{18}F -fluorohydrazinobenzene (Feliu 1988), 4- ^{18}F -fluorophenol (Livni et al. 1992), or 4- ^{18}F -fluorobenzenesulfonylchloride. Recently, a 4- ^{18}F -fluorobenzenediazonium salt was successfully employed for ^{18}F -fluoroarylation of 4- ^{18}F -fluorophenyl substituted α -, β -, and γ -amino acids (Höfling et al. 2008) and also suggested as a prosthetic group for peptide labeling (Patt and Patt 2001).

42.3.2.3 Nucleophilic Heteroaromatic Substitutions

Nucleophilic aromatic substitution was also extended to the labeling of *heteroaromatic systems*, such as thiophenes (Kilbourn 1989) or pyridines (Knust et al. 1982; Dollé 2005). Typically, high

Fig. 42.15

2-^{[18}F]fluoropyridines: (a) 6-^{[18}F]fluoronicotinic acid diethylamide (¹⁸F-for-Cl, 40% RCY), (b) 2- and 6-^{[18}F]fluoronicotine (¹⁸F-for-BR, 30–40% RCY), (c) [¹⁸F]norchloro-fluoroeipibatidine (¹⁸F-for-NME₃, 70% RCY), and (d) [¹⁸F]-A-85380 (¹⁸F-for-NO₂, 50% RCY)

temperatures are required, and DMSO is the solvent of choice. Direct fluorination of 6-chloronicotinic acid diethyl amide led to the 6-^{[18}F]fluoronicotinic acid diethylamide in about 40% yield (Knust et al. 1982). Some other substitution reactions are listed in [Table 42.7](#) (Ballinger et al. 1984; Beer et al. 1995; Horti et al. 1996, 1998; Ding et al. 1997, 2000; Dollé et al. 1998b, 1999; Dolci et al. 1999a, b; Koren et al. 2000; Dollé 2005; Carroll et al. 2007a). Highest yields were obtained with trimethylammonium triflates, both for synthesis of the 2- and 6-^{[18}F]fluorinated pyridines, with the 6-position being less reactive than the 2-position in 3-OR substituted pyridines, cf. [Fig. 42.15](#). As mentioned above, the nonactivated 3-position of pyridines and quinolines can be ¹⁸F-fluorinated via the corresponding aryl (heteroaryl)iodonium salt precursors (Carroll et al. 2007a).

42.3.2.4 Nucleophilic Aliphatic Substitution

The second broad class of radiopharmaceuticals is opened by *nucleophilic aliphatic substitutions*. Typical leaving groups are iodide, bromide, chloride, tosylate, triflate, mesylate, or nosylate. Epoxides, cyclic sulfonates, or cyclic sulfamides (Brady et al. 1989; De Groot et al. 1994; Lim et al. 1996; Van Dort et al. 1995; Wängler et al. 2009a) were also found to be useful precursor structures for introduction of [¹⁸F]fluoride. Further approaches based on nucleophilic opening of aziridines as precursors have already been reported in 1984 (Farrokhzad et al. 1984) and were successfully readopted in the last decade (Lehel et al. 2000; Kiesewetter and Eckelman 2004; Röhn et al. 2009; Vasdev et al. 2009). In most cases, the [K/2.2.2]⁺ ¹⁸F[−]/acetonitrile system (Block et al. 1986b) is used with K₂CO₃ being the source of potassium and DMSO as an alternative for acetonitrile when higher temperatures are required.

Recently, the cosolvent system of *tertiary alcohols* such as *tert*-butanol, *tert*-amylalcohol, and acetonitrile has shown very promising results for ¹⁸F-fluorination in the presence of TBA⁺ ((C₄H₉)₄N⁺) salts, e.g., hydroxide or carbonate (Kim et al. 2006). Other functionalities with acidic protons (e.g., hydroxyls, phenols, thiols, or amides) or nucleophilic character (e.g., amines, carboxyls) have to be protected. Side products formed by elimination or the formation of the corresponding alcohols by hydrolysis of the high excess of precursor may coelute during HPLC purification and thus contaminate the product (pseudo carrier).

Without a doubt, 2-^{[18}F]fluoro-2-deoxy-D-glucose is the most useful PET radiopharmaceutical. The development of [¹⁸F]FDG, labeled and used to measure regional glucose utilization with PET by Phelps et al. (1979) and Reivich et al. (1979) about 25 years ago were based on observations of Warburg (1930, 1956). He found that tumor cells are characterized by a high

■ Fig. 42.16

Synthesis of [^{18}F]FDG via nucleophilic aliphatic substitution on tetraacetyl mannosyl-2-triflate (Hamacher et al. 1986a)

increase in *glycolytic metabolism*. Sokoloff et al. (1977) used ^{14}C -labeled deoxyglucose and autoradiography for measurement of local cerebral glucose utilization using a simple compartment model. In 1999, about 85% of all PET studies in Germany were carried out using [^{18}F]FDG (Brix et al. 2002), and this even seems to be a low percentage compared to other countries.

[^{18}F]FDG is taken up by the cells by specific glucose transporters (GluT) and is then phosphorylated by hexokinase. Since [^{18}F]FDG-6-phosphate is not a substrate for the glucose-6-phosphate isomerase, it is metabolically trapped in the intracellular compartments.

A comprehensive review of the different approaches for [^{18}F]FDG production has been published by Fowler and Ido (2002) (cf. Table 42.8). [^{18}F]FDG is produced nowadays by a two-step process developed by Hamacher et al. (1986a) (Fig. 42.16). The procedure consists of a nucleophilic aliphatic substitution of tetra-acetyl-trifluoromethanesulfonyl- β -D-mannopyranose (tetraacetylated mannosyl-2-triflate) by ^{18}F -fluoride-for-triflate exchange with $[\text{K}/2.2.2]^+ \text{ } ^{18}\text{F}^-$ in acetonitrile (up to 95% incorporation of ^{18}F -fluoride).

The reaction occurs with Walden inversion, giving rise to the enantiomerically pure no-carrier-added glucose compound. After deprotection by acidic (Hamacher et al. 1986a) or alkaline hydrolysis (Füchtner et al. 1996, Lemaire et al. 2002), the product is purified and neutralized by passing the solution through an ion retardation column with a small volume of isotonic saline, formulated and filtered to sterilize. The overall synthesis including purification proceeds in about 50–70% yields, depending on further modifications implemented. One of them is the use of 4-(4-methyl-1-piperidino)pyridine immobilized on a chloromethylated polystyrene matrix. This anion exchange resin is used in the carbonate form for the fixation of ^{18}F -fluoride, recovery of [^{18}O]H $_2$ O, and subsequent fluorination. In a competing displacement reaction during hydrolysis with 1 M HCl 2-chloro-deoxy-glucose (CIDG) (typically <20–50 $\mu\text{g ml}^{-1}$) is formed. Although CIDG does not present a toxic problem in [^{18}F]FDG preparations, its formation can be avoided by alkaline hydrolysis of tetra-acetyl-2-[^{18}F]fluoro-2-deoxy-D-glucose with NaOH. Though epimerization at C-2 position is a known reaction of aldoses under basic conditions, epimerization can be limited to 0.5% by using 0.33 M NaOH (<40°C, 5 min). To avoid defluorination and epimerization at higher temperatures and higher NaOH concentrations, tetra-acetyl-[^{18}F]FDG was hydrolyzed on solid phase, allowing the use of 2 M NaOH for fast (2 min) and efficient (>99%) deprotection at room temperature (Lemaire et al. 2002).

The use of radiolabeled nucleosides, taken up into proliferating cells and incorporated into DNA, is a well-known approach for the determination of cell proliferation, e.g., utilizing [^3H]thymidine or fluorinated compounds (Shields et al. 1996). Nucleosides are taken up into cells by facilitated diffusion controlled by equilibrative and concentrative transporters. From the two groups of equilibrative transporters (*es* and *is*), the *es*-transporter is mainly expressed in human cell lines investigated so far.

■ Table 42.8

Synthesis of [¹⁸F]fluoro-2-deoxy-D-glucose ([¹⁸F]FDG): major approaches (From Fowler and Ido 2002)

Labeling precursor	Substrate
Electrophilic methods:	
[¹⁸ F]F ₂	3,4,6-tri-O-acetyl-D-glycal
[¹⁸ F]F ₂ → [¹⁸ F]AcOF	3,4,6-tri-O-acetyl-D-glycal
[¹⁸ F]F ₂ → [¹⁸ F]AcOF	D-glycal
[¹⁸ F]F ₂ → [¹⁸ F]XeF ₂	3,4,6-tri-O-acetyl-D-glycal
Nucleophilic methods:	
[¹⁸ F]HF → [¹⁸ F]CsF	Methyl-4,6-O-benzylidene-3-O-methyl-2-O-trifluoromethanesulfonyl-β-D-mannopyranoside
[¹⁸ F]HF → [¹⁸ F]CsF	Methyl- or vinyl 4,6-benzylidene-α-D-mannopyranoside-2,3-cyclic sulfate
[¹⁸ F]HF → [¹⁸ F]CsF	1,2-anhydro-3,4,5,6-di-isopropylidene-1C-nitro-D-mannitol
[¹⁸ F]HF → [K/2.2.2] ⁺ ¹⁸ F [−]	1,3,4,6-tetra-O-acetyl-2-trifluoromethanesulfonyl-β-D-mannopyranose

In 1969, a fluorinated derivative of thymidine, 3'-deoxy-3-fluorothymidine (FLT) was reported to be a new and selective inhibitor of DNA synthesis (Langen et al. 1996) and has been investigated as antiviral agent later. Preparation of the c.a. ¹⁸F-labeled compound was first described in 1991 (Wilson et al. 1991) for noninvasive imaging of drugs against AIDS. After protection of the 5'-hydroxy group with a trityl group, the 3'-hydroxy group was substituted with a mesyl group in the *lyxo*-configuration. Treatment with [¹⁸F]potassium fluoride and crown-18 ether yielded the ¹⁸F-labeled fluoro-derivative, which on detritylation afforded [¹⁸F]FLT with 7% labeling efficiency (Wilson et al. 1991). The n.c.a. synthesis was first presented by Grierson and Shields (2000) using 3-*N*-(2,4-dimethoxybenzyl)-1-[5-*O*-(4,4'-dimethoxytrityl)-3-*O*-nosyl-2-deoxy-β-D-*lyxo*-furanosyl]thymidine as precursor (► Fig. 42.17). To improve work-up and yields, several other methods have been tested (Machulla et al. 2000; Wodarski et al. 2000; Blocher et al. 2002; Martin et al. 2002; Mier et al. 2002; Windhorst et al. 2008). So far, nucleophilic ¹⁸F-fluorination of 3-*N*-Boc-1-[5-*O*-(4,4'-dimethoxytrityl)-3-*O*-nosyl-2-deoxy-β-D-*lyxo*furanosyl]thymidine followed by deprotection with HCl seems to be the most suitable method. In 2003, this approach was optimized to give [¹⁸F]FLT in high radiochemical yields of up to 54% and radiochemical purity of ≥97%, sufficient for clinical applications (Yun et al. 2003).

The synthesis of *O*-(2-[¹⁸F]fluoroethyl)-*L*-tyrosine ([¹⁸F]FET) (Wester et al. 1999), an amino acid transport tracer for tumor imaging (Weber et al. 2000) is another example for a direct nucleophilic introduction of [¹⁸F]fluoride. Initially, a three-step procedure including the ¹⁸F-fluoroalkylation of unprotected *L*-tyrosine was used for evaluation of the biochemical characteristics of the tracer. The promising in vivo data (Wester et al. 1999; Weber et al. 2000) prompted Hamacher and Coenen (2002) to design a more convenient routine synthesis via a direct ¹⁸F-fluorination of the protected precursor (► Fig. 42.18). As an alternative to the HPLC purification of [¹⁸F]FET, Wang et al. (2005) suggested a solid-phase extraction method. Recently, a precursor based on a Ni(II)-complex of a *L*-tyrosine Schiff base was developed for [¹⁸F]FET (Krasikova et al. 2008). The Ni(II)-complex was especially designed to avoid racemization of the amino acid during the ¹⁸F-labeling step.

Fig. 42.17

Approaches to [¹⁸F]FLT (see Griersen and Shields 2000; Machulla et al. 2000; Blocher et al. 2002; Wodarski et al. 2000; Martin et al. 2002; Yun et al. 2003; Windhorst et al. 2008)

Fig. 42.18

Approaches to [^{18}F]fluoroethyl-L-tyrosine ([^{18}F]FET)

Some other examples for the nucleophilic aliphatic fluorination are given in Fig. 42.19. [^{18}F]FMISO, a tracer for quantification of *tumor hypoxia*, was originally labeled by a two-step procedure: ^{18}F -for-tosylate displacement on (2R)-(-)-glycidyl tosylate leading to [^{18}F]epifluorohydrin and reaction with imidazole to [^{18}F]FMISO (Grierson et al. 1989) (Fig. 42.19a). Lim and Berridge (1993) investigated the use of four different sulfonate-protected precursors for direct displacement with ^{18}F -fluoride. After deprotection, they obtained [^{18}F]FMISO in 55–80% radiochemical yield.

A variety of steroids was investigated for the early detection and staging of prostate and breast cancer. The selective estrogen receptor ligand 16- α -[^{18}F]fluoro-17 β -estradiol ([^{18}F]FES) (Fig. 42.19b) was labeled by displacement of a triflate group of the protected precursor followed by reduction of the fluoroestrone intermediate by LiAlH_4 (43%) (Kiesewetter et al. 1984). A modified procedure utilized 3-methoxymethyl-16 β , 17 β -epiestriol-O-cyclic sulfone for the production of FES (Lim et al. 1996). [^{18}F]FP-TZTP (Fig. 42.19c), a M2 selective muscarinic ligand, has been produced in >20% overall yield by ^{18}F -for-mesylate displacement (Kiesewetter et al. 2003). Recently, Holschbach et al. (2002) described the radiosynthesis of the A_1 adenosine receptor antagonist 8-cyclopentyl-3-(3-[^{18}F]fluoropropyl)-1-propylxanthine ([^{18}F]CPFPX) (Fig. 42.19d). ^{18}F -for-tosylate displacement on the 7-pivaloyloxymethyl protected precursor and subsequent alkaline deprotection gave rise to an overall radiochemical yield of 45%. [^{18}F]FDE (Fig. 42.19e) ((1R,2S)-1-[^{18}F]fluoro-L-deoxyephedrine) was prepared as a model compound to explore the biomimetic potential of F-for-OH substitution in β -phenethanolamines (Van Dort et al. 1995). The synthesis was achieved in high radiochemical yields (62%) by reaction of [^{18}F]fluoride with the chiral cyclic sulfamidate precursor. Radiofluorinated 6-dialkylamino-2-naphthylethylidene derivatives, and especially [^{18}F]FDDNP (Fig. 42.19f) as imaging probes for β -amyloid plaques in Alzheimer's disease, are prepared by simple ^{18}F -for-tosylate exchange in about 25% yield (Agdeppa et al. 2001, 2003). Recently, an automated synthesis for [^{18}F]FDDNP was developed to make this radiotracer available for the clinical routine (Vercouillie et al. 2010).

■ Fig. 42.19

$[^{18}\text{F}]\text{FMISO}$ (a), a tracer for imaging of hypoxia, the selective estrogen receptor ligand 16- α -fluoro-17 β -estradiol $[^{18}\text{F}]\text{FES}$ (b), the M2 selective muscarinic ligand $[^{18}\text{F}]\text{FP-TZTP}$ (c), the A_1 adenosine receptor antagonist $[^{18}\text{F}]\text{CPFPX}$ (d), the model compound (1R,2S)-1- $[^{18}\text{F}]\text{fluoro-1-deoxyephedrine}$ ($[^{18}\text{F}]\text{FDE}$, see text) (e), and $[^{18}\text{F}]\text{FDDNP}$ (f), an imaging probe for β -amyloid plaques in Alzheimer's disease

A novel and very effective strategy for the isolation and separation of ^{18}F -labeled compounds from their precursor molecules by “fluorous detagging” was reported (Bejot et al. 2009). The sulfonate leaving groups on precursor molecules were additionally derivatized with polyfluorinated tags, which allowed a very fast and efficient separation from precursors by fluorous solid-phase extraction. Several prosthetic groups as well as $[^{18}\text{F}]\text{fluoroethylcholine}$, $[^{18}\text{F}]\text{FMISO}$, and *cis*-4- $[^{18}\text{F}]\text{fluoro-L-proline}$ were successfully produced in good to high radiochemical yields and simply purified by this new methodology.

42.3.3 Prosthetic Group Labeling

A variety of compounds cannot be prepared by direct nucleophilic ^{18}F -fluorination. When high specific activity is required and electrophilic fluorination thus is impossible, labeling is often carried out by a multistep route using small reactive intermediates, often named *secondary labeling precursors* or *prosthetic groups*. A whole battery of these ^{18}F -labeled intermediates was investigated and prepared, such as amines, alcohols, aldehydes, ketones, carboxylic acids, esters, and halides. Since a quantitative overview about these synthons is outside the scope of this chapter, only some examples are discussed.

42.3.3.1 Introduction of ^{18}F -Fluorine by Fluoromethylation

When approaches to direct introduction of ^{18}F -fluorine by nucleophilic displacement fail, ^{18}F -alkylation procedures are often the alternative of choice. Nevertheless, compared to the battery of tracers produced by ^{11}C -methylation, only a few ^{18}F -labeled tracers prepared via this route are used clinically.

■ Fig. 42.20

Radiochemical yields for the ^{18}F -fluoromethylation of some model compounds (selected nucleophiles) with $[^{18}\text{F}]\text{FCH}_2\text{I}$

On the basis of the aforementioned isosteric relations, production of suitable tracers by ^{18}F -fluoromethylation of precursors in analogy to standard $[^{11}\text{C}]$ methylation seems to be a straightforward method. Unfortunately, most of the compounds prepared by this assumption show low metabolic stability and are extensively defluorinated in vivo (resulting in high $[^{18}\text{F}]$ fluoride bone uptake). The most prominent exception is $[^{18}\text{F}]$ choline, a tracer developed for tumor imaging, i.e., imaging of metastatic prostate cancer. Several attempts have been made to prepare $[^{18}\text{F}]$ halofluoromethanes as methylating agents (Coenen et al. 1986; Zheng and Berridge 2000; Bergman et al. 2001).

$[^{18}\text{F}]\text{FCH}_2\text{I}$, the closest analog of methyl iodide, can be prepared in $(40 \pm 8)\%$ radiochemical yield by F-for-I exchange of CH_2I_2 (Zheng and Berridge 2000; Zhang et al. 2004) (cf. ► Fig. 42.20). Best results are obtained at room temperature using MeCN as solvent and $[\text{K}/2.2.2]^+ ^{18}\text{F}^-$. At elevated temperature, the reaction yield decreased due to decomposition. The product is co-distilled with the reaction solvent under a helium stream. Although being somewhat less reactive, production of $[^{18}\text{F}]\text{FCH}_2\text{Br}$ exhibits the advantage to optionally allow online conversion to $[^{18}\text{F}]\text{FCH}_2\text{OTf}$ (Iwata et al. 2002). $[^{18}\text{F}]\text{FCH}_2\text{Br}$ can be prepared using the $[\text{K}/2.2.2]^+$ carbonate system (4 min, reflux) in $>50\%$ radiochemical yield. After passing all volatile compounds through a batch of silica cartridges by a helium flow, subsequent alkylations can be carried out either with $[^{18}\text{F}]\text{FCH}_2\text{Br}$ or $[^{18}\text{F}]\text{FCH}_2\text{OTf}$ formed by passing $[^{18}\text{F}]\text{FCH}_2\text{Br}$ through a second column filled with AgOTf on solid support (Iwata et al. 2002). Using this methodology, $[^{18}\text{F}]$ choline was prepared either in solution or on-column. The analogs $[^{18}\text{F}]\text{FCH}_2\text{OTos}$ and $[^{18}\text{F}]\text{FCH}_2\text{OMs}$ were already developed in 1987 (Block et al. 1987). Recently, the preparation of $[^{18}\text{F}]\text{FCH}_2\text{OTos}$ from bis(tosyloxy)methane was reexamined and used for the ^{18}F -fluoromethylation of several tracers in high radiochemical yields (Neal et al. 2005).

A number of applications were tested (Zheng and Berridge 2000) and first tracers, such as S-([^{18}F]fluoromethyl)-(+)-McN5652 (► Fig. 42.21e), as a potential radiotracer for PET imaging of the 5-HT transporters (Brust et al. 2003), have been evaluated.

42.3.3.2 Introduction of ^{18}F -Fluorine by Fluoroethylation

^{18}F -Fluoroethylation represents another useful way of inserting ^{18}F into molecules containing -NH-, -SH, or -OH groups (Block et al. 1987, 1988; Chi et al. 1986; Zijlstra et al. 1993). Applications and preparations of agents for ^{18}F -fluoroethylation and ^{18}F -fluoroalkylation have been recently reviewed by Wadsak et al. (2007) and Zhang and Suzuki (2007), respectively. An often-applied route to ^{18}F -fluoroethylation or longer ^{18}F -fluoroalkylation reagents was

■ Fig. 42.21

The nonselective (μ , κ , δ) opioid receptor ligand [^{18}F]FDPN (a), the α D_2 -like receptor antagonist [^{18}F]FESP (b), the prostate cancer imaging agent [^{18}F]fluorocholine [^{18}F]FCH (c), the 5-HT $_3$ receptor partial agonist [^{18}F]MR18445 (d), [^{18}F]McN5652 (e), and the central benzodiazepine receptor ligand 5-(2'-[^{18}F]fluoroethyl)flumazenil [^{18}F]FEF (f)

introduced by Block et al. 1987. Symmetrical bis-halide or bis-toxyloxyalkanes are fluorinated in high yields ($\text{Br} < \text{mesyl} < \text{tosyl}$, Block et al. 1987). The ^{18}F -fluoroethylation agent [^{18}F]FCH $_2$ -CH $_2$ OTos ([^{18}F]FETos) can be prepared in automated systems (Tang et al. 2003a). The purification of [^{18}F]FETos can be either done by HPLC (Wester et al. 2000) or by a solid-phase extraction on cartridges (Tang et al. 2003a). Preparation of [^{18}F]fluoroethyl iodide by ^{18}F -fluorination of the corresponding di-iodide gives only negligible radiochemical yields.

Zhang et al. (2002) described an automated system for synthesis, purification, and subsequent ^{18}F -fluoroethylation via 1-bromo-2-[^{18}F]fluoroethane [^{18}F]FCH $_2$ -CH $_2$ Br. Using nitrobenzene and *ortho*-dichlorobenzene as less volatile solvents, [^{18}F]FCH $_2$ -CH $_2$ Br was produced by phase transfer-mediated nucleophilic ^{18}F -fluorination (130°C, 5 min) of Br-CH $_2$ -CH $_2$ -OTos and Br-CH $_2$ -CH $_2$ -OTf in radiochemical yields of 30–55%. Again, the product can be purified by distillation (He, 90–100 ml min $^{-1}$, 130°C, 5 min) and condensation in a cooled trap. Alternatively, isolation of [^{18}F]CH $_2$ -CH $_2$ Br is achieved using more convenient cartridge systems (Comagic et al. 2002). An improved radiochemical yield of ^{18}F -ethylation compounds could be achieved in the presence of alkali iodides (Bauman et al. 2003).

Some selected ^{18}F -compounds prepared by alkylation are shown in Fig. 42.21. Whereas 6-O-(2-[^{18}F]fluoroethyl)-6-O-desmethyldiprenorphine (Fig. 42.21a), a nonselective (μ , κ , δ) opioid receptor ligand, was prepared by [^{18}F]fluoroethylation with [^{18}F]FETos and subsequent 3-O-deprotection (trityl) in about 20% radiochemical yield (Wester et al. 2000), no protection was required to alkylate 3-N-(2'-[^{18}F]fluoroethyl)sipiperone (Fig. 42.21b),

a D₂-like receptor antagonist (Chi et al. 1986; Block et al. 1986a). Both, [¹⁸F]fluoromethylcholine (FCH) (Fig. 42.21c) (DeGrado et al. 2001) and [¹⁸F]fluoroethylcholine (Hara et al. 2002; Piel et al. 2007; Zuhayra et al. 2008) are employed for imaging metastatic prostate cancer. [¹⁸F]Fluorobenzyl iodide, prepared via labeling of the benzaldehyde followed by reduction and halogenation (HI) was used to label [¹⁸F]MR18445 (Fig. 42.21d), a 5-HT₃ receptor partial agonist (Katounina et al. 1998). S-([¹⁸F]fluoromethyl)-(+)-McN5652 has been synthesized as a new radiotracer for PET imaging of 5-HT transporter (Brust et al. 2003). Zessin et al. (2001) prepared the compound by reaction of normethyl-(+)-McN5652 with the fluoromethylation agent [¹⁸F]bromofluoromethane in about 5% overall yield. 5-(2'-[¹⁸F]fluoroethyl)flumazenil ([¹⁸F]FEF) (Fig. 42.21f) (Moerlein and Perlmutter 1992) was synthesized as a longer-lived alternative to [¹¹C]flumazenil.

42.3.3.3 Introduction of ¹⁸F-Fluorine by Other Secondary Precursors

3-[¹⁸F]fluoropropyl bromide and 3-[¹⁸F]fluoropropyl iodide are also useful alkylation reagents and were used to label various receptor ligands, like opioidergic or dopaminergic ligands (Chesis and Welch 1990; Oh et al. 1999; Bai et al. 1990; Teng et al. 1990). The tosyl analog, 3-[¹⁸F]fluoropropyl tosylate (Block et al. 1987) again provides an alternative ¹⁸F-fluoroalkylation agent, which was employed for the synthesis of O-(3-[¹⁸F]fluoropropyl)-L-tyrosine (Tang et al. 2003b). Due to the high stability against defluorination in vivo, ¹⁸F-labeled phenyl groups are often used as structural mimetic for the corresponding non-fluorinated correlates (cf. Fig. 42.22). If direct fluorination fails, multistep synthesis via alkylation reagents can open an alternative strategy. Thus, 4-[¹⁸F]fluorobenzyl

Fig. 42.22

Syntheses of 4-[¹⁸F]fluorobenzylhalides from 4-[¹⁸F]fluorobenzaldehyde

bromide (Hatano et al. 1991; Damhaut et al. 1992; Najafi et al. 1993; Iwata et al. 2000a, b), 4-[¹⁸F]fluorobenzyl iodide (Mach et al. 1993; Halldin et al. 1994; Katounina et al. 1998; Iwata et al. 2000b) and 4-[¹⁸F]fluorobenzyl chloride (Hwang et al. 1991) were prepared and used for the multistep production of radiopharmaceuticals, such as [¹⁸F]fluoropropyfan, [¹⁸F]MR18445 (► Fig. 42.21d), [¹⁸F]fluorotroprapride, [¹⁸F]NCQ 115, and [¹⁸F]fluorodexetimide. The most straightforward synthesis so far seems to be the on-column reduction of the benzaldehyde with NaBH₄ and subsequent halogenation with P₂I₄ or Ph₃PBr₂ (Iwata et al. 2000a, b).

Reductive amination has been found to be a valuable method for a variety of tracers. The fluoro-substituted analog of (*S*)-CGP 12388 (► Fig. 42.23a) was prepared by reacting (*S*)-4-(3-amino-2-hydroxypropoxy)-2*H*-benzimidazol-2-one with [¹⁸F]fluoroacetone in the presence of NaCNBH₃ and glacial acetic acid (Elsinga et al. 1997). [¹⁸F]fluorocarazolol (► Fig. 42.23b) can be produced either by reductive amination (Kindsey et al. 1992; Zheng and Berridge 1992) or by alkylation of the desisopropyl precursor with 1-[¹⁸F]fluoroisopropyl tosylate (De Groot et al. 1992).

42.3.3.4 Introduction of ¹⁸F-Fluorine by Click Chemistry

The Cu(I)-catalyzed version of the 1,3-dipolar Huisgen cycloaddition of alkynes and azides (formation of 1,4-disubstituted 1,2,3-triazoles) became the most prominent example of the so-called click chemistry. Click reactions show certain characteristics such as fast kinetics, wideness in scope, high selectivity, and high yields. In case of the Cu(I)-catalyzed click cycloaddition, these facts are additionally accompanied by orthogonality to most other functional groups and high conversions under (very) mild reaction conditions. These benefits are particularly suitable for ¹⁸F-labeling chemistry (► Fig. 42.24). Different aliphatic ω-[¹⁸F]fluoro-alkynes were purified by co-distillation with the solvent (MeCN) and then coupled to unprotected azide-functionalized peptides under Cu(I)-catalyzed click cycloaddition conditions (Marik and Sutcliffe 2006). The ¹⁸F-labeled peptides were purified by simple cartridge-based solid-phase extraction and obtained in good-to-high radiochemical yields from 20% to 81%.

After the first examples of ¹⁸F-click cycloadditions on ¹⁸F-alkynes (Marik and Sutcliffe 2006; Sirion et al. 2007; Li et al. 2007), this approach was also rapidly extended to ¹⁸F-labeled azides as click-coupling agents (Sirion et al. 2007; Glaser and Årstad 2007; Thonon et al. 2009). In both ¹⁸F-click versions, it is noteworthy that the Cu(I)-catalyzed click step, forming the 1,4-disubstituted 1,2,3-triazoles, succeeded with similarly high efficiency. A clickable version of the established prosthetic group *N*-succinidyl-4-[¹⁸F]fluorobenzoate carrying an aromatic ¹⁸F-label was designed to provide enhanced in vivo stability (Ramenda et al. 2007). Also

Fig. 42.24

¹⁸F-Click labeling of peptides via Cu(I)-catalyzed 1,3-dipolar Huisgen cycloaddition

alkyne-functionalized ¹⁸F-pyridines were developed as clickable aromatic ¹⁸F-compounds (Kuhnast et al. 2008; Inkster et al. 2008). Recently, an ¹⁸F-labeled azido-glucose was developed as clickable prosthetic groups, which was ¹⁸F-labeled in high radiochemical yields of ~70% and additionally brings extra polarity for improved pharmacokinetics into the final product (Maschauer and Prante 2009). Especially the mild conditions and the inertness to other functional groups made this approach very attractive for the ¹⁸F-labeling of peptides (Marik and Sutcliffe 2006; Ramenda et al. 2007; Li et al. 2007; Inkster et al. 2008; Glaser et al. 2009a; Lei et al. 2010). Accordingly, this convenient method was also applicable for the ¹⁸F-labeling of small molecules and provided new ¹⁸F-derivatives of biomolecules such as thymidine and glucose (Sirion et al. 2007), folic acid (Ross et al. 2008), amino acids (Glaser and Årstad 2007; Thonon et al. 2009), isatin (Smith et al. 2008), and quinazoline (Kobus et al. 2009). The attractiveness and wide applicability of the ¹⁸F-click cycloaddition encouraged many colleagues adopting this efficient and convenient ¹⁸F-labeling method for their needs (Mamat et al. 2009; Glaser and Robins 2009; Ross 2010; Wängler et al. 2010).

42.4 ¹⁸F-Labeling of Peptides and Proteins

For the development of strategies to prepare ¹⁸F-labeled peptides and proteins, which are interesting tracers for receptor mapping, diagnosis, therapy planning, dosimetric calculations, and therapy control, two major limitations have to be considered: (1) the presence of acidic functionalities (e.g., hydroxyls, amides, alcohols, amines, and thiols) does not allow for direct nucleophilic ¹⁸F-fluorination; (2) electrophilic fluorination, as exemplified by Hebel et al. (1990), can only be achieved in the presence of carrier. To overcome these limitations, the commonly used methodology includes the preparation of ¹⁸F-labeled synthons (prosthetic groups), which are subsequently activated or, in only few cases, conjugated without activation to the peptide or protein.

Among the methods listed in Table 42.9, acylation is the commonly used strategy. The isolated N-succinimidyl 4-[¹⁸F]fluorobenzoate (Vaidyanathan and Zalutsky 1992, 1994, 2006; Gohlke et al. 1994a; Wester et al. 1996; Hostetler et al. 1999a; Sutcliffe-Goulden et al. 2000; Marik and Sutcliffe 2007; Glaser et al. 2009b) and 4-nitrophenyl 2-[¹⁸F]fluoropropionate (Gohlke et al. 1994a; Wester et al. 1996) allow to couple small aliphatic (e.g., 2-[¹⁸F]fluoropropionyl) or aromatic (4-[¹⁸F]fluorobenzoyl, 4-([¹⁸F]fluoromethylbenzoyl) groups under mild basic condition (pH 8–9) predominantly to the N-terminus and Lys-side chains of the peptides and proteins. N-succinimidyl 4-([¹⁸F]fluoromethyl)benzoate can be prepared in one step by nucleophilic ¹⁸F-fluorination of the highly activated nosylate precursor (Lang and Eckelman 1994, 1997) (35 min, 18%). In other cases, direct nucleophilic fluorination of the activated ester failed and led to the formation of the acyl-[¹⁸F]fluoride. Nevertheless,

probably due a somewhat higher in vivo stability against defluorination, most of the ^{18}F -peptides used in preclinical studies were prepared using N-succinimidyl 4-[^{18}F]fluorobenzoate ([^{18}F]SFB) (3 steps, 35 min, 55%) (Wester et al. 1996) and 4-nitrophenyl 2-[^{18}F]fluoropropionate ([^{18}F]NFP) (3 steps, 90 min, 60%) (Guhlke et al. 1994b). Very recently, 6-[^{18}F]fluoronicotinic acid 2,3,5,6-tetrafluorophenyl ester was develop and enabled a direct aromatic ^{18}F -labeling of the activated ester trimethylammonium triflate precursor under mild conditions (Olberg et al. 2010).

[¹⁸F]fluorobenzoic acid can be activated by DCC/NHS (Vaidyanathan and Zalutsky 1992), DSC (Vaidyanathan and Zalutsky 1992; Gohlke et al. 1994a), or TSTU (Wester et al. 1996) prior to coupling or conjugated in situ to the peptide on solid-phase support by HATU/DIPEA (diisopropylethylamine) (Sutcliffe-Goulden et al. 2000, 2002; Marik and Sutcliffe 2007), TBTU/DIPEA (Sutcliffe-Goulden et al. 2000), or DCC/HOAt (Hostetler et al. 1999a). Acylation yields are generally high (see, e.g., [¹⁸F]SFB: Vaidyanathan and Zalutsky 1997; Bergmann et al. 2002; Fredriksson et al. 2002; Johnstrom et al. 2002; Marik and Sutcliffe 2007; [¹⁸F]NFP: Gohlke et al. 1994a, b; Wester et al. 1997, 2003; Haubner et al. 2001).

In order to overcome the increase in lipophilicity especially observed on small peptides after ¹⁸F-fluoracylation, newer approaches combine *carbohydration* with acylation.

This methodology was successfully applied for the synthesis of an ¹⁸F-labeled sugar amino acid derivative of cyclo(Arg-Gly-Asp-DPhe-Lys) (Haubner et al. 2001, 2004) and N^α-(1-deoxy-d-fructosyl)-N^ε-(2-[¹⁸F]fluoropropionyl)-Lys⁰-Tyr³-octreotate ([¹⁸F]FP-Gluc-TOCA) (Schottelius et al. 2004; Wester et al. 2003, 2004). This approach was further developed to [¹⁸F]FDG-based prosthetic groups for chemoselective ¹⁸F-glycosylation of peptides using 1,3,4,6-tetra-O-acetyl-2-deoxy-2-[¹⁸F]fluoroglucopyranoside under Königs–Knorr conditions (Maschauer et al. 2005) or 3,4,6-tri-O-acetyl-2-deoxy-2-[¹⁸F]fluoroglucopyranosyl phenylthiosulfonate (Ac₃-[¹⁸F]FGlc-PTS) for thiol functions (Prante et al. 2007). Ac₃-[¹⁸F]FGlc-PTS was produced in three steps with a radiochemical yield of ~33% and gave excellent conjugation yields of 90% with a model pentapeptide (CAKAY) and c(RGDfC). The sugar-based prosthetic group, [¹⁸F]FDG-maleimidehexyloxime ([¹⁸F]FDG-MHO) was also designed for chemoselective conjugation to thiol groups (Wüst et al. 2008). Starting from routinely produced [¹⁸F]FDG, [¹⁸F]FDG-MHO was prepared in one step by oxime formation and was obtained in radiochemical yields of 45–70% after HPLC purification. [¹⁸F]FDG-MHO was chemoselectively coupled to glutathione and annexin A5 with conjugation efficiencies of ~95% and ~60%, respectively (Wüst et al. 2008). Recently, direct conjugations of [¹⁸F]FDG to aminooxy-functionalized peptides, such as RGD-peptides (Hultsch et al. 2009; Namavari et al. 2009) and neurotensin(8–13) peptides (Wüst et al. 2009a) by oxime formation were developed and yielded [¹⁸F]FDG-labeled peptides in radiochemical yields of 40–88%.

To avoid hydrolysis of the no-carrier-added ¹⁸F-labeled active esters in aqueous buffered solution, the acylation route can be inverted, i.e., radiolabeled amines are prepared and coupled with activated carboxyls at the peptide (► Table 42.9, amidation). Oxytocin was successfully coupled with 2-[¹⁸F]fluoroethylamine in yields >90% by both preactivation (NHS, 4-nitrophenyl and pentafluorophenyl esters) and in situ activation of the C-terminus (TBTU) (Jelinski et al. 2002).

Reactions of imidates with proteins have been shown to be specific for ε-amino groups of lysines, forming a stable amidine, which is protonated under physiological conditions. Thus, and in contrast to acylation and amidation strategies, the net charge of the target molecule is not affected. In a comparative study Kilbourn et al. (1987), [¹⁸F]fluoro-5-nitrobenzimidate was utilized for labeling of human transferrin, IgG, hemoglobin, red blood cells, human platelets, etc. Conjugation yields ranged from 15% to ~60% at 1 h, based on the benzimidate (1 h, 30–65%).

Even being presumably the most applied labeling reaction for synthesis of radiopharmaceuticals, alkylation reactions for peptides are rare. α-Haloketones are known to alkylate various heteroatoms. Thus, 4-[¹⁸F]fluorophenacyl bromide was suggested to be a more indiscriminate labeling agent. Although fibrinogen was successfully labeled (25–30% yield) (Kilbourn et al. 1987), conjugation of *octreotide* failed (Downer et al. 1997). Further studies

suggest the use of 4-¹⁸F]fluorophenacyl bromide only for peptides with free thiols or carboxylic acids. Antibody labeling was carried out using N-*p*-(¹⁸F]fluorophenyl)maleimide and *m*-maleimido-N-(4-¹⁸F]fluorobenzyl)-benzamide with conjugation yields of about 50%. A 18mer *peptide nucleic acid* (PNA), bearing a cysteine at the C-terminus (Kuhnast et al. 2000a) and oligodeoxynucleotides, containing a single phosphothioate monoester (Dollé et al. 1997; Kuhnast et al. 2000b) were labeled using N-(¹⁸F]fluorobenzyl)-2-bromoacetamide and N-[3-(2-¹⁸F]fluoropyridin-3-yloxy(propyl)-2-bromoacetamide (Kuhnast et al. 2004).

In recent years, several maleimide-carrying prosthetic groups have been developed for the chemoselective conjugation to peptidic thiol functionalities; most of which have been synthesized from [¹⁸F]fluorobenzaldehyde ([¹⁸F]FBA) by reacting with aminooxy-maleimides under oxime formation. Accordingly, 4-¹⁸F]Fluorobenzylidene)aminooxy]butylmaleimide ([¹⁸F]FBABM) (Toyokuni et al. 2003; Hultsch et al. 2007; Li et al. 2008) and some derivatives were produced and successfully applied for chemoselective conjugation to peptidic cysteine groups (Berndt et al. 2007; Wüst et al. 2009b). Excellent chemoselectivity was obtained by the use of the ¹⁸F-labeled pyridine derivative 1-[3-(2-¹⁸F]fluoropyridin-3-yloxy)-pyrrole-2,5-dione ([¹⁸F]FPyME), which was obtained from a three-step synthesis in radiochemical yields of 37% within 110 min (de Bruin et al. 2005). N-[2-(4-¹⁸F]fluorobenzamido)ethyl]maleimide ([¹⁸F]FBEM) is another thiol-reactive prosthetic group, which was synthesized from [¹⁸F]SFB by conversion with the N-(2-aminoethyl)maleimide and used for the conjugation to thiolated cRGD peptides (Cai et al. 2006). The synthesis of [¹⁸F]FBEM could be optimized by starting from protected 4-¹⁸F]fluorobenzoic acid instead of [¹⁸F]SFB (Kramer-Marek et al. 2008) (► Table 42.10).

In order to overcome the time-consuming preparation of the ¹⁸F-prosthetic groups, alternative routes have been investigated. Photochemical conjugation agents, such as 4-azidophenacyl [¹⁸F]fluoride (Wester et al. 1996), 3,5-¹⁸F]difluorophenyl azide (Hashizume et al. 1995), or 3-azido-5-nitrobenzyl-¹⁸F]fluoride (Lange et al. 2002) can be prepared in one step. The “masked” electrophilic aryl nitrenes can be generated from the azides by UV-irradiation. Studies on photochemical conjugation of human serum albumin, transferrin, avidin, fibrinogen (Wester et al. 1996), and an *oligonucleotide* aptamer (Lange et al. 2002) have shown that labeling predominantly occurs at primary amines (lysine side chain or hexylamine modified 5'-aptamer terminus). This assumption is in accordance with the general proposed reaction pathways of aryl nitrenes: phenyl nitrenes mainly react by nucleophilic addition, while polyfluorinated aryl nitrenes mainly react by unspecific insertion (Bayley and Staros 1984; Doering and Odum 1966). Radiochemical conjugation yields of up to 30% can be obtained when using protein concentrations of 0.1–1 mg per 100 µl.

Two studies were carried out on the Pd-catalyzed Sonogashira coupling of alkynes with aryl halides: (1) one-step preparation of an ¹⁸F-labeled alkyne for conjugation of iodoaryl-modified peptides (Poethko, personal communication) and (2) one-step preparation of 4-¹⁸F]iodobenzene for coupling with alkyne-modified compounds (Wüst and Knieß 2003).

Conjugation of N-methyl-N-propargyl-¹⁸F]fluoroacetamide with acetyl-4-iodo phenylalanine as a model for peptides conjugated with, e.g., 4-iodobenzoic acid or bearing 4-iodo-Phe within the peptide chain could only be carried out on the carrier-added level using Pd(OAc)₂/tris(*m*-dimethylguanidinephenyl)phosphine/CuI (molar ratio 1:2:5) in yields up to 80%. Addition of carrier was necessary to enter the catalytic cycle after quantitative formation of a reactive Pd/N-methyl-N-propargyl-¹⁸F]fluoroacetamide intermediate. Thus, the use of Pd(0)-catalysts may overcome this limitation. In contrast, C–C bond formation on the n.c.a. level was achieved by Sonogashira coupling following the reverse route, i.e., coupling of

4-[¹⁸F]iodobenzene to alkynes (Wüst and Knieß 2003). However, the reverse route has not been used for peptide labeling so far.

Chemoselective conjugation of unprotected peptides in aqueous systems by oxime formation was suggested (Poethko et al. 2004; Schottelius et al. 2004; Thumshirn et al. 2003) as a very effective, time-saving, high yield ¹⁸F-labeling method, which is also adaptable to radiohalogenation in general (*radioiodination*, *radiobromination*, and *radioastatination*) (► Figs. 42.25 and ► 42.26).

4-[¹⁸F]fluorobenzaldehyde ([¹⁸F]FBA) was prepared within about 30 min in preparative yields of about 50% using solid-phase extraction cartridges for purification. Conjugation of various oxyamine acetate conjugated peptides (► Figs. 42.25 and ► 42.26) was carried out in H₂O/MeOH (pH 2) in 60–80% yield (10 min) and peptide concentrations of 0.5 mm.

Fig. 42.25

^{18}F -Labeling of unprotected peptides using [^{18}F]fluorobenzaldehyde (Poethko et al. 2004; Schottelius et al. 2004; Thumshirn et al. 2003)

Carbohydrylation and polyethylene glycol linkers were combined with chemoselective conjugation to optimize the pharmacokinetics of the peptides investigated. Oxime formation was successfully adopted for chemoselective ^{18}F -labeling of an aminoxy-modified affibody (Namavari et al. 2008) and a suitable derivative of the hormone leptin (Flavell et al. 2008). Recently, the [^{18}F]FBA synthesis was automated and yielded [^{18}F]FBA after 45 min in radiochemical yields of 54% and radiochemical purity of $\geq 99\%$ after automated cartridge purification (Speranza et al. 2009).

[^{18}F]FBA was also employed for couplings to hydrazine-functionalized peptides and proteins under hydrazone formation (Chang et al. 2005; Bruus-Jensen et al. 2006; Lee et al. 2006). Applied to octreotide and substance P HYNIC-conjugates, this variant gave conjugation yields of the ^{18}F -labeled peptides of up to 85% within 10 min (Bruus-Jensen et al. 2006).

Small ^{18}F -thiols such as the aliphatic [^{18}F]fluoropropane-1-thiol, a PEG3-derivative ([^{18}F]fluoro-PEG3-thiol) and an aromatic system, 4-[^{18}F]Fluoromethyl-N-(2-mercaptoethyl) benzamide, are also useful prosthetic groups, which allow an efficient chemoselective conjugation to N-chloroacetylated peptides (Glaser et al. 2004).

Proteins and peptides generally preclude a direct ^{18}F -labeling approach, due to the load of (unprotected) functional groups and the sensitivity to harsh reaction conditions, such as in ^{18}F -labeling steps usually employed. Nonetheless, Becaude et al. (2009) developed a successful direct ^{18}F -labeling method based on conventional ^{18}F -introduction into model peptides and *bombesin* peptides bearing highly activated aromatic systems such as 3-cyano-trimethyammoniumbenzoyl triflates. The highly activated aromatic systems facilitated an efficient and direct ^{18}F -labeling of the peptides with radiochemical yields of up to 92% under mild reaction conditions. However, this methodology is limited to peptides lacking acidic side chain functionalities.

Recently, a novel ^{18}F -labeling strategy for peptides was developed by McBride et al. (2009). After reacting aqueous [^{18}F]fluoride with aluminum trichloride, the formed [^{18}F]AlF $^{2+}$ was chelated by a NOTA(1,4,7-triazacyclononane-N,N',N''-triacetic acid)-functionalized peptide. The aluminum [^{18}F]fluoride complex showed excellent *in vivo* stability and PET imaging characteristics. This approach was further employed for *NOTA-octreotide*, which allowed fast and efficient ^{18}F -labeling in 45 min by chelator-based radiolabeling with a radiochemical yield of 50% (Laverman et al. 2010). The ^{18}F -labeled *NOTA-octreotide* showed a high stability and no *in vivo* loss or release of either [^{18}F]AlF $^{2+}$ or [^{18}F]F $^{-}$.

¹⁸F-Labeling of unprotected peptides using aldehydes or ketones (here [¹⁸F]fluorobenzaldehyde) for the formation of aldoximes and ketoximes by chemoselective conjugation of oxyamine modified peptides ([¹⁸F]FBOA = 4-[¹⁸F]C₆H₄-CH = NH-O-CH₂-CO) (Poethko et al. 2004; Schottelius et al. 2004; Thumshirn et al. 2003)

42.5 Miscellaneous

42.5.1 Microwave Applications in Radiolabeling

With the aim to reduce reaction times in organic transformations, *microwave dielectric heating* (Gedye et al. 1986; Giguere et al. 1986) is rapidly increasing worldwide. Besides the time gains from simply performing reactions faster, other advantages have been noted, e.g., cleaner reaction mixtures due to decreased sample decomposition and altered product distributions as well as improved chemical flexibility due to the ability to accelerate typically sluggish reactions of less-activated substrates. A review on the use of microwave applications in radiolabeling with short-lived PET radionuclides clearly indicates the advantages compared with conventional heating. The authors of this excellent and comprehensive review (Stone-Elander and Elander 2002) are looking forward to the day when access to application optimized microwave devices in the chemical and radiochemical laboratory is as unquestioned as it is today for applications in the home.

42.5.2 Silicon-Based ¹⁸F-Chemistry

The first study on ¹⁸F-Si compounds was published in 1985 when Rosenthal et al. reported the reaction of chlorotrimethylsilane with [¹⁸F]fluoride in aqueous acetonitrile yielding the corresponding ¹⁸F-Si-compound in radiochemical yields of 65%. Unfortunately, [¹⁸F]fluorotrimethylsilane was found to be hydrolyzed very fast in vivo, and the authors suggested to use sterical hindered ¹⁸F-Si-compounds to avoid hydrolytic loss of [¹⁸F]fluoride. In 2005, Ting et al. described the syntheses of ¹⁸F-labeled biotin derivatives by direct labeling of biotinylated p-aminophenylboronypinacolate and (aminopropyl)triethoxysilane in aqueous solution using target water in the presence of [¹⁸F]KHF₂ in nearly quantitative yields. In aqueous fluoride solution, the ¹⁸F-tetrafluorosilicate was found to be moderately stable whereas the ¹⁸F-trifluoroborate displayed high stability also in serum and blood.

Recently, the concept of isotopic ¹⁹F–¹⁸F exchange at a silicon core was introduced (Schirmacher et al. 2006). The stability of the silicon-¹⁸F bond against hydrolysis was substantially enhanced by connecting bulky substituents such as tert-butyl groups to the ¹⁸F-bearing silicon atom. Di-tert-butyl-phenyl[¹⁸F]fluorosilane, synthesized by reacting the corresponding chlorosilane with [¹⁸F]fluoride in acetonitrile, was found to be extremely stable under physiological conditions.

Since chlorosilanes are unstable and readily hydrolyzed when subjected to aqueous conditions an isotopic exchange reaction using nanomolar quantities of di-tert-butyl-phenyl-¹⁹F-fluorosilane as precursor was tested and evaluated to result at room temperature within 15 min in high radiochemical yields (► Fig. 42.27).

This *silicon-based fluorine acceptor* (SiFA) strategy was transferred to the ¹⁸F-labeling of peptides, e.g., to the N-aminoxy derivatized peptide Tyr3-octreotate coupled to p-(di-tert-butylfluorosilyl) benzaldehyde (95–97% RCY, 10–15 min, rt) with specific activities of 3–5 GBq μmol^{−1}. For the first time, Schirmacher et al. (2007) could demonstrate an unexpectedly efficient isotopic ¹⁹F–¹⁸F exchange, yielded the ¹⁸F-synthon p-(di-tert-butyl[¹⁸F]fluorosilyl) benzaldehyde ([¹⁸F]SiFA-A) in almost quantitative yields in high specific activities between 225 and 680 GBq μmol^{−1} (6,081–18,378 Ci/mmol) without applying HPLC purification (► Fig. 42.28).

■ Fig. 42.27

Silicon-based ^{18}F -Labeling via isotopic ^{19}F – ^{18}F exchange (Schirmacher et al. 2006)

■ Fig. 42.28

Isotopic ^{19}F – ^{18}F exchange for the production of the ^{18}F -labeling synthon $[\text{}^{18}\text{F}]\text{SiFA-A}$ via a silicate intermediate (Schirmacher et al. 2007)

Using this synthon and chemoselective ligation, different N-terminal amino-oxy (N-AO) derivatized peptides, such as AO-Tyr3-octreotate (AO-TATE), *cyclo*(fK(AO-N)RGD), and N-AO-PEG2-[D-Tyr-Gln-Trp-Ala-Val- β Ala-His-Thi-Nle-NH₂] (AO-BZH3, a bombesin derivative) were prepared in high radiochemical yields. The high efficient exchange was explained by a pentacoordinate silicate intermediate dissociating immediately to form the radiolabeled $[\text{}^{18}\text{F}]\text{SiFA-A}$.

Subsequently, ^{18}F -labeled bombesin analogs were prepared using a silicon-based one-step n.c.a. radiolabeling method (Höhne et al. 2008; Mu et al. 2008). Radiolabeling of the peptide precursors conjugated with the di-tert-butyl silyl building block as labeling moiety proceeded smoothly under acidic conditions (34–85% conversion). 2-(4-(di-tert-butyl- $[\text{}^{18}\text{F}]$ fluorosilyl)phenyl)acetyl-Arg-Ava-Gln-Trp-Ala-Val-NMeGly-His-Sta-Leu-NH₂ showed no significant degradation *ex vitro* and *in vitro*.

Further ^{18}F -labeled bifunctional triorganofluorosilane synthons, allowing for the introduction of $[\text{}^{18}\text{F}]$ fluoride and conjugation to peptides or proteins, such as *t*Bu₂-(*p*-HS-C₆H₄)Si ^{18}F , the corresponding isothiocyanato, isocyanato, aniline, maleimide, and activated ester derivatives were synthesized and evaluated, e.g., on model proteins (Iovkova et al. 2009).

By means of one of these synthons, 4-(di-tert-butyl $[\text{}^{18}\text{F}]$ fluorosilyl)benzenethiol (Si $[\text{}^{18}\text{F}]$ FASH), prepared by isotopic exchange in 40–60% radiochemical yield and subsequent coupling to a maleimide conjugate of serum albumin, an overall radiochemical yield of 12% was obtained within in overall synthesis time of 20–30 min (Wängler et al. 2009b).

Since, as mentioned before, the hydrolytic stability of the silicon–fluorine bond is determined by the nature of the substituents on silicon, a theoretical model of organofluorosilane hydrolysis was developed by means of density functional theory (DFT) methods. As concluded by the authors (Höhne et al. 2009), the calculation of the difference of Si–F bond lengths between optimized structures of the starting material and the intermediate structure allows the

estimation of the hydrolytic stability of newly designed compounds and thus will facilitate the development of improved building blocks for the synthesis of novel ^{18}F -silyl-modified biomolecules (Höhne et al. 2009).

Bohn et al. (2009) reported on a first study on the design of “small-sized” tracers for imaging tissue hypoxia. Using formal alkyloxy-trialkyl and alkoxy-alkyl-diarylsilane precursors of misonidazole, and a mixture of K^{18}F and Kryptofix 2.2.2 in acetonitrile, the ^{18}F -labeled silicon-based misonidazole analogs were easily synthesized (Bohn et al. 2009).

In conclusion, the next years will show whether the silicon-based ^{18}F -labeling approach and the very promising results obtained during the last 3 years will open a new class of radiopharmaceuticals.

42.5.3 Enzymatic Reactions

Although a variety of approaches to the *enzymatic synthesis* of ^{11}C -labeled compounds were described in the literature, only a few examples were investigated so far with respect to ^{18}F -labeled radiopharmaceuticals. Enzymatic reactions mostly occur under mild conditions with high efficiency and selectivity, and enzymes can be immobilized on appropriate solid phase for easy recovery and labeled products and for repeated use of the enzymes.

Liu et al. (1998) used dopamine- β -hydroxylase ($\text{D}\beta\text{H}$) to stereospecifically synthesize R-(-)-6- ^{18}F fluoronorepinephrine (6- ^{18}F FNE) (► Fig. 42.29a) from 6- ^{18}F fluorodopamine in the presence of ascorbate, sodium fumarate, and catalase in 2 M sodium acetate buffer at 37°C .

Koneko et al. (1999) developed a synthesis for 6- ^{18}F FDOPA (► Fig. 42.29b). The 4- ^{18}F fluorocatechol was prepared by nucleophilic aromatic substitution of the nitro group on 6-nitroveratryl aldehyde followed by decarbonylation with tris(triphenylphosphine) rhodium(I) chloride and hydrolysis (9.2% yield). 6- ^{18}F FDOPA was then prepared from the 4- ^{18}F fluorocatechol by a β -tyrosinase catalyzed reaction in the presence of ammonium, pyruvate, and ascorbate in an ethanolic Tris-HCl buffer within 5 min in about 60% radiochemical yield without any isomers.

■ Fig. 42.29

Enzymatic synthesis of R-(-)-6- ^{18}F fluoronorepinephrine (6- ^{18}F FNE) (a) and 6- ^{18}F FDOPA (b)

The enzyme *fluorinase* (5'-fluoro-5'-deoxyadenosine synthase) was applied to convert S-adenosyl-L-methionine (SAM) and [^{18}F]fluoride directly into 5'-[^{18}F]fluoro-5'-deoxyadenosine (5'-[^{18}F]FDA) (► Fig. 42.30a) and L-methionine, which was the first example where a radionuclide was enzymatically introduced into an organic molecule (Martarello et al. 2003). In this approach, the native wildtype fluorinase deriving from *Streptomyces cattleya* was employed in low concentrations ($\mu\text{g ml}^{-1}$) and generated only very low radiochemical yields of $\sim 1\%$. Better conversions of $\sim 20\text{--}25\%$ were achieved by the use of higher fluorinase concentrations (mg/ml), which became available by fluorinase over-expressing cloned *Escherichia coli* (Deng et al. 2006).

The aspect of a reversible reaction of fluorinase was of major importance for further optimizations and by addition of the enzyme L-amino acid oxidase (L-AAO) the oxidative removal of formed L-methionine was enabled. In this way, the equilibrium of the reaction was pulled toward 5'-[^{18}F]FDA and allowed very high radiochemical yields of 95% within 1–2 h. Accordingly, the ^{18}F -labeled compounds 5'-[^{18}F]fluoro-5'-deoxyinosine (5'-[^{18}F]FDI) (► Fig. 42.30b), 5'-[^{18}F]fluoro-5'-deoxyribose phosphate (► Fig. 42.30c), and 5'-[^{18}F]fluoro-5'-deoxyribose (► Fig. 42.30d) were successfully produced from 5'-[^{18}F]fluoro-5'-deoxyadenosine (Deng et al. 2006, Onega et al. 2009, 2010). In the “base-swap” strategy, the 5'-[^{18}F]fluoro-5'-deoxyribose phosphate (► Fig. 42.30c) could be further transformed into

■ Fig. 42.30

Direct enzymatic ^{18}F -labeling of 5'-[^{18}F]fluoro-5'-deoxyadenosine (5'-[^{18}F]FDA) (a) using the enzyme fluorinase and subsequent enzymatic conversions into 5'-[^{18}F]fluoro-5'-deoxyinosine (5'-[^{18}F]FDI) (b), 5'-[^{18}F]fluoro-5'-deoxyribose phosphate (c), 5'-[^{18}F]fluoro-5'-deoxyribose (d), and diverse ^{18}F -labeled pyrimidine nucleosides (e) (Deng et al. 2006; Winkler et al. 2008; Onega et al. 2009, 2010)

various ¹⁸F-labeled pyrimidine nucleosides by the use of the appropriate pyrimidine phosphorylase and the pyrimidine base in a one-pot procedure (Winkler et al. 2008).

42.5.4 Electrochemical Cells

Especially with respect to the use of no-carrier-added amounts of radioisotopes (fmol to nmol range), radionuclide “extraction” by means of an electrical field, e.g., the *anodic disposition* of [¹⁸F]fluoride from irradiated ¹⁸O-water seems to be a promising experimental approach. Alexoff et al. (1989) obtained good results concerning the deposition of [¹⁸F]fluoride, but only moderate yields were found for the subsequent recovery. Hamacher and Blessing (1995) designed a more convenient cell, which allows to absorb [¹⁸F]fluoride at the cylindrical surface of a glassy carbon electrode at field strength beyond 100 V/cm. While maintaining a lower electrical field of about 10 V/cm, the fluoride can be dried easily by washing the cell with dry aprotic solvents, making azeotropic drying steps under strong basic conditions unnecessary.

Thus, nucleophilic fluorinations can be carried out under milder conditions in the presence of the less basic cryptate systems such as [K/2.2.2]oxalate and [K/2.2.2]triflate. Nearly quantitative desorption of activity is reached at field strengths of ~8 V/cm (DMF, [K/2.2.2]carbonate system). Using this methodology, the authors synthesized 4-[¹⁸F]fluorobenzaldehyde, 4-[¹⁸F]fluoronitrobenzene, 2-[¹⁸F]fluorotosyloxyethane, and 1,3,4,6-tetra-O-acetyl-2-[¹⁸F]FDG in radiochemical yields of 97%, 98%, 56%, and 85%, respectively ([K/2.2.2]carbonate system) (Hamacher et al. 2002).

42.5.5 Automated Radiosyntheses and Flow Chemistry

Semiautomated and automated processes have always been tried to be implemented into ¹⁸F-labeling methods or syntheses. Such systems allow keeping the radiation dose to the operative personnel at a minimum and allow routine productions for clinical applications to comply with General Manufacturing Practise (GMP) regulations. Furthermore, automated reaction steps or procedures generally are more reliable and thus more reproducible than manual radiosyntheses. In addition, automated processes often save time and therefore enhance product yields and efficiency. Today, the radiosyntheses of almost all routine ¹⁸F-tracers are fully automated and are performed in commercially available modules or systems (Satyamurthy et al. 1999; Alexoff 2003).

In recent years, new approaches using *microreactors* and *microfluidic flow chemistry* have been employed for ¹⁸F-labeling (Lu et al. 2004; Lee et al. 2005; Gillies et al. 2006; Steel et al. 2007; Elizarov 2009). Such microscale reactions especially benefit from very small amounts of precursors, fast reaction kinetics, and very high radiochemical yields. The first systems have proven applicability and have shown promising results for the production of [¹⁸F]FDG and some other ¹⁸F-labeled compounds and tracers (Lu et al. 2004; Lee et al. 2005; Gillies et al. 2006; Steel et al. 2007; Wester et al. 2008; Elizarov 2009). One special challenge of such system is the drying and activation of the [¹⁸F]fluoride from the target water. In several systems, the [¹⁸F]fluoride was dried externally in conventional reaction vessels, mixed with an appropriate phase transfer catalyst and solvent, and then transferred into a microreactor or flow chemistry device for the ¹⁸F-labeling and subsequent reaction steps. Some miniaturized devices already

include a drying system such as a miniaturized anion exchanger column (Lee et al. 2005) or an electrochemical microreactor system based on electrochemical separation and drying (Elizarov et al. 2010).

The development of miniaturized devices for ¹⁸F-labeling is still in progress, but the proof-of-principle has already been made with several systems. The obvious advantages of such approaches will promote the development toward routinely running microreactors or microfluidic devices for routine ¹⁸F-labeling.

43 ^{99m}Tc : Labeling Chemistry and Labeled Compounds

R. Alberto¹ · U. Abram²

¹University of Zurich, Zürich, Switzerland

²Freie Universität Berlin, Berlin, Germany

43.1	<i>Introduction</i>	2074
43.2	<i>General Requirements for the Application of ^{99m}Tc-Radiopharmaceuticals</i>	2077
43.2.1	Requirements from Chemistry/Physics	2077
43.2.2	Requirements from Routine Applications	2078
43.2.3	Requirements from the Market	2080
43.3	<i>Commercial ^{99m}Tc-Radiopharmaceuticals</i>	2081
43.3.1	Myocardial Imaging Agents	2081
43.3.2	Cerebral Blood Flow Agents	2084
43.3.3	Agents for Renal Function	2087
43.3.4	Agents for Other Applications	2089
43.4	<i>Different Types (Generations) of ^{99m}Tc-Radiopharmaceuticals</i>	2090
43.4.1	Perfusion Agents	2090
43.4.2	Receptor-Specific Molecules	2091
43.4.3	Inhibitors	2091
43.5	<i>Strategies for the Labeling of Targeting Molecules</i>	2092
43.5.1	Bifunctional Chelator Approach	2092
43.5.2	Direct Labeling Approach	2100
43.5.3	Integrated Approach	2101
43.6	<i>Developments in the Labeling of Targeting Molecules</i>	2102
43.6.1	Antibodies/Peptides	2102
43.6.2	Neuroreceptor Targeting Molecules	2104
43.6.3	Myocardial Imaging Agents	2108
43.6.4	Vitamins: Folate, Biotin, and B12	2110

43.7	<i>Recent Developments and Future Role of ^{99m}Tc-Radiopharmaceuticals</i>	2113

Abstract: This chapter reviews the radiopharmaceutical chemistry of technetium related to the synthesis of perfusion agents and to the labeling of receptor-binding biomolecules. To understand the limitations of technetium chemistry imposed by future application of the complexes in nuclear medicine, an introductory section analyzes the compulsory requirements to be considered when facing the incentive of introducing a novel radiopharmaceutical into the market. Requirements from chemistry, routine application, and market are discussed. In a subsequent section, commercially available ^{99m}Tc-based radiopharmaceuticals are treated. It covers the complexes in use for imaging the most important target organs such as heart, brain, or kidney. The commercially available radiopharmaceuticals fulfill the requirements outlined earlier and are discussed with this background. In a following section, the properties and perspectives of the different generations of radiopharmaceuticals are described in a general way, covering characteristics for perfusion agents and for receptor-specific molecules. Technetium chemistry for the synthesis of perfusion agents and the different labeling approaches for target-specific biomolecules are summarized. The review comprises a general introduction to the common approaches currently in use, employing the N_xS_{4-x}, [3+1] and 2-hydrazino-nicotinic acid (HYNIC) method as well as more recent strategies such as the carbonyl and the TcN approach. Direct labeling without the need of a bifunctional chelator is briefly reviewed as well. More particularly, recent developments in the labeling of concrete targeting molecules, the second generation of radiopharmaceuticals, is then discussed and prominent examples with antibodies/peptides, neuroreceptor targeting small molecules, myocardial imaging agents, vitamins, thymidine, and complexes relevant to multidrug resistance are given. In addition, a new approach toward peptide drug development is described. The section has a focus on coordination and labeling chemistry, but biological results are briefly summarized as well. The last (and shortest) section finally intends to give a (subjective) outlook for the future role of ^{99m}Tc-based radiopharmaceuticals. Critical comments are spread over the whole article but are concentrated in this section. Despite the increasing competition of diagnostic radiopharmacy by other commonly applied methods in medicine such as magnetic resonance imaging (MRI) or ultrasound, the authors are convinced that ^{99m}Tc will play a key role also in future if novel approaches are added and the requirements from chemistry biology and the market considered in research to a stronger extent.

43.1 Introduction

The reason for the strong interest in technetium chemistry is essentially based not only on the very favorable decay characteristics of ^{99m}Tc, but also on the very convenient availability of this radionuclide from so-called ⁹⁹Mo/^{99m}Tc generator systems. Favorable decay properties such as half-life time and energy of radiation is an absolute prerequisite for routine application, but price and availability have to be considered more and more as limiting factors. At present, about 80% of all routine applications in diagnostic nuclear medicine are performed with ^{99m}Tc. For many investigations, radiopharmaceuticals can be produced at a reasonable price and the radionuclide ^{99m}Tc is readily available at the moment of demand from a generator. This online availability is a strong “pro” for ^{99m}Tc over cyclotron-produced positron emission tomography (PET) nuclides that are in general not readily available. Such ⁹⁹Mo/^{99m}Tc generators can commercially be purchased from several sources. They allow the physicians to prepare the radiopharmaceutical for a particular diagnostic study in an instant kit when required.

Furthermore, the generators are inexpensive and the price for an investigation is low, a feature becoming more and more important in contemporary health care. The principle of the ⁹⁹Mo/^{99m}Tc generator and some physicochemical aspects will be described in this section.

Historically, the first injection of [^{99m}TcO₄][−] was performed as early as 1961. This was followed by the development of the so-called Brookhaven generator, a principle that has already been described earlier (Richards 1960; Tucker et al. 1958). Subsequently, the use of ^{99m}Tc in diagnostic medicine increased exponentially. The Brookhaven generator, a principle still maintained, consists of a column that contains activated alumina as the stationary phase. This alumina is acidified and loaded with a solution of ⁹⁹Mo in the form of molybdate. In slightly acidic solution, the molybdate anion polymerizes to form a stable heteropolymer Al[Mo₆O₂₄]^{9−} that is strongly adsorbed on the column (Cotton and Wilkinson 1988; Lebedeva and Kyong 1968). This molybdate contains the parent radionuclide ⁹⁹Mo, which upon decay generates ^{99m}Tc. If the molybdate is a fission product, the total amount of molybdenum loaded onto the column is very small and very high specific activities in the range of 10⁴ Ci/g (370 TBq/g) are present. To produce no-carrier-added ⁹⁹Mo generators from products of ²³⁵U fission, many purification steps are required to make sure complete separation from other fission products. An alternative and cheaper method consists in the neutron activation of ⁹⁸Mo-enriched targets in a reactor with thermal neutrons. However, since the thermal neutron cross section of ⁹⁸Mo is only 0.13 barn, the specific activity of ⁹⁹Mo produced in that way is as low as a few Ci/g (100 GBq/g). Many milligrams of carrier ^{98/99}Mo have to be loaded onto the column, but still result in comparably low activity generators.

The ⁹⁹Mo decays with a half-life of 67 h to ^{99m}Tc. The decay yields about 87% of ^{99m}Tc and about 13% decays directly to ground state ⁹⁹Tc. About 10% of the photons are furthermore lost by internal conversion yielding electron emission from the electron shells instead of γ-quanta. Since the half-life of ^{99m}Tc is about 6 h, the system ⁹⁹Mo/^{99m}Tc is a classical parent–daughter system that can quantitatively be treated as a transient equilibrium. The activity of ^{99m}Tc approaches the one of ⁹⁹Mo left in the generator and is at equilibrium about 96.25% of that of ⁹⁹Mo. The radionuclide ^{99m}Tc is present in the form of [^{99m}TcO₄][−] and remains adsorbed on the column. It could be expected that ^{99m}Tc changes its chemical composition by the recoil received upon decay of ⁹⁹Mo but the β-decay is of not sufficient energy to change the chemical environment as is for example the case in Szilard–Chalmers (n,γ) reactions. It has even been shown with low-valency ⁹⁹Mo complexes, that the β-decay gave in very good yield the corresponding ^{99(m)}Tc complex (Baumgärtner 1961; Baumgärtner et al. 1962). In the past, problems with the amount of ^{99m}Tc elution from the generator occurred since [^{99m}TcO₄][−] was reduced to [^{99m}TcO₄]^{2−} by the ubiquitous electrons from the β-decay. The dianion [^{99m}TcO₄]^{2−} remained adsorbed on the column and significantly reduced the amount of activity but these problems are nowadays essentially eliminated in the products offered by the companies. Before or at saturation, [^{99m}TcO₄][−] is then displaced by the anions from an electrolyte that is flushed through the column and eluted into a corresponding vial, “milking the generator” is a common expression for this procedure. Since [^{99m}TcO₄][−] does not form polymers (in contrast to molybdate), it is replaced on the stationary phase by the monoanions from the electrolyte. Typically, the electrolyte is saline (0.9% NaCl in bidistilled water), which allows quantitative removal of [^{99m}TcO₄][−]. Other electrolytes are possible as well, but special attention has to be paid that the electrolyte does not induce release of molybdate from the column.

The eluate contains, beside [^{99m}TcO₄][−], the ground state [⁹⁹TcO₄][−] as a carrier, which is produced from the 13% direct decay but also from decay of [^{99m}TcO₄][−] → [⁹⁹TcO₄][−].

The longer the time period between two elutions, the higher is the content of “cold” $[\text{}^{99}\text{TcO}_4]^-$. In general, the eluate is considered as “no carrier added” (*n.c.a.*), but the direct decay to ^{99}Tc and the decay of $^{99m}\text{Tc} \rightarrow ^{99}\text{Tc}$ leads to a certain dilution with the carrier ^{99}Tc . This has to be considered in the calculations of the specific activity of ^{99m}Tc . Depending on the time period since the last elution, the concentration of the carrier ^{99}Tc can be several factors higher than the actual ^{99m}Tc concentration (see later in this section). These eluates are then the material for the subsequent syntheses of radiopharmaceuticals. The exclusive availability of $[\text{}^{99m}\text{TcO}_4]^-$ in saline explains why any useful chemistry has ultimately to be carried out in this media.

Generators are available in many sizes and activities as high as 37 GBq/ml are possible. Appropriate use of the generators yields products according to international standards. Problems are mainly encountered by so-called breakthrough of ^{99}Mo or by contamination with alumina from the column materials. Eluates have furthermore to be sterile and pyrogen-free. The maximum contaminants in a typical eluate have been regulated under the assumption that ^{99m}Tc is applied within 12 h after the elution.

A very important issue in the application of ^{99m}Tc radiopharmaceuticals is the analysis of the synthesized compound not only in terms of radiochemical purity, but also in regard of its chemical characterization. A novel compound needs to be thoroughly analyzed and characterized in order to be approved by the governmental agencies. As mentioned earlier, the absolute concentration of ^{99m}Tc in a typical eluate is between 10^{-8} and 10^{-6} M. For example, eluting 1 Ci (37 GBq) of ^{99m}Tc in 10 ml of saline 12 h after the last elution results in a solution that is about 0.2 μM in ^{99m}Tc and 0.35 μM in ^{99}Tc , corresponding to about 0.6 μg of Tc in total. For such a small amount of material (and compound) it is essentially impossible to perform a classical chemical analysis. The only way to assess the chemical structure of a novel radiopharmaceutical is then by chromatographic comparison with a surrogate prepared either with rhenium or with long-lived ^{99}Tc . Comparison is performed by chromatography such as thin-layer chromatography (TLC) or high performance liquid chromatography (HPLC). If coinjection of macroscopic amounts of cold compound and the corresponding *n.c.a.* complex ^{99m}Tc exhibits the same retention time, it is accepted that the two compounds are chemically identical. It is, however, not always possible to synthesize (and characterize) the cold complex for thermodynamic or kinetic reasons. This is for instance the case with the important class of technetium-labeled diethylenetriamine pentaacetate (Tc-DTPA) complexes (see ▶ Sect. 43.3.3), which chemical identity could still not be deciphered unambiguously. In the context of peptide labeling by the HYNIC method (see ▶ Sect. 43.5.1) a similar situation is encountered. The structure of the label is unknown and can only be anticipated on experience with related model systems. Clearly, the non-applicability of classical chemical analysis in the context of ^{99m}Tc chemistry is a disadvantage but is also found with other radiopharmaceutically relevant radionuclides. Chromatographic comparison is the only way of indirect analysis. For a few examples, it was possible to detect the mass of a complex directly by means of electrospray ionization liquid chromatography-mass spectrometry (LC-MS). Electrospray ionization-mass spectrometry (ESI-MS) is a very powerful tool to analyze small amounts of material and it was indeed possible to apply the method for unknown radiopharmaceuticals. Still, mass spectrometry is not a quantitative method and it is difficult to conclude unambiguously for the composition of a complex based on its mass number only.

In conclusion, the availability of generators in the context of ^{99m}Tc is a relevant requirement for future development of novel radiopharmaceuticals. Since costs have to be considered, online availability at a very cheap price might define in future, which radionuclides will remain on the market. Though the chemistry is likely to be successful, it is not always available, but is

ideal for ^{99m}Tc. Generator systems are also available for a number of other radionuclides. These are discussed elsewhere in this book.

43.2 General Requirements for the Application of ^{99m}Tc-Radiopharmaceuticals

This section focuses on recent developments in the coordination chemistry of technetium as relevant for radiopharmaceutical applications either for the labeling of biomolecules or for the preparation of radiopharmaceutically active complexes. The radionuclide ^{99m}Tc is still the workhorse in nuclear medicine clearly due to its favorable decay properties and its low price and its availability from generators. These advantages are combined with the disadvantages that result from the transition element nature of technetium, which means that it has to be applied in combination with a chelating agent. Obviously, a basic understanding of coordination chemistry or organometallic chemistry of technetium is a very important requirement for the design of novel radiopharmaceuticals.

43.2.1 Requirements from Chemistry/Physics

The position of technetium in the periodic table allows easily the prediction that it has an extremely rich coordination chemistry with compounds available in many oxidation states and with all type of ligands depending on the particular valency. Technetium is approximately in the middle of the transition metal series, and, according to its position, does so far not have an aquo-ion as in case of indium for instance. Technetium for radiopharmaceutical syntheses is furthermore exclusively available in one of its thermodynamic most stable form as [^{99m}TcO₄][−]. Therefore, the application of ^{99m}Tc radiopharmaceuticals always requires a reduction to a lower oxidation state. The reduction can go along with the concomitant labeling or the formation of a particular complex or can comprise the intermediate formation of a stabilized complex that is then substituted by the final chelator. Both pathways are known in radiopharmaceutical chemistry and very often both pathways might occur concertedly in the application of ^{99m}Tc radiopharmaceuticals. Lower oxidation states tend to disproportionate, which is the major pathway of decomposition of a complex. At the carrier-added level with ^{99g}Tc, Tc(VI) disproportionates to Tc(VII) and Tc(V) and the latter one decomposes to Tc(VII) and Tc(IV). Tc(IV) forms in general polymeric TcO₂ (with a rutil-type structure). Obviously disproportionation is not very likely in case of ^{99m}Tc since the solutions are in general too dilute. However, in these dilute systems, oxidation to [^{99m}TcO₄][−] with traces of O₂ is the general decomposition process if the metal is not sufficiently stabilized with a chelator. Even a chelator is sometimes not enough since decomposition pathways are not only a thermodynamic but also a mechanistic question. TcO₂ for instance is very stable with ⁹⁹Tc in the presence of air, whereas supposed ^{99m}TcO₂ is rapidly reoxidized. The same is true for coordination compounds, although some are very stable against decomposition and find application as radiopharmaceuticals. Chemical stability is a clear requirement. As a consequence, it is obvious that kinetic stability is superior over thermodynamic stability. At high dilution and under nonequilibrium conditions, a very slow decomposition reaction is crucial for applicability of the corresponding compound. Thermodynamically stable but kinetically unstable compounds are produced, in particular if follow-up reactions are coupled to the fast equilibrium, which

interfere with the reverse reaction. The design of closed shell complexes is probably an important physicochemical requirement for a successful development and application of ^{99m}Tc radiopharmaceuticals. Some of the most successful radiopharmaceuticals discussed later in this chapter clearly demonstrate the impact of this argument. High thermodynamic stability combined with low activation barrier is not possible for a radiopharmaceutical, whereas low (even very low) thermodynamic stability in combination with a very robust nature is a preferable combination.

A further requirement beside chemical stability under biological conditions is chemical purity. To be applied as a radiopharmaceutical, the reaction must end up with reproducible purity of better than 98%. This has some impact on the complexes and ligands to be chosen. Since the conditions for the preparation of a radiopharmaceutical in routine use can change, the compound must be formed reliably on a range of parameters. Therefore, the product should be in general a thermodynamic or kinetic trap. This limits the type of ligands considered as useful to multidentate chelators with donating groups matching the valency to be stabilized or the electronic state to d^3 or d^6 . These requirements do not let an extended choice in combinations and indeed the ligands applied so far are more or less similar. The exceptions to this rule are again kinetically stable compounds in which monodentate ligands are sufficient for stabilization. Still, ligands of lower denticity have to fit the aimed valency – isocyanides, carbonyls, and thioether are examples. Although the first ligand type is known to thermodynamically stabilize a broader range of oxidation states, only the one in which most robust complexes are formed is found.

Redox inactive behavior is a further requirement although this characteristic is sometimes not easily to be satisfied. Reduction processes are a particular problem. This essential demand turned out to be a problem in the development of cationic complexes for heart imaging. It could be shown with some Tc(III) phosphine complexes that they are not decomposed in a chemical sense but are reduced to a lower oxidation state and correspondingly been deactivated. Thus, it is highly important that the redox chemistry of technetium complexes is investigated in detail prior to biological studies. Sometimes even a good redox potential does not prevent from being reduced by certain enzymes.

Finally, the occurrence of one and only one stereoisomer is an important chemical requirement. The formation of isomers upon, e.g., the reconstitution of cold kits can be connected to the properties of the metal fragment the ligand coordinates to and/or to the ligand as such. It is difficult to predict whether different complex isomers such as stereoisomers, enantiomers, diastereomers, and others will exhibit a comparable biological behavior and, thus, lead to a useful radiopharmaceutical. It has been shown and will be discussed later in this text that even enantiomers can alter the bioactivity of the vectors they are linked to in a significant way.

43.2.2 Requirements from Routine Applications

The preparation of a radiopharmaceutical in routine application is usually done in a one- or two-step procedure.  [Figure 43.1](#) gives in the context of coordination chemistry later an overview of the different processes for the production of a radiopharmaceutical in relation to the required fundamental coordination chemistry. Perfusion agents such as pure complexes can be prepared in most cases in one single step upon kit reconstitution. The kit is a vial that contains all the ingredients necessary for performing the chemical reaction to form the

Fig. 43.1

Major pathways toward new complexes and radiopharmaceuticals (i) synthesis of reactive precursor complexes, any condition; (ii) coordination chemistry, new compounds, any condition; (iii) synthesis, characterization of stabilized complexes, water/air stability, serum stability, in vivo behavior, if promising; (iv) one pot kit-based preparation in saline \rightarrow nontargeting perfusion agent; (v) bifunctionalization, if favorable in vivo behavior; (vi) covalent coupling to targeting biomolecule; (vii) labeling under any condition, purification, assessment of in vivo behavior, affinity, stability, etc. (viii) if good biological properties, labeling in one step in saline \rightarrow new targeting radiopharmaceutical with pendant metal complex (pendant, postlabeling approach) (ix) if (viii) not possible, synthesis of complex and coupling to biomolecule, not preferred but possible, two-step prelabeling approach. (xi) Functionalities in the biomolecule are used for labeling, i.e., disulfide bridges are reduced and coordinate to Tc \rightarrow integrated approach, structure often not very well known. Steps (i) through (v) are crucial prerequisites from coordination or organometallic chemistry for the development of novel radiopharmaceuticals

complex in >98% yield. The preparation can be done at room temperature or in boiling water, while other conditions are not convenient for routine application. Obviously, the preparation of the complex or the labeled biomolecule must be performed in aqueous solution, since the generator elute is a saline solution. Other solvents in the cold kit are not feasible. The full preparation from water limits the possibilities of complexes that could be provided by the coordination chemistry. The cold kits contain reductant, antioxidants, buffers, ligands, and stabilizers that must be either destroyed after the preparation or being nontoxic. After the reconstitution of the cold kit with $[\text{}^{99m}\text{TcO}_4]^-$, the product should in principle be ready to be administered to the patient.

The situation presents slightly differently in the case of labeling biomolecules to yield then the corresponding radiopharmaceutical vectors. Here the composition of the cold kit and the biomolecule are often not compatible. A reducing agent such as Sn^{2+} interferes, e.g., with the disulfide bond often encountered in antibodies or peptides. Higher temperatures to be applied for complex formation are not compatible as well since certain biomolecules retain their bioactivity only in a small temperature and pH range. In such cases it is feasible that a precursor complex is prepared separately in a first step according to the requirements outlined above and is then mixed with the biomolecule to be labeled in a second step. For this second vial the same requirements are valid. Again, like in simple complex formation, the labeling must occur in >98% yield and the labeled biomolecule must have the same properties as the corresponding complex. Such “precursor kits” are for instance the glucoheptonate kits in which Tc(V) is stabilized by some weak ligands, which are present in large excess to sufficiently stabilize the Tc(V) center for a convenient time period during which the actual labeling process occurs. These different approaches are depicted in ► Fig. 43.1.

Quality control of the once prepared radiopharmaceutical is important, in particular for therapeutic agents. A chromatographic system must be available that allows a quantitative characterization of the compound. This is usually a TLC method that allows assessment of quality within a reasonable short period of time.

43.2.3 Requirements from the Market

Requirements from the market are not only a scientific aspect but to a large extent also commercial. Following this philosophy, only radiopharmaceuticals that target at diseases concerning a large number of patients will seriously be introduced in the market. This concerns in particular all types of radiopharmaceuticals for cancer diagnosis and therapy, and also myocardial imaging agents. Inflammations and infections represent also an important field in which ^{99m}Tc radiopharmaceuticals could play a future role. Commercial radiopharmaceutical must be cheap and provide an added value over other more and more competing techniques such as MRI or ultrasound although the latter two are not particular methods for functional imaging.

The most important requirement that has to be met before ^{99m}Tc -radiopharmaceuticals can be used routinely in Nuclear Medicine is to have a registration file approved. For all radiopharmaceuticals, extensive information on the “active ingredient” (=the ^{99m}Tc -compound) is to be provided, including data on the exact chemical structure, the analytical methods to proof its purity and identity, the method to produce it from the precursor “kit,” batch data, etc. Another very important aspect of the registration file is the ADME (administration, distribution, metabolism, excretion) part, where especially the metabolic fate of the

^{99m}Tc compound after administration may need major analytical-chemical studies. Furthermore, toxicological (including carcinogenicity and mutagenicity) studies are warranted; although the extent of these studies is clearly less than with “normal” drugs, the different aspects of the administration of a radioactive compound needs to be discussed extensively. The clinical section (including the dosimetry of the compound after administration) needs to contain proof that the ^{99m}Tc compound is a safe and effective compound for the diagnostic uses envisioned. Total costs of these investigations, plus the administrative effort to present it in a readable format, are often several million euros; the sheer costs of the registration effort may therefore hamper the possible registration of ^{99m}Tc compounds for a clinical indication where relatively few patients are involved. Often it takes 3–6 years before a new ^{99m}Tc-radiopharmaceutical is fully accepted by all users.

43.3 Commercial ^{99m}Tc-Radiopharmaceuticals

A number of excellent reviews on radiopharmaceuticals appeared recently covering some of the topics outlined in the following sections (Dilworth and Parrott 1998; Jurisson and Lxdon 1999; Liu and Edwards 1999).

43.3.1 Myocardial Imaging Agents

The biological behavior of myocardial imaging agents has excellently been reviewed in particular in respect of the mechanism of myocardial uptake, the relationship between myocardial blood flow and radiotracer uptake, and redistribution of the tracers (Jain 1999).

Radiopharmaceuticals with ^{99m}Tc for the noninvasive diagnosis of myocardial diseases have significantly progressed during the past decade. This is due to the fact that some excellent and convenient radiopharmaceuticals (see below) are commercially available and in addition there is a large market for such compounds. Myocardial perfusion agents such as sestamibi (*Cardiolite*[®] DuPont) provide important prognostic information about diagnostic evaluation or prognostic stratification for patients with known or suspected coronary artery disease. Although some excellent compounds are on the market, there are still limitations for these compounds and ongoing research in this field mirrors the high interest and potential of developing novel radiopharmaceuticals for the diagnosis of myocardial diseases. Originally, it was postulated that monocationic and lipophilic metal complexes or cations should accumulate in the heart tissue, following the Na⁺/K⁺ATPase mechanism as K⁺ mimics. This conceptual framework seemed to be confirmed by the fact that ²⁰¹Tl⁺, introduced in the mid-1970s, allowed for the first time to image patients with coronary artery disease (Kaul et al. 1986; Wackers et al. 1976). The mechanism of uptake into the myocytes is indeed via the Na⁺/K⁺ATP pump (Sands et al. 1985). Despite this success, ²⁰¹Tl⁺ has rather unfavorable decay characteristics: its half-life is 73 h and the decay energy is 70–80 keV, far from being optimal for good imaging. Furthermore, due to the long physiological half-life of about 10 days, a high dose is burden to the patient. The search for monocationic agents mimicking K⁺ was even more stimulated when it was found that Tc(III) complexes with phosphine ligands showed good accumulation in the heart of animals (Deutsch et al. 1981a, b; Hom et al. 1996; Kung et al. 1997), (Meegalla et al. 1997). Unfortunately, images obtained with these compounds were of very poor quality in humans and not suitable for reasonable imaging. This

behavior was later explained by the conversion of the cationic Tc(III) complex into a neutral Tc(II) complex through in vivo reduction (Deutsch et al. 1989). The reduced form is washed out rapidly from the heart and accumulates in the liver. After these early findings, many approaches were pursued to reduce the oxidation potential of Tc(III) compounds and a number of other cationic complexes have been investigated. Loss of susceptibility toward reduction was achieved by, e.g., exchanging the phosphines in $[\text{Tc}(\text{P}(\text{O})\text{P})_2\text{Cl}_2]^+$ by diars (diars = o-phenylenebis(dimethylarsine)) and the halides by thiولات to yield complexes of the form $[\text{Tc}(\text{diars})_2(\text{SR})_2]^+$. A wide range of such cationic complexes has been investigated. Although many of them showed reasonable myocardial uptake, they failed from sufficiently rapid washout from the other organs, resulting in images of bad quality and high heart/background ratio. Beside the phosphines and arsine complexes tested for this purpose, organometallic bis-arene and hexakis phosphite Tc(I) complexes are worthwhile to be mentioned (Wester et al. 1987). A real breakthrough in the development of myocardial imaging agents was achieved by changing from redox active oxidation states +V or +III to redox inactive oxidation state +I. Compounds of composition $[\text{}^{99\text{m}}\text{Tc}(\text{CN-R})_6]^+$ have six identical isonitrile ligands, and can be synthesized in one step from $[\text{}^{99\text{m}}\text{TcO}_4]^-$. The original synthesis goes back to 1984 and the compound is commercially available and in extensive clinical use since about 1992 (Abrams et al. 1983; Jones et al. 1984). This complex lead structure $[\text{}^{99\text{m}}\text{Tc}(\text{CN-R})_6]^+$ allows very convenient fine-tuning of the biological properties and a wide variety of residues have been subjected to structure–activity relationships (Holman et al. 1987; Sia et al. 1986). Among the compounds tested, the ligand methoxy-isobutyl-isonitrile (MIBI) showed the most favorable behavior and the complex $[\text{Tc}(\text{MIBI})_6]^+$ (sestamibi, *Cardiolite*®, DuPont) has nowadays replaced $^{201}\text{Tl}^+$ completely and became the market leader (Holman et al. 1987; Sia et al. 1986; Wackers et al. 1989). The preparation of $[\text{Tc}(\text{MIBI})_6]^+$ clearly mirrors the requirements from routine application. Since the isonitriles are usually very volatile compounds, they cannot be lyophilized. Instead, MIBI is coordinated in the kit formulation to Cu(I) to form $[\text{Cu}(\text{MIBI})_4]^+$, a complex that stabilizes the free ligand and makes the kit lyophilizable. SnCl_2 serves as the usual reducing agent in this composition. The kit needs boiling to afford quantitative formation of the radiopharmaceutical. After injection, sestamibi rapidly clears from the blood pool and the organs resulting in a good organ-to-background ratio. One percent heart uptake is observed 1 min postinjection, and less than 5% after 5 min. The residence time is reasonable to allow good images and remains at about 1% after 4 h (Narahara et al. 1990).

Attempts to develop non-reducible and cationic Tc(III) complexes with a reasonable in vivo behavior were finally successful with the preparation of a tetradentate Schiff-base (SB4)-containing complex. These compounds of general composition $[\text{Tc}(\text{SB4})(\text{P})_2]^+$ are referred to as Q compounds, a wide series of which were investigated varying in SB4 as well as in the phosphines. The most promising candidate of this series is Tc-Q12; cf. Fig. 43.2. The radiopharmaceutical has undergone clinical evaluation and is known as Tc-*furifosmin* (*Technecard*®, Mallinckrodt Med.). This complex localizes in the heart according to blood flow (Rossetti et al. 1994). The furanone group in the ligand is believed to support rapid blood clearance. The overall in vivo behavior of *Technecard* was found to be similar to sestamibi but shows a faster hepatobiliary clearance (Deutsch et al. 1989). A very nice feature of the kit formulation is the fact, that additional reducing agents such as SnCl_2 are not required since the phosphines are reduced enough to bring the technetium to the oxidation state +III.

From the series of cationic complexes investigated for myocardial imaging a Tc(V) complex containing the $[\text{O}=\text{Tc}=\text{O}]^+$ moiety has been introduced into the market. The study of complexes of general composition $[\text{TcO}_2(\text{P})_4]^+$, where P is an aliphatic phosphine, based on

early observation that they accumulate in heart (Kelly et al. 1990). Subsequently, many phosphines were studied, and it turned out that those bearing an ether residue show the most favorable in vivo properties (Nunn 1992). Among several ether groups containing phosphines, the one called tetrofosmin-encoded P53 was finally found to have the best properties (Lahiri et al. 1989; Libson et al. 1990). The ligand P53 is a bidentate phosphine containing a total of four ether groups per ligand. The complex $[TcO_2(P53)_2]^+$ was launched into the market under the trade name *Myoview*[®] (Nycomed Amersham). In contrast to other phosphine-containing radiopharmaceuticals, reduction takes place in the kit formulation through $SnCl_2$ and the complex forms slowly at room temperature. Good images are recorded 5 min p.i. The major activity is in the gall bladder, whereas liver retention is low (Jain et al. 1993). Consequently, the gall bladder is burdened with the highest radiation dose of all organs. *Myoview* turned out to be one of the most promising myocardial imaging agents. Comparative studies between *Cardiolite* and *Myoview* showed, in particular, that the two compounds are rather complementary than competing since each of the two has special features. Whereas *Cardiolite* allows better differentiation between high and low flow regions, the lower retention time of *Myoview* enables investigation of the same day a patient at stress and at rest (Higley et al. 1993).

A mono-positive charge is not an absolute prerequisite for designing a potential myocardial imaging agent. In fact, the first approved compound was a neutral and highly lipophilic BATO (BATO = boronic acid adducts of technetium dioximes)-type Tc(III) complex. A number of such complexes has been described and the one with cyclohexanedione-bis-dioxime (CDOH2) has been approved and is known as ^{99m}Tc-teboroxime (*CardioteC*[®], Bristol Myers Squibb) (Jurisson et al. 1993; Linder et al. 1990; Linder et al. 1991; Treher et al. 1989). The complex has the formula $[TcCl(CDO)(CDOH)_2(BMe)]$ and is seven-coordinate. The structure comprises three vicinal dioximes. One end of the three dioximes is capped by a B-Me unit which forms a boronic acid ester to the -OH groups of three oximes. The seventh site is coordinated in the solid-state structure by a chloride. Although seven-coordinate Tc(III) complexes are not

uncommon, this unusual composition is reliably produced also on the ^{99m}Tc level by simple reduction of [^{99m}TcO₄][−] with SnCl₂ in the presence of the ligand and methyl-boronic acid. *CardioteC* showed considerable potential for myocardial and brain imaging, and has been registered in Europe and the United States (Jurisson et al. 1993). The in vivo behavior of ^{99m}Tc-teboroxime differs significantly from those of the cationic myocardial imaging agents. It shows very high and rapid accumulation in heart (2.2% after 5 min) via an unknown mechanism but the following clearance is rapid as well. The fast washout from the heart requires a fast imaging protocol but again allow images at rest and at stress to be taken the same day. Good Single Photon Emission Computed Tomography (SPECT) and planar images can be acquired, but for full performance the use of multihead SPECT for image acquisition is recommended due to the rapid heart washout (Seldin et al. 1989).

A new class of neutral myocardial imaging agents is [^{99m}TcN(NOEt)₂], which comprises the [Tc≡N]²⁺ core as a central moiety (Pasqualini and Duatti 1992; Pasqualini et al. 1994). Compounds of this general compositions with various substituents on the nitrogen can be prepared in high yield and radiochemical purity directly from [^{99m}TcO₄][−] (Bolzati et al. 2000b). In a first step, the nitrido precursor is generated by methyldithiocarbamate with water-soluble phosphines as a reducing agent. Subsequently, the addition of dithiocarbamates generates the complex [^{99m}TcN(S₂CNR₂)₂] in general and [^{99m}TcN(NOEt)₂] in particular in very high yield (Ghezzi et al. 1995). Studies for the biological behavior of [^{99m}TcN(NOEt)₂] showed that it is localized predominantly in the cell membrane fraction of myocardial tissue and there was no evidence for chemical decomposition of the complex (Colombo et al. 2001; Riou et al. 1998; Uccelli et al. 1995). The in vivo behavior is quite different to the cationic myocardial imaging agents: the clearance from the blood pool is significantly slower; the myocardial washout is faster. Although the initial uptake is high, the myocardial activity decreases by about 50% after 60 min (Johnson et al. 1997; Vanzetto et al. 2000; Vanzetto et al. 1997).

It remains a major challenge to develop novel myocardial imaging agents with improved pharmacokinetics and biodistribution. The examples shown above are very promising and the chemistry behind inspires future work. As an interesting fact, these examples show in particular that the same ligand can be selected for different metal cores. Thus, improving the biological behavior can not only be done by (an often tedious procedure) variations of the ligand, but also by altering the metal core bound to the same chelator.

Many studies have been performed in order to compare the mode of action, retention kinetics in the myocardium, and the way of excretion of these different cationic and neutral species for both cell cultures as well as in whole heart preparations. Even ⁹⁹Tc NMR spectroscopy has been used to characterize in vivo the nature of the compounds for sestamibi. A recent comparative kinetic study between the different cations can be taken as a base for the clinical interpretation of the different perfusion imaging findings (Narahara et al. 1990; Schaefer et al. 2002).

43.3.2 Cerebral Blood Flow Agents

Brain imaging is still an active field of research in radiopharmaceutical chemistry. The compounds for brain imaging can be divided into two classes, one of which is discussed in this section. For the evaluation of the brain, one can apply either regional blood flow agents or receptor specific agents. Currently, the only Food and Drug Administration (FDA)-approved ^{99m}Tc radiopharmaceuticals are from the first class, so-called perfusion agents, but substantial efforts for the introduction of radiopharmaceuticals of the second class are currently

undertaken (see later in this section). The constraints for a ^{99m}Tc based-cerebral blood flow agents are quite high. The complex should be in vivo stable, be extracted to a high extent into the brain, and in proportion to the blood flow over a wide range, cross the blood-brain barrier (BBB) passively, should show no redistribution in the brain and should ideally be trapped in the brain by some change of the chemical composition to prevent rapid washout from the brain (Brodie and Hogben 1957). In addition, to pass easily the BBB, they have to be of low molecular weight, preferentially <500 Da, and the log P value (defined as the distribution coefficient between octanol and water) has to be between 0.5 and 2.5 (Dischino et al. 1983). Cerebral blood flow imaging agents represent a good example for the complementarity of other diagnostic methods such as CT or MRI with nuclear medicine. Although these techniques are highly developed and well established for visualizing structural changes, functional deficiencies causing no or few structural changes are hard to detect. Therefore, the development of corresponding tracers is of great importance and it was indeed possible to develop at least two of them which are nowadays in routine clinical application.

In the earlier stages of technetium chemistry, it was found that tetradentate ligands of the amine-oxime type formed neutral and highly lipophilic complexes with the [Tc=O]³⁺ core. One of the first was the complex with the ligand PnAO (3,3,9,9-tetramethyl-4,8-diazaundecane-2,10-dione). The structure comprises a tetradentate N₄ ligand in which the two aliphatic amines are deprotonated. Together with one deprotonated oxime and the terminal oxo function the overall charge is neutral and the complex due to the methyl substituents of high lipophilicity (Troutner et al. 1984). Many variants of derivatives were tested keeping the structural framework of coordination intact but changing the substituents at the periphery. The original complex [TcO(PnAO)] was very well able to traverse the BBB but was not retained and washed out very fast (Chaplin et al. 1985; Hoffman et al. 1985; Holmes et al. 1985). Further developments of this class of complexes at Amersham was finally successful with the ligand (RR,SS)-4,8-diaza-3,6,9-tetra-methyl-undecane-2,10-dione dioxime (*d,l*-HM-PAO, see ► Fig. 43.3). The ligand is also called hexametazime, and loses again three protons upon coordination to the [Tc=O]³⁺ core. The proligand has two chiral centers, therefore a *meso* and a *d,l*-form exist. The complexes with the *meso* and the *d,l*-form of the ligand show both trapping in the brain, however to a different extent and the brain uptake is dependent on the blood flow in animals (Hoffman et al. 1985; Neirinckx et al. 1987) as well as in humans (Ell et al. 1985; Leonard et al. 1986). The complex with the *d,l*-form of the ligand is better retained in the brain. Although the exact mechanism of retention is not known, it seems that the complexes are converted by enzymatic processes to hydrophilic species. The conversion of [TcO(*d,l*-HMPAO)] is faster, hence, retention is better (Nowotnik et al. 1985; Sharp et al. 1986). The complex with *d,l*-HMPAO is nowadays commercially available and in clinical use

■ Fig. 43.3

Brain perfusion agents: (a) *d,l*-TcO(HMPAO), *Ceretec* (b) Tc-ECD *Neurolite*, (c) Tc-MRP20

(Ceretek[®], Amersham Int.). Its faster transformation to hydrophilic species goes along with a lower stability of the complex [TcO(*d,l*-HM-PAO)]. After preparation it should be applied within 30 min, otherwise too many decomposition products are present. On the other hand, the complex with the *meso*-form of the ligand is significantly more stable and does not decompose within this time period. In principle, the complex with the *meso*-ligand could also have two different stereoisomers, one with the methyl groups *syn* to the oxo group and *anti*, respectively. In fact, only the one with the *syn* conformation has been observed and isolated. Ceretek is a very interesting example since it clearly shows that stereochemical characteristics are essential and can influence the in vivo behavior to a significant extent. This is not surprising, considering the stereoselectivity of enzymes involved in the metabolism of small molecules but is unexpected in the sense that nonbiological molecules are treated the same way. Stereochemical differences clearly fine-tune biological parameters such as biodistribution and pharmacokinetics even in small artificial complexes. Thus, stereochemistry has seriously to be considered in the design of novel perfusion agents and or targeting radiopharmaceuticals.

A similar stereoselective reaction is the base for the use of certain (diamino-dithiol (DADS) ligands in the context of brain perfusion agents. DADS ligands stabilize the [Tc=O]³⁺ core by coordination through the two deprotonated thiol groups and one deprotonated aliphatic amine. The second aliphatic amine remains protonated and coordinates as a normal tertiary amine. In total, the complex is uncharged and, depending on the substituents, of medium to high lipophilic character. The basic complex composition is shown in  Fig. 43.3. Furthermore, the DADS framework has been used for many purposes and in particular in the context of brain imaging agents. An excellent and critical review has recently been published by Johannsen and coworkers (Johannsen and Pietzsch 2002). The complex that is nowadays routinely applied in brain imaging is built up from the dimerization of two cysteines through an ethylene bridge to yield so called ethylene–cysteine dimere (ECD). It is essentially based on earlier efforts to produce neutral [TcO(N2S2)] complexes (Epps et al. 1987; Kung et al. 1990; Kung et al. 1989; Lever et al. 1985). Most of the complexes based on the N2S2 ligands are sufficiently lipophilic to pass the BBB but they are not trapped. ECD on the other hand contains two ester functionalities, which can be subject to hydrolysis, thus, due to strongly increased hydrophilicity, expected to be trapped, which is indeed the case. Esterases hydrolyze the ester groups with surprising stereoselectivity (Vallabhajosula et al. 1989; Walovitch et al. 1989; Walovitch et al. 1988). The complex with the *d,d*-form of the ligand is relatively insensitive for hydrolysis, whereas the *l,l*-form is readily trapped in the brain by fast hydrolysis. These in vivo results were confirmed in vitro with monkey brain homogenate in which the *d,d*-form was clearly much slower hydrolyzed than the *l,l*-form (Walovitch et al. 1994). The partially or fully hydrolyzed species in the blood are readily excreted through the kidneys. It could be shown that the metabolites contained the basic coordination framework intact and no decomposition took place (Walovitch et al. 1994). The complexes are retained in the brain only and no back-diffusion was observed. Apart of the easier preparation, this remarkable stability is also a clear advantage of Tc-ECD over Tc-HM-PAO. Byproducts that still form in the case of HM-PAO can accumulate in the soft tissue around the brain and decrease the quality of the images.

Beside such practical consideration, it should also be emphasized in the case of Tc-ECD that stereochemical behavior is very important. In the case of ECD, clearly an unidentified esterase is responsible for the crucial trapping of the metal complex in the brain.

Beside the two discussed “market leaders” in brain imaging, a number of other coordination compounds has been investigated with respect to practical application. One of these are

complexes of the already mentioned class of BATO compounds. BATO-type complexes are very lipophilic ($\log P > 3.8$), which results in longer residence time in blood due to hydrophobic interaction with serum proteins. This clear disadvantage goes along with a slow but significant washout from the brain, which is unique among brain imaging agents (Narra et al. 1989; Narra et al. 1990). It is anticipated that an equilibrium between a cationic and a neutral complex is responsible for the reversible trapping. In a basic study, it could be shown that in vitro the seventh ligand in the BATO complexes, usually a Cl^- exchanges for water, to give a monocationic complex that is trapped. Equilibrium with the form in which water is again replaced by Cl^- yields a neutral species that is washed out (Jurisson et al. 1991). This illustrates an interesting (chemical) form of interconverting a complex to yield an activated species. A further example of a brain perfusion complex is based on an N3O ligand. The ligand MRP-20 is depicted in  Fig. 43.3. It stabilizes the $[\text{Tc}=\text{O}]^{3+}$ moiety. The pyrrol nitrogen, the aliphatic amine, and the hydroxo group are deprotonated to afford an overall neutral complex. The complex $[\text{TcO}(\text{MRP-20})]$ did not exhibit significant advantages over the other two discussed above and was not pursued any longer (Bossuyt et al. 1991; Morgan et al. 1991).

43.3.3 Agents for Renal Function

Imaging of the kidney function is a very thoroughly investigated field of ^{99m}Tc radiopharmaceuticals. In case of the kidneys it is important to study both function as well as morphology. Significant research has therefore been invested to the design and syntheses of complexes that allow imaging those two features. A number of complexes are nowadays commercially available and a recent excellent review covered not only the chemistry of such ^{99m}Tc complexes but also some physiological aspects of kidney as such (Nosco and Beaty-Nosco 1999). Originally simple $\text{Na}[\text{}^{99\text{m}}\text{TcO}_4]$ was used as kidney imaging agent, but due to rapid clearance through the liver, it was never seriously considered to be a viable renal imaging agent. This is unexpected since $[\text{}^{99\text{m}}\text{TcO}_4]^-$ met the criteria of hydrophilicity, rapid clearance from the blood stream (>98% through kidneys), in vivo and in vitro stability, and other conditions that are considered to be essential for a functional renal imaging agent for potential application. Soon after the investigations on $[\text{}^{99\text{m}}\text{TcO}_4]^-$, two coordination compounds were introduced, exhibiting the required physicochemical properties. One complex used DTPA as a ligand, while a second one took DMSA (dimercaptosuccinic acid) (Blaufox 1991; Eshima et al. 1990; Fritzberg 1984; Ponto et al. 1990; Verbruggen and Deroo 1992; Villa et al. 1986). ^{99m}Tc-DTPA is one of the early radiopharmaceuticals the structure of which is still unknown. Although many attempts were done to properly characterize the complex on the ⁹⁹Tc level, its structure is not unambiguously clear. Oxidation states +III, +IV, and +V have been proposed and complexes with DTPA in these different valencies partially were confirmed to exist (Bandoli et al. 1982; Eckelman et al. 1972; Kempf et al. 1980; Seifert et al. 1982).

However, the product formation is dependent upon the pH and the amount of SnCl_2 used for reduction. Despite the lacking structure of Tc-DTPA, kits (^{99m}Tc-pentetate) are commercially available from different companies and in extensive use, mainly due to the low-cost and the low-radiation dose delivered to the patient. ^{99m}Tc-DTPA allows the measurement of the glomerular filtration rate. Since the extraction efficiency is only about 20% for each path through the kidneys, a relatively high background harms the quality of the images (Harbert et al. 1996). An increase in rate of clearances from the circulation can be achieved by parallel or exclusive excretion through the renal tubules. This is an active process, which is about four

times more efficient than glomerular excretion. One of the latest ^{99m}Tc complexes that is actively excreted by tubular secretion is ^{99m}Tc -MAG3 (Fritzberg et al. 1986). MAG3 (mercaptoacetyl-triglycine) is a peptide-like ligand that stabilizes the metal center in the oxidation state +V, cf. ► Fig. 43.4.

Different from the DTPA agent, structure and composition of $[\text{}^{99m}\text{TcO}(\text{MAG3})]^-$ are well established. Originally developed by Fritzberg and coworkers (Eshima et al. 1987), it has been demonstrated earlier that tetradentate diamido-dithiolato ligands proved to form physiologically stable complexes with the $[\text{Tc}=\text{O}]^{3+}$ moiety (Davison et al. 1981). Although the basic framework was given, problems arose from the presence of different stereoisomers when the charged acetyl functionality was attached to the five-membered ring. *Syn* and *anti* conformations in respect of the $[\text{Tc}=\text{O}]^{3+}$ moiety were found. The two conformers excreted differently. Fritzberg moved this group to the terminal amido group and circumvented this problem elegantly by eliminating the chiral center but keeping the overall hydrophilicity essentially unchanged. The thiol group in the free ligand is somewhat problematic since it tends, even when stored under N_2 , to form disulfide bridges. Therefore, in the commercially available kits, this group is protected with a benzyl group, which is released during the 10 min process of heating when reconstituting the kit. Labeling efficiency is very high, would even be higher if the ligand was available in its free form not requiring concomitant deprotection (Rao et al. 1990). Furthermore, SnCl_2 is a reasonably strong reducing agent to switch $\text{Tc}(\text{VII})$ to $\text{Tc}(\text{III})$ when heated (and to even lower valencies), thus, relatively few SnCl_2 are in the kit, which is destroyed prior to administration by ventilating the kit with air to destroy excess SnCl_2 . At physiological pH, the free carboxylate is deprotonated, making the complex monoanionic. After administration, the complex binds to a large extent by non-covalent forces to plasma proteins. To be excreted, it seems that the free carboxylate is essential in order to be recognized by the corresponding receptors in the kidney, which entails active excretion through tubular secretion (Despopoulos 1965). About 50% of the radioactivity is excreted for each blood pass through the kidneys. This is less than in case of o-iodohippuran (the golden standard of kidney radiopharmaceuticals), but sufficient to obtain good images for this function of the kidneys. Nowadays, *Technescan*[®] MAG3 (Mallinckrodt Med) has mostly replaced o-iodohippuran.

► Fig. 43.4

(a) Tc -MAG3, *Technescan*[®], (b) Tc -MAG2, and (c) $[\text{TcO}(\text{dmsa})_2]^{n-}$, (d) Tc -EC

The purpose of a third kind of renal imaging agent is to measure the actual renal mass. To achieve this objective, the metal complex now needs to have different characteristics. Typically, it should have high affinity for the proteins localized in the tubular walls or be thermodynamically weak, allowing transmetalation into renal tubule proteins. Two commercially available ^{99m}Tc complexes fall in this class. The first one is the Tc(V) complex with dimercaptosuccinic acid (dmsa) and the other one is with glucoheptonate. The structure for the first one is quite well known, whereas for the second one a structure is assumed, cf. [Fig. 43.4](#).

These two complexes behave in the kidneys in a biological way that it is not well understood (Blaufox 1987; Nosco and Beaty-Nosco 1999). The complex with glucoheptonate, tentatively formulated as $[\text{TcO}(\text{gh})_2]^-$, is not stable once released from the conditions in the kit. Decomposition leads to retention in the kidneys with up to 15% of the injected dose still present after 4 h (Harbert et al. 1996). This retention is a useful measure for the determination of the effective renal plasma flow. The composition of the dmsa complex is most likely to be $[\text{TcO}(\text{dmsa})_2]^-$. Several stereoisomers are possible. Using the *meso*-form of the ligand, three isomers (*syn-endo*, *syn-exo*, and *anti* conformation of the $-\text{COOH}$ groups with respect to the $[\text{Tc}=\text{O}]$ group) are possible, which have been identified indeed for the synthesis of the corresponding ¹⁸⁶Re complexes. It has been shown by ¹H-NMR studies that they all are interconverting rapidly (Spies and Johannsen 1981). Since more precise information on the morphology of kidneys can nowadays be acquired from alternative methods such as ultrasound, CT, or MRI, both compounds are rarely used.

Beside the agents mentioned in this section, it is worthwhile to describe to further agents that are under development and show promising properties for renal imaging. The Tc(V) complex with ethylene–dicysteine shows also promise and contains the same coordination unit as already described in the section on cerebral blood flow agents (ECD) (Verbruggen et al. 1992). A structure of the complex is depicted in [Fig. 43.4](#). The complex is hydrophilic and bears an overall charge of 2−. It has been shown that this complex is actively excreted through the renal tubules with a rate of clearance that is about 40% higher than the one of Tc-MAG3 (Gupta et al. 1995). Another very interesting compound is a homoleptic Tc(I) complex with six monoanionic-charged ligands to afford an overall charge of 5−. Although of more academic interest, the complex is prepared from the ligand present in the ester form and subsequent hydrolysis in the free or coordinated form (Kronauge et al. 1993). The complex has shown promise for the measurement of effective renal plasma flow.

43.3.4 Agents for Other Applications

Attempts have been made to introduce ^{99m}Tc-based radiopharmaceuticals for the imaging of various other functions and diseases as well. Among the most successful ones are bone and liver imaging agents, some of which have been commercialized. Since for most of the corresponding compounds the structure is not clear, they shall not be discussed at this place. Among the recent trends in diagnostic nuclear medicine, imaging of hypoxia is a major development and complexes containing a nitroimidazole group play an important role in this field. Nitroimidazole is reduced in hypoxic cells to compounds that cannot diffuse out of the cell or remain bound in the cell to unknown molecules inside the cytoplasm. The gold standard for imaging hypoxia is the fluorinated compound ¹⁸F-misonidazole (Martin et al. 1992). Basically two approaches have been chosen to develop a useful ^{99m}Tc-based hypoxia radiopharmaceutical. One of the ligands to stabilize Tc is a PnAO-type ligand as depicted in

► **Fig. 43.5.** The ligand is derivatized with nitroimidazole at the oxime group. It is trapped in hypoxic tissue. However, due to the high lipophilicity, it clears too slowly, affording images of poor quality. Some derivatizations have been performed to increase hydrophilicity through the introduction of oxygen in the backbone (Dirocco et al. 1993; Linder et al. 1994). Certain variations in the ligand type have been pursued and the tridentate amine-phenol ligand bis (amine-phenol)nitroimidazole (► **Fig. 43.5**) was introduced (Johnson et al. 1998; Pillai et al. 1990; Ramalingam et al. 1994). A further variation included the extension of the propylene backbone in PnAO to butylene in BnAO. The variation is very interesting from the background that PnAO forms a mono-oxo core, whereas a pentylene backbone gives the dioxo-core $[\text{O}=\text{Tc}=\text{O}]^+$. The behavior of the butylene is not unambiguously clear but from the behavior in hypoxic tissue it seems likely that the complex is reduced to a lower oxidation state complex. It is remarkable that the complex without a nitroimidazole group proved to be more effective than the complex with the nitroimidazole group.

A very recent approach used the [3+1] strategy (see also ► **Sect. 43.4.1**) to introduce a redox active methyl-pyridinium derivative into the $[\text{Tc}=\text{O}]^{3+}$ core, cf. ► **Fig. 43.5**. The redox-active moiety is derivatized with a thiol that acts as the monodentate ligand, whereas the tridentate ligand is represented by a thioether-dithiol framework (Kniess et al. 1998).

43.4 Different Types (Generations) of ^{99m}Tc -Radiopharmaceuticals

43.4.1 Perfusion Agents

Perfusion agents are the most commonly used radiopharmaceuticals containing ^{99m}Tc . They are also referred to as first-generation radiopharmaceuticals or technetium-essential radiopharmaceuticals. As described in the preceding chapters, they have been developed over the past decades with great success and are in manifold clinical use for the diagnosis of, e.g., renal and heart function, cerebral blood flow, and many others. The radiopharmaceutical is “ ^{99m}Tc essential” since it would obviously not work without technetium: The pharmaceutical has to be considered as an entity in which the Tc-center plays the role of an important structure and

► **Fig. 43.5**

Compounds for imaging of hypoxia (a) Tc-PnAO (BMS181321), (b) alternative ligand BnAO, and (c/d) 3+1 approach with dihydropyridin

physicochemical imposing part. The ligands on the other hand are mono- or multidentate, designed for the particular purpose that the complex is intended to be applied. Essentially any technetium complex could be a perfusion agent, provided that it fulfills the very basic requirements outlined. For the in vivo behavior of the perfusion agent, predictions are difficult to make and the design remains finally a trial-and-error approach as obvious from the development of many of the successful perfusion agents. Some characteristics may help in designing a novel radiopharmaceutical, but, at the end, only the biological experiments will tell the usefulness of a particular compound. Sometimes even animal experiments in mammals are not conclusive for the behavior of the compounds in human as impressively shown with the development of the first myocardial imaging agents based on cationic Tc(III) complexes. An interesting feature that merits probably more consideration in future is the processing of “innocent” radiopharmaceuticals by enzymes. In the case of [TcO(HM-PAO)], for instance, the conversion to a more hydrophilic compound is crucial for the in vivo behavior. It can be concluded that the administered compound is rather a prodrug that is converted at the organ into the actual drug. This working hypothesis, although very demanding for the design of novel perfusion agents, is challenging not only for the chemist but also for the biochemist. It has to be emphasized that perfusion agents are not “out of fashion” although the major actual research efforts focus on the second generation of radiopharmaceuticals. The motivation to further research in this field is of course on one hand to yield improved quality images paralleled by a lower radiation dose to the patient, but is clearly also a question of the market.

43.4.2 Receptor-Specific Molecules

The major actual research efforts are in the development of ^{99m}Tc-labeled vectors, also called targeting biomolecules. Such radioconjugates are referred to as second-generation radiopharmaceuticals. While radiopharmaceuticals of the first generation are technetium essential, those of the second generation are not. It can even be anticipated that the metal complex affects the biological behavior of the biomolecule, although the precise fate of the unlabeled molecule is in most of the cases completely unknown. A second-generation radiopharmaceutical consists of the biologically active molecule, in general an organic molecule such as a peptide, an antibody, or a central nervous system (CNS) receptor binding small molecule that carries at its periphery the metal complex. The metal complex should be “innocent,” not influence the physicochemical properties of the biologically active molecule, and not interfere with receptor binding, requirements that are at least in the case of very small molecules difficult to achieve. A ^{99m}Tc metal complex attached to anyone of these vectors allows monitoring the biodistribution of the biomolecule and, even in case where the receptor affinity is fully maintained, exhibits often unfavorable biological behavior.

43.4.3 Inhibitors

A perspective for the development of novel radiopharmaceuticals is a molecule in which the complex is part of the topology required for the recognition and binding by a particular receptor. After receptor binding, the receptor should be blocked and its function be inhibited. The inhibitor might act as an agonist or an antagonist. So far there is no example in ^{99m}Tc chemistry in which this situation occurs. Katzenellenbogen recently described examples

pointing in the direction of a ^{99m}Tc complex that is able to interfere with the estradiol receptor. The structures of these complexes are depicted in ► Fig. 43.6 (Chi and Katzenellenbogen 1993; Chi et al. 1994; Hom and Katzenellenbogen 1997a; Hom et al. 1996).

The approach, as outlined above, to mimic a naturally occurring structure shows also that it is important to copy not only the actual surface of the molecule but also its electronic properties. The later point is by far more challenging (if possible at all) than just the consideration of topological properties. Although for the coordination chemist a real challenging task, it remains at least doubtful if a de novo inhibitor can ever be achieved and transferred into a versatile product for routine use.

43.5 Strategies for the Labeling of Targeting Molecules

43.5.1 Bifunctional Chelator Approach

The labeling of targeting molecules entails the question of tightly binding the metal center to the biologically active molecule without affecting its physiological properties. This means in concrete that the metal center in its particular oxidation states needs to be stabilized and covalently linked to the vector. The ligand, an organic molecule, has thus two functions. It is called a bifunctional chelator (BFC). One part of the molecule, the first function, coordinates the technetium, whereas the second function is to covalently bind the ligand to the targeting vector via a suitable spacer. The coordinating part can be chosen from the armory of known ligands as discussed above (i.e., MAG3). The connecting functionality to the biomolecule is usually a carboxylate or an amine group that can conveniently be activated with known strategies from organic chemistry.

Labeling of targeting molecules requires a chelator that is strong enough (1) to coordinate to the technetium center at low concentration (to avoid subsequent purification from cold material), (2) to give one single product, and (3) to stabilize the metal under in vivo conditions (Brenner et al. 1984; Davison et al. 1981; Edwards et al. 1990; Grummon et al. 1995; Jurisson et al. 1986; Wong et al. 1997). In principle, these requirements hold also true for the first-generation radiopharmaceuticals but these also need to be subject of well-controlled metabolic processing, whereas the pendant metal complex in the second-generation radiopharmaceuticals clearly should not. The chelator should afford an innocent metal complex. The most widely applied BFC are those based on a combination of nitrogen and sulfur donors to give the class of tetradentate N_xS_{4-x} ligands. The donor S is in general a thiol group, more rarely a thioether, whereas N represents an amide, an aliphatic amine, or an imine in which case additional sulfur donors are rare. A number of examples for such chelators is given in ► Fig. 43.7.

The basic N_xS_{4-x} framework yields neutral or anionic complexes depending on the type and combination of the nitrogen donors. Since amide functions cannot coordinate without deprotonation, an amide in the ligand framework counts for one negative charge in the coordinated form. The ligands coordinate the [Tc=O]³⁺ moiety very efficiently and at low concentration. For labeling, the thiol groups are in general protected (mostly as benzoyl or trityl) since the free thiol groups are susceptible to disulfide formation, and the complex formation gives then often mixtures of products. Protecting the thiol on the other hand results in one well-defined product but requires boiling in order to cleave the protecting groups. The basic ligand framework can now be further derivatized with the second functionality required for binding to the vector. Several strategies have been used for that purpose and some examples are depicted in ► Fig. 43.8.

A selection of N2S2 ligands that form anionic and neutral Tc(V) complexes

The linking group can either be attached to one of the aliphatic amines resulting in a tertiary amine if the nitrogen is in the chain or in a secondary amine if the linking amine group is terminal. It can also be attached to one of the carbon atoms in the ligand backbone. This is usually the case if the ligand is built up of a sequence of amino acids or pseudo amino acids. The carboxylic group represents then the C-terminus of such a peptide sequence. The same strategy is also applied to yield an amine group as a second function. The advantage of good stability and high labeling yield is often compensated by the formation of stereoisomers. Any optical active center in the backbone of the ligand gives rise to the formation of a complex with the side chain in *syn* or *anti* orientation in respect of the Tc=O group. Fortunately, one of the possible products is usually thermodynamically preferred and one product only (in general the *syn* stereoisomer) is formed.

A pseudo peptide sequence such as found in MAG_3 may contain a variety of other amino acids instead of the glycines. This allows structure–activity relationships of the biodistribution characteristics by substituting one of the glycines in MAG_3 by another naturally occurring amino acid (Bormans et al. 1992; Hansen et al. 1992; Hansen et al. 1994; Verbruggen et al. 1989). Introduction of, e.g., an alanine instead of the central glycine residue (MAAG) resulted in the *syn* conformation of the structurally analogous complex $[\text{TcO}(\text{MAAG})]^-$ with the same coordination sphere as $[\text{TcO}(\text{MAG}_3)]^-$. Decreasing the number of available amido groups for coordination as in the mercaptoacetyl-glycine-glycine (MAG_2) ligand significantly diminishes the ability of the ligand to stabilize the $[\text{Tc=O}]^{3+}$ core. Nevertheless reaction of $^{99m}\text{Tc(V)}$ -gluconate with MAG_2 gave $[\text{TcO}(\text{MAG}_2)]$. The terminal carboxylato group is now engaged in coordination yielding an N_2SO ligand donor set with an overall square pyramidal geometry (Johannsen et al. 1993). In the presence of excess ligand, additional uncharacterized anionic species were found. It is assumed that these represent 2:1 and probably 4:1 complexes as a consequence of the dominance of the thiol groups over other donors in coordination to the Tc(V) center. In general, it has, however, been found that peptide-based ligands different from the MAG_3 set sometimes suffer of lacking stability (apart the stereochemical problems). Hence, glycine-based peptide sequences still remain the most widely used chelators. The free terminal carboxylate group provides a coupling site for the N-terminus of a receptor binding peptide.

■ Fig. 43.8

Sequences of amino acids that are terminal or integrated parts of a longer sequence

In principle, such chelators cannot only be tagged to a targeting vector but can even be an integrated part of it. A clear drawback of the introduction of MAG₃ as a chelator was the possibility of ^{99m}Tc complex formation by peptide sequences (Brandau et al. 1988; Fritzberg et al. 1986; Fritzberg et al. 1982; Verbeke et al. 1995; Visser et al. 1993).

It is appropriate to introduce here a peptide-based ligand, which has a unique chemical behavior and the perspectives of which has so far not been used to an even nearly sufficient extent. It was recently found that a linear peptide based on four coupled alanines (L-ala)₄ formed, as expected, a tetradentate chelate, wrapping around the [Tc=O]³⁺ core. After coordination, a metal-templated ring closure in (L-ala)₄ took place through amide formation between the terminal amino and carboxylate group and the complex [TcO(cyc-ala₄)][−] formed (Bormans et al. 1996). The ring closure reduces the number of potential coordinating atoms from five to four and provides additional macrocyclic stabilization. The alanine methyl groups are *syn* in relation to the oxo-core. This type of reaction is relatively rare but does indicate a potential for analogous complexes and for the formation of cyclic peptides. It is in particular remarkable that attempts to get complexes directly with cyclic tetrapeptides were unsuccessful. Attempts to increase the denticity of N,S-based ligands as in the (L-ala)₄ ligand often results in intermolecular reactions. Several approaches in respect of peptides have shown that this might be a promising way of labeling bioactive peptides (Wong et al. 2001).

Various alternatives to tetradentate N_xS_{4−x} ligands exist. In terms of flexibility, the so-called mixed ligand [3+1] approach is convenient. The approach is based on the [Tc=O]³⁺ moiety and applies a tridentate and a monodentate ligand. In general, [3+1]-mixed ligand complexes of the type [TcO(SXY)(SR)] (X=O,N,S and Y=N or S) are prepared by the reaction of a potentially dianionic tridentate ligand H₂L and a monodentate monoanionic thiolate coligand with a suitable oxo-technetium precursor (Pietzsch et al. 1989) (Pietzsch et al. 1990; Spies et al. 1990; Spies et al. 1995). The targeting molecule can be attached to the monodentate ligand, which is in general an −SH group or to the middle donor in the tridentate ligand, which is then a tertiary amine. Various combinations of the tridentate ligand have been studied but it seems that the combination of HS−N−SH is the most promising one. This mixed ligand approach has found interest in particular for the labeling of CNS receptor binding molecules. In this case the receptor binding part is in general derivatized with an additional monodentate thiol group. A review on CNS receptor ligands in the context of the [3+1] approach has recently been published (Johannsen and Pietzsch 2002). Actually, the interest in the [3+1] approach is decreasing for biomolecules different from CNS receptor ligands since it was shown that some of the complexes are of limited serum stability (Seifert et al. 1999; Seifert et al. 2000; Syhre et al. 1998). The stability strongly depends on the tridentate ligand and there in particular on the substituent attached to the middle nitrogen donor. Improvements of this situation are currently studied. The [3+1] approach was applied to many biomolecules and model complexes. One of the major problems related to mixed ligand approaches is the feasibility of the synthesis of the final complex. With CNS receptor ligands, the product still needs to be extracted into an organic solvent (often chloroform) to separate it from byproducts. For practical reasons this approach is less convenient for other biomolecules such as peptides or antibodies. Recently, an *n.c.a.* preparation has been introduced which is based on a convenient HPLC separation at the end of the preparation (Seifert et al. 1997).

A different approach that is subject of intense developments is the HYNIC approach. Originally, this method was applied for the labeling of polyclonal IgG with ^{99m}Tc for imaging focal sites of infections (Abrams et al. 1990; Larsen et al. 1995; Schwartz et al. 1991). The HYNIC technology has recently been reviewed extensively in the context of small peptide

labeling (Liu and Edwards 1999). Although HYNIC (2-hydrazino-nicotinic acid) is widely used in the labeling of peptides and antibodies, its chemistry is not well understood. The HYNIC is linked through the carboxylic acid to an amine group in the targeting vector. The coordination chemistry of the hydrazine group has been investigated with HYNIC but also with surrogates, however, despite the elucidation of at least three X-ray structures, still does not allow a distinct formulation of the coordination with ^{99m}Tc (Hirsch-Kuchma et al. 1997; Hirsch-Kuchma et al. 1997; Nicholson et al. 1996a, b; Rose et al. 1998). It is believed that the bond to the hydrazine in HYNIC is in fact a Tc==N double bond, as depicted in Fig. 43.9, the so-called diazenido form of a coordinated hydrazine. This formulation is rationalized on the basis of a need for auxiliary ligands to stabilize the overall complex with additional multidentate chelators. The labeling studies with HYNIC chelates are therefore performed in conjunction with additional ligands such as tricine or EDDA. It is believed that the pendant complex can be formulated as [Tc(HYNIC)(EDDA)] or [Tc(HYNIC)(tricine)₂]. The application of these binary systems were associated with disadvantages such as formation of side products, complex instability, and binding to plasma proteins by coligand exchange (Liu et al. 1996; Ono et al. 2001). It was elegantly shown that one additional monodentate ligand would improve these stability disadvantages. Such ternary systems were investigated with phosphines and aromatic amines (Liu et al. 1998a, b). It is likely that the composition of the complexes in the ternary system is [Tc(HYNIC)(tricine)L], where L represents the aromatic amine or the phosphine.

A more recent approach employs the coupling of tridentate or bidentate BFC to target vectors for the application of the [^{99m}Tc(CO)₃]⁺ moiety in the second-generation radiopharmaceuticals. The complex [^{99m}Tc(OH₂)₃(CO)₃]⁺ can conveniently be synthesized from a kit formulation (Isolink[®], Mallinckrodt) in which the three water ligands are replaced by

Fig. 43.9

HYNIC technology (a) hydrazine–nicotinic acid, (b) [Tc(HYNIC)(tricine)₂], (c) [Tc(HYNIC)(edda)], (d) [Tc(HYNIC)(tricine)L], where L is a monodentate ligand such as (e)

incoming ligands. Complexes of high kinetic stability are formed (Alberto et al. 2001; Alberto et al. 1994; Alberto et al. 1996). It is remarkable that essentially all kinds of donors can be used since the stability of complexation is purely kinetic (Schibli et al. 1999; Schibli et al. 2000). Mono-, bis-, and tridentate ligands are cleaved only under highly acidic conditions and at high temperature. The advantage of this method is the fact that the pendant metal complexes are well defined and their structures are known. The $[\text{}^{99m}\text{Tc}(\text{CO})_3]^+$ moiety shows in particular a high affinity for aromatic amines such as imidazoles or pyridine. Several complexes have been prepared on that base and the concept has proven useful for the direct labeling of his-tagged recombinant single chain variable Fragments (scFv) (Waibel et al. 1999). More recently, the introduction of bifunctional histidine derivatized at N^{ϵ} was published. Histidine is a highly efficient ligand and enables the labeling of a model peptide at very low concentrations (Egli et al. 1999; La Bella et al. 2002; Schibli et al. 2002; Wust et al. 1998). Different neurotensin analogues have been labeled with the same approach and biologically tested (Garcia-Garayoa et al. 2002; Garcia-Garayoa et al. 2001). The approach of preparing second-generation radio-pharmaceuticals based on the $[\text{}^{99m}\text{Tc}(\text{CO})_3]^+$ moiety is relatively recent and under extensive investigation. Procedures and some structures are depicted in [Fig. 43.10](#).

Half sandwich complexes of the type $[(\text{Cp})\text{M}(\text{CO})_3]$ (Cp =cyclopentadienyl, $[\text{C}_5\text{H}_5]^-$) are very useful complexes since they are small and highly lipophilic and therefore of high interest in the context of labeling, i.e., estradiol (Jaouen et al. 2000; Jaouen et al. 2001; Top et al. 1995). To bifunctionalize cyclopentadienyl is not routine, and Cp has in general not been introduced as a classical BFC but coupled in the course of a normal organic synthesis. Jaouen and coworkers showed that half sandwich complexes attached to a biomolecule affected its receptor affinity the least, whereas the introduction of N_xS_{4-x} chelator significantly reduced the binding constant. The preparation of $[(\text{R-Cp})^{99m}\text{Tc}(\text{CO})_3]$ found much attention in particular for attempted labeling of CNS receptor ligands. Wenzel originally proved the principle but the double ligand transfer reaction is far from being useful for routine (Wenzel 1992; Wenzel and Klinge 1994). Some improvements were realized and the cyclopentadienyl ligand was even attached to peptides (Minutolo and Katzenellenbogen 1998; Minutolo and Katzenellenbogen 1999). Only recently it could be demonstrated that the introduction of an acetyl functionality at the cyclopentadienyl ring does stabilize the water- and air-sensitive cyclopentadienyl significantly. A potential vector could be coupled to this BFC. The C-acidity increased by several

orders of magnitude, which now enabled the synthesis of $[(R-Cp)^{99m}Tc(CO)_3]$ in one single step directly from water (Wald et al. 2001). The synthetic procedures are depicted in Fig. 43.11.

A relatively recent approach with promise for the labeling of targeting molecules is based on the nitrido core $[Tc \equiv N]^{2+}$. In the well-established complexes $[TcN(PS)_2]$ (where PS is, i.e., $R_2PCH_2CH_2SH$ (R =phenyl, methoxypropyl)), the changing of the connectivity in $[TcN(PS)_2]$ to $[TcN(P_2)(S_2)]$ was expected to give asymmetric complexes with comparable stabilities. The S_2 or SO could then act as bidentate BFC's. The reaction of $[Ph_2P(CH_2)_2O]$ (pop) with a nitrido precursor gave $[TcNCl_2(pop)]$ in which the two P donors are both *cis* and *trans*. The further substitution chemistry, which would allow the coordination of a BFC was investigated with bidentate OSH_2 ligands such as 2-mercaptoethanol or mercaptoacetic acid. The *cis* isomers reacted readily with these ligands forming complexes of general composition $[TcN(PXP)(OS)]$ ($X=O,N$) (Bolzati et al. 2000a). Hence, conveniently available precursors of the type $[^{99m}TcNCl_2(PXP)]$ can be used to label biomolecules by the replacement of the chlorides with an appropriate bifunctional ligand (Boschi et al. 2001).

In conclusion, there are two strategies available for this purpose, the so-called postlabeling and the prelabeling methods. The bifunctional chelator can be coupled to the biomolecule before the labeling reaction. The derivatized biomolecule is then purified and lyophilized prior to labeling. Coupling might occur through amide formation between an activated carboxylic acid pendant of the BFC and the ϵ - NH_2 group of lysin or by the introduction of additional $-SH$ groups in the biomolecule (i.e., by the reaction with iminothiolane) and subsequent reaction with maleinimide derivatized BFC. The labeling reaction is performed by transmetalation from, e.g., a reconstituted Tc-glucoseheptonate kit or directly by reduction and concomitant complexation/labeling. Depending on the biomolecule, high labeling yields can be achieved in which the radiopharmaceutical does not require further purification. However, a drawback might be minor amounts of unspecific labeling, in particular for antibodies that contain other potentially chelating groups. In any case, the postlabeling approach is the most convenient one in particular when considering future routine application (Verbruggen 1990).

The second method of indirect labeling through a BFC consists in the prelabeling strategy. This method includes the preparation of a ^{99m}Tc complex in a first step that enables the preparation at very different conditions which would sometimes not be compatible with the biomolecule. Subsequently, the second function which is not involved in coordination can be activated by a common method in water and reacted with the vector to afford the final targeting

radiopharmaceutical. Clearly, the advantage of this approach is the preparation of the complex at high purity and yield; however, the coupling process to the biomolecule is limiting since covalent coupling is very often not going to completion since hydrolysis of the activated function represents the major competing reaction. Therefore, prelabeling requires in most of the cases purification after the actual labeling, and is not the method of choice for routine application unless it is possible to achieve close to 100% labeling yield.

43.5.2 Direct Labeling Approach

The direct labeling approach is defined as the labeling of a biomolecule by ligand atoms, which are already an integral part of the structure of the biomolecule. For a direct labeling, no additional atoms (donors) are required. It is therefore in principle possible to use functional side chains bearing donor atoms directly as ligands for coordination to the ^{99m}Tc moiety. Considering the position of Tc in the periodic table it is obvious that thiols, thioether groups, and aliphatic or aromatic amines are preferential binding sites. Sulfur donors provide in general high thermodynamic stability to a variety of oxidation states. Therefore it is difficult to predict a preferred valency. On the other hand, the thermodynamic stability provided by the other groups is in general weak, and it is not sufficient to stabilize a metal center under biological conditions, as undesired transmetalation will be the consequence. A direct labeling must be based on kinetics and is suitable for lower valencies. Two feasible approaches for direct labeling have been described – one of them even applied in clinical studies with a number of peptides, antibodies, and antibody fragments. The first successful method, the so-called pretinning method, was introduced in the late 1980s and commercially applied in, e.g., an *anti-melanoma* antibody. Antibodies contain a considerable number of disulfide groups, which stabilize their tertiary structure. These disulfide groups in intact antibodies, F(ab')₂ and in F(ab') fragments, can carefully be incubated with Sn²⁺, which results in the reduction of the disulfides to two thiol groups. Depending on time and Sn²⁺ concentration, the fragments are even created by themselves through such a process. These reactive antibody species are then incubated with [^{99m}TcO₄][−]. Excess Sn²⁺ and/or the thiol groups do reduce Tc(VII) to an unknown oxidation state and bind the Tc very tightly. Since the labeling yield is in general not quantitative, purification is required. The pre-tinning method, if carefully performed, allows a good and stable labeling of antibodies under retention of the bioactivity. Many studies have been performed applying this method. Some variations have been developed for a similar labeling methodology.

The reducing agent Sn²⁺ represents a problem since it tends to form colloids and to stick itself on functionalities of the antibody. Therefore, the well-known mild reducing agent dithiothreitol (DTT) has been employed as well for the same purpose. DTT can be used to reduce an intact antibody to the Fab' state, which is then reacted with, e.g., a reconstituted Tc-glucoheptonate kit. Transmetalation results in high radiochemical yield after a short period of time. The high reactivity and the fast reaction rationalize the assumption that in all of these preparations the oxidation state of Tc is +V. From model complexes, it is well known that thiols stabilize this valency very well (see previous section). Another even milder technique uses 2-mercaptoethanol as a reducing agent. This reagent generates under well-controlled conditions thiol groups. Different kits like Tc-MDP or Tc-glucoheptonate are then reacted with the reduced antibody to give within a short period of time quantitatively labeled antibody that does not require additional purification.

Many antibodies have been labeled in one or the other way and kits for patient studies are commercially available. The method is difficult to apply for smaller molecules. Despite the fact that some important (cyclic) peptides have at least one disulfide bridge in their structure, the coordination affects the structure of this small molecules resulting frequently in the loss of bioactivity. The indirect labeling method is essentially limited to antibodies.

A more recent but yet less-well-developed approach for the direct labeling of antibodies employs the $[\text{Tc}(\text{CO})_3]^+$ moiety. This moiety has a high preference to bind to aromatic amines by substituting one or more water ligands from its coordination sphere. This is in particular true for imidazole. Once an amine is bound to the technetium center, it is only cleaved very slowly if ever. Recombinant scFv have a histidine tag, comprising a peptide sequence made out of histidins only. This tag is used for affinity column purification, but has no biological relevance. It could be shown that this tag is excellent for the direct labeling with $[\text{Tc}(\text{OH})_2(\text{CO})_3]^+$ (Waibel et al. 1999). No additional ligands were required. Although the exact coordination sphere at the metal center remains unknown, the method is convenient for the labeling of such proteins. This is in particular important since no alternatives are available due to the lack of disulfide bridges to be cleaved according to the pre-tinning method.

43.5.3 Integrated Approach

The third approach to incorporate ^{99m}Tc in a receptor targeting molecule is the so-called integrated approach. This is by far the most demanding approach since it does not use a bioactive molecule as vector but attempts to mimic physicochemically and topologically the properties of a lead structure, thereby using the Tc center itself as an important part of the overall structure. The design of such a de novo biomolecule comprises the metal center that coordinates different chelators giving a structure that roughly surrogates the “parent” molecule or the origin. Resulting lipophilicity and dipole moments are important properties of such a new construction. The few examples have already been depicted in [Fig. 43.6](#).

Of particular interest are steroid hormones since they contain five- and six-membered rings that can be considered as chelate rings. These purely structural analogy prompted investigations for the synthesis of Tc(V) complexes, which once coordinated to the appropriate ligands resemble an androgen or progesterone receptor binding steroid (Hom and Katzenellenbogen 1997a; Hom et al. 1996; Katzenellenbogen et al. 1997). Two principle approaches have been described, one using an integrated tetradentate ligand and the other one two asymmetric bidentate ligands of the N,S type. The bidentate ligands are critical for several reasons. The synthesis must carefully be carried out in order to get only one complex out of the three possibilities and, more critically, the in vivo stability of a Tc(V) complex with bidentate ligands only. In one example, the synthetic conditions resulted predominantly in one species of the mixed ligand complex for the examples shown in [Fig. 43.6](#). The complex exhibited only a very weak affinity for the receptor, and the stability was too low to be of practical relevance (Chi and Katzenellenbogen 1993; Chi et al. 1994).

The second complex was designed with a tetradentate chelator based on N2S2 donor set and one of the rare examples of a chelator containing a thioether group. Two diastereomers are possible, and both were found in fact and characterized. The relative binding affinity were again low (Hom and Katzenellenbogen 1997a). Taking the difficulties encountered for the integrated approach into account, it is remarkable that the lead structures in these early examples could be mimicked quite reasonably. The integrated approach is demanding possibly not only due the

design of chelator around an (octahedral) metal center, but also for the design of a novel metal core not containing a dominant group like the $[\text{Tc}=\text{O}]^{3+}$ moiety. It would be of high interest to apply a Tc precursor that is for electronic reasons four-coordinate.

43.6 Developments in the Labeling of Targeting Molecules

The different approaches for the labeling of targeting molecules described in the previous section are routinely applied. Depending on the bioactive molecule, one or the other might be more promising in respect of a particular target. Thus, the following chapter will highlight the developments in the labeling of peptides which experienced an exponential growth. Peptide labeling still relies on one or two approaches only and most of the labeling techniques employ the N_xS_{4-x} approach. It can be more or less easily combined with solid phase chemistry applied in the synthesis of the peptides.

43.6.1 Antibodies/Peptides

Some recent papers reviewed the clinical implications of labeled peptides and antibodies in respect of the targeting molecule and the actually applied radioisotope (Banerjee et al. 2001; Fichna and Janecka 2003; Virgolini et al. 2001; Weiner and Thakur 2002). Peptides are furthermore attractive since they have in general a high affinity for receptors that are overexpressed on malignant mammalian cells. In contrast to antibodies, they penetrate the tumors rather well but are excreted rapidly from the blood stream. On the other hand, susceptibility toward enzymatic degradation is high and requires stabilization by, e.g., the introduction of nonnatural amino acids or the replacement of certain highly sensitive sequences. Stabilization can also be achieved by chemically modifying the original sequence. It is not the issue of this chapter to discuss the implication of particular peptides but rather give an overview for the employed labeling techniques related to the peptides.

The detection of thrombi is a long-standing issue in radiopharmaceutical chemistry. The biochemical events following a rupture in a vessel are well understood. After activation of the clotting process, the glycoprotein IIb/IIIa is exposed to which the fibrinogen will bind. Bridging different platelets will result in aggregation and formation of plugs. This simplified view entails that radioiodinated fibrinogen was the most commonly used radiopharmaceutical. Since this radiopharmaceutical had some inconvenient implications it is not in use anymore. Extensive research efforts have been made, mainly in developing and labeling peptides for clot detection. A successful agent is ^{99m}Tc-apticide (*AcuTect*[®] P280, *Diatide*, Nycomed Amersham), which has recently been FDA-approved. The peptide is a homodimer that contains an RGD (Arg–Gly–Asp) sequence. The labeling uses a glucoheptonate kit for reconstitution, and the labeling takes place at 100°C for 15 min. The glucoheptonate can also be given directly to the peptide solution. The ligand consists of an $\text{N}_x\text{S}_{(4-x)}$ -type located remote in the backbone of the peptide but peptide sequences as chelators have been applied as well (Jackson et al. 1994; Muto et al. 1995; Pearson et al. 1996; Xue and Degrado 1995). To minimize the effect of labeling on the affinity of the peptides, spacers have been introduced between the BFCA and the vector. Newer work with peptidomimetics comprise modified RGD sequences, which are designed to contain in the triple amino acid sequence an N2S2 unit that is able to coordinate directly to ^{99m}Tc (Ali et al. 1994; Lister-Jones et al. 1996; Pearson et al. 1996).

Peptides containing the RGD sequence can also be used in cancer diagnostics due to their ability of interacting with integrins that are responsible parts for platelet adhesion, activation, and leukocyte mobility and for cancer cell dissemination. As a consequence, RGD peptides and RGD mimetics bind to cancer cells and can be used for diagnosis (Sivolapenko et al. 1998).

Neurotensin is another peptide of oncological relevance. Neurotensin analogues are used for the diagnosis of carcinomas such as pancreas, prostate lung, and colon (Reubi et al. 1999; Reubi et al. 1998). Neurotensin has been derivatized with DTPA and more recently with chelators convenient for labeling with the [^{99m}Tc(CO)₃]⁺ moiety. Neurotensin and analogues suffer from fast degradation and various methods have been used for stabilization. Affinity, biodistribution, and labeling conditions for some of these stabilized neurotensin analogues are excellent and preclinical studies currently underway (Garcia-Garayoa et al. 2002). Another peptide in this context is neuropeptide Y (NPY), which is a 36 amino acid peptide from the pancreatic polypeptide family. It is one of the most abundant peptides in the brain (Tatemoto 1982). Its receptors are expressed in a number of neuroblastoma making them optimal targets for tumor scintigraphy. Modified NPY's have been labeled with the [Tc(CO)₃]⁺ approach. The radioconjugates showed high binding affinities that made them good candidates for further studies (Langer et al. 2001).

Bombesin is a further peptide that has been the subject of intensive investigations. Bombesin is a 14 amino acid linear peptide and an analogue of the human gastrin-releasing peptide (GRP). It binds with high affinity and specificity to the corresponding receptors (Mahmoud et al. 1991; Qin et al. 1994; Qin et al. 1995). The synthesis and characterization of radiolabeled BBN have been reported by different groups and various methods of labeling have been applied including all common methods ranging from N_xS_{4-x} to the labeling with the [Tc(CO)₃]⁺ moiety (Baidoo et al. 1998; Breeman et al. 1999a, b; Gali et al. 2001; Hoffman et al. 2001; Karra et al. 1999; La Bella et al. 2002; Moody and Perry 1989; Rogers et al. 1999; Rogers et al. 1997; Van de Wiele et al. 2000). In a recent work, structure–activity relationships of bombesin analogues comprising aliphatic spacers of variable lengths between the chelator and the peptide demonstrated that all compounds with a C3, C5, or C8 tether have high binding affinities and good biodistribution (Smith et al. 2003). As a chelating group, an N3S ligand has been employed, which allowed post-conjugation via the ^{99m}Tc-glucoheptonate intermediate in very good yields. A recent approach used demobesin, a novel linear bombesin analogue that was derivatized at the N-terminus through a spacer with a linear tetramine ligand. Labeling occurs according to a convenient method and gave the relatively rare Tc(V) complex containing the central [O=Tc=O]⁺ moiety (Nock et al. 2003).

Somatostatin is the peptide that has attracted most attention for the labeling of peptides. Receptors for somatostatin are expressed on numerous tumors, which is basic for its application as a radiopharmaceutical. Analogues for somatostatin have been developed and the cyclic octapeptide octreotide is a convenient compound that is reasonably stable toward enzymatic degradation while having similar bioactivity (Anderson et al. 2001; Lamberts 1988). In addition, many derivatives of octreotide have been synthesized. The labeling strategies are essentially based on conjugates with DTPA and DOTA (De Jong et al. 1999; De Jong et al. 1998; Heppeler et al. 2000; Krenning et al. 1993; Otte et al. 1997) and most important with the HYNIC approach discussed earlier in this section (Vallabhajosula et al. 1996).

A further class of peptides is the so-called tat-peptides, which are permeation peptides. It has been observed that tat peptides have rapid translocation properties seemingly independent of receptor-mediated endocytosis. Since membrane translocation is an important feature in drug delivery, tat-peptides are useful also for imaging and probably for therapeutic purposes

(Liu and Edwards 1999; Schwarze et al. 2000). In a recent study, a tat-peptide was tagged and labeled by the $[\text{Tc}(\text{CO})_3]^+$ approach. The conjugate was of excellent stability but accumulated in the liver. It could be shown in the radio assay that cell accumulation is occurring and it was confirmed with a dual labeled tat-peptide that the measured activity in the cell was largely due to peptide translocation into the cell, both in vivo and in vitro, confirming that the function of the peptide was fully retained (Bullok et al. 2002).

Finally, a newer methodology for the labeling of peptides shall be presented. Ligands and complexes are decisive for labeling and for the biological behavior of the tagged vectors. The same ligand but with a different ^{99m}Tc core does normally show very different biological behavior. Parallel studies of equal ligands and biomolecules but with different cores are feasible for chelators designed for the $[\text{Re}(\text{CO})_3]^+$ and the $[\text{Tc}(\text{CO})_3]^+$ core. An alternative strategy would be to keep the ligand constant, while altering the biomolecule. This strategy has been chosen with, e.g., the MAG3 ligand system or the hynic approach with the rationale of high complex stability and convenient labeling. To keep the ligand constant might not be justified when attempting to improve, e.g., biodistribution, but is justified when additional properties are introduced by the ligand or the complex. This is the case with the so-called single amino acid chelate (SAAC) approach. The basic ligands used in this approach are based on bis-methylpyridylamine, a very stable ligand for the $[\text{Tc}(\text{CO})_3]^+$ core. The central aliphatic amine is linked via an alkyl spacer to an α -amino acid group, which can be introduced in peptide chains at any place. Since the formed complexes are very robust, incorporation of the corresponding rhenium complexes can already be done during the automated peptide syntheses on solid phases. This allows for an easy and rapid preparation of libraries of peptides with the SAAC at various positions. Along this line an optimal peptide can be synthesized and selected for ^{99m}Tc labeling studies (Banerjee et al. 2005; Banerjee et al. 2003; Bartholoma et al. 2009).

If the pyridine ligands in bis-methylpyridylamine are replaced by quinolines (SAACQ), the important feature of fluorescence is introduced after coordination to the $[\text{Re}(\text{CO})_3]^+$ core. It is not possible to monitor the radioactivity distribution of a radiopharmaceutical on the cellular or subcellular level, but fluorescence microscopy allows for this option. Accordingly, the accumulation of the “cold,” rhenium-bearing pharmaceutical can be visualized via luminescence and, due to the matched pair Re and Tc, one can conclude for the behavior of the ^{99m}Tc analogue. This procedure has successfully been applied for peptides and biotin by the groups of Zubietta and Valliant (James et al. 2006a, b; Stephenson et al. 2004). Equally, isostructural compounds were applied for monitoring neural stem and progenitor cell transplants with fluorescence microscopy and radioactivity (Schaffer et al. 2008). The SAAC approach was used for the labeling of many different biomolecules according to the strategy of keeping the ligand constant, while altering the biomolecule. Besides the aforementioned peptide libraries, there are amyloid plaques (Stephenson et al. 2008), nucleosides (Wei et al. 2005; Wei et al. 2006), carbohydrates, and others (► Fig. 43.12).

43.6.2 Neuroreceptor Targeting Molecules

‘Some excellent reviews about neuroreceptor targeting agents recently appeared covering many important aspects of this field (Banerjee et al. 2001; Johannsen and Pietzsch 2002; Jurisson and Lxdon 1999; Kung et al. 2003). In the context of small receptor binding ^{99m}Tc-labeled biomolecules and pharmacophores, central nervous system (CNS) receptor targeting radiopharmaceuticals are most prominent, a vital need, and under active pursuit. A successful CNS

Fig. 43.12

The general design of SAAC(Q)-type ligands (top) (Bartholoma et al. 2009) and two examples of labeled thymidine with the bis-methylpyridineamine ligand (bottom) (Wei et al. 2005)

receptor targeting ^{99m}Tc radiopharmaceutical should have a small size ($\text{mw} < 600$), appropriate lipophilicity, and high specificity and selectivity for the particular receptor. Furthermore, for practical application, the labeling process with ^{99m}Tc should take place at low ligand concentration in order to prevent saturation of the receptors. This requirement is sometimes not an issue since the unlabeled vector is often not able to pass the BBB due to the presence of protonated amines and the resulting charge. Despite many efforts only a very limited number achieved the stage of preclinical investigations. Considerable effort is actually directed toward the use of dopamine transporter agents (DAT). They are useful in the evaluation of changes in the presynaptic DAT sites in vivo and in vitro. Several disorders such as Parkinson's disease are characterized by loss of dopamine neurones in basal ganglia or substantial nigra. The successful DAT imaging agents are based on tropane derivatives and some reviews have been dedicated to these compounds (Hom and Katzenellenbogen 1997b; Kung 2001). A relevant number of these derivatives and radiopharmaceuticals are depicted in Fig. 43.13.

The pioneering work in that respect was performed with DAT antagonist β -CIT (2-beta-carboxymethoxy-3-beta(4-iodophenyl)tropane) by Kung and coworkers who developed a potential DAT imaging agent possessing a tropane analogue derivatized with an N2S2 ligand. The ligand is linked through a tertiary amine to the lead structure that gives after labeling a neutral and highly lipophilic Tc(V) complex comprising the $[\text{Tc}=\text{O}]^{3+}$ moiety. This compound is generally referred to as TRODAT-1 (Kung et al. 1997; Meegalla et al. 1996, 1997). A second and similar approach was introduced by Madras who derivatized at the bridging nitrogen in the tropane framework. An aliphatic spacer links to an N2S2 ligand that contains one amido group and leads also to a neutral complex as required for a brain imaging agent (Madras et al. 1996). This compound is called ^{99m}Tc -Technepine.

■ Fig. 43.13

^{99m}Tc -based DAT radiopharmaceuticals: (a) [3+1] approach, (b/c) N2S2 approach (B=TRODAT-1), and (d) $[\text{Tc}(\text{CO})_3]^+$ approach TROTEC-1

The affinity constant of TRODAT-1 displays a K_i of about 10 nM/L, sufficiently high for excellent binding. (The determination of K_i values for all compounds is in general performed with the corresponding homologues containing cold rhenium instead of radioactive Tc isotopes.) As found with other compounds of the DADT type, two diastereomers exist, both of which are formed at the same time in about equal yields. Interestingly, both show about the same affinity and displayed selective uptake in the striatum, suggesting that the localization is consistent with the DAT distribution (Meegalla et al. 1998). Phase I clinical studies with TRODAT-1 have been performed for practical reasons with the mixture of the diastereomers. This is reasonable based on the available physicochemical and biological data of the compound (Mozley et al. 1998, 1999). Beside the approach described here, there are at least three different other approaches for the labeling of DAT, including the use of NS3 systems, cyclopentadienyl coordination, the [3+1] mixed ligand system, and others (Cesati et al. 1999; Fischmann et al. 1999; Hoepping et al. 1998; Meegalla et al. 1995; Meegalla et al. 1996; Meltzer et al. 2000). The importance of tiny alteration in, e.g., linker length has impressively been shown by introducing an ethyl spacer between tropane and the ligand in contrast the methylene spacer in TRODAT-1. The extension of only one carbon atom resulted in complete lack of brain uptake (Zhuang et al. 1999).

A further brain receptor targeting vector is WAY 100635, which is directed toward 5-HT_{1A} receptor, one of the most thoroughly studied serotonergic receptors. The lead structure has been reduced as shown in Fig. 43.14 and derivatized with various chelators.

The derivatization include MAMA (*monoamino-monoamido*) and DADT (*diamino-dithiol*)-type chelators, dithioethers for the labeling with the $[\text{Tc}(\text{CO})_3]^+$ moiety, the mixed ligand [3+1] approach, and, more recently, monodentate isocyanides for application in the mixed ligand [4+1] approach (Alberto et al. 1999; Baidoo 1995; Drews et al. 2001; Drews et al. 2002; Heimbold et al. 2002; Mahmood et al. 1999; Mallo et al. 1999; Oya et al. 1996; Plössl et al. 1995). Despite the engaged efforts, no valuable candidate is clinically evaluated.

Fig. 43.14

Different structures of ^{99m}Tc labeled-WAY, a serotonergic 5-HT_{1A} ligand

Most of the CNS receptors targeting radiopharmaceuticals mentioned before show high to very high affinity to the receptors, however, brain uptake and specificity remain a problem that represent an incentive for chemists. Penetration and high in vitro affinity is obviously not a guarantee for a successful radiopharmaceutical. The failure of receptor binding in brain of candidates with a comparable brain uptake to TRODAT-1 (~0.4%) might be due to the lack of the pyridine ring in the reduced version of the ligand, which is on the other hand not required for affinity. It has been argued that this structural feature is required for action as antagonist since no agonist has so far resulted in specific in vivo binding to the 5-HT_{1A}.

Beside these two important brain receptors, a number of others such as D₁, D₂, and D₃ as well as 5-HT_{2A} have been the subject of studies with ^{99m}Tc-labeled receptor ligands. Many efforts are not really successful so far and apart from TRODAT-1 only one other compound has entered phase I clinical trials (Callahan et al. 2001). This failure is however not a principle behavior of ^{99m}Tc compounds since the above-mentioned excellent candidates exists. A thorough analysis of the present situation indicates that inconsistent conceptual conditions in the evaluation of the biological behavior and structure–activity relationships between different groups hardly allow guiding the design of new compounds (Johannsen and Pietzsch 2002). Furthermore, the low or absent brain uptake of many high affinity ^{99m}Tc compounds is a main obstacle in the development of novel radiopharmaceuticals, a feature that must challenge the chemists since this is in fact a chemical problem that can probably be overcome

with the introduction of other smaller moieties of high lipophilicity and less influence on the topological features of the receptor-binding part.

The major approaches applied so far for the labeling of CNS receptor ligands are summarized in ► Fig. 43.15.

43.6.3 Myocardial Imaging Agents

Beside these established approaches, there has been progress toward novel myocardial imaging agents based on the so-called new cores. The nitrido approach mentioned before has been extended by introducing cyclic crown ethers to the thiocarbamate ligand bound to the $[\text{}^{99m}\text{TcN}(\text{PNP})]^{2+}$ moiety introduced by Duatti et al. (Liu 2007; Liu et al. 2006). The key finding of this study is that crown ether groups are very useful for modifying the biological properties of cationic compounds. In rats, some of these compounds had heart/liver ratios four to five times better than Sestamibi. The crown ether approach was extended with the same ligand also to the $[\text{}^{99m}\text{Tc}(\text{CO})_3]^+$ core. It could again be shown that the corresponding complex had biological properties superior to Sestamibi and was about identical to the complex with the respective complex with the $[\text{}^{99m}\text{TcN}(\text{PNP})]^{2+}$ core (He et al. 2006). A further significant improvement was achieved by Santos et al. who applied tris(pyrazolyl)methane-based ligands with the $[\text{}^{99m}\text{Tc}(\text{CO})_3]^+$ core (Maria et al. 2007, 2009). They received within very short time a stable heart uptake and a liver clearance rate that has not achieved by any of the other ^{99m}Tc complexes for myocardial imaging. These results provide an impetus for pursuing the search for novel radiopharmaceuticals to yield faster and more accurate diagnosis of coronary artery disease in humans (► Fig. 43.16).

To develop novel myocardial imaging agents with improved pharmacokinetics and biodistribution remains a major challenge in radiopharmaceutical chemistry. The previous examples are promising and the chemistry behind inspires future work. As an interesting fact, these examples show in particular that the same ligand can be selected for different metal cores. Thus, improving the biological behavior can not only be done by variations of the ligand (an often tedious procedure), but also by altering the metal core bound to the chelator.

43.6.4 Vitamins: Folate, Biotin, and B12

Vitamins are essential lead compounds for the development of novel radiopharmaceuticals. Many vitamin receptors such as the folate receptor are overexpressed on different tumor cell lines (Parker et al. 2005). Biotin labeled with ^{99m}Tc is under investigation since many years in different settings. A vitamin that has not found as much interest as biotin is vitamin B12. Since it is a relatively large molecule, it has been proposed to use B12 as a Trojan horse since rapidly proliferating cells and some bacterial stems show a high demand for this growth essential vitamin. While research toward labeled folate and B12 has intensified over the past couple of years, research with biotin rather slowed down. The biochemical pathways of folate and B12 are interlinked since folate delivers the –CH₃ group to the apoenzyme in order to activate it toward its function in the methionine synthase cycle.

Most attempts to label folate are based on the [^{99m}Tc=O]³⁺ core. BFC were usually DTPA- or MAG3-type chelators. More recently, chemistry with the [^{99m}Tc(CO)₃]⁺ core moved in (Liu et al. 2005; Okarvi and Jammaz 2006). Since DTPA can also be labeled with the [^{99m}Tc(CO)₃]⁺ core, Green et al. used the folate–DTPA conjugate (originally designed for [Tc=O]³⁺) for exploring its in vivo behavior with [^{99m}Tc(CO)₃]⁺ (Trump et al. 2002). Although it is not clear through which donors of DTPA the [^{99m}Tc(CO)₃]⁺ core coordinates, they received one single product in very good yield. The labeled conjugate underwent receptor-mediated uptake in KB cells in vitro. In vivo, the tracer showed accumulation in tissues with high levels of folate receptors but was not superior as compared to other compounds due to accumulation in nontarget tissue. Schibli et al. extended the field by systematically varying folate-bound chelators. At the same time, they administered antifolates together with the ^{99m}Tc-labeled folate. According to this strategy, they stated that parallel application of, e.g., methotrexate suppressed the kidney uptake of ^{99m}Tc-folate in the α-folate receptor positive kidneys. On the other hand, this method left uptake in other α-folate receptor positive neoplastic tissue unaltered opening new perspectives for the diagnosis and treatment of cancer patients (Muller et al. 2007; 2006a, b). Zubieta et al. finally applied folate derivatized with a bis-quinoline amine ligand via a PEG spacer. In vitro imaging and cytotoxic properties of these compounds were tested in detail. The conjugates were internalized by receptor-mediated endocytosis and exerted a substantial cytotoxic action. This behavior implied a concerted therapeutic action of the cold compounds and the ^{99m}Tc-labeled compounds for diagnosis (Viola-Villegas et al. 2008). Derivatives of folic acid are displayed in ► Fig. 43.17.

In the context of biotin, a chemically interesting approach was the combination of this vitamin with a luminescent complex based on a polypyridine ligand sphere bound to the [Re(CO)₃]⁺ core. Such complexes are also feasible for ^{99m}Tc, which would again enable the important combination of light and radioactivity (Lo and Hui 2005). It was found that the K_d value decreased by 4–6 log units upon conjugation of the complex and that the affinity was strongly spacer-dependent. The longer the spacer, the higher is the affinity, an observation which has been made several times in other studies with radiolabeled biotin and which is rationalized by the bulkiness of the complexes (► Figs. 43.17 and ► 43.18).

Studies toward ^{99m}Tc-labeled B12 have been reinforced over the past few years. B12 offers several sites to which a ligand and a complex may be bound. These sites are the propionato groups at the central corrin ring or the 2'-OH group in the ribose of the back loop. Both sites have extensively been derivatized with functionalities mainly for binding to ^{99m}Tc(V) or ¹¹¹In³⁺ (Collins and Hogenkamp 1997; Collins et al. 1999). Kidney and liver are critical and in vivo studies showed often high accumulation in these organs. More recently, B12 was also labeled

Fig. 43.17

Different folic acid derivatives used for labeling with ^{99m}Tc 

with the $[\text{}^{99m}\text{Tc}(\text{CO})_3]^+$ core using different ligands such as PAMA or histidine and bound to the b- or d-propionato groups via amide formation (► Fig. 43.19) (Alberto et al. 2004; Spingler et al. 2007; van Staveren et al. 2004a, b).

Some of these conjugates did not bind anymore to transcobalamin II (TCII), the transport protein for B12. Waibel et al. showed that TCII non-binders were still taken up in vivo by various cancer cell lines but showed only little retention in the kidneys. This approach resulted in excellent imaging opportunities in mice. Although it is not yet fully understood how these B12 derivatives are taken up by cancer cells, the results are very promising justifying studies in patients (Waibel et al. 2008).

In an uncommon approach, Mundwiler et al. introduced a different way of labeling vitamin B12 by coordinating various $[\text{}^{99m}\text{Tc}(\text{CO})_3]^+$ -core-based compounds directly to the cyanide in B12. According to this methodology, B12 acts as a simple (although structurally rather complex) ligand for the $[\text{}^{99m}\text{Tc}(\text{CO})_3]^+$ core. Despite the relative sterical bulk of these conjugates, these B12 derivatives did still bind to TCII. This is in agreement with the observation that many β -axial derivatives of B12 are tolerated by TCII (Kunze et al. 2004). Since some cancer cell lines and bacteria are high vitamin B12 consumers, B12 certainly merits more consideration as a radiopharmaceutical. Chemistry and biology of B12 are relatively complex.

■ Fig. 43.18

Synthetic strategy toward a biotin derivative with fluorescence properties after coordination of a tridentate ligand to the $[\text{Re}(\text{CO})_3]^+$ core (James et al. 2006a) and a [2+1] mixed ligand system (Lo and Hui 2005)

Still, the biological importance of B12 as a proliferation tracer merits endeavors to step into this field, which is justified by the unique authenticity of B12.

43.6.5 Multidrug Resistance

Tumors that are initially sensitive to cytotoxic agents often become refractory to multiple chemotherapeutic drugs. Cells grown in the presence of a specific cytotoxic drug can develop cross-resistance to this and other drugs in the same class and to other classes of drugs entirely. This phenomenon is related to the overexpression of the multidrug resistance (MDR1) transmembrane P-glycoprotein (Pgp). It is an objective of pharmaceutical research to develop molecules called modulators that are able to block the action of Pgp in order to re-establish chemotherapy. A noninvasive method to detect MDR in tumors would be an important diagnostic assay for management and prognostic stratification of cancer patients and a number of ^{99m}Tc coordination compounds have been tested for their ability to indicate the Pgp level in tumor cells. These are cationic and/or highly lipophilic complexes such as ^{99m}Tc -sestamibi (Wackers et al. 1989), ^{99m}Tc -tetrafosmin (Higley et al. 1993), and ^{99m}Tc -furifosmin (Q-compounds) (Crankshaw et al. 1998; Rossetti et al. 1994). The structures of these compounds have been discussed under the section on myocardial imaging agents, since they fall in this class of radiopharmaceuticals. These compounds have been tested as transport substrates

Fig. 43.19

Vitamin B12 derivatives with the chelators at two different sites: bound to the b-acid position (left) and to the 2'-OH group of the ribose in the back loop (right) (Collins and Hogenkamp 1997; Collins et al. 1999)

for Pgp for a variety of multidrug resistant cells in humans (Piwnicaworms et al. 1993). It was shown that the net cellular accumulation is inversely proportional to the amount of Pgp expressed and was significantly enhanced after the administration of modulators.

43.7 Recent Developments and Future Role of ^{99m}Tc -Radiopharmaceuticals

Fundamental technetium chemistry plays an essential role in the development of future radiopharmaceuticals. Although a number of reliable techniques for high-yield and high-stability labeling of targeting biomolecules exist, the possibility of variations is still limited. The metal complex plays an important role in the biological behavior of a radiopharmaceutical and is decisive for success or failure. This implies that more efforts have to be undertaken in the field of basic technetium chemistry, which is actually essentially limited to application in order to develop novel moieties and compounds that allow a convenient and reliable labeling of biomolecules while considering the other limitations given by future clinical application. These aspects have recently lead to the development of two different approaches based on the $[\text{TcN}]^{3+}$ moiety and the $[\text{Tc}(\text{CO})_3]^+$ core. Both concepts have one feature in common, which is probably essential for having extended possibilities in the selection of chelators and therefore in the properties of

the radiopharmaceutical. They represent a water-stable precursor that has two and three coordination sites left that can be substituted by a variety of incoming ligands. New radiopharmaceuticals are therefore not any longer restricted to more or less fixed ligands but allow a choice according to biological considerations. This is an important development that should inspire similar concepts but probably with other novel and even more convenient cores.

A concept which has not been explicitly described in here is the integration of technetium in the topology of the binding part of a biomolecule. Only a very limited number of such attempts have been described so far and are currently not under intense investigations. It is challenging to mimic a structure of a compound comprising main group element only with in general tetrahedral coordination by a transition metal element with octahedral or square pyramidal structure. Thus, it is compulsory to either find *de novo* receptor ligands based on technetium complexes or to introduce a tetrahedral technetium in an existing framework, both highly difficult objectives to be faced by the coordination chemist.

These novel cores mentioned above have already been subjected to the labeling of biomolecules. These approaches represent the only recent developments in ^{99m}Tc labeling chemistry. Since only a limited amount of biological data is available so far, it cannot be yet compared to the existing procedures. Clearly, the labeling chemistry is of comparable convenience and yield or characterization of the compounds much easier than in, e.g., the HYNIC approach. Again, only the development of new cores will also allow the introduction of new labeling techniques more convenient than the existing ones.

Despite the fact that methods such as MRI, ultrasound, and others become more and more competitive in fields previously reserved to radiopharmaceuticals, ^{99m}Tc will continue to play an important role in nuclear medicine because of the possibility of true functional diagnostics on the molecular level. PET also can substitute SPECT (and therefore ^{99m}Tc) in certain aspects, and the more and more cyclotrons built in hospitals underline this tendency. However, the price argument and availability are becoming more and more important factors in diagnostic medicine considering the costs of public health care. Last but not least radiotherapy is a strong factor of nuclear medicine. Probably ^{99m}Tc can act as a surrogate of processes and compounds produced in future with ¹⁸⁸Re, or ¹⁸⁶Re become active as a therapeutic radionuclide as such, again a role that cannot be taken over by the other methods. To keep ^{99m}Tc-based radiopharmaceuticals competitive it is clearly required that more techniques and labeled targeting molecules become available in near future; the first aspect concerns the innovation of the chemist and the second one the biologist and the physician.

Abstract: An overview of the chemistry of radioiodination is presented. The focus is directed on the labeling of iodine-containing radiopharmaceuticals, with emphasis on practical aspects of the various radioiodination methods. The advantages and disadvantages of these methods with respect to efficiency and ease of handling are discussed. Examples of the labeling methods are illustrated by protocols.

44.1 Introduction

The following paragraphs describe, for the most part, the practical aspects of the radioiodination methods followed, particularly, in radiopharmaceutical chemistry laboratories. Reviews describing the various aspects of radioiodination have been published elsewhere (see, e.g., Coenen et al. 1983; Wilbur 1992). The objective, here, is not so much to cover all the achievements in this field as to provide experimental instructions for routine laboratory work. Thus, a great part of the experimental details stems from experiences acquired in the authors' laboratories. The other experimental details have been taken from the literature.

All manipulations and procedures with radioactive material presented below have to be performed in appropriately shielded fume hoods or glove boxes. In addition, all preparations delivered for human application must meet good manufacturing practice (GMP) standards. Several constraints originating from these conventions should, however, be modified for practicability and radiation safety of personnel.

44.2 Radioisotopes of Iodine for Life Sciences

The Chart of Nuclides summarizes 33 radioactive isotopes of iodine (Pfennig et al. 2006). Four of these isotopes, namely ^{123}I , ^{124}I , ^{125}I , and ^{131}I , are currently applied in the field of life science, either for imaging, therapy, or in vitro studies. In addition, $^{120\text{m}}\text{I}$, $^{120\text{g}}\text{I}$, and ^{121}I are considered as potentially useful positron-emitting iodine isotopes (see also ▶ Chap. 39 in this Volume). ▶ Table 44.1 presents an overview of the physical characteristics of the commercially available radioiodoisotopes ^{123}I , ^{125}I , and ^{131}I . Sources of ^{124}I are mostly academic, but one supplier offers ^{124}I via internet (Ritverc 2003).

The four iodine isotopes are produced in a cyclotron or nuclear reactor (▶ Table 44.1; cf. also ▶ Chaps. 38 and ▶ 39 in this Volume). The nuclear reactions currently used for the commercial production of these isotopes are:

Many more nuclear reactions, which might better apply for other accelerators, are feasible. The irradiated targets have to be processed in order to obtain pure radioiodine isotopes in a solution with high activity concentrations. In case of tellurium-oxide targets, this is generally achieved by dry distillation and trapping of hydrogen iodide in 0.02 M NaOH.

Table 44.1

Radioiodine isotopes used in life sciences

Isotope	Production	Modes of decay	Half-life	E_{γ}/E_{β}^a	Specific activity ^b	Application
¹²³ I	Cyclotron	EC	13.2 h	159/–	>600 ^c	Imaging
¹²⁴ I	Cyclotron	EC/ β^+ (25%)	4.18 days	603/1,530	>30 ^d	Imaging
¹²⁵ I	Nuclear reactor	EC	59.4 days	35/–	>90	In vitro and therapy
¹³¹ I	Nuclear reactor	β^-	8.04 days	364/606	110	Imaging and therapy

^akeV/keV^bGBq μmol^{-1} at time of delivery; theoretic specific activities in GBq μmol^{-1} ^c8,780^d1,147

The *specific activities* summarized in ▶ Table 44.1 indicate differences that might have an impact on the desired application. Especially, radiopharmaceuticals used as receptor ligands are susceptible to a low specific activity of the applied radioisotope. Thus, contamination with stable iodine due to an intrinsic low specific activity and choice of radiolabeling method (*vide infra*) should be a matter of consideration. Another parameter influencing the success of radiolabeling is the activity concentration per volume. This value should also be high in order to obtain sufficiently high radiochemical yields (RCY). In case of diluted [¹²³I]iodide shipments, excess 0.02 M NaOH solution may be concentrated, but the outcome of the labeling is often unpredictable. This may be the result of the concentration of unknown contaminants.

44.3 Radioiodination of Organic Compounds

44.3.1 Radioiododethallation

One of the first reports on the application of *thallium(III) trifluoroacetate* (Tl(TFA)₃) for the radioiodination of organic compounds was given by the synthesis of 15-(4-[¹²³I]iodophenyl)pentadecanoic acid ([¹²³I]IPPA), which was used for the diagnosis of myocardial infarction (Kulkarni and Parkey 1982; Rellas et al. 1983). At the same time, methyl-branched ω -phenyl fatty acids were radiolabeled using the same procedure (Goodman et al. 1982). In the first step, Tl(TFA)₃ was reacted with 15-phenylpentadecanoic acid. This reaction, also called thallation, was performed in situ using trifluoroacetic acid as a solvent. Finally, addition of [¹²³I]iodide admixed with small amounts of carrier iodide (4 mol%) and heating to 50–100°C yielded [¹²³I]IPPA at about 70% yield. The still unresolved reaction mechanism is illustrated in ▶ Fig. 44.1.

In this case, a 4-[¹²³I]iodoaryl derivative is formed as the main product. Depending on the substituent positions, the formation of other derivatives is possible. In each case, this has to be investigated in detail. For more information refer, e.g., to Mekushev (1988).

The original radioiodination conditions have subsequently been changed as far as reactant concentrations, their molar ratios, and reaction temperatures are concerned. The following labeling procedure has been applied to ω -phenyl fatty acids (Eisenhut et al. 2000a).

Radioiododethallation. Twenty microliters of a 10 mM TFA solution of the ω -phenyl fatty acid is mixed with 10 μ l of 10 mM $\text{I}(\text{TFA})_3$ dissolved in TFA. After 10 min at ambient temperature, the solution is mixed with ^{131}I iodide. The volume of the latter solution should not exceed 10% of the total volume, because the solubility and water may impair the RCY. Alternatively, the ^{131}I iodide solution should be evaporated. Five minutes later, the reaction mixture is injected into an analytical RP18-HPLC column and separated with isocratic or gradient elution. The RCY ranges between 70% and 80% (isolated) and the specific activity is 70–90 GBq μmol^{-1} . The RCY drops considerably if no-carrier-added (n.c.a.) iodide solutions are used. This effect can be avoided by the addition of 10 nM carrier iodide/GBq ^{123}I .

Other compounds have also been labeled using the radioiododethallation method: benzamide derivatives (Nicholl et al. 1997; Mohammed et al. 1997; Eisenhut et al. 2000b), the benzoyloxycarbonyl group in zVAD-fmk (Haberkorn et al. 2001), and the nucleoside deoxycytidine. In comparison to previous methods using Chloramine-T, the latter reaction can be improved by the action of thallium(III) (Scherberg 1974; Linz 1982).  Figure 44.2 illustrates this reaction, which uses thallium(III) as an oxidant.

Thallium(III) catalyzed iodination of 2'-deoxycytidine (Mier 2002). In a screw-cap vial, 50 μ l of a solution of 2'-deoxycytidine hydrochloride (2.63 mg in 1 ml 0.5 M acetate buffer pH 5) are mixed with the Na^{131}I -solution. Twenty microliters of a solution of $\text{I}(\text{TFA})_3$ (5.43 mg in 1 ml 0.5 M acetate buffer pH 5) are added and the mixture is heated for 1 h to 60° C. Twenty microliters of a sodium thiosulfate solution (10 mg in 1 ml 0.5 M acetate buffer pH 5) are added and the mixture is separated by RP-HPLC. Elution with a linear gradient of a methanol / Tris-phosphate buffer (pH 2.6) yields no-carrier-added 5- ^{131}I iodo-deoxycytidine.

 Fig. 44.1

The radioiododethallation reaction

 Fig. 44.2

Radiodination of 2'-deoxycytidine

44.3.2 Radioiododehalogenation

A straightforward method for the introduction of radioiodine into aromatic compounds represents the radioiododehalogenation reaction. Regioselective halogen replacement induced by nucleophilic attack of radioiodide is an energy-demanding process, which is forced at its equilibrium state to the product side by the large molar excess of the starting material. Only the replacement of iodine and bromine by radioiodine is of interest in radiopharmaceutical chemistry. While radioiododeiodination takes place at about 160°C, radioiododebromination is fast enough only above 200°C (Liefhold and Eisenhut 1986). Appropriate solvents or melts providing an acidic environment are necessary to perform this kind of exchange reaction. The impact of energy, however, limits the scope of this method as degradation of the original compound and the product might occur.

An example for the radioiododeiodination reaction represents the preparation of o-[¹²³I] iodo-hippuric acid ([¹²³I]OIH); this preparation method was most often used in the early days of radiopharmaceutical chemistry. OIH (e.g., 15 mg) and [¹²³I]iodide were melted for 10 min at 160°C yielding >99% [¹²³I]OIH (Sinn et al. 1986). Exchange labeling was also applied for the radioiodination of 15-(4-iodophenyl) pentadecanoic acid (IPPA). In order to reduce the amount of starting material (1 mg) and to maintain the acidic environment, benzoic acid was added to the reaction mixture (Eisenhut 1982). A solid phase support was used to radioiodinate meta-iodobenzylguanidine (mIBG). (NH₄)₂SO₄ facilitated the radioiododeiodination reaction, resulting in a lowered exchange temperature (140°C) (Mangner et al. 1982). For radioiodinated benzodiazepines, this method is illustrated by the following procedure (Van Dort et al. 1988).

(NH₄)₂SO₄ facilitated radioiododeiodination. *A mixture of 5 mg (NH₄)₂SO₄ dissolved in 15 µl H₂O, 15 µg 7-iodo-1,3-dihydro-1-methyl-5-(4-chlorophenyl)-2H-1,4-benzodiazepine-2-one in 15 µl of acetone and 300 MBq ¹²³I is heated to dryness at 140°C. Air is then slowly passed through the reaction vial for 1 min and the dry reaction mixture maintained at 140°C for 30 min. The reaction mixture is dissolved in CH₂Cl₂ and separated on a silica cartridge using a series of solvents with 26% RCY.*

The radiochemical yields of all radioiododeiodination reactions strongly depend on the amount of the starting material. Consequently, low specific activities must still be considered as the major drawback of this method. In particular, this problem arose with large dose preparations of [¹³¹I]mIBG needed for therapy purposes. The pharmacological efficacy of mIBG necessitated the load limit of starting material. The various labeling techniques of mIBG have recently been reviewed and discussed (Wafelman et al. 1994).

In contrast to radioiododeiodination, exchange of bromine with radioiodine on aromatic systems is feasible for no-carrier-added syntheses. This method was, e.g., used to label fatty acid derivatives. Thus, 13-(4-[¹²³I]iodophenyl)-3-(p-phenylene)tridecanoic acid ([¹²³I]PHIPA 3-10) was prepared from the 4-bromophenyl derivative in a benzoic acid melt at an exchange temperature of 200°C (Liefhold and Eisenhut 1986). However, the method is laborious because two evaporation steps are needed before exchange can take place.

Radioiododebromination [¹²³I]iodide is evaporated under vacuum in a 1 ml glass ampoule made from a Pasteur Pipette. 10 µl (5 mM) of the bromo precursor and 40 µl 0.2 M benzoic acid are added, both dissolved in EtOH. The solution is shaken in order to dissolve the ¹²³I and evaporated slowly (!) until the precipitating solid appears dry. The ampoule is sealed under vacuum with a gas torch and heated at 200–230°C for 10 min. Then the cold ampoule is opened and the reaction mixture dissolved in 60-µl ethanol. For separation, this solution is injected completely in an analytical RP18-HPLC column. Seventy percent RCY is obtained for [¹²³I]PHIPA 3-10.

Reduction of the exchange temperature is achieved by the addition of catalytic amounts of Cu(I) and Cu(II) salts as well as HAuCl_4 . A series of methods have been published, e.g., mIBG, demonstrating the enhancement of labeling yields and specific activities at 100–140°C (reviewed in Wafelman et al. 1994). Although lower exchange temperatures are feasible, the presence of a transition metal may be another reason for product degradation. The following procedure exemplifies the transition metal-assisted exchange (Kämpfer et al. 1996).

Cu(I) assisted radioiododebromination. Forty microliter 11.5 mM (R,R)BrQNB dissolved in $\text{H}_2\text{O}/\text{EtOH}$ was mixed with 50 μl each of 10 mM Cu(I), Sn(II)SO_4 , and 9 mM ascorbic acid as well as 100 μl [^{123}I]iodide (150 MBq). The closed vial was heated in an autoclave at 132°C for 60 min. The resulting mixture was neutralized and purified over RP-18 cartridges with 57% RCY.

Radioiododehalogenation of aliphatic compounds parallel the experiences with the above mentioned aromatic systems. Due to the 40 kJ M^{-1} smaller bond strength, the exchange is effective at lower temperatures as compared to haloaryl groups. Less energy is, however, also required for the in vivo cleavage of the aliphatic I–C bond. In case of radioiodinated aliphatic long-chain fatty acids, the in vivo cleavage of radioiodine was prominent, mainly induced by the degradation of iodoacetic acid, the final product of β -oxidation. For new compounds, the stability of the aliphatic I–C bond has to be investigated in advance using in vivo experiments on animals.

44.3.3 Radioiododestannylation

One of the most effective and convenient radioiodination methods represents the radioiododestannylation reaction (Fig. 44.3). The advantages of this technology can be summarized as follows: (1) product formation proceeds with high specific activity, (2) little experimental effort is necessary for a fast reaction, and (3) the regioselectivity of the label is given. In particular, obtaining a high specific activity is attractive for receptor-selective radiopharmaceuticals (e.g., Baldwin et al. 1993) and for the improvement of efficacy of therapeutic agents like mIBG (Vaidyanathan and Zalutsky 1993).

At the beginning, the bromo- or iodoaryl derivative intended for the labeling has to be stannylated. Most often, the $(\text{nBu})_3\text{Sn}$ group is used to replace the aryl halogen, but Me_3Sn groups have also been applied. As an example, the tributylstannylation of 4'-iodococaine illustrates the procedure (Metwally et al. 1992).

Tributylstannylation. A mixture of 4'-iodococaine (429 mg, 1 mM), bis-(tributyl)distannane (1,734 mg, 3 mM), tetrakis(triphenylphosphine)palladium(0) (15 mg, 0.013 mM) and anhydrous toluene (20 ml) was stirred at 60°C for 72 h under dry nitrogen. After cooling to room temperature,

Fig. 44.3

The radioiododestannylation reaction

the reaction mixture was filtered and the solvent was removed in a rotary evaporator. The residue was applied to a column of silica gel (230–400 mesh, 2×20 cm) and eluted with a step gradient of hexane followed by a mixture of hexane, diethyl ether, and isopropylamine (70:30:3). The fractions containing product were pooled and evaporated. The stannylated product was obtained as an oil (350 mg, 60% yield).

The stannylation yields vary considerably. 3β -(4-iodophenyl)tropane-2 β -carboxylate, β -CIT was, e.g., tributylstannylated with only 4% yield (Baldwin et al. 1993). Therefore, to avoid the loss of valuable iodinated starting material column, chromatography should not end after the tributylstannylated product has been separated. More polar solvents may allow to elute the starting material for future stannylation reactions. Great care should be focused on the contamination of the stannylated product with the iodinated starting material, since this would result in a reduction of the specific activity which in turn has an impact on receptor binding. The stannylated precursor should be protected from light and stored in a refrigerator. Aliquots of stock solutions in, e.g., ethanol can be used for months, but the quality has to be checked from time to time by HPLC. A general example is given with the following procedure.

Radioiododestannylation. [^{123}I]iodide (0.4–1 GBq) is mixed with 5 μl of a 10 mM solution of the tributylstannylated precursor. Check for homogeneity of the solution and add ethanol if necessary. Add 10 μl H_2O_2 (4.5% in acetic acid), vortex and let the mixture stand for 10 min at room temperature. Inject the mixture on a RP-18 HPLC column (270×4 mm) and perform either isocratic or gradient elution. Seventy to ninety percent of RCY (isolated) is usually obtained.

It should be noted that volatile [^{123}I]iodomethane was produced during the preparation of 5-[^{123}I]iodo-6-nitroquipazine from the respective trimethylstannylated precursor. In contrast to the procedure described above, heating to about 100°C might explain [^{123}I]iodomethane formation.

The introduction of a tri(*n*-butyl)stannylated vinyl or prop-2-enyl group as prosthetic groups represents another feature of the radioiododestannylation reaction of small organic compounds. (*E*)- and (*Z*)-3-(tri-*n*-butylstannyl)prop-2-en-1-yl *p*-toluenesulfonate were, e.g., used as synthons to form propenyl stannanes of spiperone and diprenorphine (Musachio and Lever 1992). The preparation of the synthon started with propargyl alcohol, tri-*n*-butyltin hydride, and the radical initiator α,α' -azoisobutyronitril. After tosylation, the resulting stannylated alcohols are ready for the synthesis of various stannylated compounds. Similar labeling strategies have been applied to cocaine and quinuclidinylbenzilate derivatives (Goodman et al. 1994; McPherson et al. 1993).

44.3.4 Radioiododeboronation

The oxidative cleavage of the boron–carbon bond with radioiodide/Chloramine-T has been shown to be useful for the radioiodination of various organic compounds (Kabalka et al. 1981). This method is characterized by the reaction sequence in  Fig. 44.4.

After hydroboration, oxidation of radioiodide is performed with Chloramine-T, forming HO-I, which then adds to the C–B bond. The reactivity of the C–B bonds depends on the position of boron, which can either be formed from a terminal double bond or from an internal alkene. While the former case produces two radioiodinated compounds, the latter forms only one. Therefore, dicyclohexylborane is used for the hydroboration step. Both reactions, hydroboration of the alkene and radioiodination can be performed in one sequence without isolating the intermediately formed trialkylborane.

■ Fig. 44.4

The radioiododeboronation reaction

Apart from aliphatic derivatives, radioiodovinyl and radioiodoaryl compounds are obtained from vinylboronic and arylboronic acid intermediates. Thus, catecholborane was used for the hydroboration of alkynes. The following example published for the preparation of 11-cholesterylundec-1-en-1-yl boronic acid (Kabalka et al. 1988) may serve as a generalized hydroboration procedure.

Hydroboration with catecholborane. A solution of ω -undecynyl cholesteryl ether (2.06 g, 3.81 mM), dry THF (15 ml), and catecholborane (1.2 ml, 10.3 mM) was stirred under nitrogen at 60°C overnight. After cooling the solution to room temperature, THF (28 ml) was added, followed by the dropwise addition of water (24 ml). The resulting mixture was stirred for 3 days. Water (150 ml) was added dropwise with vigorous stirring to precipitate the product. The crude product was collected and reprecipitated from THF (15 ml) using water, as described above, to facilitate the removal of catechol. The resulting white precipitate was collected and chromatographed on a silica gel (100 g) column eluting with methanol/dichloromethane to provide the 11-cholesterylundec-1-en-1-yl boronic acid (1.53 g, 69%).

The boronated precursor is stable and may be used from stock for radioiodination as described by the following procedure (Kabalka et al. 1988).

Radioiododeboronation. A solution of 11-cholesterylundec-1-en-1-yl boronic acid (20 μ l of a 0.5 M solution in 50 aqueous THF), THF (85 μ l), and Na¹²⁵I (5 μ l) was mixed in a vial. Chloramine-T (25 μ l of a 0.5 M solution in 50% aqueous THF) was added and the reaction mixture capped and allowed to stand at room temperature for 1 h. The product was extracted into ether (4 \times 1 ml) and concentrated with a stream of nitrogen. The concentrate was spotted equally on two TLC plates and developed with 4% ether/petroleum ether. The radioactive bands corresponding to the product were scraped and extracted with ether (4 \times 1 ml). The radiochemical yield was 17%.

The work-up of the reaction mixture may alternatively be performed with more convenience and higher separation efficiency by using RP18-HPLC technology. The radiochemical yields reported from other boronated compounds amounted up to 61% (Kabalka et al. 2000).

Compared to the radioiododestannylation and radioiododeboronation reactions described above, the radioiododesilylation and radioiododemercuration reactions currently play a minor role in the radioiodination of imaging agents.

44.3.5 Direct Radioiodination

Chloramine-T and *N*-chlorosuccinimide have often been used for the labeling of activated aromatic compounds with radioiodine (see also ▶ Sect. 44.4.1). The reaction is illustrated by the scheme outlined in ▶ Fig. 44.5.

Fig. 44.5

Direct radioiodination by electrophilic aromatic substitution

Both agents are widely applied as auxiliary agents for radioiodination. The in situ formed $\text{Cl-}^{123}\text{I}$ or Na^{123}I adds to activated phenyl residues by an electrophilic aromatic substitution reaction. Since tyrosine comprises an activated phenyl residue, the labeling of proteins and peptides is performed with this method (*vide infra*). For smaller organic compounds like 2-hydroxy-6-methoxy-*N*-[(1-ethyl-2-pyrrolidinyl)methyl]benzamide (BZM), Chloramine-T has also been applied for radioiodination (Kung et al. 1988).

Direct radioiodination with Chloramine-T. Chloramine-T solution ($50\ \mu\text{l}$, $1\ \text{mg}\ \text{mL}^{-1}$) was added to a mixture of BZM ($50\ \mu\text{l}$, $1\ \text{mg}\ \text{mL}^{-1}$), sodium [^{125}I]iodide ($10\ \mu\text{l}$, 37–185 MBq [$1\text{--}5\ \text{mCi}$]), no-carrier-added, and phosphate buffer ($0.3\ \text{mL}$, pH 3) in a sealed vial. The reaction was allowed to proceed at room temperature for 1.5 min. The reaction was terminated with the addition of sodium bisulfite ($0.1\ \text{mL}$, $10\ \text{mg}\ \text{mL}^{-1}$) and neutralized with $0.4\ \text{M}$ sodium bicarbonate ($0.5\ \text{mL}$). The product was extracted with ethyl acetate ($3 \times 1\ \text{mL}$). The combined organic layers were dried by passing through an anhydrous sodium sulfate column ($0.2 \times 5\ \text{cm}$). The organic solution was evaporated under a stream of nitrogen, and the residue was dissolved in absolute ethanol ($50\text{--}200\ \mu\text{l}$). The desired product, [^{125}I]BZM, was isolated from the unreacted BZM and a small amount of unknown radioactive impurities by HPLC on a reverse phase column, with an isocratic solvent system 82:18 acetonitrile – pH 7 buffer ($10\ \text{mM}$ 3,3-dimethylglutaric acid). After the appropriate fractions were collected, the solvent was evaporated under a stream of nitrogen, and the product was re-extracted with ethyl acetate ($1 \times 3\ \text{mL}$). The solution containing the no-carrier-added product was condensed to dryness and redissolved in absolute ethanol (radiochemical purity >95%, overall yield 60%).

The orientation of the substitution reaction is sometimes not predictable (► Fig. 44.6). The formation of [^{125}I]BZM may result in two isomers but only the (S)-(–)-3-[^{125}I]iodo-2-hydroxy derivative is formed. The position of the radioiodine can be investigated by ^1H -NMR of the stable iodo derivative. Comparison of the stable and radioiodinated compounds with HPLC is proving the substituent position.

1,3,4,6-Tetrachloro-3,6-diphenylglycoluril (for structure refer to ► Sect. 44.4.2), better known as IodogenTM, has been introduced as an alternative to Chloramine-T for direct radioiodination (Fraker and Speck 1978). The advantage of IodogenTM lies in its stability and sparing solubility in water which has made use of for radiolabeling proteins (*vide infra*). Thus, IodogenTM dissolved in methylene chloride provides a ready-to-use stock solution from which aliquots are transferred into a conical glass vial and evaporated. Addition of the precursor molecule together with radioiodide results in a reaction mixture ready for RP18-HPLC separation. The following procedure exemplifies the procedure for the production of [^{123}I]SCH23982 (dopamine D_1 antagonist) on an industrial scale (Beer et al. 1993).

Chemical structure of 1,3,4,6-tetrachloro-3,6-diphenyl-1,2,3,4-tetrahydro-2H-benzazepine

Direct radioiodination with IodogenTM. [¹²³I]NaI (9.25–18.5 GBq in 0.1 N NaOH) was evaporated to dryness by means of a gentle stream of nitrogen and elevated temperature. Five hundred micrograms of (R)-(+)-2,3,4,5-tetrahydro-3-methyl-5-phenyl-1H-3-benzazepine-7-ol, (R)-(+)-SCH23390, was dissolved in 1 ml of 0.36 M H₃PO₄ and added to the vial with the radioactivity. This mixture was transferred to a vial coated with 500 µg of IodogenTM and stirred for 20 min at room temperature. The reaction mixture was purified using RP-HPLC. The product peak was collected, neutralized with an equal volume of 0.45 N NaOH and passed through a sterile filter.

I-Cl is also formed by the reaction illustrated in [Fig. 44.7](#).

Radioiodination of organic compounds applying this redox reaction has therefore been proven useful in various preparations, e.g., L-3-[¹²³I]iodo-α-methyltyrosine ([¹²³I]IMT). This labeling procedure has been applied to preparations in clinical studies (Henze et al. 2002).

Direct radioiodination with KIO₃. Twenty microliters of 10 mM L-α-methyltyrosine in 1 N HCl and 5 µl 50 mM KIO₃ in water were mixed and transferred to a vial containing 400–1,200 MBq [¹²³I]NaI in 0.02 M NaOH. After 10 min, the mixture was purified using an analytical RP₁₈-HPLC column. The RCY amounted to 80–95%. In order to obtain reproducible high radiochemical yields, 10-µl 0.1 mM NaI solution in water may be added to the radioiodine if

Fig. 44.6

3-[¹²⁵I]iodo- (left) and 5-[¹²⁵I]iodo-IBZM derivative

Fig. 44.7

ICI formation from radioiodide/IO₃[−]/HCl mixture

labeling with ^{123}I has to be performed. ^{131}I does not need this addition because intrinsic amounts of stable iodide are present.

An alternative oxidation agent for direct radioiodination is peracetic acid (Kung et al. 1991).

44.3.6 Other Methods

The preparation of radioiodinated arenes from aryl amines by means of the Sandmeyer reaction has proven to be impractical. The unstable diazonium compounds, however, may be converted into stable pyrrolidine triazenes or dialkyltriazenes and used as precursors for labeling. The reaction sequence using pyrrolidine is shown in Fig. 44.8.

For example, the labeling of (*R,S*)-(-)-1-azabicyclo[2.2.2]oct-3-yl-(*R,S*)- α -hydroxy- α -[4-[2-(3-methylpiperidin-1-yl)-1,2-diazaethylen-1-yl]phenyl]- α -phenylacetate (the 4-triazeno derivative of QNB) with ^{123}I using this reaction pathway was accomplished by the following procedure (Rzeszutarski et al. 1984).

One milligram (2.16 μM) of the 4-triazeno derivative of QNB in 100 μl trifluoroethanol (TFE) was added to 407–555 MBq sodium [^{123}I]iodide in 50–120 μl of 0.1 N NaOH. The pH was adjusted to 5.5 ± 0.5 with methanesulfonic acid in TFE. If the need arose, an additional amount of TFE was added to dissolve the reactants. The mixture was sealed in a vial and heated under stirring at 78°C for 50 min. After cooling, the reaction mixture was processed by HPLC. The average specific activity amounted to 20 GBq μM^{-1} and the RCY was 8%.

44.4 Radioiodination of Peptides and Proteins

As described in the previous paragraphs, radioiodination of aromatic compounds is usually performed by the electrophilic substitution mechanism. Peptides and proteins containing amino acids with aryl substituents can be labeled with radioiodine using this reaction. While the susceptibility of phenylalanine for electrophilic aromatic substitution is low, the reactivity is strongly increased by additional electron-donating substituents such as hydroxy or amine groups. The increase of the electron density in the aromatic ring leads to an activation for electrophilic attack. Consequently, tyrosine, in particular in its phenolate form at $\text{pH} > 7$, is the main site of protein iodination. In comparison with tyrosine, the electron density of the imidazole ring of histidine is lower. Therefore, electrophilic substitution reactions require higher pH and a higher amount of oxidant.

Most of the other alternatives to incorporate radioiodine into peptides and proteins such as the sulfenyl iodide formation of cysteine are reversible and do not, therefore, lead to stable

Fig. 44.8

The radioiododetriazene reaction

iodinated products. The indole ring of tryptophane can also be radioiodinated. However, iodinated tryptophane undergoes hydrolysis and oxidation reactions, resulting in the formation of an unstable oxindole. This leads to the cleavage of the peptide chain (Alexander 1974).

The addition of one radioiodine atom to large molecules such as antibodies does not usually affect their immunoreactivity. The iodine substituent is too small to induce significant conformational changes of the structure of large molecules. In contrast, the labeling process using oxidation agents as well as the addition of reducing agents to stop the labeling reaction may have destructive effects on sensitive sites of the biomolecules. Depending on the labeling conditions, denaturation can occur due to oligomerization, conformational changes due to the changes of functional groups, or the cleavage of disulfide bonds. Consequently, labeling reactions have to be adapted to the individual proteins or peptides including proof of functional integrity.

Due to the ease of handling and efficiency, the Chloramine-T method is still the most widely used radioiodination procedure and represents an effective way to label a variety of proteins and peptides such as albumins, globulins, neuropeptides, and chemokines. Several other methods, such as the enzymatically catalyzed iodination with lactoperoxidase, have been developed. These methods allow the labeling with mild reaction conditions. In the case of extreme oxidation, sensitive proteins such as pituitary hormones and reactive pre-iodinated compounds such as the Bolton and Hunter reagent can be used to incorporate radioiodine.

44.4.1 Chloramine-T

The sodium salt of *N*-chloro-*p*-toluenesulfonamide, Chloramine-T is a water-soluble reagent with strong oxidizing properties. At pH 7–8, Chloramine-T hydrolyzes and releases hypochlorite (ClO^-), which is an effective oxidizing agent that forms ICl upon contact with radioiodide (for reaction scheme refer to [Fig. 44.5](#), [Sect. 44.3.5](#)).

ICl rapidly undergoes electrophilic substitution predominantly with tyrosine residues of the target molecule. The reaction is fast and finishes within a few seconds. The optimum conditions for the mild incorporation of radioiodine into proteins are a low temperature of 4°C, a pH value in the range of 6–8, and a short reaction time of <1 min. Chloramine-T often degrades sensitive peptides. This has to be prevented by the addition of a reducing agent.

The use of cysteine as a reducing agent is not advisable for peptides or proteins with disulfide bridges. In this case, tyrosine is recommended as it stops the reaction by consuming excess I–Cl, or methionine, which is oxidized. Even though it induces harsher reaction conditions than iodogen, iodobeads, or lactoperoxidase (*vide infra*), Chloramine-T is the most commonly employed agent for radioiodinating peptides and proteins. Iodogen and iodobeads do not allow the labeling of tyrosine residues that are not present on the surface of a protein. Consequently, the amount of iodine that is incorporated into antibodies, e.g., is higher with Chloramine-T. Yields of up to 90% can be obtained with high specific activity. Chloramine-T has to be stored in darkness because it decomposes if exposed to light.

Radioiodination of proteins using Chloramine-T (McConahey and Dixon 1980). In a reaction vial, 10 µg of the protein is mixed with radioiodide in 50-µl 0.25 M phosphate buffer pH 7.5. Five microliters of a freshly prepared solution of Chloramine-T (2 mg ml⁻¹) in 0.25 M phosphate buffer pH 7.5 is added and the solution is mixed. After 30 s, 20 µl of a saturated solution of methionine in 0.25 M phosphate buffer pH 7.5 and 20 ml of a 1% solution

of a suitable carrier-protein (e.g., BSA) is added. The reaction mixture is purified on a size exclusion column or using another appropriate method.

The following example illustrates the procedure for the radioiodination of peptides.

Radioiodination of Tyr³-octreotide using Chloramine-T (modified from Bakker et al. 1990). Twenty-five microliters of 10^{−3} M Tyr³-octreotide is mixed in a reaction vial with 10 MBq ¹²⁵I. 10 μl of a freshly prepared solution of 10^{−2} M Chloramine-T in 0.25 M phosphate buffer pH 7.4 is added. After 30 s, 10 μl of a saturated solution of methionine in 0.25 M phosphate buffer pH 7.4 is added and the reaction mixture is vortexed. Purification is accomplished by reversed-phase HPLC. As Chloramine-T reveals a very similar retention time as the ¹²⁵I labeled Tyr³-octreotide, the eluent system H₂O/acetonitrile containing TFA is not suited for this purpose. Using a gradient of 0% B → 100% B in 30 min (A = Tris-phosphate buffer pH 2.6 and B = methanol), flow rate = 0.7 ml min^{−1}, the radiolabeled peptide can be purified. The ¹²⁵I-labeled peptide can be stored for up to 1 month at −20°C.

44.4.2 Iodogen

Iodogen, 1,3,4,6-tetrachloro-3α,6α-diphenylglycouril, was first described as a mild oxidizing agent for radioiodination by Fraker et al. (see also ▶ Sect. 44.3.5). This *N*-chloro compound is highly insoluble under aqueous conditions and can, therefore, be used as a “solid phase” oxidant.

The reaction mixture is simply separated from the oxidant by decantation. For this purpose, the compound is dissolved, e.g., in chloroform, added to the reaction vial, and coated onto the surface by careful evaporation of the solvent. The coated vials can be prepared in advance and stored in a desiccator. A mixture of the protein and radioiodide is incubated in the reaction vial for a few minutes. Thereafter, the mixture is transferred to a size exclusion or ion exchange column and separated from unbound radioiodide. The reaction proceeds with very little protein denaturation, which may be explained by the reaction on the solid phase (IodogenTM).

Iodination using IodogenTM (Fukunaga et al. 1990). 18.5 MBq of Na¹²⁵I in 50 μl of distilled water was added to a glass tube coated with 10 μg of IodogenTM and incubated for 7 min on ice. The solution was then transferred to a tube containing 1.5 μg of recombinant mouse G-CSF dissolved in 6 μl of 0.25 M sodium phosphate buffer (pH 7.1) and allowed to react for 10 min at 0°C. The reaction was stopped by adding approximately 1 mg of tyrosine powder, and the labeled G-CSF was separated from free [¹²⁵I]iodide by gel filtration on a PD-10 column (GE Healthcare) equilibrated with Dubbecco's phosphate-buffered saline (PBS) containing 0.1% gelatin, 0.005% Tween 20, and 0.02% NaN₃. The material eluted at void volume was then further purified using a Superose 12 column.

44.4.3 Iodobeads

Iodobeads represent an immobilized form of Chloramine-T (Markwell 1982). This commercially available reagent (Pierce) consists of hydrophilized polystyrene beads labeled with *N*-chlorobenzenesulfonamide. The labeling reaction starts when the beads are added to a mixture of radioiodide and protein to be labeled (▶ Fig. 44.9). The removal of the beads with tweezers or a Pasteur pipette stops the reaction. Consequently, no reducing agent has to be added to terminate the reaction. The method works over a fairly broad pH range (5.5–8.5) with the most favorable pH at 6.5.

■ Fig. 44.9

Reaction sequence for the radioiodination of a protein with Iodobeads. In the first step, the *N*-chloro substituent of the benzenesulfonamide is substituted by radioiodide. The covalently bound iodine reacts subsequently with an activated aromatic side chain of the protein. The degree of damage to the protein is restricted because the reaction only proceeds on the surface of the polymer beads.

Under these conditions, radioiodine incorporation of up to 99% can be achieved at labeled protein recovery rates of >90%. The reaction is more gentle than soluble Chloramine-T because there is less contact between the protein and the immobilized oxidizing agent. If the reaction is conducted at pH values above 8, it is possible to radioiodinate histidine residues. The reaction is believed to proceed in the close proximity of the surface of the polymer beads. An electrophilic iodosulfonamide intermediate species that reacts with either tyrosine or histidine residues of the protein to be labeled is formed.

Iodination using Iodobeads (derived from the manufacturers protocol, Pierce). One Iodobead is rinsed with phosphate buffer (depending on the amount of protein to be labeled, several beads have to be used; the maximum of protein is 500 µg/bead). The bead is placed into the reaction vial containing 100 µl 0.1 M phosphate buffer pH 6.5 followed by a solution of the [¹²⁵I]NaI. After 2 min, a solution of 100 µg of the protein in 100 µl 0.1 M phosphate buffer pH 6.5 is added and the mixture is shaken for 5 min. In order to separate the labeled protein from free iodine, the entire reaction mixture is applied to size exclusion chromatography using Sephadex G-25M. The concentration of protein can be determined by measuring the absorption at 280 nm.

44.4.4 Lactoperoxidase

In search of alternatives to Chloramine-T, Morrison (1980) demonstrated that lactoperoxidase from bovine milk was particularly effective for iodide oxidation and the radioiodination of proteins. The single strand polypeptide lactoperoxidase has a molecular weight of approximately 78 kD. The structure of lactoperoxidase contains a prosthetic heme group which is covalently linked to the protein at the active site of the enzyme. In the presence of minute quantities of hydrogen peroxide, lactoperoxidase oxidizes and binds radioiodide to proteins in the reaction mixture. The pH optimum of iodide oxidation by lactoperoxidase is 4–8.5 with an optimum at pH 5. The reaction is extremely rapid, allowing reaction times of less than 1 min. This provides very mild conditions and denaturation of proteins is low. Yields of up to 85% can be obtained and the method is widely used for labeling proteins and hormones. Lactoperoxidase may itself

become radioiodinated. It is difficult to remove the labeled peroxidase, particularly if the protein of interest is of similar molecular size. Therefore, this method is only suitable if the contamination with labeled lactoperoxidase does not interfere with the application of the labeled protein.

Iodination using lactoperoxidase (derived from the manufacturers protocol, Sigma-Aldrich). Lactoperoxidase is dissolved at a concentration of 10 mg mL^{-1} in 0.1 M sodium acetate buffer at pH 5.6. Aliquots can be stored at -80°C . Care should be taken because the enzyme is sensitive to extraneous substances in the reaction mixture, in particular azide and hydrazides. Ten micrograms of the protein are mixed with radioiodine and 100 ng of lactoperoxidase in $100 \mu\text{l}$ of 0.25 M sodium acetate buffer at pH 5.6. The reaction is started by gently mixing with 100 ng of a freshly prepared hydrogen peroxide solution ($10 \mu\text{g mL}^{-1}$). After standing at room temperature for 20 min , the reaction is stopped by the addition of 0.9 ml of a solution of 0.05 M sodium phosphate buffer at pH 7.4 and the reaction mixture is immediately purified on a Sephadex G-25 column.

The separation of lactoperoxidase from the labeled protein may be avoided by using the immobilized enzyme (David and Reisfeld 1974). This technique applies immobilized lactoperoxidase together with glucose oxidase, which produces H_2O_2 in the presence of glucose.

44.4.5 Heterobifunctional Reagents

Heterobifunctional reagents can be used to radioiodinate peptides or proteins, which do not contain a tyrosine residue or peptides whose biological function is impaired by tyrosine iodination. Heterobifunctional reagents typically combine 4-hydroxyphenyl groups with a moiety that is reactive toward, e.g., amine or thiol groups of the target molecule. The reactive groups include succinimidyl or sulfosuccinimidyl esters, which can be coupled to lysine residues; maleimides, which can be coupled to thiols; diazonium salts, which can be coupled to tyrosine; or histidine residues and hydrazides, which can be coupled to oxidized glycoproteins. In most of these heterobifunctional compounds, the moiety susceptible to radioiodination is a phenol derivative. Phenolic groups are, however, iodinated in the *ortho*- and *para*-position, yielding products which are analogous to naturally occurring iodotyrosines such as the thyroid hormone thyroxine. Due to the action of deiodinases and due to the reversibility of the electrophile aromatic substitution, these compounds are unstable in vivo.

As outlined in [Fig. 44.10](#), organotin derivatives have therefore been developed for radioiodination in the *meta*-position of the phenyl residue (Zalutsky and Narula 1987). Organotin derivatives can be iodinated by the radioiododestannylation reaction (see also

Fig. 44.10

Chemical structures of representative heterobifunctional reagents for the radioiodination of proteins. (a) Bolton and Hunter reagent, (b) water-soluble Bolton and Hunter reagent, (c) succinimidyl 3-(tributylstannyl)benzoate

► Sect. 44.3.3) in the presence of hydroperoxide. These compounds proved to be highly resistant to deiodination processes in vivo (Zalutsky et al. 1989).

The radioiodinated Bolton and Hunter reagent (3-(4-hydroxy-3-[125 I]iodo-phenyl)-*N*-succinimidyl-propionate) is the prototype of a heterobifunctional reagent used for the labeling of peptides and proteins (Bolton and Hunter 1973, 1973) (► Fig. 44.10). Proteins lacking tyrosines or proteins sensitive against the denaturing influence of oxidizing agents are labeled via amide bond formation at lysine residues. The optimum condition for the conjugation of the Bolton and Hunter reagent with *N*-terminal amino groups is at a pH of 8.5.

Iodination of Annexin V with water-soluble Bolton and Hunter reagent (Russel et al. 2002). Water-soluble Bolton and Hunter reagent was dissolved in a glass vial in dimethyl sulfoxide at 1.5 mM (0.55 mg mL⁻¹). Ten microliters of Chloramine-T (5 mg mL⁻¹ in PBS) were added to Na¹²⁵I (37 MBq) neutralized in 10 µl PBS, followed by 1 µl water-soluble Bolton and Hunter reagent. The reaction was allowed to proceed for 1 min, stopped by the addition of 10 µl sodium metabisulfite (12 mg mL⁻¹ in PBS), and immediate addition of the Annexin (50 µg protein in 0.5 M borate pH 9.2). After 1 h, the conjugation reaction was stopped by the addition of 300 µl of 0.2 M glycine in 0.2 M borate (pH 8). Annexin V was purified by spinning repeatedly through a Microcon concentrator (Millipore).

44.5 Rating of Radioiodination Methods

For routine labeling of radiopharmaceuticals, the most convenient procedures are recommended because time is a factor barely available for chemists, especially from the physician's point of view. Needless to state, the physical half-life of the more exotic iodine radioisotopes requires similar efforts. Thus, simple pipetting steps are mandatory for the preparation to fulfill the requirements speed and radiation protection. In addition, pipetting steps can be automated and help to optimize the latter aspect.

A key position for radiolabeling is therefore assigned for a suitable labeling precursor, which assures high yields of the expected radiopharmaceutical. The reactions summarized in ► Table 44.2 are in the authors' view the most appropriate radioiodination methods.

The assessment of the radioiododestannylation reaction as the best method relies on the ease of reaction performance giving high radiochemical yields with high specific activity and a predictable regioselective attachment of the radioiodine. This advantage has its price, however: the preceding synthesis of the stannylated precursor is labor intensive. Nevertheless,

■ Table 44.2

Radioiodination methods

Method	Specific activity ^a	RCY ^b	Position of radioiodine	Rating
Radioiododethallation	Medium/high	High	Varies	Good
Radioiododehalogenation	Medium/high	High	Regioselective	Labor intensive
Radioiododestannylation	High	High	Regioselective	Best
direct radioiodination	Medium/high	High	Varies	Good
heterobifunctional reagents	Low	Low	Varies	Labor intensive

^aHigh: >50 GBq µM⁻¹; medium: between 10 and 50 GBq µM⁻¹; low: <10 GBq µM⁻¹

^bRCY radiochemical yield: high: >60%; low: <30% (isolated final product)

■ Fig. 44.11

Disseminated visceral, soft-tissue and lymph node metastases 20 h after injection of [^{123}I]IMBA (Image by courtesy of B. Bubeck)

owing to the stability of the stannylated precursors and the very small quantities needed for the radioiododestannylation reaction, this work is worth the effort. The other methods, such as radioiododethallation and direct radioiodination, are also often applied in routine radiolabeling reactions. The only disadvantage of these methods is the potential formation of by-products, which have to be removed from the final product.

■ Fig. 44.12

Bilateral pheochromocytoma (M. Recklinghausen), 1 (left) and 24 h post injection of [^{123}I]mIBG (Image by courtesy of U. Haberkorn)

The removal of by-products, precursor, and unreacted radioiodide is mandatory for all radiolabeling reactions. Several chromatographic techniques may be applied to this purpose. Among them, RP_{18} HPLC is currently the most powerful method because it is easy to perform and the separation efficiency is very high under gradient conditions. Evaporation of the organic solvent from the separated radiopharmaceutical may sometimes be time consuming. It should therefore be tested whether ethanol can be used in combination with, e.g., Tris-phosphate buffer for the separation task. This eluate may be formulated for intravenous application without solvent evaporation.

■ Fig. 44.13

Transaxial SPECT image showing striatal accumulation of [^{123}I] β -CIT (Image by courtesy of K. Tatsch)

■ Fig. 44.14

Transaxial SPECT image showing accumulation of [^{123}I]IBZM in the basal ganglia and to a lesser extent in the cortex (Image by courtesy of K. Tatsch)

In case unreacted radioiodide is the only contaminant after, e.g., direct radioiodination, its removal may be accomplished by filtration over AgCl

Dry AgCl of 0.5 g is transferred to a Pasteur Pipette which was tipped before with glass wool. This small column removed quantitatively radioiodide from the reaction mixtures of the

radioiododehalogenation reaction used for [^{123}I]OIH (Sinn et al. 1986) and the direct radioiodination of benzylidenediphosphonates (Eisenhut 1984).

RP₁₈ cartridges (e.g., SepPack, Waters) have also been used for the removal of unwanted reaction products. The efforts to establish reliable separation techniques using cartridge technology are, however, hampered by several drawbacks: (1) The separation efficiency is low because of a small bed volume. (2) The cartridge capacity is too small to separate the labeling mixture. (3) UV and gamma online monitoring is not possible, and (4) the radiation exposure is higher because of the more complicated handling. Compared to the analytical RP₁₈ HPLC columns, RP₁₈ cartridges may be useful only for simple separation steps depending on large lipophilicity differences.

44.6 Examples of Clinical Applications

44.6.1 Radioiododethallation

[^{123}I]IMBA (*N*-(2-diethylaminoethyl)-3-[^{123}I]iodo-4-methoxybenzamide) (► Fig. 44.11)

44.6.2 Radioiododehalogenation

[^{123}I]mIBG (3-[^{123}I]iodo-meta-benzylguanidine) (► Fig. 44.12)

44.6.3 Radioiododestannylation

[^{123}I]β-CIT (3β-(4-[^{123}I]iodophenyl)tropane-2β-carboxylate) (► Fig. 44.13)

44.6.4 Direct Radioiodination

[^{123}I]IBZM ((S)-(-)-3-[^{123}I]iodo-2-hydroxy-6-methoxy-*N*-[(1-ethyl-2-pyrrolidinyl)methyl]benzamide) (► Fig. 44.14)

Abstract: Radiometals are of increased current interest because of the growing use of targeted radiotherapy for tumors and the development of generators that produce positron-emitting radiometals. In addition, biomedical cyclotrons allow the cheap production of some relevant radiometals. The design of the corresponding radiopharmaceuticals includes the synthesis of bifunctional chelators, which carry a functional unit for the immobilization of the radiometal and a functional group for the covalent attachment to a vector molecule. Radiometals of interest for therapeutic applications are some lanthanides, ^{67}Cu , and ^{90}Y . For diagnostic applications ^{61}Cu , ^{62}Cu , ^{64}Cu , ^{89}Zr , and ^{68}Ga are currently used and corresponding radiopharmaceuticals are being designed. In this chapter, some properties and the synthesis of bifunctional chelators including metal ion selectivity and special aspects of coupling chemistry are being described.

45.1 Introduction

The use of radiometals (non-Tc, non-Re) has increased over the last 10 years and their chemistry and radiopharmacy have received renewed interest. One of the reasons is the development of generators that produce positron-emitting radiometals along with the technological progress, which led to the combination of imaging techniques, such as the positron emission tomography/computerized tomography (PET/CT) instruments, but the main reason is the fast development of clinical targeted radiotherapy in nuclear oncology. In principle, this technique can deliver selectively high linear energy transfer (LET) radiation to the tumor site. The search for an ideal therapeutic radionuclide – which most likely does not exist – has been the driving force to produce radionuclides with different half-lives and energy or even emitting different particles. In addition, efforts to produce some of the interesting carrier-free lanthanides appear to be successful and may lead to new therapeutic radionuclides. The currently most often used therapeutic radiometals are ^{90}Y , ^{177}Lu , and the two Re-isotopes ^{186}Re and ^{188}Re (see [Chap. 46](#) of this Volume).

Of particular interest in this respect is the class of lanthanides including $^{90}\text{Y}^{3+}$; several of them can be produced in high-flux reactors. As they have similar chemical characteristics, their production and use in therapeutic radiopharmaceuticals would allow studying the influence of dose rate and β^- energy on tumor response as it can be assumed that the same labeling chemistry can be applied to all lanthanide-based radiopharmaceuticals. This will most likely result in identical or at least very similar pharmacokinetics. The radiophysical properties of the radiolanthanides under study are compiled in [Table 45.2](#) (ICRP 1983).

Yttrium-90 has similar chemical properties and is usually being considered an analog of the lanthanides (Cotton and Wilkinson 1988). Its major production route is via the $^{90}\text{Sr}/^{90}\text{Y}$ generator (see [Chap. 40](#) of this Volume). All lanthanides in their major oxidation state 3+ can be considered hard Lewis acids and the best way to stabilize them for in vivo use is with macrocyclic chelators like DOTA (1,4,7,10-tetraaza-dodecane-1,4,7,10-tetraacetic acid) and modifications thereof.

The radioisotopes of copper represent another important group. Copper radioisotopes and their radiopharmaceuticals have been discussed in some recent reviews (Wadas et al. 2007; Anderson and Ferdani 2009; Shokeen and Anderson 2009). Radioisotopes of copper offer a variety of potential applications as their radiophysical properties are almost unique ([Tables 45.1](#) and [45.2](#)) (ICRP 1983). They offer a selection of different decay patterns: β^- , electron capture, and positron emission (β^+). Copper-64 combines all three decay modes, which makes it particularly attractive and versatile. It can be produced in large quantities using

Table 45.1

Nuclear properties of some gamma and positron emitting diagnostic radionuclides (ICRP 1983)

Isotope	Half-life [h]	Decay mode	\bar{E}_β [keV] (%)	E_γ [keV] (%)
⁶⁷ Ga	78.3	EC, Auger		93 (38), 185 (21)
¹¹¹ In	67.2	Auger, γ		171 (90), 247 (94)

Lanthanides				
¹⁴⁹ Pm	2.21 days	β^- , γ	0.37 (97)	286 (2.9)
¹⁵³ Sm	1.95 days	β^- , γ	0.23 (43), 0.20 (35)	103 (28)
¹⁶⁶ Dy	3.40 days	β^- , γ	0.12 (91)	82.5 (13)
¹⁶⁶ Ho	1.12 days	β^- , γ	0.69 (51), 0.65 (48)	80.6 (6.2)
¹⁷⁷ Lu	6.71 days	β^- , γ	0.15 (79)	208 (11)

biomedical cyclotrons (McCarthy et al. 1997; Obata et al. 2003, see also Chap. 39 of this Volume). It may be used in PET imaging and targeted radiotherapy.

Another attractive aspect of copper radiopharmacy is the fact that the ⁶²Zn/⁶²Cu PET generator can be inexpensively and reliably produced and was shown to be of use in the clinic successfully in the production of the PET perfusion agent ⁶²Cu-PTSM (see Chap. 40 of this Volume).

The coordination chemistry of copper is somewhat more complex than the one of the lanthanides. The most important oxidation state in aqueous solution is Cu^{II} but Cu^{I} is accessible in physiological medium and appears to play a role in the trapping mechanism of copper radiopharmaceuticals used to image hypoxia. Cu^{II} has the electron configuration $[\text{Ar}]3\text{d}^9$, which causes the octahedral and tetrahedral complexes to be distorted by Jahn–Teller effect. This has a profound effect on the stereochemistry and Cu^{II} complexes of planar, distorted tetrahedral, pentacoordinate, and tetragonally distorted octahedral geometry have been characterized. The kinetics of ligand exchange usually is very fast, Cu^{II} complexes are labile, and the design of Cu^{II} radiopharmaceuticals relies on the use of macrocyclic ligands. This condition affords kinetically stable radiocopper complexes.

Another successfully used and commercially available generator system is the $^{68}\text{Ge}/^{68}\text{Ga}$ generator that produces $^{68}\text{Ga}^{3+}$ in 0.1–1 N HCl, which may become an additional incentive to develop radiogallium-based radiopharmaceuticals (Al-Nahhas et al. 2007; Fani et al. 2008, see also [Chap. 40](#) of this Volume). The development of small receptor avid peptides that clear the blood very quickly and show fast target localization are ideally suited for short-lived positron emitters (Hoffmann et al. 2001; Henze et al. 2001; Maecke et al. 2005; Antunes et al. 2007a; Prasad et al. 2010). In addition, ^{66}Ga , a 9.4 h half-life positron emitter, and ^{67}Ga ($T_{1/2} = 78.3$ h) decaying via electron capture with three emissions at 93 keV (38%), 185 keV (24%), and 300 keV (16%) are available. Gallium-67 was also proposed as a therapeutic radionuclide for it is a reasonably efficient Auger-emitter. Ga^{3+} is quite similar to the high-spin Fe^{3+} ion with respect to its coordination chemistry, is also classified as a hard Lewis acid, forming thermodynamically stable complexes with ligands that are hard Lewis bases, such as ligands containing oxygen and nitrogen.

45.2 Choice and Synthesis of Bifunctional Chelators

45.2.1 Role of the Chelator in the Design of Radiopharmaceuticals

Within the last decades, much research has been done in the development of new receptor targeting radiometal labeled pharmaceuticals, in particular peptides (Fichna and Janecka 2003; Reubi and Maecke 2008; Eberle and Mild 2009). In general, the design of these pharmaceuticals can be divided into four different parts ([Fig. 45.1](#)):

- A biomolecule (peptide, antibody) that acts as a target specific vector
- A linker

Fig. 45.1

Design of a receptor targeting radiometal labeled radiopharmaceutical

- A bifunctional chelator (BFC)
- A metallic radionuclide

The BFC consists of a chelating moiety to complex the radiometal and a functional group for the covalent attachment of the biomolecule or the linker (Volkert and Hoffmann 1999; Heppeler et al. 2000; Mäcke and Good 2002; Brechbiel 2008; Liu 2008).

While the nature of the vector molecule is determined by the cellular target (i.e., cell surface receptor), the linker is dependent on the pharmacokinetic requirements of the pharmaceutical (Antunes et al. 2007b; Fragozeorgi et al. 2009). It may influence the hydrophilicity of the conjugate and so improve the pharmacokinetics. The linker can also act as a separator between the BFC and the biomolecule to prevent steric influence of the chelator on the binding affinity of the receptor targeting part of the pharmaceutical. The choice of the radiometal is dependent on the following:

- The medical objective (diagnosis, therapy)
- The availability
- The required radiation dose
- The physical half-life
- The cost
- Other factors

(Volkert et al. 1991; Schubiger et al. 1996; Reichert et al. 1999).

The chemical nature of the radiometal then determines the choice of the BFC.

45.2.2 Requirements for a BFC

There is a broad range of requirements for a BFC (Liu and Edwards 2001; Brechbiel 2008; Liu 2008). As mentioned before, a BFC has to form metal chelates with high thermodynamic stability or better kinetic inertness at $5 < \text{pH} < 7.5$. These physicochemical properties are needed because the loss of radiometal would cause undesirable side effects by accumulation in nontarget organs. This is especially important because the free radiometals may show a high toxicity (i.e., $^{177}\text{Lu}^{3+}$, $^{90}\text{Y}^{3+}$, or $^{153}\text{Sm}^{3+}$ are “bone seekers” and would cause bone marrow damage). The BFC is often competing with natural chelators present in the blood stream like transferrin or serum albumin for instance.

At least as important as the thermodynamic stability is the kinetic inertness because this is the factor that reflects the rate of dissociation of the metal ion from the BFC. Fast dissociation kinetics is often observed in complexes with acyclic chelators or chelators with nonoptimal

■ Fig. 45.2

Selected acyclic chelators based on polyazaalkanes with carboxylate functionalization

■ Fig. 45.3

Selected macrocyclic chelators based on polyazamacrocyclic cores with carboxylate functionalization

denticity (● Fig. 45.2) leading to low in vivo stability. Complexes based on a macrocyclic framework (● Fig. 45.3) often show much higher kinetic inertness.

Unfortunately, macrocyclic BFCs often require harsh labeling conditions (high temperature) to achieve a high labeling yield. Elevated temperature may be problematic especially in the labeling of antibodies because of unfolding of the protein and loss of the binding affinity of the antibody to the desired target receptor. Therefore, for the use with antibodies, it might be of advantage to use acyclic chelators. Finally, the BFC needs to be stable against radiolytic decomposition. This might become a crucial point if radiometals with a high linear energy transfer (LET) like α -emitters or high-energy β^- emitters are used.

The BFC needs to be attached to a biomolecule. There are many functional groups for conjugation available; some will be discussed later in this chapter. The conditions to perform the reaction between biomolecule and BFC have to be compatible with the properties of the two molecules. Undesired modifications of the biomolecule might lead to a loss of binding affinity of the radiopharmaceutical. To introduce a conjugation site to the BFC, the backbone of the chelator may be modified as follows:

- By attaching an additional functional group
- By modifying an existing functional group
- By following a selective protection strategy

While the first route preserves the number of functional groups for complexation of the radiometal, the other two strategies both use one of the complexation functions for coupling to the biomolecule and so potentially reduce the number of offered donors for the metal. The last strategy that provides a prochelator (synthon that becomes a chelator after deprotection) is

Table 45.3

Radiometals of interest (Shannon 1976)

Metal	Ionic radius [pm], octahedral	Nuclides
Sc ³⁺	75	⁴⁷ Sc
Ga ³⁺	62	⁶⁶ Ga, ⁶⁷ Ga, ⁶⁸ Ga
Y ³⁺	90 (105)	⁸⁶ Y, ⁹⁰ Y
In ³⁺	80	¹¹¹ In, ¹¹⁰ In
Dy ³⁺	105	¹⁶⁶ Dy
Ho ³⁺	104	¹⁶⁶ Ho
Lu ³⁺	100	¹⁷⁷ Lu
Bi ³⁺	103	²¹² Bi, ²¹³ Bi
Ac ³⁺	126	²²⁵ Ac
Sm ³⁺	110	¹⁵³ Sm
Cu ²⁺	87	⁶⁷ Cu, ⁶⁴ Cu, ⁶² Cu, ⁶¹ Cu, ⁶⁰ Cu
Ag ⁺	129	¹¹¹ Ag

especially interesting for the conjugation to peptides, which can be performed during solid phase peptide synthesis (SPPS) (Sherry et al. 1989; Albert et al. 1998; Heppeler et al. 1999a; Schottelius et al. 2003). The deprotection, which is required after coupling to the biomolecule, makes this strategy impracticable if antibodies or other sensitive proteins are used as vectors.

Most of the interesting radiometals are hard acids with 2+ and 3+ as their major oxidation states in aqueous solution. As they are kinetically labile, polydentate BFCs should be used to afford efficient encapsulation and in vivo stabilization. An important aspect of the choice of BFC is the ionic radius of the selected metal, as the metal ion has to fit into the cavity offered by the chelator (Table 45.3). Dependent on its size, the size and denticity of the BFC moiety should be selected (Figs. 45.2 and 45.3).

Apart from the size of the metal ion, it is also important to choose the suitable chelating donor groups for every radiometal. There are several donor groups available like amines, carboxylic acids, thiols, alcohols, phosphonic acids, and so on. The metal–ligand compatibility is dependent on the hard and soft acid and base character of the involved atoms. Oxygen donors have a good affinity to alkali, alkaline earth, and lanthanide atoms; nitrogen donors are favorable for transition metals; and sulfur is a good donor for silver and gold cations.

45.2.3 Acyclic Bifunctional Chelators

While the first BFCs were based on ethylenediaminetetraacetic acid (EDTA) (Sundberg et al. 1974a, b), most of the acyclic bifunctional chelators are based on the structure of diethylenetriaminepentaacetic acid (DTPA) (Fig. 45.4). The first clinically approved peptide-based tumor imaging agent was the DTPA-derivatized somatostatin analog octreotide labeled with ¹¹¹In. For this radionuclide, DTPA is an ideal chelator providing stable chelation and fast chelation kinetics (Maecke et al. 1989). Several analogs of DTPA have been synthesized as BFCs (Krejcarek and Tucker 1977; Hnatowich et al. 1983; Brechbiel et al. 1986; Westerberg et al. 1989; Williams and Rapoport 1993; Safavy et al. 2002a, b; Clifford et al. 2006; Xua et al. 2008).

Synthesis of a backbone-modified DTPA derivative for coupling to biomolecules

(Stolz et al. 1996) have not been as successful as the use of macrocyclic BFC for the labeling of peptides (Otte et al. 1997; De Jong et al. 1997; Stolz et al. 1998; Otte et al. 1998; Kwekkeboom et al. 2001; Waldherr et al. 2002; Chinol et al. 2002; Jamar et al. 2003; Forrer et al. 2006).

To increase the stability, preorganizing groups have been attached to the carbon backbone of EDTA and DTPA (Brechtel et al. 1996; Wu et al. 1997; McMurry et al. 1998; Gouin et al. 2002a, b). Preorganization obviously stabilizes the conformation of the free chelator in a manner that is comparable to the metal chelate (Hancock and Martell 1989; Hancock 1989). The reduction of the entropy, which in general works against the complexation of a metal, leads to faster complexation kinetics. There are BFCs designed this way (Fig. 45.5) (Williams and Rapoport 1994; Brechtel et al. 1991). One of these BFCs is called *tiuxetan* (Cummins et al. 1991; Chinn et al. 2003). Based on this BFC a conjugate with the murine anti-CD20 antibody *Ibritumomab* has been developed. This commercial product *Zevalin*TM is intended to be labeled with ¹¹¹In for imaging as well as with ⁹⁰Y for therapy. It is the first radiolabeled antibody for therapeutic application approved of by the US Food and Drug Administration (FDA).

Further refinements in the preorganization geometry of the DTPA led to BFCs for the labeling of antibodies with ²¹³Bi (Jurcic et al. 2002; Chinn et al. 2003; Abbas Rizvi et al. 2008), while other developments used for the same purpose (Brechtel and Gansow 1991; Nikula et al. 1999) had a peptide as a starting material, where new backbone modifications of the final DTPA derivative may be achieved by simply modifying the starting peptide (Fig. 45.6).

Acyclic BFCs have also been used for inserting Ga³⁺ into peptides and antibodies. One example is Desferrioxamine-B (DFO), which forms stable complexes with Fe³⁺ as well as with Ga³⁺. The stability constant of the Fe–DFO complex is log *K* = 30.4. DFO can be conjugated to a biomolecule via an activated primary amine group or derivatized with succinic acid anhydride as a spacer for coupling to the N-terminus (Mäcke et al. 1993; Smith-Jones et al. 1994; Stolz et al. 1994) (Fig. 45.7).

Interestingly, Desferrioxamine-B appeared to be of particular relevance for the complexation of tetra- and pentavalent radiometals. DFO-conjugated compounds such as DFO-succinyl-D-Phe-octreotide have been successfully labeled with the two longer-lived positron emitting radionuclides ⁸⁹Zr^{IV} (Meijs et al. 1992) and ⁹⁰Nb^V (Busse et al. 1999).

A more recent work on the development of a BFC for Ga³⁺ is based on a S₃N tetra-coordinate chelator (Fig. 45.8) (Luyt and Katzenellenbogen 2002). It shows high stability at neutral aqueous conditions when coupled to an amino acid mimicking a peptidic vector molecule. This could be interesting for the use with gallium labeled diagnostic radiopharmaceuticals.

■ Fig. 45.7

Structure of Desferrioxamine-B (DFO). Coupling sites to biomolecules may be NH_2 or a succinyl spacer

Additionally, the modified DTPA derivatives have also been used for the labeling of antibodies with ^{68}Ga (Koop et al. 2007).

Finally, it should be pointed out again that acyclic BFCs are of special interest when antibodies or short-lived radiometals are used. The fast complexation even at ambient temperature may prevail over the shortcomings of lower stability compared to macrocyclic BFCs.

45.2.4 Macrocyclic Bifunctional Chelators

The labeling of biomolecules with longer-lived radiometals is preferably performed with BFCs based on a macrocyclic core. If peptides are used as vector molecules, the slow kinetic of

Fig. 45.8

Synthesis of a bifunctional prochelator based on S_3N chelation moiety for complexation of Ga^{III} (Luyt and Katzenellenbogen 2002)

formation can be overcome by heating (Breeman et al. 2003) or the use of microwave technology (Velikyan et al. 2004), which usually does not destroy the biomolecule.

One of the most popular macrocyclic frameworks for the design of BFCs is 1,4,7,10-tetraazacyclododecane (cyclen) which – if modified with side arms – results, e.g., in the structure of DOTA (► Fig. 45.3). As DOTA is known to form stable complexes with many radiometals as, e.g. Y^{3+} , In^{3+} or Cu^{2+} , with all the lanthanides as well as with Bi^{3+} and Ac^{3+} , it has been used, modified as BFC, for the radiolabeling of many biomolecules (Heppeler et al. 1999a, b; Cutler et al. 2000; McDevitt et al. 2001; Hu et al. 2002).

The key step in the synthesis of macrocyclic chelators based on linear precursors is the cyclization. There are different strategies for this step. One common route is called the Richman–Atkins method (Richman and Atkins 1974). This method uses tosylated polyamines, reacting with dihalogenides or ditosylates. The yields have been reported to range between 40% and 90% for different sizes of macrocyclic polyamines. Later, an alternative route that uses cheaper starting materials for the synthesis of cyclen has been described (Weisman and Reed 1996). Starting from cyclen, the amines could be functionalized by carboxymethylation, which leads to DOTA or derivatives thereof.

The direct coupling of a biomolecule by one acetic acid function of DOTA leads to a conversion of this group to an amide offering the carbonyl oxygen for potential complexation of the radiometal, which consequently may lead to a decrease in thermodynamic stability compared to the acid. The difference is in one order of magnitude (Good 2006; Heppeler et al. 2008). To prevent this problem, a special coupling moiety should be introduced into the macrocycle.

The first approach in the synthesis of a bifunctional DOTA-derivative is to start with a tetrapeptide. This precursor may be obtained by a peptide route. The treatment with borane to convert the peptide to a linear polyamino alcohol, followed by tosylation and cyclization leads to the macrocycle (► Fig. 45.9). The modification for the coupling of the final BFC to a biomolecule is introduced already at the beginning with the choice of the first amino acid. The final alkylation of the amines of the macrocycle leads to a BFC with four acetic acid groups for the complexation of the radiometal (Moi and Meares 1988).

A different strategy for the formation of the cyclic core of the BFC is based on peptide bond formations (► Fig. 45.10). The macrocycle is formed by an intermolecular reaction of an activated disuccinimido ester with a diamine under high-dilution conditions with a yield of >40%. Reduction of the carbonyl groups and alkylation lead to a BFC, which possesses an attachment function for biomolecules on the carbon backbone of the macrocyclic core (McMurry et al. 1992).

Based on malonic ester synthesis, a bifunctional derivative of 1,4,7,10-tetraazacyclotridecane- N,N',N'',N''' -tetraacetic acid (TRITA) has been developed as well (Ruser et al. 1990). Again, an intermolecular reaction between a diamine and a diester leads to the macrocycle forming peptide bonds (► Fig. 45.11). The final BFCs have been studied as complexation agents for ^{111}In and have shown fast chelate formation, high radiochemical yield, and high stability.

An alternative way to couple a BFC to a vector molecule is to use one of the side chains for the attachment. One example is based on cyclen and alkylation of the amines with orthogonally protected acetic acids. By selective deprotection of only one of the acid functions, a prochelator is achieved, which can also be used in solid phase peptide synthesis protocols; the remaining protecting groups will be cleaved under the same conditions as the protecting groups of the peptide (Heppeler et al. 1999a) (► Fig. 45.12).

Of course, such a prochelator might not be used for attachment to an antibody, as the deprotection needs harsh conditions, which are not compatible with the integrity of the

■ Fig. 45.9

Synthesis of 2-(p-nitrobenzyl)-1,4,7,10-tetraazacyclododecane-N,N',N'',N'''-tetraacetic acid (Moi and Meares 1988)

antibody. For this purpose, DOTA has been activated at a single carboxylate group with N-hydroxysulfosuccinimide. This sulfo-N-hydroxysuccinimide (NHS) active ester of DOTA, which is nowadays a commercially available product, may be coupled to an antibody without subsequent deprotection steps (Lewis et al. 2001). Compared to backbone-modified DOTA derivatives, a disadvantage of this type of BFC may be the loss of one of the carboxylate

■ Fig. 45.10

Synthesis of 2-(p-nitrobenzyl)-1,4,7,10-tetraazacyclododecane-N,N',N'',N'''-tetraacetic acid (McMurry et al. 1992)

■ Fig. 45.11

Synthesis of a bifunctional derivative of TRITA (Ruser et al. 1990)

■ Fig. 45.12

Synthesis of DOTA-based bifunctional prochelator (4,7,10-tricarboxymethyl-*tert*-butyl ester 1,4,7,10-tetraazacyclododecane-1-acetate) (Heppeler et al. 1999a)

groups for metal bonding. The amide carbonyl oxygen would have to fill the remaining coordination site of the metal.

A strategy to prevent this potential loss of complexation functionality is the introduction of an additional coupling site on a modified acetic acid arm via an alkylation step maintaining the full-fledged functionalities of DOTA (Eisenwiener et al. 2000). Starting from cyclen, an orthogonally protected bis-carboxylic acid is attached to an amino group via alkylation. After carboxymethylation of the three remaining free amines and selective deprotection of the coupling site, a bifunctional prochelator is obtained (► Fig. 45.13). Coupling to a biomolecule and deprotection of the conjugate leads to a BFC designated for the labeling with different radiometals (^{111}In , $^{67/68}\text{Ga}$, ^{90}Y , and ^{177}Lu) (Kneifel et al. 2006; Ginj et al. 2008; Good et al. 2008). This strategy of an additional coupling site might be applied not only to derivatives of DOTA but as a general method to modify chelators based on a polyazaalkyl structure. Such a BFC should show a higher stability because of the higher denticity and possibly also faster complexation kinetics.

One example for the variable applications of this strategy has been demonstrated utilizing a NOTA-based BFC (Eisenwiener et al. 2002) (► Fig. 45.14). 1,4,7-triazacyclononane-1,4,7-triacetic acid (NOTA) has a smaller ring size than DOTA (► Fig. 45.3) and is known to be an excellent chelator for Ga^{3+} . Therefore, NOTA has been modified for coupling to a biomolecule (Cox et al. 1990; Broan et al. 1991; Velikyan et al. 2008). The bifunctional derivative is still a potent chelator for $^{67, 68}\text{Ga}$ (André et al. 1998) and has the additional advantage in regard to DOTA as labeling with radiogallium isotopes can be done at room temperature. It may preferably be coupled in standard peptide synthesis protocols while the proposed preconjugation labeling approach (André et al. 1998) seems to be inferior especially with higher amounts of radioactivity because of the low coupling yields. Other BFCs have been

■ Fig. 45.13

Synthesis of DOTA-based bifunctional prochelators DOTAGA(^tBu)₄ (1) and DOTASA(^tBu)₄ (2) (Eisenwiener et al. 2000)

developed, which do also have an additional coupling site for biomolecules at one carboxylic acid arm but without protecting groups on the free carboxylic acids (Chappell et al. 1999). This type of BFC is proposed for the use of coupling to antibodies.

Synthesis starting from a commercially available polyazamacrocycle such as the described strategies (► Figs. 45.12 and ► 45.13) is easier to perform (McMurry et al. 1993).

A common drawback with macrocyclic ligands is their slow complexation rate (Jang et al. 1999). A way to overcome this problem is to increase the ring size. Following this idea, two larger chelators have been developed, one based on a pentaaza macrocycle (PEPA) and the other on a hexaaza macrocycle (HEHA) (► Fig. 45.3). Both these chelators show much faster labeling kinetics with some radiometals (by a factor of about 100 times faster). Still, they have slower labeling kinetics than the acyclic chelator DTPA (by a factor of about 10) (► Table 45.4).

The stability of the PEPA and HEHA complexes is lower than the one of the DOTA complexes, but higher than the one of the acyclic DTPA (Kimura et al. 1985; Kodama et al. 1991)

■ Fig. 45.14

(► Table 45.5). HEHA has been reported to be a suitable chelator for the use with ²²⁵Ac (Deal et al. 1999; Kennel et al. 2000). Based on these chelators, BFCs have been developed as well.

Again, the most crucial synthetic step is the formation of the macrocycle. In one successful synthesis, the macrocyclic core is formed by an intermolecular reaction forming two peptide

■ Table 45.5

bonds (► Fig. 45.15) (Ouadi et al. 2000). The yield of the cyclization step is reported to be 50%. Reduction with borane and the following alkylation have been performed as described above.

A different method for the synthesis of the same bifunctional derivative of HEHA has also been reported (Chappell et al. 2000). This BFC has been coupled to an antibody and labeled with the α -emitter ²²⁵Ac. The daughters (²²¹Fr, ²¹⁷At, ²¹³Bi) are α -emitters as well. As the radiation from this metal has a very high linear energy transfer (LET), one should expect a loss of the daughters of actinium by the destructive effect of the radiation on the chelator. Even a rupture of the bond between the chelators and the coupled antibody might be possible. The half-lives of ²²¹Fr and ²¹⁷At are short enough to disable de-complexated radiometals to reach organs and regions far from the tumor but ²¹³Bi has a half-life that is long enough to accumulate thus having a potential negative side effect on organs like the kidneys.

A BFC derived from PEPA has also been developed following the peptide way for cyclization (Garmestani et al. 2001). This chelator was coupled to a monoclonal antibody and labeled with ²⁰⁵, ²⁰⁶Bi. Unfortunately, the results of the biodistribution of this conjugate show that a complex of p-NCS-PEPA is not stable enough in vivo and that even the complexation kinetics at room temperature were not rapid. It appears to be favorable to use backbone-stabilized derivatives of the acyclic chelator DTPA for the application of bismuth (Hassfjell and Brechbiel 2001).

While all syntheses originally presented had been based on the strategy of coupling the biomolecule to a prochelator, a different approach has been presented by Peterson et al. (1999). This new way uses a solid phase bound peptide as anchor to build the chelator step by step (► Fig. 45.16). Solid phase synthesis offers many advantages; one of the major advantages is that by-products may simply be washed away from the solid phase while the desired product stays bound.

A further advantage of this solid phase supported, combined synthesis of biomolecule and chelator is the reduction of purification steps. When using a bifunctional prochelator, this synthon has to be purified prior to the coupling to a biomolecule whereas with the combined strategy only the final product has to be purified.

As Cu²⁺ has many interesting radionuclides for therapeutic as well as for diagnostic applications (► Tables 45.1 and ► 45.2), the development of ideal chelators for this metal is of interest. BFCs used for the coupling of Cu-radioisotopes to biomolecules are based on the 14-membered tetraazamacrocyclic cyclam 14 (1,4,8,11-tetraazacyclotetradecane) (► Fig. 45.17). Two bifunctional versions of cyclam-14, 4-[(1,4,8,11-tetraazacyclotetradec-1-yl)methyl]-benzoic acid (= CPTA) and [6-(p-bromoacetamido)benzyl]-1,4,8,11-tetraazacyclotetradecane-1,4,8,11-tetraacetic acid (= BAT) (► Fig. 45.17), were coupled to monoclonal antibodies and somatostatin analogs (Smith-Jones et al. 1991; Anderson et al. 1995; Wilder et al. 1996). In addition to

Structures of cyclam-14 and bifunctional derivatives CPTA and BAT

these conjugates, 1,4,8,11-tetraazacyclotetradecane-1,4,8,11-tetraacetic acid (TETA) and DOTA (► Fig. 45.3) as monofunctional versions were shown to be excellent chelators for ^{64}Cu if conjugated to cyclic octapeptides based on octreotide.

Many DOTA and TETA (► Fig. 45.3) derivatives have been used for Cu-complexation to different biomolecules (Anderson et al. 2001; Wu et al. 2005; Parry et al. 2007). Despite the considerable efforts made by researchers to use tetraaza-tetracarboxylate macrocyclic ligands as effective BFCs for Cu, it is evident that the in vivo instability of these Cu complexes emphasizes the need for more stable Cu chelators. The class of ethylene cross-bridged cyclam and its pendant-armed derivatives (► Fig. 45.18), synthesized by Weisman and Wong (Weisman et al. 1990, 1996; Wong et al. 2000) have attracted attention as chelators for radiocopper. Attachment of two carboxymethyl pendant arms to CB-cyclam leads to CB-TE2A, which further ensures complete envelopment of a six-coordinate Cu(II). Studies also focused upon modifying these chelators for the synthesis of BFC (Sprague et al. 2007; Boswell et al. 2008), while ^{64}Cu -labeled peptide-conjugates based on these chelators showed superiority compared to more conventional chelators, such as TETA (Sprague et al. 2004; Wadas et al. 2008). More recently, NOTA (► Fig. 45.3) has been used for labeling of different peptides with ^{64}Cu , exhibiting high in vivo stability (Prasanphanich et al. 2007; Liu et al. 2009).

Another class of ligands is the hexaazamacrobicyclic cage type ligands, which are based upon the sepulchrate, or sarcophagine cage motifs shown in ► Fig. 45.19 and whose syntheses were first described by Sargeson and coworkers (Geue et al. 1984; Sargeson 1996). Sarcophagine (Sar) analogs substituted at the apical bridgehead carbons with a variety of functional groups including NH_2 , OH , Cl , and NO_2 or other alkyl or aryl organic groups have also been synthesized. DiBartolo et al. investigated a family of Sar derivatives with various functional groups at the apical sites, such as diamSar and SarAr (► Fig. 45.19) (Di Bartolo et al. 2001).

■ Fig. 45.18

Cross-bridged cyclic polyamine and cross-bridged cyclicpolyaminocarboxylate ligands

■ Fig. 45.19

Sarcophagine and sepulchrate ligands

Different BFCs based on the cage type ligands have been used for ^{64}Cu -labeling of antibodies (Smith 2004; Di Bartolo et al. 2006) and peptides (Ma et al. 2009; Cai et al. 2009).

45.3 Examples of Radiometal–Chelate–Biomolecule Conjugates

45.3.1 Synthesis and Characterization of Chelator–Biomolecule Conjugates

There are many interesting biological targets for radiopharmaceuticals. As already mentioned in Sect. 45.2.1, cell surface receptors of cancer cells allow specific attacks to these cells. This specificity is due to an overexpression of certain receptor types on tumor cells. The biomolecules for this targeting might be antibodies as well as peptides.

Antibodies are proteins to which a varying number of chelators might be coupled. A detailed discussion of antibodies in radionuclide therapy can be found in Chap. 46 of this Volume.

Peptides as biomolecular vectors in radiotherapy are getting more and more popular as a variety of tumors overexpress different peptide receptors as potential targets. They consist of a small number of amino acids (10–50) and may be synthesized quickly and at relatively low cost using solid phase synthesis (Merrifield 1963). The attachment of the chelating moiety to the peptide sequence may be performed at the non-active end of the main chain, mostly the N-terminus of the molecule. As an advantage, the low molecular weight of the conjugate results in a fast diffusion rate. Larger tumors will be penetrated faster than by using radiolabeled proteins and the areas in the center of a spherical tumor will receive a higher radiation dose. Peptides can also withstand harsher conditions for modification and labeling than antibodies, they are less likely to produce immunogenic response, and blood clearance and tumor uptake are faster. The faster clearance of nontarget tissue leads to a better tumor-to-background ratio (better imaging) and therefore to less irradiation of nontarget organs. As a drawback, the used peptides normally play a regulatory role in the human body. Even if the number of receptors on the surface of cancer cells is upregulated, there are receptors on normal tissue that will be attacked as well, and already small amounts of peptides may lead to undesirable side effects. As native peptides are degraded very rapidly by endogenous peptidases and proteases, stabilized derivatives have to be developed. The conjugation of a BFC to a relatively small biomolecule also has a higher potential to influence the binding affinity. To reduce this negative influence, spacers between the peptide and the chelator may be introduced.

The best developed peptides in the field of targeted radiotherapy are analogs of somatostatin. Endogenous somatostatin consists of a family of two forms of 14 (SS-14) or 28 (SS-28) amino acids (Patel et al. 1996). They both show low metabolic stability in human blood with

Structure of native somatostatin SS-14 (a) and its derivative octreotide (b)

The first radiopeptide used for the localization of tumors was (3-[^{123}I]iodo-Tyr 3)-octreotide. Early results had been very promising (Krenning et al. 1989; Lamberts et al. 1990), but later it has been shown that this compound is not useful as a diagnostic tool because of its low diagnostic sensitivity in the abdomen. As mentioned above the first chelator-conjugate of octreotide, DTPA-octreotide, designed for complexation of $^{111}\text{In}^{3+}$, shows a low in vitro pharmacologic profile (low binding affinity of 22 ± 3.6 nM, slow internalization rate) but the hydrophilic metal complex changes the hydrophilicity of the radiopharmaceutical and its pharmacokinetics dramatically. DTPA-octreotide therefore became the first registered radiopeptide worldwide, its commercial name being *Octreoscan*TM. As DTPA shows favorable labeling kinetics with $^{111}\text{In}^{3+}$, it can be performed in any nuclear medical department whereas iodination needs specially trained personnel.

In the pre-conjugation labeling approach, a metal is encapsulated by a chelator prior to the conjugation of a biomolecule to the chelator. This strategy even allows nonaqueous conditions for the complexation step. It also allows the covalent coupling of a well-defined radiometal complex of high specific activity to a biomolecule. As the conjugation is often not quantitative, a final purification step is needed. In general, after the radionuclide is introduced, the synthesis is time consuming and causes economical and radioecological problems. Both aspects make this strategy unsuitable for routine applications in standard nuclear medicine facilities (Liu and Edwards 2001; Liu 2008).

For the conjugation of the chelator to the biomolecule, the activation of a carboxylate group of the chelator via an active ester and the reaction with a primary amine of the biomolecule (side-chain of a lysine residue or *N*-terminal amine of a peptide) leads to a stable attachment via a peptide bond. This peptide bond is highly stable under physiological conditions. One popular example of activation of the carboxylate is the formation of *N*-hydroxysuccinimide (NHS) esters (► [Fig. 45.21](#)). NHS-activated esters are selective for primary amines in aqueous

■ Fig. 45.21

Conjugation of a bifunctional chelator (R) to a biomolecule

solutions and slightly basic pH as reaction conditions for the conjugation. These esters are useful for reactions with antibodies and peptides (Liu and Edwards 1999).

Isothiocyanates are reactive to amines as well (► Fig. 45.21). They may be formed from nitro groups (► Fig. 45.6) and react in aqueous solutions at pH 9–9.5 with primary amines to form thiourea bonds. This reaction restricts this method to biomolecules, which are not sensitive to alkaline conditions (Fichna and Janecka 2003).

Maleimides are reacting selectively with thiols (► Fig. 45.21). The thiol groups in the biomolecules come from cysteine where a thioether bond with the chelator is formed. The pH for this reaction is close to 7 so that this reaction is ideal for biomolecules (Lewis and Shively 1998).

Anhydrides of the chelator react with primary amines of the biomolecules. Symmetrical dianhydride of DTPA is commercially available and the conjugation may be performed in both aqueous and nonaqueous media. As the dianhydride might react to form a DTPA-monoamide as well as a DTPA-bisamide, cross-linkage of two biomolecules may occur. To circumvent this, asymmetric anhydrides of DTPA but also of DOTA have been developed and used (Sherry et al. 1989; Sieving et al. 1990).

A different approach for the conjugation of a chelator to a biomolecule is the use of monoreactive chelator derivatives. This approach includes the use of protection strategies as shown before (► Figs. 45.12–45.14) and the use of this protected precursors in standard peptide chemistry protocols. The chelator is introduced as a synthon and will be transformed to the final, functional BFC after the coupling to the biomolecule by deprotection of the carboxylic acids (► Fig. 45.22).

■ Fig. 45.22

Solid phase synthesis of DOTA-peptides (Eisenwiener et al. 2000)

As an example, the prochelator of DOTA, which carries three ^tBu protected carboxylate groups whereas the fourth remains free for coupling to the peptide, is compatible with solid and solution phase peptide chemistry, and was coupled to somatostatin analogs in solution with 65 ± 5% yields after deprotection and purification (Heppeler et al. 1999a, b). DOTA, used unprotected, was also coupled to the same peptide with about 40% overall yield (Albert et al. 1998; Hsieh et al. 1999). Coupling of the unprotected chelator has recently been improved, leading to >98% yield for the coupling of the chelator to a peptide (Schottelius et al. 2003).

Recently, click chemistry has received considerable attention as powerful synthesis approach by utilizing a few practical and reliable reactions with applications in many areas, including drug discovery (Kolb and Sharpless 2003; Mamat et al. 2009). A very popular reaction of click chemistry is the Cu(I)-catalyzed version of Huisgen's dipolar [2 + 3] cycloaddition of terminal alkynes and azides to yield 1,4-disubstituted 1,2,3-triazoles, discovered by the groups of Sharpless and Meldal (Rostovtsev et al. 2002; Tornøe et al. 2002). This new synthetic approach has recently found application in the preparation of bifunctional chelators, bearing the alkyne functionality in their molecule, such as DOTA and DTPA and their conjugation to azido functionalized biomolecules (Fig. 45.23) (Knör et al. 2007; Mindt et al. 2009). This reaction is mild and very efficient, is easy to perform, and is insensitive to oxygen and water. Moreover, it requires no protecting groups, while the azide and alkyne functional groups are largely inert toward biological molecules and aqueous environments. The very mild reaction conditions and the high chemoselectivity and efficiency make this reaction particularly suitable for bioconjugations.

Fig. 45.23

Chemoselective Cu(I)-catalyzed azide-alkyne cycloaddition of an alkyne-bifunctional chelator (R) to an azido-functionalized biomolecule

As the compounds described in this chapter will be applied to humans, quality control is essential. One has to define first a few terms therefore:

Radiolabeling yield	Percentage of radiometal-labeled biomolecule–chelator conjugate
Radiochemical purity	Percentage of total radioactivity in the desired chemical form (as radiopharmaceutical)
Radiolabeling efficiency	Ability of a chelator to form its radiometal complex at a low concentration under mild conditions

The standard technique to check the radiochemical purity of a labeled compound is thin layer chromatography/instant thin layer chromatography (TLC/ITLC) combined with a radioactivity counter. This method is quick and easy to perform. Different isomeric forms of a radiopharmaceutical may not be determined. A more sophisticated method for quality control is high performance liquid chromatography (HPLC) combined with a radioactivity detector. Radiochemical purity as well as isomeric forms and small modifications due to instability, radiolysis, etc., may be determined. To achieve an accurate determination of non-chelated radiometal, a mM solution of DTPA (pH 4–5) has to be added to the HPLC sample to ensure a complexation of the free metal. If DTPA is not added, unchelated metal might bind and stick to the HPLC column and thus indicate a too high radiochemical purity (Smith-Jones et al. 1998).

Radiolabeling efficiency is dependent on the radiolabeling conditions: concentration of the BFC-biomolecule conjugate, concentration of trace metal contaminants, pH, temperature, and reaction time (Brechtel et al. 1996; Breeman et al. 2003; Wu et al. 1997; Williams and Rapoport 1994; Kukis et al. 1998). The conclusions for the labeling of DOTA with ^{90}Y are the following:

- The radiolabeling efficiency is best when the chelator-to-metal ratio is >3
- Increasing amounts of trace metals (Ca^{2+} , Fe^{2+} , Zn^{2+}), present in common commercial ^{90}Y preparations, inhibit the labeling in a concentration-dependent manner
- Higher pH results in faster complexation rate
- Longer reaction time and higher temperature usually enhance the radiolabeling yield

45.3.2 Dependence of Radiometal on Target Binding Affinity and Biodistribution

The binding affinity and the biodistribution are of major importance in the assessment of radiopharmaceuticals (Reubi 1995). The first reflects the potential to fulfill its objective to target a receptor while the second is elementary for reaching the target and avoiding an

undesired radiation of nontarget organs. Both are related to a major advantage of receptor-mediated radiopharmaceuticals, compared to other pharmaceuticals, such as chemotherapeutics: the selectivity.

For evaluation in biodistribution studies, tumor cells for which the bioconjugate is being developed are inoculated to animals (mice, rats) inducing the expression of a tumor. After administration of the labeled radiopharmaceutical, uptake in different organs, especially the receptor-positive organs and in the critical organs concerning toxicity effects, may be determined.

As already exemplified in [Sect. 45.3.1](#), the radiometal bound to the chelator–biomolecule conjugate might influence the binding affinity as well as the biodistribution. It was mentioned there the case of DTPA–octreotide where the non-labeled compound shows poor binding affinity and a bad pharmacological profile while the introduction of the metal influences this behavior positively. The metal itself influences the hydrophilicity of the whole radiopharmaceutical and for that reason the pharmacological profile of the compound.

A good example for the influence of the metal is the somatostatin derivative [DOTA⁰, Tyr³]-octreotide (DOTATOC), which can be labeled with different metals. Binding affinities are determined as IC₅₀ values (Stimmel and Kull 1998). In the case of somatostatin derivatives, ¹²⁵I-[Leu⁸, D-Trp²², Tyr²⁵]-somatostatin 28 is used as radioligand. The nonradioactive metal analogs should behave as the radioactive congeners. [Table 45.6](#) shows the binding affinities to the somatostatin receptor subtype 2 (sstr2).

Co^{II}-DOTATOC shows the best binding affinity of this series, which is even higher than the one of native somatostatin 28. This effect is not yet fully understood. As both Co^{II} and Ga^{III} form hexacoordinated complexes with DOTA, the biomolecule bound carboxymethyl arm remains not coordinated to the metal (Heppeler et al. 1999a). It keeps its flexibility and could play the role of a spacer between the biomolecule and the chelator, reducing the influence of the bulky BFC. In addition, Co^{II} also has a different charge compared to the other metals. Y^{III} shows an octacoordinated structure with DOTA, the biomolecule bound carboxymethyl arm is coordinated to the metal as well; the chelator is more fixed in its position relative to the biomolecule.

45.4 Structure and Stability of (Radio) Metal Complexes

Applications of radionuclides to biological vectors and their use in vivo demands that the radiometal (metallic radionuclide) remains strongly associated with the targeting biomolecule.

Table 45.6

Binding affinities of DOTATOC labeled with different metals

Ligand	IC ₅₀ for sstr2 (nM)
SS 28 (native somatostatin)	2.7 ± 0.3
Co ^{II} -DOTA-[Tyr] ³ -octreotide	0.14 ± 0.1
Ga ^{III} -DOTA-[Tyr] ³ -octreotide	2.5 ± 0.5
Y ^{III} -DOTA-[Tyr] ³ -octreotide	11 ± 1.7
Bi ^{III} -DOTA-[Tyr] ³ -octreotide	30 ± 3

Ligand structure, ligand denticity, thermodynamic and kinetic stability as well as serum stability have been included to rationalize and predict potential in vivo dissociation of radiometals.

Log K -values (1) are usually determined by potentiometric or spectrophotometric methods (McMurry et al. 1998; Kumar et al. 1994; Moore et al. 1989; Jones-Wilson et al. 1995):

$$K_{ML} = [ML]/[M][L] \quad (45.1)$$

As mentioned before, Copper prefers macrocyclic chelators like cyclam-14 and its derivatives. Cyclam-14 forms thermodynamically stable complexes and its X-ray structure shows a square-plane configuration with four equal Cu–N bonds (Tasker and Sklar 1975). This complex with coordination number four lose less than 0.5% metal when incubated for 24 h in human serum. Open chain chelators do not reach this stability. Its bifunctional derivative CPTA (Fig. 45.17) coupled to an antibody and labeled with ^{67}Cu shows a half-life for copper exchange in phosphate buffer >1,000 days (Smith-Jones et al. 1991).

The polyaminocarboxylate-derivative of cyclam, TETA, forms Cu-complexes with coordination number 6 with involvement of four amino groups and two pendant carboxylates (Moi et al. 1987). Surprisingly, Jahn–Teller distortion involves two amines and not the carboxylates as expected. Again, the Copper-complex coupled to an antibody loses less than 1% of its metal per day when incubated in human serum.

Fig. 45.24

Complexes of Ga^{3+} prefer hexacoordination. An example of a complex with a macrocyclic bifunctional chelator is the structure of $\text{Ga}(\text{NODASA})$ (► Fig. 45.24) (André et al. 1998). It has a slightly distorted octahedral configuration with a plane defined by the amino groups and a second plane defined by three carboxylate oxygens, both in a facial arrangement. The fourth carboxylate (the β -carboxylate) remains free and offers a potential conjugation site in a prelabeling approach. The complex has a high kinetic stability, as it shows no transmetallation to transferrin in blood serum over a period of 5 days.

Ga^{3+} builds complexes with larger chelators as well; it will be shown here the X-ray structure of $\text{Ga}\text{-DOTA-D-Phe-amide}$, where the amino acid serves as model peptide. Again, the complex is hexacoordinated, having *cis*-pseudooctahedral geometry (Heppeler et al. 2000). The polyaza macrocycle is folded and the equatorial plane of the complex is formed by two *trans*-annular nitrogens of the cyclen ring and two corresponding carboxy oxygens (► Fig. 45.25).

When the attachment of a DOTA-based chelator to a biomolecule is performed on one of the acetate arms via an amide bond, the resulting complex with a radiometal also shows a fundamental difference; the radiometal uses a carbonyl oxygen instead of a carboxylate oxygen (► Fig. 45.26). A carbonyl oxygen is a weaker donor than the corresponding carboxylate oxygen. This is reflected in a lower thermodynamic stability of the resulting complex (e.g., $\log K_{\text{Y-DOTA-monoamide}} \approx 21.8$; $\log K_{\text{Y-DOTA}} \approx 23.5$) (Liu and Edwards 2001; Caravan et al. 1999; Sherry et al. 1989). Using a ligand–ligand competition approach performed via potentiometric titration, similar results have been obtained for Y-DTPA-peptides (Brockmann and Rösch 1999). Stability constants $\log K$ decrease from the Y-DTPA complex ($\log K = 22.05$) to Y-DTPA-Phe-Gly-Gly ($\log K = 19.7$), Y-DTPA-Phe-Trp ($\log K = 18.5$), and Y-DTPA-Phe-Tyr

[illegible]

A promising therapeutic radionuclide is ^{111}Ag because of its suitable physical characteristics (▶ [Table 45.2](#)). It also represents an interesting example of how the lack of kinetic and thermodynamic stability prevents its in vivo application. Ag^+ presents one of the most labile coordination spheres. The development of a chelator with high affinity to Ag^+ and introducing high kinetic stability is extremely demanding. A strategy using a polyazamacrocyclic scaffold led to the chelator 1,4,7,10-tetrakis[2-(methylsulfanyl)ethyl]-1,4,7,10-tetraazacyclododecane (DOTETE) (Gyr et al. 1997). While [18]aneS6 (1,4,7,10,13,16-hexathiacyclooctadecane) is known as a strong chelating ligand for Ag^+ with a stability constant $\log K$ of 12.67 ± 0.13

■ Fig. 45.27

X-ray structure $\text{Na}[\text{Lu}(\text{DOTA})(\text{H}_2\text{O})]$ (Aime et al. 1996). Reprinted with permission from Elsevier

(Alberto et al. 1996), the DOTETE beats this stability by far with $\log K$ of 19.63, which is the highest stability observed for a silver(I) complex (Heppeler et al. 1999b). X-ray crystallographic studies of DOTETE indicate that this high stability is the result of the preorganization of the metal free chelator (► Fig. 45.28). The N4 plane is already visible in the uncoordinated chelator and all sulfur-bearing side chains are *syn* to the N4 plane. The introduction of a silver ion causes only minor changes in the structure of the chelator, leading to a hexacoordinated complex.

An nuclear magnetic resonance (NMR) study of the same complex indicates that the observed hexacoordination in the crystal structure is combined with a fast exchange of the donor thioethers in solution as all carbon atoms of the side chains have equivalent signals. Even at temperatures of 183 K, the signals remain equivalent. This could lead to an extra stability, but despite the high thermodynamic stability the kinetic stability is still too low and slow exchange with serum proteins has been observed.

45.5 Outlook

It appears that for most radiometals optimal bifunctional chelators have been developed. Improvements may be necessary in cases where very high specific activity labeling is needed, e.g., with pharmacologically active molecules. Strategies to increase the on-rate (rate of labeling) will help in these situations.

An unsolved and hardly to be solved problem appears to be the development of chelators that immobilize α -emitters. The recoil energy will destroy all currently used chelators. Strategies to use fullerenes to encapsulate α -emitters are under way. These and other nanocontainers may finally serve as the ultimate chelators.

Abstract: Radionuclide therapy utilizes unsealed sources of radionuclides as a treatment for cancer or other pathological conditions such as rheumatoid arthritis. Radionuclides that decay by the emission of β and α particles, as well as those that emit Auger electrons, have been used for this purpose. In this chapter, radiochemical aspects of radionuclide therapy, including criteria for radionuclide selection, radionuclide production, radiolabeling chemistry, and radiation dosimetry are discussed.

46.1 Introduction

The toxic effects of radiation have long been recognized and applied to the treatment of a variety of pathological conditions, notably cancer and rheumatoid arthritis. In its most widely applied manifestation, tumor irradiation is achieved by focusing an external beam of radiation on the malignancy. A less common approach, brachytherapy, involves the implantation of an unsealed source of radiation, usually in the form of a wire or a pellet, in close proximity to the tumor. Although these forms of radiation therapy have been effective in the treatment of many diseases, they have intrinsic limitations that compromise their effectiveness. To be effective, external beam radiation and brachytherapy require knowledge of the precise location and geometrical configuration of the tumor in order to maximize the destruction of cancer cells, while minimizing the radiation dose to neighboring normal tissues. In addition, these treatment modalities are of limited utility for treating multifocal tumors and metastasis cancer sites. In order to circumvent this limitation, a concerted effort has been devoted to developing radionuclide therapy (also known as endoradiotherapy) as an alternative radiation-based treatment strategy.

Targeted radionuclide therapy involves the use of a radiolabeled molecule to selectively deliver a cytotoxic level of radiation to a disease site. The overriding objectives of radionuclide therapy and external beam therapy are the same: obtaining the maximum radiation dose for the tumor while minimizing the irradiation of normal organs. However, the two treatment approaches differ considerably with regard to the impediments that must be overcome to achieve this goal.

Advances in tumor biology, recombinant antibody technology, and radio synthetic chemistry have led to a flurry of activity in the development and clinical application of endoradiotherapeutic agents. However, it is important to bear in mind that radionuclide therapy is actually not a new concept, having been used in patients for more than 60 years. A number of textbooks provide excellent chronicles of early efforts in radionuclide therapy (Spencer 1978; Harbert 1987; Spencer et al. 1987). A notable example is sodium [^{131}I]iodide, which has been utilized for the treatment of hyperthyroidism and thyroid carcinomas and remains the most widely utilized targeted radiotherapeutic in current clinical use. Radiocolloids such as those labeled with either ^{198}Au or ^{32}P have been used for more than 50 years for the treatment of diseases such as malignant pleural effusions and intraperitoneal tumors.

46.2 Design of Targeted Radiotherapeutics

The design of an effective endoradiotherapeutic agent requires a careful optimization of its two components, namely the radionuclide and the carrier system that is used to direct the radionuclide to the tumor, so that the radiation emitted during its de-excitation will have

a high probability of being deposited within the malignant cell population. With physical carriers, barriers created by isolated body cavities are utilized to confine a radiolabeled colloid, particulate, or other inert, nondiffusible substance to that cavity. This approach has been applied in the treatment of rheumatoid arthritis as well as tumors spread throughout the peritoneum or intrathecal space. Biological carriers attempt to exploit a biochemical or metabolic difference between tumor and normal tissue in order to identify a compound that will preferentially localize in the cancer after being injected into the patient. Because they can be applied to a wider variety of disease processes and can be used to treat metastatic cancers, biological carrier systems are particularly attractive for targeted radionuclide therapy.

46.2.1 Selection of the Radionuclide

A number of factors influence the choice of radionuclide for a particular therapeutic application. The first consideration is to ensure that the decay mode and radiation range are well matched to the size, location, and geometry of a tumor. As discussed in subsequent sections of this chapter, the irradiation of tissue volumes with multicellular, cellular, and subcellular dimensions can be accomplished with *radionuclides emitting β particles, α particles, and Auger electrons*, respectively. The ideal radionuclide for treating a large solid tumor such as a hepatoma will be clearly different from that which would be preferred for elimination of metastatic deposits consisting of a few hundred cells. In addition to radiation range, a number of other factors must be considered in selecting a radionuclide for endoradiotherapy. In addition to the characteristics of the emissions, the following parameters should be considered: (1) half-life, (2) production method, (3) chemistry, and (4) biological behavior.

46.2.1.1 Geometrical Considerations

The objective of radionuclide therapy is to deliver a cytotoxic dose of radiation to all the cells within a tumor, while sparing normal tissues. Clearly, the size and geometrical configuration of a particular tumor will be important considerations. The idea of optimizing radiation range for a particular tumor is obviously idealistic because that would necessitate a priori detailed knowledge of tumor volume and configuration for each patient. Furthermore, different radionuclides would be required for different patients and this would be impractical. Nonetheless, generalizations can be made to guide in the selection of a radionuclide that would be best for an individual type of malignancy. Particularly for smaller tumors, even under conditions where the radionuclide is deposited uniformly, the radiation dose received by tumor cells will be dependent upon their position within the lesion. Finally, it must be recognized that the site of decay in subcellular dimensions can have a major effect on the radiation dose received by the cell nucleus, generally considered to be the subcellular target for radiation-mediated cell killing (Hall 2000).

For larger tumors such as a 500-g hepatoma in the liver, radionuclides emitting long-range β particles such as ^{186}Re and ^{90}Y were calculated to be ideal because most of their decay energy would be deposited within the tumor (Wessels and Rogus 1984). However, for smaller tumors, generally considered to be the ideal setting for endoradiotherapy (Sautterbihl et al. 1996), different radionuclides should be used. Humm (1986) compared the fraction of decay energy that would be absorbed for a high-energy β emitter (^{90}Y), a low-energy β emitter (^{131}I), and an

α emitter (^{211}At) when uniformly distributed in spherical tumors. In 1-cm-diameter tumors, the absorbed fractions were calculated to be 0.097, 0.54, and ~ 0.9 , for the particulate emissions of ^{90}Y , ^{131}I , and ^{211}At , respectively; for 0.2-cm-diameter tumors, absorbed fractions of 0.015, 0.17, and ~ 0.5 were calculated. For 1-cm-diameter tumors, more than 90% of the β -particle energy of ^{90}Y is already deposited outside the lesion, resulting in less efficient cell kill, and higher dose to neighboring normal tissues.

Monte Carlo transport simulations have been utilized to calculate the radiation absorbed dose received by normal tissues in close proximity to tumors containing a radiotherapeutic (Sparks et al. 2002). For normal tissues 1 mm from tumors containing ^{90}Y - or ^{131}I -labeled compounds, doses were 24% and 4% of the absorbed dose in the tumor itself. For small structures such as arteries or nerves surrounded by tumor, these doses were 103% and 46%, respectively. Another setting in which the effects of radiation range have been investigated is in the treatment of neoplastic meningitis, a malignancy characterized by free-floating tumor cells in the cerebrospinal fluid (CSF). Direct injection of a labeled compound into the CSF can be effective in irradiating these tumor cells; however, deleterious effects to normal spinal cord must be avoided. Millar and Barrett (1990) calculated that as a consequence of its shorter-range β emissions, CSF-to-normal-spinal-cord dose ratios for ^{131}I were up to nine times higher than those for ^{90}Y .

The above discussion has focused on a comparison of ^{90}Y and ^{131}I because these are the most frequently utilized radionuclides in endoradiotherapy; however, the effect of particle range on therapeutic utility has been evaluated theoretically for other radionuclides as well. For a comprehensive discussion of the relationship between tumor size and therapeutic effectiveness for 22 uniformly distributed β emitters, the reader is referred to a paper by O'Donoghue et al. (1995). In this study, a model was developed that took into account both *tumor radiosensitivity and proliferation* and yielded the diameter of tumor that could be optimally treated by each radionuclide. These ranged from 0.6 mm for ^{33}P to 3.4 cm for ^{90}Y . A tumor control probability model has also been utilized to compare the potential therapeutic efficacy of six β emitters (Nahum 1996).

In selecting radionuclides for a particular endoradiotherapeutic strategy, it is important to note that for a given radionuclide, geometrical factors also can result in considerable variation in radiation dose to the radiosensitive cell element, the nucleus.  Figure 46.1 illustrates two

 Fig. 46.1

Radiation dose to the cell nucleus can come from either self-irradiation or cross fire (left) and will vary depending upon whether the site of decay was in the cell membrane, in the cytoplasm, or in the cell nucleus (right)

processes that must be considered: radiation crossfire and the subcellular site of radioactive decay. Even with a uniformly distributed radionuclide, the dose received by individual cells can vary because of differences in crossfire dose and the fraction of the radiation bound to the cell that is deposited in the tumor. This is particularly apparent for micrometastatic disease, which presents as small clusters of tumor cells, magnifying the impact of these factors.

Hartman et al. (2000) utilized numerical integration and a point kernel approach to investigate these effects for cells with diameters of 10, 14, and 20 μm using ^{131}I as the radionuclide. It was found that the dose received under single-cell conditions was about half that which was delivered in cell clusters containing six cells. The regional variation in cell dose also was calculated for larger clusters of tumor cells. For a 100- μm -diameter tumor, the radiation absorbed dose received at the surface of the cluster was only about half that delivered to the center. With regard to the effect of the subcellular site of decay, Hartman et al. (2000) showed that shifting the site of ^{131}I decay from the cell membrane to the nucleus would increase the dose to the cell nucleus by an order of magnitude.

46.2.1.2 Heterogeneity

If the only goal from a radiation range perspective were maximizing absorbed dose fraction to tumor while minimizing irradiation of adjacent normal tissue structures, then it would appear that radionuclides emitting short-range radiation would be preferred. However, the success of radionuclide therapy is also critically dependent upon achieving *homogeneous dose deposition within the tumor*, so that regrowth from an untreated subpopulation will be avoided. Unfortunately, autoradiographic studies have documented the highly heterogeneous distribution of labeled molecules in tumors (Sands et al. 1988; Gridley et al. 1991).

The heterogeneous nature of radionuclide distribution after intravenous injection of a targeted radiotherapeutic compound is illustrated in [Fig. 46.2](#). These autoradiographs are of an EMT-6 lung tumor in a mouse obtained after the intravenous administration of a ^{125}I -labeled monoclonal antibody. In [Fig. 46.2a](#) obtained at $4\times$ magnification, an absence of black grains corresponding to ^{125}I activity in the central region of the tumor is apparent. At $40\times$

Fig. 46.2

Autoradiographs of an EMT-6 lung tumor obtained from a mouse injected with a ^{125}I -labeled monoclonal antibody; (a) $4\times$ and (b) $40\times$ magnification (Akabani et al. unpublished data)

magnification (► [Fig. 46.2b](#)), even in the region that accumulated the labeled antibody, a heterogeneous pattern of radionuclide is observed, with the activity being localized primarily in the extracellular matrix (i.e., the regions between the cells).

There are many impediments to delivering a uniform dose of radiation to tumors from exogenously administered targeted radiotherapeutic compound (Hauck et al. 1995). Some of these are dependent on the nature of the tumor and others on the characteristics of the labeled compound and its molecular target. Because it is often difficult to overcome these heterogeneities by other means, radionuclides emitting longer-range radiation are frequently utilized for radionuclide therapy.

Heterogeneities Related to the Nature of the Tumor

Because most endoradiotherapeutic agents are administered via intravenous injection, tumor hemodynamic factors play an important role in defining the degree of heterogeneity in their delivery. Regional variations in delivery can be influenced by blood flow, vascular density and permeability. Tumor vasculature is arranged differently from that in normal tissues, in that it is more irregular, may lack an endothelial lining, and exhibits variations in blood flow with time (Warren 1979; Jain and Ward-Hartley 1984; Jain 1988). On the other hand, tumor vasculature is generally more leaky than that of normal tissues, and this increased permeability can facilitate the distribution of labeled drugs within the tumor (Sands et al. 1988). Unfortunately, increased permeability in tumor vessels is of little benefit if blood flow to these vessels is compromised, as is often the case (Warren 1979).

Another feature of tumors that can have a major impact on the distribution of targeted radiotherapeutics is *tumor interstitial fluid pressure*. Interstitial fluid pressure results in a pressure gradient that can inhibit the delivery of molecules from the plasma to the extracellular fluid in central regions of a tumor. This pressure gradient is not present in normal tissues because they have a lymphatic system; however, tumors do not, creating an additional barrier that must be overcome. Experimental evidence of an elevated interstitial pressure in murine tumor models has been reported by Boucher et al. (1990). As expected, the effect was most apparent at the tumor periphery. Using a mathematical model, the magnitude of this outward convection fluid flow was predicted to be 0.1–0.2 $\mu\text{m/s}$ (Jain and Baxter 1988).

Heterogeneities Related to the Properties of the Labeled Molecule

The most promising strategies for radionuclide therapy are those that offer the prospect of achieving preferential uptake in tumor compared with normal tissues by binding to a molecule such as an antigen or receptor that is present in high concentrations on tumor cells. If the forward rate constant for binding is very high and the concentration of the endoradiotherapeutic is low, then rapid binding to tumor cells close to the capillary can occur. This *binding-site barrier* can inhibit the penetration of the labeled compound into the interior of the tumor (Weinstein et al. 1987). An additional problem for macromolecules is their slow diffusion; it has been predicted that diffusion of a 150 kDa protein into the center of a 150-m-diameter spherical tumor would take days (van Osdol et al. 1991). Mathematical models have been developed that suggest greater tumor penetration could be achieved with molecules that bound with lower affinity (Baxter and Jain 1991). From a theoretical perspective, the best solution appears to be a molecule that maintains a high affinity constant by combining a relatively slow association rate constant with a slow dissociation rate constant (Fujimori et al. 1989).

An additional factor that must be considered is the uniformity of the concentration of the molecular target within the tumor. The concentrations of tumor-associated antigens (Hayes et al. 1989) and receptors (Wikstrand et al. 1995) among tumors from patients with a particular type of malignancy can vary from over 10^5 molecules per cell to undetectable levels. Furthermore, wide variations in antigen or receptor expression have been reported both within the cells of a particular tumor as well as between different tumors from the same patient (Del Vecchio et al. 1989, Mattes et al. 1990). For targeted radiotherapy, a particularly problematic aspect of heterogeneous target molecule expression is that in many cases, large regions of tumor lack the capacity for binding the targeted radiotherapeutic. As noted above, one strategy for circumventing this problem is to utilize radionuclides with sufficient range to deliver meaningful radiation doses to tumor regions that do not express appreciable levels of the target molecule through radiation crossfire.

46.2.1.3 Other Considerations

The *physical half-life of the radionuclide* is another factor that must be considered in the design of endoradiotherapeutic agents. The half-life should be long enough to permit radio synthesis and quality control and in some cases, distribution to locations distant from the production site of the radiopharmaceutical. More importantly, the half-life should be compatible with the *pharmacokinetics of localization* in tumor and clearance from normal tissues. Finally, it is generally easier to achieve higher radiation dose rates with shorter half-life radionuclides. This is an important consideration because cell culture experiments (Bedford and Mitchell 1973) and clinical studies (Mazeron et al. 1991) have shown that increasing the dose rate for low linear energy transfer radiation can lead to a greater degree of tumor control.

Radionuclide availability also must be considered. Reactors, cyclotrons, and natural decay chains have all been utilized as sources of radionuclides for targeted radiotherapy; cf. ➤ Chaps. 38, ➤ 39 and ➤ 40 in this Volume. A high degree of radionuclidic purity is required for therapeutic radiopharmaceuticals. Depending on the nature of the molecule that will be labeled, *specific activity* (GBq/mmol) may also be an important consideration. For radiocolloids or other agents that are taken up by a nonsaturable process, specific activity is less important, and low specific activity production methods such as (n,γ) reactions on nuclear reactors are acceptable. However, if the targeting mechanism is easily saturated, as is often the case with tumor-associated antigens, receptors or transporters, then no-carrier-added production methods may be required (Eckelman 1995). In any case, cost and availability of the radionuclide must be considered in the development of a practical endoradiotherapeutic agent. Indeed, lack of availability of the radionuclide has sometimes been the largest impediment to the development of promising α-particle emitters such as ^{213}Bi and ^{211}At .

Selection of a radionuclide for targeted radiotherapy must also take into account its chemical-biological properties. Chemical methods must be devised for attaching the radionuclide to the targeting molecule of interest without compromising the tumor localizing capacity of the molecule. In addition, the bond between the radionuclide and the carrier molecule must be stable in the *in vivo* environment over a time period consistent with the physical half-life of the radionuclide in order to minimize damage to normal organs from released activity.

Because some dissociation of radionuclide from the carrier molecule is likely to occur either due to instability or metabolism, it is important to also consider the *in vivo* localization

and clearance properties of the free radionuclide and other labeled catabolic species. For example, radioiodine distributes primarily in the thyroid and the stomach, and for radioiodinated biomolecules, this background activity can be minimized through the administration of blocking doses of potassium iodide (Larsen et al. 1998a). On the other hand, many metallic radionuclides, when released in ionic form, are avidly accumulated in the bone. This can result in irradiation of the bone marrow, one of the most highly radiosensitive normal tissues, and compromise the effectiveness of these agents. This difference between radio metals and radioiodine is illustrated by comparisons of proteins labeled with the β emitters ^{131}I and ^{90}Y , which showed that at the maximum tolerated dose of the radio metal–labeled, protein was considerably lower than that of its radioiodinated counterpart (Sharkey et al. 1990, 1997; Buchsbaum et al. 1993). Clearly, such comparisons are influenced not only by the disposition of the labeled catabolites generated from the radio metal– and radioiodine-labeled proteins (including the free metal ions and halides), but also by the methodologies used to attach the radio metal to the protein.

46.2.2 Selection of the Targeting Vehicle

With the exception of carriers that rely on tumor localization by physical entrapment such as colloids, the development of effective targeting agents for delivering radionuclides to tumors involves two steps: *identification of a molecular target* that is either uniquely expressed or over expressed on tumors, and generation of a molecule that can be radiolabeled and can bind to the tumor-associated target. A wide variety of targeting vehicles have been investigated for radio-nuclide therapy and some of these are summarized in ▶ Table 46.1. After a brief discussion of radiolabeled particulates, the following sections will describe the properties of monoclonal antibodies and peptides because these targeting vehicles are the focus of the majority of current radionuclide therapy research.

■ Table 46.1
Some targeting vehicles utilized for radionuclide therapy

Vehicle	Example	Reference
Colloid	^{165}Dy -labeled ferric hydroxide macroaggregates	Sledge et al. (1986)
Organic molecule	Meta- ^{131}I iodobenzylguanidine	Wieland et al. (1980)
Inorganic complex	^{153}Sm EDTMP	Goeckeler et al. (1987)
Peptide	^{90}Y -labeled DOTA-octreotide	de Jong et al. (2002)
Protein	^{131}I -labeled anti-tenascin antibody 81C6	Zalutsky et al. (1989a)
Drug	^{211}At -labeled Syncovit	Brown and Mitchell (1998)
Steroid	^{125}I -labeled estradiol analogs	Hanson (2000)
Nucleoside	5- ^{125}I iodo-2'-deoxyuridine	Bloomer and Adelstein (1977)

46.2.2.1 Particulate Carriers

Much of the early work with radionuclide therapy involved *radiolabeled particulates* (Spencer 1978; Harbert 1987), and these agents are still routinely used in certain clinical applications. In general, this type of agent is used when the tumor or other disease state is confined to an isolated body cavity. The goal is to obtain a uniformly distributed radiation dose within the cavity, while minimizing *leakage* into the rest of the body. In addition to stability, the most important characteristic of particulate carriers is their size because this dictates not only homogeneity of dose deposition but also leakage from the treatment site.

Perhaps the most frequent current use of radiolabeled particulates is not in the cancer field but in the treatment of rheumatoid arthritis. In this procedure, the goal is to selectively destroy the inflamed joint lining, the hallmark of rheumatoid arthritis, through the intra-articular administration of a radionuclide. This is an attractive alternative to the conventional surgical approach because *radiation synovectomy* is considerably less expensive and requires less extensive hospitalization. Initially, radiation synovectomy was performed using a ^{198}Au colloid; however, leakage of this particulate from the knee joint was excessive, with over 10% of the injected dose generally being taken up in the regional lymph nodes (Virkkunen et al. 1967). A variety of ^{90}Y -labeled colloids were also evaluated, but the leakage from the joint to the lymph node was again problematic (Rekonen et al. 1972; Gumpel et al. 1975). A common characteristic of these colloids was their small size, less than $0.1\text{ }\mu\text{m}$ in diameter.

To circumvent this problem, Sledge et al. (1977) utilized ferric hydroxide macroaggregates as a particulate in tandem with the 3.3-h half-life β emitter, ^{165}Dy , which was produced by a neutron bombardment of natural dysprosium. Leakage rates of this 5–10- μm -diameter particulate from knee joints were considerably lower than that observed with the ^{198}Au and ^{90}Y colloids noted above (Zalutsky et al. 1986). From a practical standpoint, the short half-life of ^{165}Dy limits the utility of this endoradiotherapeutic agent to medical centers that are located in reasonable proximity to a nuclear reactor. This has led to the search for a particulate carrier than can be used for radiation synovectomy that can be labeled with a longer half-life radionuclide. Among the radionuclides that have been investigated for this purpose are ^{188}Re (Wang et al. 2001), ^{169}Er (Ruotsi et al. 1979), ^{32}P (Onetti et al. 1982), ^{166}Ho (Song et al. 2001), and ^{153}Sm (Shin et al. 2001).

46.2.2.2 Monoclonal Antibodies

No advance has done more to resurrect interest in targeted radionuclide therapy than the development of *monoclonal antibody (mAb) technology*. Antibodies are proteins that are generated in response to a specific molecular stimulus, which is known as the antigen. In principle, antibodies can be produced that react with antigenic structures that are present on cancer cells, and this has been possible even when the molecular nature of the antigen has not been determined. As the knowledge on the molecular biology of tumor cells has grown, the ability to define the structure of these antigenic targets has improved, making it easier to generate antibodies that bind with high affinity to tumor cells. Many laboratories throughout the world have attempted to exploit the molecular specificity of antibody binding to tumor-associated antigens in order to selectively target radionuclides to tumors. In the past few years, this form of targeted radiotherapy, known as radioimmunotherapy, has reached the stage of

development that a number of labeled antibodies are commercially available for the treatment of certain types of cancer.

Initially, antibodies first were generated by immunizing goats or rabbits, and these were utilized to demonstrate the feasibility of antibody-mediated targeting of radionuclides to tumors. For example, Primus et al. (1977) showed preferential uptake of radioiodine in human tumors implanted in hamsters after the injection of a radioiodinated antibody reactive with carcinoembryonic antigen, a molecule found on human colorectal cancers. A severe limitation of these animal-generated antisera that compromised their utility as carrier molecules for targeted radiotherapy was their polyclonal nature. Polyclonal antibodies consist of a family of proteins with a range of specificity and affinity for the antigenic target of interest. It was not until the introduction of hybridoma technology by Kohler and Milstein (1975) that it became possible to circumvent this problem. This methodology yields mAbs, which are proteins with a defined amino acid sequence, resulting in a carrier with a defined antigen specificity and affinity. Other advantages of mAbs that have facilitated the development of antibody-based therapeutic radiopharmaceuticals is the fact that large quantities of these proteins can be produced more conveniently, at a lower cost, and in a more reproducible fashion.

Fate of the Antibody–Antigen Complex

The suitability of a particular antigen–mAb system for therapeutic applications depends in part on the biological fate of the antigen–mAb complex (Hayes et al. 1989). The ideal scenario is if the complex remains on the cell membrane or extracellular matrix after binding for a time period compatible with the physical half-life of the radionuclide. In some cases, after antibody binding, the resultant immune complex is rapidly released from the tumor. This process, known as shedding, decreases the radiation dose received by the tumor, and depending on the size of the antigen–antibody complex, can increase the radiation dose received by the blood, bone marrow, and liver.

An additional possibility is that the antigen–antibody complex can be internalized into the tumor cell. This is an important consideration from a labeling perspective because in general, internalization exposes the labeled mAb to intracellular catabolic processes. Of primary concern is lysosomal proteolysis, which can lead to rapid loss of the radionuclide from the tumor cell (Press et al. 1990; Geissler et al. 1991), significantly decreasing the efficacy of radioimmunotherapy. This is an important problem for antibody-mediated radiotherapy because many of the most tumor-specific antigenic targets rapidly internalize (Slamon et al. 1989; Press et al. 1994; Wikstrand et al. 1995), exposing labeled mAbs reactive with these molecules to the intracellular environment. Although methods for minimizing the release of radio halogens from internalizing mAbs have been developed recently (Foulon et al. 2000), labeling internalizing mAbs with radio metals generally results in better retention of the radionuclide in tumor cells compared with conventional radioiodination methods (Novak-Hofer et al. 1994).

Antibody Structure

Unlike most other endoradiotherapeutic agents, radiolabeled mAbs are macromolecules. While there are five classes of human immunoglobulins from which this type of agent could be developed, the vast majority of mAbs utilized for radioimmunotherapy are IgG. These molecules have an approximate molecular weight of 150 kDa and are the predominant immunoglobulin class found in the blood. A schematic structure of an IgG molecule is

■ Fig. 46.3

Simplified structure of IgG molecules. Monoclonal antibodies (mAbs) consist of two heavy (H) and light (L) chains composed of a series of constant (C) and variable (V) region domains. Chimeric mAbs are composed of murine V region domains and C domains of human origin, while humanized mAbs only contain the murine amino acid sequences (represented by dotted bars) involved in antigen recognition

illustrated in Fig. 46.3. The IgG molecule is composed of two identical polypeptide heavy (H) and light (L) chains coupled together by multiple disulfide bonds in order to form a $(HL)_2$ dimeric species.

The heavy chain includes five *separate domains* – V_H , C_{H1} , hinge, C_{H2} , and C_{H3} – and has a molecular weight of about 50 kDa, and the L chain is composed of the V_L and C_L domains and has a molecular weight of about 25 kDa.

The binding of an IgG molecule to its antigenic target is controlled by the variable (V) domains, and the specificity of this recognition is controlled by the configuration of only a few amino acid residues within these regions. In contrast, the amino acid sequences of the constant (C) region domains, which are not involved in antigen recognition, are the same for all mAbs of a particular subclass. For human IgG, there are four subclasses – IgG₁, IgG₂, IgG₃, and IgG₄ – that differ with regard to the nature of the hinge region containing the interchain disulfide bonds linking the molecule and the amino acid sequence of the Fc region containing the C_{H2} and C_{H3} domains (Turner 1981). These hinge regions differ with regard to their length, and the number and position of the disulfide bonds linking the HL monomers.

Because of these differences, the four human IgG subclasses bind with different affinities to Fc receptors. The Fc receptor affinity of human IgG₂ is less than 10^5 M^{-1} , while those of the other three IgG subclasses range from 10^8 to 10^9 M^{-1} (Shin 1991). This is important for radioimmunotherapy because Fc receptors are found on many normal tissues such as the liver,

and IgG molecules with a higher binding affinity to these receptors could result in higher radiation-absorbed doses to these organs. Unfortunately, most radioimmunotherapy trials have utilized IgG₁ and IgG₃ mAbs that were originally developed for other antibody-dependent therapeutic approaches, where Fc receptor binding was advantageous.

Most mAbs that have been utilized for radioimmunotherapy are of murine origin because they were produced through the immunization of mice with the antigen of interest. A problem with these mAbs for human use is that patients frequently develop an immune response to murine proteins, compromising their usefulness for targeted radiotherapy, particularly when multiple injections are desired. To circumvent this limitation, two types of mAbs have been developed, chimeric mAbs and humanized mAbs. As shown in [Fig. 46.3](#), chimeric mAbs consist of a combination of murine V domains and human C domains and are constructed by genetic engineering techniques (Morrison 1985). On the other hand, humanized mAbs are essentially human proteins with the exception of the amino acid residues from the murine V domains that make up the antigen recognition site of the original murine parent (Riechmann et al. 1988).

Clinical studies have confirmed that chimeric and humanized mAbs are less immunogenic. However, the half time for clearance of these molecules from the blood pool in humans is much slower than their murine counterparts due to the fact that they have human Fc regions. This feature must be considered in selecting the optimal radionuclide-mAb combination for radioimmunotherapy. Indeed, the ideal radionuclide for labeling a particular mAb may be different depending upon whether the protein is in murine, chimeric, or humanized form.

An additional characteristic of mAb constant regions of importance for radionuclide therapy is that the stability of the molecule is dependent on the characteristics of the constant region. The flexibility of the mAb hinge region may be the critical parameter because it can have a major impact on the accessibility of the molecule to proteases that can rapidly degrade the protein (Tao and Morrison 1989). Rotational correlation studies have shown that the human IgG₂ hinge region is more rigid than other murine and human IgG subclasses (Dangl et al. 1988). A number of chimeric mAbs have been constructed with human IgG₂ constant regions and shown to have prolonged tissue residence times relative to their murine counterparts (Batra et al. 1994; He et al. 1994; Reist et al. 1997). A comparative analysis of the labeled catabolites generated from a radioiodinated human IgG₂ chimeric and a murine IgG_{2b} mAb demonstrated that the chimeric mAb was more resistant to both proteolytic degradation and deiodination (Reist et al. 1998). These results suggest that mAbs containing human IgG₂ constant regions might be the molecules of choice for radioimmunotherapy not only because of their low Fc receptor binding but also because of their enhanced stability in vivo.

Antibody Fragments

One of the advantages of utilizing mAbs as carriers for targeted radiotherapy is that one can choose to label either an intact, 150-kDa IgG molecule or a smaller mAb fragment that has the same tumor specificity as the whole IgG. mAb fragments clear more rapidly than the intact IgG from normal tissues, and their penetration into the tumor is also more rapid, making it possible to utilize radionuclides with relatively short half-lives. A variety of enzymatically and genetically derived mAb fragments have been investigated for targeting radionuclides to tumors ([Fig. 46.4](#)).

Fab fragments (~50 kDa) and single-chain scFv (~26 kDa) are monovalent species that exhibit rapid clearance from the blood pool and other tissues. On the other hand, both F(ab')₂

■ Fig. 46.4

Schematic structure of some mAb fragments that have been evaluated as molecular carriers for targeted radionuclide therapy

and $(scFv)_2$ dimers have two antigen-binding sites, which increases their functional affinity. Trimeric and tetrameric $scFv$ have also been developed but have yet to be evaluated as molecular carriers for radiotherapeutic applications.

General Considerations for Labeling mAbs and Their Fragments

Unlike most other carrier molecules of potential utility for targeted radiotherapy, mAbs contain multiple sites for labeling. An important consideration is to determine the *number of radionuclides per protein molecule* that will be optimal. Clearly, as the number of labels per IgG increases, the probability of altering the antigen-binding capacity of the mAb also increases. On the other hand, if the number of antigenic sites per tumor cell is relatively low, substitution of multiple radionuclides per mAb may be required in order to deliver sufficient radiation dose to the tumor. This is of particular importance when the specific activity of the radionuclide is relatively low, as is sometimes the case when reactor production methods are used. In general, mAbs can be labeled without significant loss of antigen-binding capacity when the substitution level (i.e., the number of iodines or chelates for radio metal labeling) is below four per molecule. However, with some mAbs, it is necessary to utilize an even lower substitution level.

When deciding whether an intact mAb or mAb fragment would be preferable, radiolabeling issues also must be considered. As will be discussed in other chapters in this volume, the vast majority of mAb labeling strategies involve modification of either tyrosine or lysine residues on the protein through electrophilic iodination and conjugation reactions, respectively. According to the amino acid sequence compilation of Kabat et al. (1991), an intact IgG molecule contains an average of 88 lysine and 54 tyrosine residues per molecule. For the mAb to retain its antigen-binding capacity, substitution of the label into the antigen recognition site must be avoided. The antigen recognition site is also known as the complementary determining regions, i.e., CDRs, located within the V domains shown in ► Fig. 46.3. Because the CDRs are such small portions of the IgG molecule, the probability of labeling an amino acid within the CDRs is quite low, assuming that all tyrosine or lysine residues are equally reactive.

In the followings, the situation with mAb fragments is considered. As the size of the protein decreases, the probability of modifying the CDRs increases because mAb fragments maintain the same CDRs as intact mAbs but exclude one or more C region domains. This issue is particularly important for the labeling of scFv fragments (either monomers or multimers), which are constructed by combining only the V_L and V_H domains from an mAb. In order to select the best mAb fragment and labeling strategy for scFv, it is sometimes necessary to determine the location and number of tyrosine and lysine residues on candidate molecules. Olafsen et al. (1995) have performed this type of analysis for the V domains of two mAbs reactive with osteosarcoma, TP-1 and TP-3. For both mAbs, less than 25% of the lysine residues were in the CDR regions, while about 50% of the tyrosine residues were found in the CDRs. Therefore, a radiolabeling method that involved modification of lysine residues instead of tyrosine residues would be the more prudent approach for labeling the scFv fragments of TP-1 and TP-3 mAbs.

The reactivity of amino acids within a protein actually can vary considerably with regard to their reactivity for labeling due to variations in the microenvironment of the residues. These differences in reactivity are related to a number of factors including proximity to hydrophobic sequences or bulky amino acids such as tryptophan. Accessibility to solvent also must be considered. The relative amino acid reactivity of amino acids toward labeling has not been investigated on mAbs because of their complexity. However, studies with smaller proteins and peptides have documented, for example, that the rate of iodination of tyrosine residues in these molecules can vary by factors of 50–100 (Dube et al. 1966; Seon et al. 1970).

46.2.2.3 Peptides as Radionuclide Carriers

Peptides, like mAbs, are composed of amino acids; however, they are much smaller, generally consisting of 50 amino acids or less. The differences between peptides and proteins have important implications for radionuclide therapy (Weiner and Thakur 2001). Because of the smaller size of peptides, they clear much more rapidly from the blood pool and most normal tissues. In addition, a consequence of their lower molecular weight is more rapid penetration into tumors, offering the possibility of more rapidly achieving homogeneous distribution of the radionuclide in the tumor. Peptides are also considerably less immunogenic than proteins, making radiotherapeutic strategies involving multiple dose administrations possible. Finally, although hybridoma technology has markedly decreased the cost of producing mAbs, the synthesis of peptides is even more convenient, being readily accomplished using automated solid-phase procedures. A recent development is the application of phage display and other combinatorial techniques to provide peptides with improved properties for radiolabeling (Ladner 1999).

Peptides are not without their disadvantages. As will be discussed below, most of the peptides being investigated for targeted radiotherapy are *regulatory peptides*. Although their corresponding receptors are upregulated in certain malignant cell populations, they are also present in some normal tissues, notably, those in the gastrointestinal tract (Warner and O'Dorisio 2002). Furthermore, these regulatory peptides cause physiological effects at very small concentrations, making it important to maximize the specific activity of labeled peptide preparations. Native peptides are rapidly degraded in vivo (Reubi 1997), making it necessary to develop analogs with improved stability. Generally, this can be accomplished by the insertion of D-amino acids at critical locations and the cyclization of a portion of the molecule

(Lamberts et al. 1987). A final issue is that as a consequence of their rapid elimination via urinary excretion, labeled peptides can cause dose-limiting radiotoxicity to the kidneys (Breeman et al. 2001). A potential solution to this problem is the coadministration of basic amino acids to inhibit the tubular reabsorption of glomerularly filtered peptides (Behr and Behe 2002).

Some of the regulatory peptides and corresponding receptors that are being evaluated for radionuclide targeting applications are summarized in [Table 46.2](#). By far the most widely investigated receptor for peptide-mediated targeting of radionuclides to tumors is the somatostatin receptor (Heppeler et al. 2000; Kwekkeboom et al. 2001; de Jong et al. 2002). The concentration of these receptors on tumors is a critical feature in determining their potential as molecular targets for radionuclide therapy. For example, the concentration of somatostatin receptors on different types of tumor is quite different. Medulloblastomas have very high levels of expression, about 2 pmol/mg tumor tissue, while the expression on gliomas is about an order of magnitude lower (Mueller et al. 1998; Cervera et al. 2002). A potential problem with α -melanocyte stimulating hormone receptor targeting is that human melanomas have only a few hundred to a thousand receptors per cell (Tatro et al. 1990; Siegrist and Eberle 1995), requiring very high specific activity-labeled peptides for effective treatment. In evaluating the potential of a receptor system for targeted radiotherapy, it is important to consider that some receptor types, including many listed in [Table 46.2](#), can rapidly recycle to the cell membrane after ligand binding, offering the possibility of a single receptor being able to deliver multiple peptide molecules to the tumor cell.

The fact that peptides are much smaller than mAbs presents different issues that must be addressed in order to develop them as a targeted radiotherapeutic. With peptides, the probability of label substitution in the binding recognition portion of the molecule is much higher

Table 46.2

Peptides and corresponding receptors that are overexpressed on human tumors

Peptide/receptor	Amino acids	Tumors over expressing receptor
Somatostatin	14, 28	Neuroendocrine, small cell lung cancer, medullary thyroid carcinoma, astrocytoma
Vasoactive intestinal peptide	28	Small cell lung cancer, colon carcinoma, pancreatic cancer, stomach cancer
α -melanocyte stimulating hormone	13	Melanoma
Bombesin, gastric releasing peptide	14, 27	Small cell lung cancer, colon carcinoma, glioblastoma
Substance P	11	Glioblastoma, astrocytoma, medullary thyroid carcinoma, breast tumors, small cell lung cancer
Neurotensin	13	Pancreatic cancer, colon carcinoma, small cell lung cancer, prostate cancer
Cholecystokinin B, gastrin	17, 12	Medullary thyroid carcinoma, small cell lung cancer, ovarian cancer, astrocytoma
Epidermal growth factor	53	Glioblastoma, squamous cell carcinoma, breast carcinoma

than with mAbs. However, with peptides, the amino acids involved in receptor recognition generally are known, while in most cases, this information is not available for mAbs. Because of the ease of peptide synthesis, amino acids can be changed or added in order to create a site for labeling that does not interfere with receptor binding.

Native somatostatin binds with high affinity to all five of the *somatostatin receptor* subtypes; however, the affinity of the various stabilized somatostatin analogs for these receptor subtypes varies considerably. *Octreotide*, the most commonly used somatostatin analog, binds with high affinity to receptor subtype-2, with lower affinity to subtype-3 and subtype-5, but does not bind to subtype-1 or subtype-4 (Patel 1999). Reubi et al. (2000) have shown that modifying the nature of the chelate or the radio metal had a significant effect on the affinity profile of a series of octreotide analogs. For example, complexation of yttrium had no effect on the 50% inhibitory concentration of *DOTA-[Tyr³]octreotate* for the human somatostatin subtype-2 receptor; in contrast, complexation with gallium, another Group III metal, increased the affinity for this receptor subtype by about a factor of 7. This illustrates the difficulty in predicting the effect of peptide radiolabeling on affinity and specificity for the intended receptor target.

Peptides bind to their receptors in univalent fashion and are washed out of tissues quite rapidly. Thus, it might seem counterintuitive to consider these molecules as carriers for targeted radiotherapy due to the anticipated difficulty in maintaining adequate levels of radioactivity in tumor over a sufficient time period to deliver an effective radiation absorbed dose. However, prolonged retention of radionuclide in tumors does occur due to the rapid internalization of these labeled peptides after binding to their corresponding receptor. It should be noted that the degree of internalization can vary considerably for different receptor targets and individual peptides.

Translocation of the peptide–receptor complex to the lysosomes is problematic from a labeling perspective because of the exposure of the labeled peptide to proteolysis. For this reason, it is critical to utilize a labeling method that yields labeled catabolites that do not cross the lysosomal or cell membranes. For example, after a somatostatin-receptor-mediated internalization of [¹¹¹In-DTPA]octreotide, the radioactivity was trapped in tumor cells as an ¹¹¹In-DTPA-D-phenylalanine conjugate (Duncan et al. 1997). Evaluation of the retention of radioactivity in tumor cells in vitro after the binding of labeled peptides has emerged as an important predictor of in vivo tumor localizing capacity (de Jong et al. 1998a, b; Hofland et al. 1999).

46.3 Radionuclides for Targeted Radiotherapy

46.3.1 Beta-Particle-Emitting Radionuclides

Radionuclides that decay by the emission of β particles were the first to be utilized in patients for radionuclide therapy. For an excellent review of early studies with [¹³¹I]iodide, various radiocolloids and other compounds, the reader is referred to a book by Harbert (1987). Beta emitters remain the type of radionuclide used most frequently for targeted radiotherapy. When negatively charged electrons are emitted from the nucleus as β particles, their energy spectrum consists of a continuum of energies ranging from almost zero to their maximum energy. The average energy for a β -particle spectrum is about one-third of the maximum energy. For therapeutic applications, an important energy-dependent parameter is the mean and

maximum range of the β particles in tissue. The range of electrons in biologically relevant media as a function of energy can be found in ICRU Report 37 (1984).

There are β -particle-emitting radionuclides available for radionuclide therapy with a wide variety of tissue ranges. In ► [Tables 46.3–46.5](#), the physical properties of some β -particle-emitting radionuclides of potential utility for radionuclide therapy have been arranged into three groups according to range: short range ($<1,000\ \mu\text{m}$; ► [Table 46.3](#)), medium range ($1,000\text{--}2,000\ \mu\text{m}$; ► [Table 46.4](#)), and long range ($>2,000\ \mu\text{m}$; ► [Table 46.5](#)).

As discussed in the previous section, in selecting a radionuclide, it is important to *match the range of the radionuclide with the anticipated size of the tumor target*. The practical advantage of this strategy has been demonstrated in radiotherapy experiments performed in animal models. As would be predicted from the calculations of O'Donoghue et al. (1995), small tumors were more effectively treated by a short-range β emitter, while a higher cure rate could be obtained in larger tumors with a long-range β emitter (de Jong et al. 2002).

■ **Table 46.3**

Selected short-range β -particle-emitting radionuclides for targeted radiotherapy

Radionuclide	Half-life (days)	Mean range (μm)	Average β energy (keV)
^{199}Au	3.1	410	82
^{169}Er	9.3	510	101
^{177}Lu	6.7	670	133
^{67}Cu	2.6	710	141
^{105}Rh	1.5	760	152
^{161}Tb	6.9	770	154
^{47}Sc	3.4	810	162
^{131}I	8.1	910	182

^{90}Y	2.7	3,900	935
^{76}As	1.1	5,000	1,000

46.3.1.1 Short Range β -Particle Emitters

All the radionuclides listed in Table 46.3 emit β particles with relatively short tissue ranges. Erbium-169 colloids have found application for the treatment of arthritis in small joints (Menkes et al. 1982). Three other radionuclides that have been explored in clinical radionuclide therapy studies are ^{131}I , ^{67}Cu , and ^{177}Lu . All of the others have not been pursued either due to problems with their production in sufficient specific activity and radionuclidic purity, or lack of suitable chemistry for attaching them to carrier molecules of interest. Nonetheless, all the radionuclides listed in Table 46.3 would be suited, from an energetic perspective, to the treatment of small tumor metastases (O'Donoghue et al. 1995).

Iodine-131

Iodine-131, with a half-life of 8.1 days, has been the most frequently utilized radionuclide for therapeutic applications and has a mean range of 910 μm . Although ^{131}I has a tissue range that is well suited to the treatment of small tumors, it also emits a 364-keV γ ray in 81% abundance. The energy of this γ ray is not ideal for conventional or single photon emission tomographic imaging devices; however, it does permit monitoring of the distribution of ^{131}I -labeled endoradiotherapeutic agents in a semiquantitative fashion. Such procedures are important because they permit the calculation of patient-specific radiation dosimetry (Akabani et al. 1999). In this way, it is possible to attempt to relate the response of a particular patient to the radiation dose delivered to the tumor, or to study the radiation dose dependence of normal tissue toxicities. An additional problem with radionuclides such as ^{131}I that emit medium-energy γ rays is that it complicates the radiotherapy procedure. First, it can increase the radiation dose received by health-care personnel and second, it is frequently necessary to confine the patient to a lead-lined room until body radioactivity has decayed to a reasonable level.

Copper-67

Copper-67 is perhaps the most attractive alternative to ^{131}I as a short-range β emitter. Because of its 2.6-day half-life, it can be considered for use with a variety of molecular carriers including mAbs and peptides. An advantage of ^{67}Cu is that it emits several γ rays with energies ranging

from 91 to 185 keV that are ideal for imaging. The shorter physical half-life and lower γ -ray energies of ^{67}Cu combine to make patient handling easier than with ^{131}I . Unfortunately, use of ^{67}Cu for radionuclide therapy has been rather limited because of the poor availability of this radionuclide due to the fact that its production requires a high-energy accelerator. Furthermore, none of the currently available chelators for Cu(II) are ideal in terms of *in vivo* stability.

Lutetium-177

In recent years, 6.7-day half-life ^{177}Lu has emerged as a *promising short-range β emitter* for targeted radiotherapy. The mean range of ^{177}Lu β particles is 670 μm , making this radionuclide ideal for treating micro-metastatic disease. Because it also emits γ rays (208 keV, 11% abundance), imaging of ^{177}Lu -labeled endoradiotherapeutic agents is possible. Lutetium-177 can be produced by neutron bombardment of lutetium; with high flux reactors and isotopically enriched ^{176}Lu (71%), specific activities of about 740 GBq mg^{-1} can be obtained (Hu et al. 2002). Production of no-carrier-added ^{177}Lu is also possible, and this approach is recommended for applications where very high specific activities of the labeled molecule are needed because of low concentration of receptor or antigen sites on the tumor. To provide no-carrier-added ^{177}Lu , Lebedev et al. (2000) utilized the $^{176}\text{Yb}(n,\gamma)^{177}\text{Yb}$ (1.9-h half-life), which decays by β emission to ^{177}Lu . Isolation of ^{177}Lu from the ytterbium target is then performed via a two-step process.

The therapeutic potential of ^{177}Lu is currently being evaluated in tandem with a variety of molecular carriers. In a comparative study of the somatostatin-avid peptide [DOTA^0 , Tyr^3] octreotate (*DOTA macrocycle = 1,4,7,10-tetraaza-cyclodecane- N,N',N'',N''' -tetraacetic acid*) in rats with CA20948 xenografts, the tumor uptake of the ^{177}Lu -labeled peptide was higher than that of the same peptide labeled with either ^{111}In or ^{90}Y (de Jong et al. 2001). Based on these encouraging results, [^{177}Lu - DOTA^0 , Tyr^3]octreotate is currently being evaluated in patients (Kwekkeboom et al. 2001). Bombesin peptide analogs also have been labeled with ^{177}Lu (Hu et al. 2002).

Lutetium-177 complexes with several polyphosphate ligands have been reported as potential agents for the palliation of pain associated with bone metastasis (Chakraborty et al. 2002). A recent study has compared the potential utility of several macrocyclic and acyclic ligands for labeling mAbs with ^{177}Lu (Milenic et al. 2002). The acyclic ligand $\text{CHX-A}''\text{-DTPA}$ [2-(*p*-isothiocyanatobenzyl)-cyclohexyl-diethylenetriamine-pentaacetic acid] yielded similar *in vivo* behavior of a ^{177}Lu -labeled mAb fragment as was observed with the DOTA conjugate; however, ease of synthesis was an important advantage for $\text{CHX-A}''\text{-DTPA}$. More extensive investigations will be required in order to identify the optimal ligand system for labeling mAbs and peptides with ^{177}Lu .

46.3.1.2 Medium Range β -Particle Emitters

Only a few of the β emitters listed in [Table 46.4](#) have been investigated for therapeutic applications. Many of these radionuclides are reactor produced, limiting the types of carrier molecules for which they are suitable. Several radiocolloids labeled with ^{198}Au have been studied for intracavitary therapies; however, their relatively high degree of leakage from the treatment site has limited their clinical utility (Virkkunen et al. 1967; Spencer 1978; Harbert 1987). Treatment of bone pain with polyphosphate complexes of both ^{153}Sm and ^{186}Re has been investigated. With ^{186}Re , work has focused on the hydroxylethylenediphosphonate complex

(de Klerck et al. 1994; McEwan 1997). The most useful agent for treating bone pain with ^{153}Sm is the ethylenediamine-tetramethylphosphonate complex (Farhanghi et al. 1992) that has progressed to the stage where it is commercially available (Serafini et al. 1998). For a more extensive discussion of the development of these complexes as therapeutic radiopharmaceuticals for treating bone pain, the reader is referred to an excellent review by Volkert and Hoffman (1999).

46.3.1.3 Long Range β -Particle Emitters

Long-range β -particle emitters such as those listed in [Table 46.5](#) have an average range in tissue of more than 2 mm. They offer the prospect of compensating for heterogeneous distribution of the labeled compound within the tumor by the irradiation of non-accumulating cells through radiation cross fire. Radiocolloids and other particulate carriers have been labeled with ^{165}Dy , ^{166}Ho , ^{32}P , and ^{188}Re and utilized for the treatment of rheumatoid arthritis and compartmentally spread neoplasms (Sledge et al. 1977; Harbert 1987; Wang et al. 2001; Song et al. 2001). Strontium-89, in the form of the ionic chloride, was one of the first radiopharmaceuticals utilized for the treatment of painful skeletal metastases, and it is still utilized for this purpose. The long range of ^{89}Sr β particles can be problematic for this purpose because their range is sufficient to cause significant *bone marrow toxicity*, decreasing the dose that can be administered (McEwan 1997).

Yttrium-90 has been the most widely investigated long-range β emitter for radionuclide therapy. This radionuclide is routinely available commercially at reasonable cost in high specific activity. However, because ^{90}Y does not emit γ rays, imaging its distribution in animal models or in patients is difficult. A wide variety of proteins and peptides have been labeled with ^{90}Y using *bifunctional chelates*, molecules that contain a ligand system for metal complexation and a second functionality that permits coupling of the ligand to the molecule of interest. Derivatives of both DOTA and DTPA have been investigated, with macrocyclic ligands generally providing a more stable product (Hnatowich et al. 1988; Kozak et al. 1989; Deshpande et al. 1990; Lewis et al. 1994; Camera et al. 1994). The radiochemistry of ^{90}Y -labeled radiotherapeutics is discussed in depth in [Chap. 45 of this Volume](#).

46.3.2 Alpha-Particle-Emitting Radionuclides

The range of α particles in tissue is equivalent to only *a few cell diameters*, offering the prospect of matching the cell-specific nature of targeted molecular carriers with radiation having a similar range of action (Zalutsky and Vaidyanathan 2000). The short range of α particles also may be ideally suited for minimal residual disease settings, applications in which radionuclide therapy has the greatest chance of making a meaningful clinical impact (Sautterbihl et al. 1996). These include the treatment of micrometastases, residual tumor margins left after surgical debulking, such as gliomas, and tumors present in the circulation such as leukemia and lymphoma. Another type of application that appears to be ideally suited to targeted α -particle therapy is the treatment of malignancies such as neoplastic meningitis and ovarian cancer that spread as thin sheets on body compartment surfaces, frequently accompanied by free floating tumor cells.

■ Table 46.6

Selected α -particle-emitting radionuclides for targeted radiotherapy

Radionuclide	Daughters	Half-life	α -particle energy (MeV)	Yield per 100 decays
^{149}Tb		4.15 h	3.97	17
^{211}At		7.21 h	5.87	42
	^{211}Po	516 ms	7.44	58
^{212}Bi		61 min	6.05	36
	^{212}Po	298 ns	8.78	64
^{213}Bi		45.6 min	5.84	36
	^{213}Po	4.2 μs	8.38	64
^{225}Ac		10 days	5.75	100
	^{221}Fr	4.9 min	6.36	100
	^{217}At	32.3 ms	7.07	100
	^{213}Bi	45.6 min	5.84	2
	^{213}Po	4.2 μs	8.38	98

Utilization of α -particle emitters for radionuclide therapy offers several important advantages from a radiobiological perspective. Alpha particles have higher decay energies than β emitters, generally in the range of 4.0–8.8 MeV for the radionuclides that have been considered for endoradiotherapy (► Table 46.6). This characteristic, in combination with their short range, makes α -particles radiation with high *linear energy transfer* (LET). For example, the α particles from ^{211}At have a mean LET of about $97 \text{ keV } \mu\text{m}^{-1}$ compared with a value of $0.22 \text{ keV } \mu\text{m}^{-1}$ for the high-energy β particles emitted by ^{90}Y . This is a critical distinction for therapeutic purposes because the mean LET for ^{211}At occurs where the relative biological effectiveness of radiation is maximum (Hall 2000). Radiation at $100 \text{ keV } \mu\text{m}^{-1}$ has this quality because at this LET, the distance between ionizing events is nearly identical to that between DNA strands, increasing the probability of creating highly cytotoxic double DNA strand breaks (Kampf 1988). In contrast to low LET radiation such as β emitters, α particles are also cytotoxic in hypoxic regions within a tumor (Langmuir and Sutherland 1988). Finally, the cytotoxicity of high LET radiation is nearly independent of dose rate (Hall 2000). This is an important feature for radionuclide therapy where radiation dose is often delivered at a relatively low dose rate, where repair of DNA lesions can compromise effectiveness.

Although there are approximately 100 radionuclides that decay by the emission of α particles, only a few possess half-lives that are compatible with radionuclide therapy applications (McDevitt et al. 1998). The physical properties of the radionuclides that have been evaluated for this purpose are summarized in ► Table 46.6. In selecting an α emitter for radiotherapy, one must also consider its availability and radionuclidic purity, and the half-life and chemistry of its radionuclide daughters.

46.3.2.1 Terbium-149

Terbium-149 was first proposed as a candidate radionuclide for α -particle radiotherapy by Allen and Blagojevic (1996). This radiolanthanide has a half-life of 4.14 h, and α -particle

emission is associated with 17% of its decays. The production of ^{149}Tb has been accomplished at the CERN spallation source using 600 MeV protons and isolated using the ISOLDE magnetic separator (Allen et al. 1996, 2001a). This group was able to label two mAbs with ^{149}Tb using the DTPA-CHX-A'' chelate and demonstrate the ability of these immunoconjugates to kill human cancer cells (Allen et al. 2001b). The potential utility of ^{149}Tb -labeled mAbs cannot be ascertained at this time because of the lack of information concerning the stability of these labeled mAbs and their tissue distribution in animals.

46.3.2.2 Astatine-211

Astatine-211 has many attractive features for targeted α -particle radiotherapy. It has a half-life of 7.2 h that is long enough to permit multistep labeling strategies. It is also well matched to the biokinetics of a variety of molecular carriers including peptides, mAbs and small organic molecules. Alpha-particle emission is associated with each decay of ^{211}At either by direct α emission to ^{207}Bi (42%) or by electron capture decay to 520 ms ^{211}Po (58%), followed by α emission. As a consequence of the electron capture branch, 77–92-keV polonium x-rays are emitted, and these can be used to monitor ^{211}At distributions in animals or patients using either conventional nuclear medicine planar or single photon emission tomographic imaging devices (Turkington et al. 1993; Johnson et al. 1995).

Astatine-211 is produced by the cyclotron bombardment of natural bismuth metal targets with α particles via the $^{209}\text{Bi}(\alpha, 2n)^{211}\text{At}$ reaction. For radiotherapy applications, it is important to utilize an incident α -particle energy that minimizes the production of 8.1 h ^{210}At . This nuclide is a concern because it decays to ^{210}Po , a 138-day α emitter that could cause bone marrow toxicity. For this reason, incident beam energies for ^{211}At production are generally kept below 29 MeV. Separation of ^{211}At from the bismuth metal target is readily accomplished using a dry distillation procedure (Friedman et al. 1977). Internal cyclotron target systems have been developed that permit the production of clinically useful levels of ^{211}At (Larsen et al. 1996; Schwartz et al. 1998). The highest production level reported to date is 6.6 GBq after a 4-h irradiation with a 55- μA beam of 28-MeV α particles (Zalutsky et al. 2001).

Because astatine is a halogen, radioiodination methods can be adapted for use with ^{211}At , sometimes without significant modification. However, astatine also exhibits metallic properties under certain circumstances (Visser 1989). Direct astatination of proteins is not useful because this results in transient binding to thiol groups, with the activity rapidly released from the protein in vivo. A wide variety of ^{211}At -labeled molecules have been synthesized and evaluated as potential targeted radiotherapeutics (Zalutsky and Vaidyanathan 2000). Some of these approaches are summarized in [Table 46.7](#). Radiotoxicity determinations in cell culture models of human cancers have demonstrated that significant cell killing can be achieved with only 1–10 ^{211}At atoms bound per cell (Strickland et al. 1994; Vaidyanathan et al. 1996; Larsen et al. 1998b).

Studies involving ^{211}At -labeled anti-tenascin mAbs are illustrative of the steps required to develop labeling procedures with an α -particle emitter to the stage where clinical evaluation was possible. The first step was the development of a method for labeling the mAb with ^{211}At , which was accomplished via an *N*-succinimidyl 3- ^{211}At astatobenzoate intermediate, which was synthesized from the corresponding trialkylstannyl precursor (Zalutsky et al. 1989b). The in vivo stability of ^{211}At -labeled 81C6-labeled anti-tenascin 81C6 was then confirmed in mice (Zalutsky et al. 1997). The cytotoxicity of ^{211}At -labeled 81C6 mAb was demonstrated in both in

■ Table 46.7

Some ^{211}At -labeled compounds developed for targeted radiotherapy

Agent	Application	Reference
^{211}At astatine-tellurium colloid	Compartmental tumors	Bloomer et al. (1981a,b, 1984)
6- ^{211}At astato-2-methyl-1,4-naphthoquinol diphosphate	Adenocarcinomas	Brown et al. (1992)
		Brown and Mitchell (1998)
^{211}At -labeled methylene blue	Melanoma	Link and Carpenter (1990, 1992)
Meta- ^{211}At astatobenzyl guanidine	Neuroendocrine tumors	Vaidyanathan and Zalutsky (1992)
		Strickland et al. (1994)
5- ^{211}At astato-2'-deoxyuridine	Various	Vaidyanathan et al. (1996)
		Larsen et al. (1997)
^{211}At -labeled biotin conjugates	Various pretargeting	Foulon et al. (1997, 1998)
^{211}At -labeled octreotide	Somatostatin receptor	Vaidyanathan et al. (2000)
^{211}At -labeled mAbs and fragments	Various	Zalutsky et al. (1989b), Wilbur et al. (1993), Larsen et al. (1994)
^{211}At -labeled bisphosphonates	Bone metastases	Murud et al. (1999)
		Larsen et al. (1999)

vitro and in vivo models of human cancer (Zalutsky et al. 1994; Larsen et al. 1998b). Finally, the toxicity of ^{211}At -labeled human/mouse chimeric 81C6 was determined in normal mice (McLendon et al. 1999).

With these data in hand, permission was obtained from the United States Food and Drug Administration to initiate the first clinical trial of an ^{211}At -labeled therapeutic. This protocol involves the injection of ^{211}At -labeled chimeric 81C6 directly into the surgical tumor resection cavity of patients with recurrent brain tumors (Zalutsky et al. 2001). The results to date have been very encouraging with a median survival of about 60 weeks observed, compared with about 25–30 weeks for recurrent brain tumor patients treated by conventional therapies.

46.3.2.3 Bismuth-212

Bismuth-212 is a 60.6-min daughter of the ^{228}Th natural decay chain. This radionuclide has two decay modes: by the emission of 6.05-MeV α particles (36%) as well as by β decay to 298-ns ^{212}Po , which in turn, decays by the emission of 8.78-MeV α particles. Radionuclide generators have been developed that utilize 3.6-day ^{224}Ra as the parent (Atcher et al. 1988). First, ^{224}Ra is separated from ^{228}Th by isolating the parent on an anion exchange resin in nitric acid. The ^{224}Ra that is eluted is dissolved in 0.1 N HCl and added to a cation exchange column, and this serves as the generator for ^{212}Bi . Separation of ^{212}Bi from ^{224}Ra is accomplished using either 0.15 N HI or 0.5 N HCl as the eluent.

Several mAbs have been labeled with ^{212}Bi via DTPA- or DOTA-coupled bifunctional chelates (Kozak et al. 1986; Junghans et al. 1993). These mAbs were very efficient at killing cancer cells in vitro (Kozak et al. 1986; Black et al. 1988; Kurtzman et al. 1988). Promising results were also observed in some radiotherapy trials in animal models (Macklis et al. 1988; Huneke et al. 1992); however, in other reports, the very short half-life of ^{212}Bi compromised therapeutic utility (Hartmann et al. 1994). An EDTMP complex of ^{212}Bi also has been described as an α -particle emitting agent for the treatment of bone pain (Hassfjell et al. 1994).

In recent years, practical concerns have caused most researchers to abandon ^{212}Bi as a potential therapeutic radionuclide in favor of ^{213}Bi . The ^{224}Ra parent decays to ^{220}Rn , and this gaseous α -emitting radionuclide is of great concern from a radiation safety perspective, and requires that the $^{224}\text{Ra}/^{212}\text{Bi}$ generator be placed in an isolated, gas-tight enclosure. In addition, the ^{208}Tl produced by the β -decay branch of ^{212}Bi emits a 2.6-MeV γ ray, which increases radiation dose to personnel and nonspecific whole body dose to the patient.

46.3.2.4 Bismuth-213

Bismuth-213 has a 45.6-min half-life and α -particle emission is associated with each of its decays, either directly to 2.2-min ^{209}Tl (2%) or after β decay to 4.2- μs ^{213}Po (98%), followed by α emission to 3.25-h ^{209}Pb . A radionuclide generator system has been developed using 10-day ^{225}Ac as the parent that can provide clinically useful levels of ^{213}Bi (McDevitt et al. 1996, 1999b; Ma et al. 2001). The generator consists of an AGMP-50 column and is eluted with 0.1 M HCl/NaI.

Several tumor-specific mAbs have been labeled with ^{213}Bi using the bifunctional *trans*-cyclohexyldiethylenetriaminepentaacetic acid SCN-CHXA"-DTPA and evaluated for their therapeutic potential. The anti-prostate-specific membrane antigen (PSMA) mAb J591 was labeled with ^{213}Bi and shown to be highly cytotoxic for human prostate carcinoma cells grown in culture, as tumor spheroids, and as subcutaneous tumor xenografts grown in athymic mice (McDevitt et al. 2000; Ballangrud et al. 2001). Intraperitoneal injection of a ^{213}Bi -labeled mAb reactive with a tumor-specific mutant E-cadherin molecule was reported to be effective in treating a peritoneally spread gastric cancer in mice (Senekowitsch-Schmidke et al. 2001). And finally, a humanized anti-CD33 mAb, HuM195, has been labeled with ^{213}Bi and is currently being evaluated in patients with leukemia (McDevitt et al. 1999a; Sgouros et al. 1999). This study involves the administration of multiple doses of ^{213}Bi -labeled HuM195. Although it is too early to determine the therapeutic efficacy of this targeted radiotherapeutic, it is important to note that no dose-limiting normal tissue toxicities have been observed.

46.3.2.5 Actinium-225

The short half-life of the α emitters discussed above is problematic for several reasons. First, particularly for 46-min ^{213}Bi , delivery of the endoradiotherapeutic to the tumor must be accomplished very rapidly in order to achieve reasonable tumor-to-normal organ radiation absorbed dose ratios. Second, decay during radionuclide purification, radiolabeling, and transport of the labeled compound to the clinic decreases the activity that is available for use. And third, the short half-life of these α emitters impedes their application at centers distant

from radionuclide production facilities. For this reason, investigators have been searching for a longer-lived α emitter for radionuclide therapy.

Of the radionuclides that have been proposed (Zweit 1996), 10-day ^{225}Ac has received the most attention. As shown in ► Table 46.6, each decay of ^{225}Ac results in the production of four α particles, making it an extremely cytotoxic radionuclide (Davis et al. 1999). There are several relatively long-lived ^{225}Ac daughters such as 4.9-min ^{221}Fr and 46-min ^{213}Bi , and there is considerable concern that the release of these and other daughter radionuclides will result in excessive toxicity to normal organs. The design of a ligand system that will form stable complexes with Ac, Fr, At, and Bi will be a formidable task from a chemical perspective. This will be even more difficult when the effects of the high α -particle recoil energy on the stability of the daughter complex is considered.

A $^{229}\text{Th}/^{225}\text{Ac}$ generator system has been reported that utilizes a two-column system to provide ^{225}Ac in reasonable radionuclidic purity (Geerlings et al. 1993). A number of acyclic chelators have been investigated for ^{225}Ac complex formation; however, their in vivo stability was poor (Davis et al. 1999). A series of ^{225}Ac acyclic and macrocyclic ligands have been evaluated with regard to their in vivo stability (Deal et al. 1999). Excellent stability was reported for ^{225}Ac chelated with 1,4,7,10,13,16-hexaazacyclo-hexadecane-N,N',N'',N''',N''''-hexaacetic acid (HEHA). However, when 2-(4-isothiocyanatobenzyl)-HEHA was utilized to label mAbs with ^{225}Ac , more than half of the ^{225}Ac activity in the serum of mice at 24 h was no longer associated with the mAb (Chappell et al. 2000). Another study using the HEHA chelate concluded that the results suggested that release of ^{225}Ac from the chelate and the radiotoxicity of daughter radionuclides released from the mAb compromised the potential utility of this approach (Kennel et al. 2000).

Recently, McDevitt et al. (2001) described an interesting approach for trapping the daughter radionuclides from ^{225}Ac in the tumor cell that involved labeling mAbs that are rapidly internalized after binding to their antigen or receptor target. A DOTA derivative was utilized for binding ^{225}Ac and excellent therapeutic responses were obtained in several murine tumor models. However, a potential problem with utilizing this tactic in patients is that in most clinical radioimmunotherapy trials, only of the order of 1% of the injected dose of labeled mAb is taken up by the tumor. Thus, one might anticipate that release and redistribution of the daughter radionuclides of ^{225}Ac could occur with 99% of the administered activity.

46.3.3 Low-Energy Electron Emitters

For the purposes of radionuclide therapy, low-energy electrons are considered to be those that deposit their energy in subcellular dimensions. These electrons can arise from two decay processes, internal conversion and electron capture. Internal conversion and electron capture both create inner atomic shell vacancies that are transferred by a series of rearrangements to outer atomic shells. The binding energy difference between the inner and outer shells may then be transferred to other outer shell electrons that are ejected from the atom. These electrons are called *Auger electrons* if they arise from higher shells and are called *Coster-Kronig electrons* if they originate from higher sub shells. Thus, the decay of a single atom by electron capture or internal conversion can result in the emission of a multitude of low-energy electrons, most with ranges in tissue on the order of nanometers (O'Donoghue and Wheldon 1996).

Some of the radionuclides emitting electrons of *subcellular range*, which are of potential utility for radionuclide therapy, are given in ► Table 46.8. Because of this very short range,

■ Table 46.8

Selected radionuclides emitting electrons of subcellular range

Radionuclide	Half-life (days)	Mean electron yield per decay ^a
⁶⁷ Ga	3.3	4.7
⁷⁷ Br	2.4	6.7
¹¹¹ In	2.8	14.7
^{115m} In	4.5	6.1
¹¹⁹ Sb	1.6	4.4
¹²³ I	0.6	14.9
¹²⁵ I	60	24.9
^{193m} Pt	4.3	26.4
^{195m} Pt	4.0	32.8

^aData from Howell (1992)

low-energy electron emitters require targeting strategies that can localize the radionuclide in close proximity to the cell nucleus. The majority of studies evaluating the therapeutic potential of low-energy electron emitters have utilized ¹²⁵I. Although its 60-day half-life is not ideal for most potential therapeutic applications, ¹²⁵I emits about 25 subcellular-range electrons per decay. In addition, it is commercially available and can be readily attached to a wide variety of molecular carriers.

The most widely used approach for targeting low-energy electron emitters to the cell nucleus is to incorporate them into cellular DNA via labeled nucleosides. The thymidine uptake analog 5- [¹²⁵I]iodo-2'-deoxyuridine is rapidly accumulated in proliferating cells and has been shown to be highly cytotoxic (Chan et al. 1976); similar behavior was observed when low-energy-electron-emitting ¹²³I (Makrigiorgos et al. 1989) and ⁷⁷Br (Kassis et al. 1982) were used for labeling. A lack of shoulder at low doses, a feature of high-LET radiation, characterized the cell survival curves obtained with these compounds. When low-energy electron emitters are localized in cellular DNA, their relative biological effectiveness is similar to that observed with α -particle emitters (Howell et al. 1991). A number of studies have confirmed that localization of the decay site in the cell nucleus is required for low-energy electron emitters to exert high-LET cytotoxic effects (Hofer et al. 1975; Warters et al. 1977).

Although 5- [¹²⁵I]iodo-2'-deoxyuridine has served as a useful model compound for investigating the cytotoxicity of low-energy electron emitters, it has several problems that limit its clinical utility. The 60-day half-life of ¹²⁵I is considerably longer than desirable for a targeted radiotherapeutic. Only cells that are rapidly dividing (in S-phase) take up the labeled drug, so quiescent cells are not killed. Finally, 5- [¹²⁵I]iodo-2'-deoxyuridine is rapidly dehalogenated in vivo. This has led to the investigation of other radionuclides and carrier molecules in order to identify an agent that can more effectively exploit the therapeutic potential for low-energy electron emitters.

The estrogen receptor has been evaluated as a means of delivering low-energy electron emitters to the cell nucleus. The nonsteroidal ligand tamoxifen has been labeled with ¹²⁵I and shown to be highly cytotoxic for cells that express the estrogen receptor, but not control cell lines (Bloomer et al. 1980, 1981a,b). Steroidal ligands labeled with ^{80m}Br and ¹²⁵I have also been evaluated (De Sombre et al. 1988, 1992; Holt et al. 1992; Beckman et al. 1993; Hughes et al.

1993). Other steroid hormone receptors have been considered including both the androgen and progesterone receptors (Hanson 2000).

Another method that has been pursued for delivering radionuclides to the cell nucleus is to attach them to DNA intrachelating agents. The synthesis and evaluation of both [^{125}I]iodo-Hoechst 33342 (Kassis et al. 1999a, b) and iodo-Hoechst 33258 (Squire et al. 2000) have been reported. Because growth factors are overexpressed on many types of cancer cells and are rapidly internalized (Zalutsky 1997), they are excellent molecular targets for low-energy electron emitters. Both mAbs (Wikstrand et al. 1995) and growth factors (Lindstron and Carlsson 1993) have been considered. Finally, a recent report suggests that radiolabeled somatostatin receptor-avid peptides are rapidly internalized and translocated to the cell nucleus (Hornick et al. 2000). This approach has been evaluated clinically using [^{111}In -DTPA]octreotide (Kwekkeboom et al. 2000; de Jong et al. 2002).

Abstract: The extension of the use of ionizing radiation and the new biological information on the effects of radiation exposure that is now becoming available, present new challenges to the development of concepts and methodology in determination of doses and assessment of hazards for the protection of living systems. Concise information is given on the deterministic and stochastic effects, on the debate concerning the effects of low doses, the detection of injuries by biological assays, and the radiation sickness.

47.1 Introduction

Soon after the discovery of X-rays and radioactivity at the end of the nineteenth century, biological effects of ionizing radiation were observed. Experience shows that radiation exposure can damage living cells, killing some of them and modifying others. The ultimate damage is related to a number of factors, such as the spatial distribution in the cells of the energy deposition along the radiation tracks, the distribution of the absorbed energy with time, and the radiosensitivity of the cells within the organism. Most tissues in the living body are unaffected by the loss of even a considerable number of cells; however, if the number of cells lost is large enough, there will be observable harm to tissues or organs that may lead to death.

During the first decades following the introduction of ionizing radiation, many serious accidents occurred before there was an adequate understanding of its biological effects. By 1922, approximately 100 radiologists (medical practitioners) had died due to the harmful effects of radiation.

The early deaths and other effects of radiation on man led to the initiation of the second International Congress of Radiology to establish the International X-Ray and Radium Protection Committee in 1928. The Committee forced an international cooperation to introduce protective criteria in the use of X-rays and radium therapy. After the beginning of the nuclear age in the 1940s, the increasing interest and extended fields in radiation were restructured and the Committee was renamed the International Commission on Radiological Protection (ICRP), in 1950. Because of the different conditions that apply in various countries, the Commission sets out recommendations but does not intend to provide a regulatory text.

In general, the Recommendation for the System of Radiological Protection (revised every 15–20 years) updates the former one and develops the additional guidance on the control of exposure from radiation sources. The new recommendation is based on the latest available scientific information of the biology and physics of radiation exposure.

Currently, the international standards, such as International Basic Safety Standards (IBSS) and European Directives on radiological protection, and most national regulations are based on the ICRP-1990 recommendations (ICRP Publication No. 60). New scientific data have been published since 1990, but the concept and philosophy of the system have not been changed. The overall estimates of deterministic effects remain fundamentally the same and the estimates of cancer risk have not changed much either, whereas the estimated risks of heritable effects are currently lower than were before.

The ICRP works closely with the International Commission on Radiation Units and Measurements (ICRU), with UN bodies such as the World Health Organization (WHO), International Atomic Energy Agency (IAEA), and Scientific Committee on the Effects of Atomic Radiation (UNSCEAR), and other special and regional organizations. The most important results of the ICRP are reported in the ICRP Publications, several of them as general recommendations for radiation protection, including dosimetry and health effects (ICRP 1977). The most

recent recommendations concerned with the protection of humans appeared in 2007 (ICRP 2007) and are concerned only with ionizing radiation. On the basis of the recommendations, standards for practical use of the concepts have been issued by the IAEA in collaboration with many other bodies. The last one – based on ICRP 2007 – is in preparation, as are the new EU directives and national regulations.

In the last decades, the advice that all exposures should be kept as low as possible has been modified to the requirement to keep all the exposures “as low as reasonably achievable (ALARA), taking economic and social factors into account.” The new ICRP emphasizes the greater importance of the optimization in the protective procedures, in comparison with the former one.

The practical aim in work with radiation must take into account the protective point of view by the introduction of standards, methods, and measures to protect living systems without unduly limiting the beneficial practices. The aim should be achieved on the bases of both scientific concepts about the biological effects of radiation and judgments about the relative importance of different kinds of risk.

47.2 Interaction of Ionizing Radiation with Biological Substances on Molecular, Cellular, and Tissue Levels

Radiation can interact with the atoms and molecules of the absorbing material while passing through it, producing excitation of molecular vibrations and orbital electrons, and ionization of atoms. Radiation is called ionizing radiation when the energy transferred to the orbital electron is sufficient to eject the electron from the atom, producing a positively charged ion. The positive ion and the electron thus formed are known as an ion pair. The ejected electron may have sufficient kinetic energy to produce further excitations and ionization in the matter, and the processes will continue until the incident particle and all electrons come to rest. Most of the atomic processes that occur are transient ones and take nanoseconds, but others manifestly cause changes in the absorbing matter.

The atomic and molecular effects of radiation depend on many factors, in general on the composition of the absorbing matter and the amount of energy deposited by the radiation. The energy required to produce an ion pair varies with the type of matter, falling in the range of 20–50 eV for most gaseous materials and living tissues. For the same absorbing material, it is nearly independent of the type of radiation and the energy (Choppin et al. 1995).

Radiation with energy less than the ionization energy is called nonionizing radiation (Mosely 1988; Dennis and Stather 1997); this primarily excites the vibrational and rotational spectra of the molecules in absorbing matter, including tissues.

47.2.1 Overview of the Effects of Ionizing Radiation on Living Systems

The process of ionization necessarily changes atoms and molecules, at least transiently, and may rupture chemical bonds in the molecules of the absorbing material, forming various chemical entities.

If the affected molecules are in a living cell, the cell itself may sometimes be damaged, either directly or indirectly, for example, by production of free radicals due to radiolysis, etc. With respect to the life function, one of the most serious types of damage is a strand break in a DNA chain. The direct or indirect effects of the radiation on DNA may result in irreversible damage

or alterations to the genetic code; the responses may be latent or immediately apparent. The damage in DNA may occur in the genes and chromosome, for example, resulting in an increased frequency of aberrations such as dicentric chromosomes. If enough cells in an organ or tissue are killed or prevented from reproducing and functioning normally, there will be a loss of organ function. The loss of function becomes more serious as the number of affected cells is increased.

Radiation exposure has been associated with most forms of cancer in many organs, such as the lung, breast, and thyroid gland. If the cell is only modified by the radiation damage, the damage is usually repaired. In some conditions, the repair mechanism may not be perfect, and the modification will be transmitted to daughter cells. This may eventually lead to cancer in the tissue of the exposed individual. Radiation-induced cancer may manifest itself decades after the exposure and does not differ from cancers that arise spontaneously or are attributable to other factors.

Exposure to radiation also has the potential to cause hereditary effects in the offspring of persons exposed to radiation. However, radiation-induced hereditary effects have yet to be detected in human populations exposed to radiation, although they are known to occur in other species.

47.2.2 Specific Ionization and Linear Energy Transfer

In radiation absorption processes of living tissue, the probability of interaction with electrons is considerably greater than that of nuclear reactions, and the number of electrons produced in secondary ionization is often larger than that of the primary ionization. Therefore, in general, the dominant part of the energy deposited in living tissue results in ionization.

Specific ionization (J) means the total number of ion pairs produced per unit length of the path of the incident radiation. The mathematical definition is

$$J = \frac{dN}{dl}, \quad (47.1)$$

where dN is the number of ion pairs produced along the path of length dl .

For heavy charged particles, the specific ionization increases with decreasing energy of the charged particles because of the increased probability of interaction at low energies. The specific ionization, the number of ion pairs formed per millimeter in normal air, is shown in [Fig. 47.1](#) for electrons, protons, and α particles.

Because γ -rays and neutrons are uncharged radiation, they may ionize the matter only indirectly. A photon imparts a large fraction of its energy to a single electron – mainly by the photoelectric effect, Compton scattering, and pair production – which ionizes and excites many other atoms and molecules along its path. Therefore, the specific ionization of γ -rays is similar to that of electrons.

The neutron interacts primarily with the nucleus of the absorbing atom, by elastic and inelastic scattering. In elastic collisions, the target nucleus is not itself ionized. However, it may produce ionization in other atoms. In inelastic scattering, including nuclear transformation, the newly formed nuclide and the emitted photon or charged particle may produce ions.

The quantity of *linear energy transfer* (abbreviated as LET) is the amount of energy deposited by the radiation per unit length of the path. In mathematical form, it is defined as:

$$\text{LET} = \frac{d\varepsilon}{dl} \quad (47.2)$$

■ Fig. 47.1

Energy dependence of specific ionization in air

where $d\varepsilon$ is the fraction of energy lost to the medium along a section dl of a charged particle's path. The SI unit is J m^{-1} , but the most frequently used unit is $\text{keV } \mu\text{m}^{-1}$. The LET is equivalent to the restricted linear collision stopping power used in particle physics.

47.3 Dosimetric Quantities and Units

According to experience, ionization is the major cause of the biological effects of radiation. Since the microdistribution of the ionizations and excitations in the atoms produced by ionizing radiation cannot be fully quantified at present, approximations are used to assess, for example, the number of ion pairs in cells or in other parts of living tissues. Therefore, the energy imparted to the matter, the absorbed dose, and other specific quantities are used conventionally to express the effects on the living function of the body. These approaches omit consideration of the discontinuous nature of the radiation energy and matter exposed, but are justified empirically by observations that the gross quantities correlate sufficiently well with the resulting biological effects.

Future developments in microdosimetry may indicate use of quantities based on the probability distribution of events in a small volume of material corresponding to the dimensions of biological entities such as the cell nucleus or its molecular DNA (ICRP 1977). Meanwhile, however, use of macroscopic quantities in dosimetry of ionizing radiation is recommended.

To assess exposure, a number of specialized quantities and units are used. The present chapter depends mainly on the bases of quantities introduced in 1980 by the ICRU (ICRU 1980) and on revised terminology and definitions proposed in 1990 by the ICRP (ICRP 1991). Additionally, the recent results and interpretations of the UNSCEAR reports have been included (UNSCEAR 1996, 2000).

Radiation can cause changes in living systems; the effects depend on various factors, such as absorbed energy, dose, dose rate, etc. All the quantities and important factors are to be defined in adequate forms, usable to predict the future outcome of the biological effects and measurable with proper precision.

In general, to assess the delayed effects of current exposure, dose quantities of the ionizing radiations are introduced. The term dose is used in a general sense as a measure of the “quantity of radiation” or the energy deposited by radiation in a target. For the strictest use in dosimetry, the term must be specified as absorbed dose, equivalent dose, organ dose, etc. These quantities may refer to exposed individuals (individual dose) or to a group of people (collective dose).

47.3.1 Dosimetric Quantities and Factors

The fundamental dosimetric quantity used is the absorbed dose. The equivalent dose and the effective dose are also important quantities. Special circumstances might be characterized by committed dose, kerma dose, and some other dose quantities and factors.

47.3.1.1 Absorbed Dose, D

The absorbed dose (D) is defined as:

$$D = \frac{d\varepsilon}{dm} \quad (47.3)$$

where $d\varepsilon$ is the mean energy imparted by ionizing radiation to matter in a volume element, and dm is the mass of matter in the volume element. The energy can be averaged over any defined volume, the average dose being equal to the total energy imparted in the volume divided by the mass in the volume. Usually, the absorbed dose is an averaged dose over a tissue or organ.

The SI unit of the absorbed dose is the gray (Gy); $1 \text{ Gy} = 1 \text{ J kg}^{-1}$. The old unit is the rad (roentgen absorbed dose); $1 \text{ Gy} = 100 \text{ rad}$.

The absorbed dose may be used for any type of ionizing radiation (α , β , X-ray, etc.) and to any type of matter (both living systems and nonliving materials).

47.3.1.2 Equivalent Dose, H_T

The equivalent dose (H_T) to a tissue T is defined as the product of the absorbed dose delivered by radiation type R averaged over tissue or organ T, times the radiation weighting factor w_R for radiation type R. In mathematical form:

$$H_T = w_R D_T, \quad (47.4)$$

where D_T is the absorbed dose over tissue T and w_R is the *radiation weighting factor* for radiation type and energy R. The weighting factor w_R varies between 1 and 20. [Table 47.1](#) contains values of weighting factors recommended by the ICRP (ICRP 1991). The SI unit of the equivalent dose is the sievert (Sv); $1 \text{ Sv} = 1 \text{ J kg}^{-1}$. The equivalent dose has the same fundamental units (J kg^{-1}) as the absorbed dose. However, it is given its own special name, the sievert, in recognition that it is obtained from the gray by multiplying by a dimensionless scale factor.

Usually the values w_R are broadly compatible with the values of the quality factor (Q) and the *relative biological effectiveness* (RBE), used more frequently in the past (ICRP 1977, 1991) and with respect to personal dose measurements, even nowadays (IBSS 1996).

■ Table 47.1

Radiation weighting factors, w_R and LET-values

Type and energy range of radiation	w_R	LET in water (fJ μm^{-1})
Photons, all energies	1	0.03–5
Electrons and muons, all energies	1 ^a	0.03–0.2
Neutrons, energy dependency	🔗 Fig. 47.2)	2–10
Protons, other than recoil protons, energy >2 MeV	5	~2
Alpha particles, fission fragments, heavy nuclei	20	~20

^aExcluding auger electrons emitted from nuclei to DNA, for which special microdosimetric considerations apply.

When the radiation field is composed of different types of radiation with different values of w_R , the equivalent dose is the following sum:

$$H_T = \sum_R w_R D_{TR}. \quad (47.5)$$

The equivalent dose partly corresponds to the formerly used *dose equivalent*, where, instead of w_R , the quality factor (Q) of the radiation type was used. In this case, the values of Q and w_R are identical or nearly identical.

Both the step function and the continuous function in 🔗 Fig. 47.2 had been introduced in the former recommendation (in ICRP 1991). The recently recommended continuous function of radiation weighting factors for neutrons reflects only practical considerations and does not imply the availability of more precise data. Mainly due to the continuous energy spectrum of the neutrons, in calculations the continuous function of the w_R has been used rather than the step function.

The *directional dose equivalent* $H^*(d, \Omega)$ at a point in a radiation field is defined as the dose equivalent that would be produced by the corresponding expanded field in the ICRU sphere at a depth d on a radius in a specified direction Ω . The depth, $d = 0.07$ mm, is used for weakly penetrating (e.g., β^-) radiation. In personal monitoring of occupational impact, the quantity of *personal dose equivalent* is recommended for use (ICRU 1980). The equivalent dose is defined only for living systems, including biota and man, but strictly, only for man. Steps are made to introduce and determine values of w_R for other living systems too (IAEA-TECDOC 1999). The equivalent dose expresses that the biological effect (more precisely, the *stochastic effect*; see later) depends – in addition to the absorbed dose – on the type and energy of radiation or, more directly, on the value of LET.

47.3.1.3 Effective Dose, E

It is necessary to take into account the different sensitivities of various tissues and organs to the induction of deleterious health effects to the whole organism. The effective dose (E) is defined as a summation of the tissue *equivalent doses* multiplied by the appropriate tissue weighting factor w_T . According to this definition,

$$E = \sum_T w_T H_T, \quad (47.6)$$

■ Fig. 47.2

Radiation weighting factors (w_R) for neutrons versus neutron energy

where H_T is the equivalent dose in organ or tissue T, and w_T is the tissue weighting factor for the organ or tissue T.

Mainly due to the additional experimental data, the concept of tissue weighting factors is to be extended. Based on new data, the improved values of the factors are issued regularly. In general, the w_T -values recommended by the ICRP were based on the risk of fatal cancer and of serious heritable disease. The last concept and the values of w_T are based on the incidence of radiation-induced cancer, rather than on mortality, as well as on the risk of heritable disease over the first two generations.

The recommended values of w_T are given in ▶ Table 47.2. The differences between the corresponding values of the two columns show the development of fundamental knowledge in dosimetry over a short period.

According to the definition of the tissue weighting factor, the summation of the factor over all the tissues results in the value 1, that is

$$\sum_T w_T = 1. \quad (47.7)$$

From the definition of the equivalent dose, it follows that

$$E = \sum_T w_T \sum_R w_R D_{TR}, \quad (47.8)$$

where D_{TR} is the average absorbed dose in the organ or tissue T due to radiation R. ▶ Equation (47.8) indicates that the various doses due to the different types of radiation and different tissues are additive quantities without any cross-contributions or synergism among them. Very probably, this is valid only for sufficiently small doses in the range of occupational exposures.

The Commission is an advisory body that offers its recommendations to regulatory and advisory agencies, mainly by providing development of the ICRP recommendations including weight factors.

■ Table 47.2

Tissue weighting factors, w_T

Tissue or organ	ICRP-1990/IBSS-1996	ICRP-2007
Gonads	0.20	0.08
Bone marrow, red	0.12	0.12
Colon	0.12	0.12
Lung	0.12	0.12
Stomach	0.12	0.12
Bladder	0.05	0.04
Breast	0.05	0.12
Liver	0.05	0.04
Esophagus	0.05	0.04
Thyroid	0.05	0.04
Skin	0.01	0.01
Bone surface	0.01	0.01
Brain	–	0.01
Salivary glands	–	0.01
Remainder	0.05	0.12
Total	1.00	1.00

47.3.1.4 Individual and Collective Doses

The dose incurred by an individual member of the population is an individual dose. More generally, the individual dose can be extended to other living organisms besides man.

The collective dose quantity represents the total consequences of exposures of a population or group. The use should be limited to situations in which the consequences are truly proportional to both the dosimetric quantity and the number of people exposed. The *collective equivalent dose*, S_T , is the average dose to a tissue or organ T in the exposed group multiplied by the number of individuals in the group. If several groups are involved, the total collective quantity is the sum of the collective quantities for each group. The *collective effective dose*, S , has similarly been defined by ICRP:

$$S = \sum_i \bar{E}_i N_i, \quad (47.9)$$

where \bar{E} is the mean effective dose and N_i is the number of individuals in population subgroup i . The unit of both the collective equivalent dose and collective effective dose is man-Sv (or person-Sv).

47.3.1.5 Dose Rate

The dose rate (\dot{D}) expresses the time variation of the dose. It is defined as follows:

$$\dot{D} = \frac{dD}{dt}, \quad (47.10)$$

where D is the dose and t is the time. The SI units are Gy s^{-1} or Sv s^{-1} ; for environmental radiation monitoring, however, the units nGy h^{-1} and nSv h^{-1} are more frequently used.

In radiation protection practice, most of the dose limits correspond to an annual dose (IBSS 1996). The annual dose is the sum of the external exposure in a year and the *committed dose* (see ▶ Sect. 47.3.2.1) the sum of intakes of radionuclides in that year.

47.3.2 Subsidiary Dose Quantities and Units

At the same time that there is a close cooperation among the international commissions and bodies involved in radiation dosimetry, practical problems and changes in concepts involve a mixed use of various derived quantities. The following dose quantities are not primary ones, but for special circumstances, they may become important.

47.3.2.1 Committed Dose

Committed doses are defined in cases of intakes of radioactive materials, mainly by ingestion, inhalation, or absorption through the skin, in terms of internal radiation impact. In most cases, the quantities of *committed absorbed dose*, committed equivalent dose, and committed effective dose are used.

The quantity of *committed effective dose*, $E(\tau)$, is defined as:

$$E(\tau) = \int_{t_0}^{t_0+\tau} \dot{E}(t) dt, \quad (47.11)$$

where t_0 is the time of intake, $\dot{E}(t)$ is the effective dose rate at time t , and τ is the time elapsed since the intake of radioactive substances. When τ is not specified it will be taken as 50 years for adults and 70 years for children.

The SI unit of committed effective dose is Sv, the same as for effective dose. Similarly, one can derive a *committed equivalent dose*. The quantity of *dose commitment* differs from the committed dose only by the upper integration limit. It is defined as the infinite time integral ($\tau = \infty$) of the per caput dose rate (\dot{H}_T or \dot{E}) of the population due to a specified event. The unit of the dose commitment is the same as for committed dose. Both individual dose commitment and collective dose commitment can be defined.

47.3.2.2 Exposure Dose, X

The exposure dose with its unit R (roentgen) was the first defined quantity in radiology, in 1928. It refers to ionization in air by the γ - (or X-) rays, and its determination could be provided by a relatively simple technique, using an air-filled ionization chamber. The quantity X is defined as:

$$X = \frac{dq}{dm} \quad (47.12)$$

where dq is the total electrical charge of the particles produced by the photons in the volume element of air in unperturbed circumstances and dm is the mass of the volume element.

The SI unit is C kg^{-1} , without any special name. The unit roentgen (R) is the photon exposure that produces in air ion pairs with total – either positive or negative – electrical charge per unit mass of $2.58 \times 10^{-4} \text{ C kg}^{-1}$. The unit R is still used in practice, especially in medical fields, in spite of the problems of defining it with respect to the newly introduced quantities recommended by the ICRP. The advantage of its use probably comes from the ease of determining the electrical charge in practical ranges by ionization chambers or other electrical devices.

The unit 1 R corresponds to 1.61×10^{15} ion pairs per kg in air or $8.80 \times 10^{-3} \text{ J kg}^{-1}$ absorbed dose in air and similarly in soft tissues. The corresponding absorbed dose in bones, etc., may be by 20–30% higher.

47.3.2.3 Kerma, K

For indirectly ionizing radiation, the quantity K is defined as:

$$K = \frac{d\varepsilon_{\text{tr}}}{dm} \quad (47.13)$$

where $d\varepsilon_{\text{tr}}$ is the sum of the initial kinetic energies of all charged ionizing particles liberated by uncharged ionizing particles in a material of mass dm .

The expression kerma is an acronym from *kinetic energy released in material*. The SI unit is the gray (Gy), and $1 \text{ Gy} = 1 \text{ J kg}^{-1}$.

47.3.2.4 Ambient Dose Equivalent, $H^*(d)$

This quantity is defined by the ICRU, not by the ICRP, and is used mainly for operational aims in measurement of the radiation impact together with the quantities of *directional dose equivalent* and *personal dose equivalent* (see description of equivalent dose). The quantity $H^*(d)$ at a point in the radiation field is defined as the dose equivalent that would be produced by the corresponding aligned and expanded field in the ICRU-sphere at a depth d on the radius opposing the direction of the aligned field. The depth $d = 10 \text{ mm}$ is recommended for strongly penetrating radiation such as γ - or neutron radiation.

47.3.2.5 Organ Dose, D_T

The mean dose D_T in a specific tissue or organ T of the living body is given by:

$$D_T = \frac{1}{m_T} \int_{m_T} D(m) dm \quad (47.14)$$

where m_T is the mass of the organ and $D(m)$ is the local absorbed dose in the mass element dm . The SI unit is termed the gray (Gy), as with the absorbed dose; $1 \text{ Gy} = 1 \text{ J kg}^{-1}$. Because the radiosensitive cells nearest the skin surface are located at the basal layer of the epidermis, the dose rate in skin is evaluated at $d = 0.07 \text{ mm}$ depth, primarily for external β radiations.

47.4 Mechanisms of External and Internal Exposure

Dose assessments are usually based on both measurements and calculations, taking into account the distribution of the radionuclides and the radiation fields influenced by the absorption, scattering, and other effects of the environment close to the source and to the individual body exposed. Whenever direct measurements are not feasible, or if they must be generalized and extended, dose assessment methods are applied. For example, for discharges from industrial processes, it is not usually possible to measure dose rates and activity concentrations in the environment, and so models are required to calculate the dispersion in the environment.

The choice of the method depends primarily on the type of information available. In general, the determination of dose needs the following two main types of procedures.

1. Assessment of the distribution of the radionuclides both outside and inside the body, including the distance and orientation between the source and detector and kinetic aspects (the transport and transformation of the source of radiation with any radioactive daughter elements produced).
2. Estimation of the dose from a radiation field due to the distribution of the radionuclides or other sources of radiation. The radiation field may be influenced by shielding and by the scattering configuration of the geometry.

Individuals can be exposed from sources of radiation outside the body and by radionuclides incorporated into the body. The radiation pathway from a source outside the body produces an external dose, from incorporated radioactive material an internal dose.

47.4.1 External Exposures

The external dose results primarily from γ radiation arising from the decay of radionuclides at locations outside the specified body. Secondly, the exposures from neutron radiation and to the skin from β radiation may be considered as an external pathway. The α , proton, and ion radiations are to be considered as an external impact only in very special cases, for example, for a geometry extremely close to the eyes.

The external dose is usually determined by the absorbed dose. The effective dose and the other dose quantities are derived by multiplying the absorbed dose by appropriate factors.

Depending on the volumetric distribution of the source of radiation, the following typical geometries may be selected for assessment of external doses: point source, immersion in a plume, and radioactivity deposited on surfaces. In addition, more complex arrangements of sources and geometries can often be described. For those cases, the point-kernel numeric integration method is performed based on calculations as a point source solution (Wood 1982).

47.4.1.1 Point Source

Around a point source, the external absorbed dose rate \dot{D} with an isotropic radiation field can be assessed by

$$\dot{D} = \Gamma \frac{A}{r^2}, \quad (47.15)$$

where A is the source activity (Bq), r is the distance from the source (m), and Γ is the *external dose coefficient*, taking into account the yield of the radionuclide decay and energy of the γ radiation. Values of Γ for several radionuclides are listed in ▶ [Table 47.3](#) together with other types of dose coefficients.

More exactly, the absorbed dose in ▶ [Eq. \(47.15\)](#) refers to the absorption dose in air without any absorption in the material around the point source or any influence by scattering of radiation. In the most realistic situation, the body of the person may affect the radiation field; for example, the dose rate (in units of nGy h^{-1}) measured in a geometry of anterior-posterior (A-P) differs slightly from the posterior-anterior (P-A) measured dose rate (▶ [Fig. 47.3](#)).

By use of shielding layers produced from different materials (lead, copper, iron, etc.), the dose calculation must take into account the buildup of lower energy photons together with attenuation in the shielding materials, including air and self-absorption of the human body (Wood [1982](#)).

Methods for assessing the dose rate from a source with varying volume, size, shape, and distribution, including absorption and scattering of the radiation, usually require numerical approximations with integration in space (Wood [1982](#)). Assessments can take into account the modifying effect of the human body on absorption and scattering of the radiation, and in addition to the effective dose, the equivalent dose to the different organs and tissues may be estimated using various sizes and shapes of anthropomorphic phantoms (Jacob et al. [1990](#)). That kind of calculation is provided primarily for occupational dose assessments.

■ **Table 47.3**

Dose coefficients (Jacob et al. [1990](#); Eckerman and Ryman [1993](#); IBSS [1996](#))

Radio-nuclides	Half-life	Γ	K_B	$K_{\gamma v}$	$K_{\gamma s}$	K_{inh}	K_{ing}
		(nGy h^{-1} per Bq m^{-2})	(nSv h^{-1} per Bq m^{-3})	(nSv h^{-1} per Bq m^{-3})	(nSv h^{-1} per kBq m^{-2})	(nSv per Bq)	(nSv per Bq)

■ Fig. 47.3

Energy dependency of dose quantities assessed from external γ radiation at a distance of 1 m from a point source of 1 photon s^{-1} (D: absorbed dose rate in air, nGy h^{-1} , A-P: effective dose rate measured by geometry anterior/posterior, P-A: effective dose rate measured posterior/anterior, nSv h^{-1})

47.4.1.2 Cloud Immersion and Surface Contamination

After a release of radionuclides into the atmosphere and deposition to the ground surface, the main exposure pathways are the external doses from the air and from the deposited γ exposure. From the average height of the human body, listed values of dose rates without any special remarks are calculated for a height of 1 m above the soil surface.

Because the range of β particles in air is only 1–2 m, the equivalent dose to the skin from β radiation is determined by the very volume of air very close around the location of the body. For γ radiation of the most common energies (50–1,500 keV), the half thickness in air is 50–200 m; therefore, the local external doses both from the air volume and the ground surface are determined by a distance of several hundred meters. Due to the relatively small ranges of the radiation in the environment, a homogeneous contamination of the air and ground surface may be assumed as a semi-infinite geometry. Dose rates from monoenergetic and semi-infinite volume sources in air and plane sources at the ground can be assessed by

$$H_k = \sum_l K_{kl} F_{kl} C_l \tau_k \quad (47.16)$$

where H_k is the dose quantity (effective dose, equivalent dose to the organ or tissue, etc.) by pathway k (external exposure from air volume, from contaminated surface, etc.), C_l is the radionuclide concentration of the environmental element l (air, surface), K_{kl} is the dose coefficient relevant to pathway k and environmental element l , F_{kl} is a reduction factor relative to the absorption of radiation by buildings, trees, etc. at the location, and τ_k is the duration of exposure at the location due to pathway k . Representative units include the following:

H is usually expressed in Sv, C is expressed in Bq m^{-3} for the air volume or Bq m^{-2} for deposition on the surface, the quantity F is dimensionless, τ is usually expressed in hours or seconds, and K is expressed in Sv h^{-1} per Bq m^{-3} or per Bq m^{-2} , depending on the pathway and units of C .

External irradiation from β -emitters deposited on the ground usually produces a negligible contribution to the skin dose. ➤ Equation (47.16) assumes constant contamination during time τ . In the case of time-dependent contamination in air or on a surface, the product $C\tau$ is replaced by the time-integration of the concentration C . Dose coefficients are listed in ➤ Table 47.3 for frequently used radionuclides, namely for the equivalent dose to skin by β radiation (K_β) and for the effective dose due to the contaminated air volume (K_{air}) and the ground surface (K_{gs}). Dose coefficients K_{inh} and K_{ing} pertain to the internal pathways.

Effective dose from γ -emitters distributed in soil for depth $d > 0$ is less than assessed by the coefficient K_{gs} due to absorption in the soil layer above the radionuclides. The attenuation coefficient and build-up factor in soil depends primarily on the γ energy, depth of distribution, soil composition, and density.

External exposure can be measured by personnel monitoring using film badges or thermoluminescent dosimeters (TLD); in occupational and environmental monitoring, additionally, dose rate meters based on G-M tubes, proportional counters, scintillation detectors, etc., are introduced.

47.4.2 Internal Pathways

Incorporation of radionuclides into the body may occur by inhalation, by ingestion, and, rarely, through the skin. Intake by inhalation and ingestion is determined by the activity concentrations in air, in foods, and in water and by age-specific estimates of breathing rate and food consumption. The ICRP has provided the following representative ages: 3 months (for the 0–1 year age group), 1 year (for the 1–2 year group), 5 years (2–7 years), 10 years (7–12 years), 15 years (12–17 years), and adults (>17 years old).

Following an intake to the body, the retention of the radionuclides depends on the chemical form administered and the metabolism, including uptake by the lung or gastrointestinal tract, transport by blood, and excretion. The dose is influenced by the physical decay of radioactivity, and in the case of a decay series, the metabolism and radiation of daughters as well.

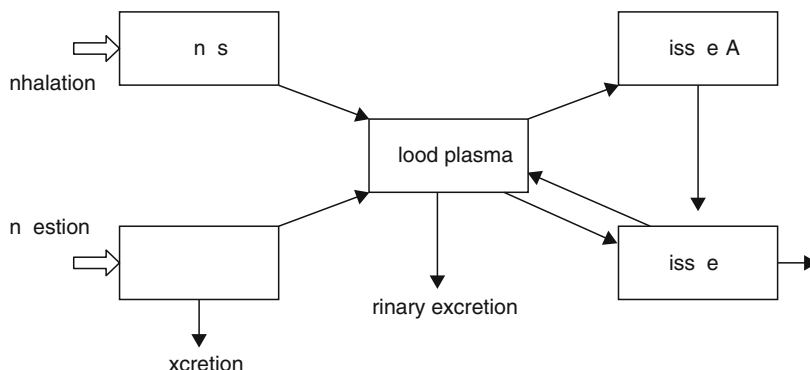

Models taking into consideration the metabolism and time variation of the radionuclide concentrations in man are conceptualized as compartmental systems, including dynamic processes (ICRP 1994; Jacquez 1996; Thorne 2001).

The transport processes in man without any details are illustrated in ➤ Fig. 47.4. Intake of radionuclides through the lungs (inhalation) or gastrointestinal tract (ingestion) produces an increasing concentration in the central circulation system, usually in blood plasma. Depending on the chemical species of the radionuclide in the central circulation, various tissues or organs incorporate the activity, or it may be excreted through the kidney and urinary system.

Recent models tend to be much more complex than previous ones and involve recycling between tissues, taking into consideration the chemical forms of the radionuclides administered and the physiological functions of tissues. A different binding site of a tracer in the same tissue may be represented by a different compartment. Therefore, in internal dose assessments, models with more than 10 compartments are frequently used; only rarely will more than 50 compartments be used.

Fig. 47.4

Compartmental model for illustration of the transport of radionuclides in man (GIT: gastrointestinal tract)

Most of the transport phenomena are described by linear processes, but, for example, the uptake of inorganic iodine by the thyroid from the blood plasma is primarily a zero-order process, and several enzyme kinetic reactions and bindings are second-order processes.

47.4.2.1 Inhalation Pathway

In steady-state conditions, or for a long-time average, the committed dose due to inhalation of contaminated air during time τ may be assessed in the following form:

$$H_k = K_k I C \tau, \quad (47.17)$$

where H_k is the proper dose quantity (committed effective dose, committed equivalent dose to the organ k , etc., in units of Sv), I is the inhalation rate ($\text{m}^3 \text{h}^{-1}$), and C is the activity concentration in air (Bq m^{-3}). The *inhalation dose coefficient*, K_k (Sv Bq^{-1}), concerning either the k th organ or whole body doses, means the dose due to a unit inhalation of activity. Table 47.3 includes the dose coefficient (K_{inh}) for the committed effective (whole body) dose for the adult age group. Similar values can be derived for all the tissues (lung, bone marrow, etc.) as *committed equivalent dose coefficients*, in units of Sv Bq^{-1} .

For most radionuclides, the inhalation dose coefficient is higher for children than for adults, but the inhalation rate (I) is probably lower for children. Therefore, the inhalation dose rates for the same level of air contamination may be even less for children and infants than for adults. The inhalation rate (I), consumption habits, and committed dose conversion coefficients with respect to groups of different ages, species of contamination in air (ionic, aerosol bound, aerosol diameter, etc.) or foodstuffs, and radionuclides are listed in tables of dose assessments (Jacob et al. 1990; IBSS 1996). These values are derived from calculations assuming various types of body phantoms and measurements.

47.4.2.2 Ingestion Pathway

In steady-state conditions, the committed dose from ingested radionuclides may be assessed in a similar way as given for the inhalation pathway. Instead of the inhalation rate I , the

consumption rate is used to assess the total intake of radioactivity from the contamination of the foodstuffs (IAEA-SRS 2001). The uptake and metabolism of the radionuclides also depend on the chemical form administered. Therefore, the *ingestion (committed) dose coefficient* depends on the chemical binding of the radionuclide ingested, uptake by the intestine, and other physiological factors, including age. Coefficient K_{ing} related to the committed effective dose is listed in ► Table 47.3 (last column).

Direct monitoring of incorporated radionuclides is based on whole-body measurement of the penetrating (primarily γ) radiation. Indirect methods are used for those radionuclides, such as tritium, which do not emit a significant amount of penetrating radiation and are based on the determination of activity concentrations in biological materials separated from the body (urine, feces, and breath samples), or in other physical samples taken from the close environment.

To assess the total committed (internal) dose, the results obtained from each pathway (inhalation, ingestion, different foodstuffs, and radionuclides, etc.) are to be summed. In radiation protection, the total committed dose due to a whole year's uptake is determined and monitored systematically.

47.4.2.3 The MIRD Methodology

The technique for estimation of the absorbed dose to organs and tissues from radionuclides inside the human body has been developed by the Medical Internal Radiation Dose (MIRD) Committee of the Society of Nuclear Medicine, USA. The schema and pamphlets issued by the Committee since the 1960s contain measurement and calculation procedures and examples of the use of methodology. The methodology is widely accepted throughout the world (Watson 1994; Zanzonico et al. 1995).

The MIRD techniques are primarily intended for assessment of absorbed radiation doses received by patients who are undergoing nuclear medical tests and not for directly linking the dose to the radiation effects. The population of patients studied with radiopharmaceuticals is not well represented in the determination of tissue weighting factors or committed equivalent or effective doses due to inhalation and ingestion. Therefore, the MIRD schema are prepared to estimate doses for various situations and purposes, to each age-specific and gender-specific body habitus, extending the applicability beyond the original 70 kg adult anthropomorphic “standard man.”

In the MIRD formalism, the mean absorbed dose to a target region r_k from uniformly distributed, cumulative activity in the source region r_h becomes the following:

$$\overline{D}(r_k \leftarrow r_h) = \frac{\overline{A}_h \sum_i A_i \phi_i(r_k \leftarrow r_h)}{M_k} = \overline{A}_h S(r_k \leftarrow r_h), \quad (47.18)$$

where \overline{A}_h is the cumulative activity (e.g., in units MBq h) in the source region r_h , A_i is the equilibrium dose constant (in Gy h⁻¹ per MBq kg⁻¹) for radiation i , $\phi_i(r_k \leftarrow r_h)$ is the absorbed fraction in target region r_k for radiation i emitted in source region r_h , M_k is the mass (in kg) of target region r_k , and $S(r_k \leftarrow r_h)$ is the radionuclide specific S factor (in Gy per MBq h) for target region r_k and source region r_h . The S factor is the absorbed dose to target region r_k per unit of cumulative activity in source region r_h .

The total mean absorbed dose to the target region r_k is calculated by the sum of the absorbed dose contributions from all the source regions r_h :

$$\overline{D}(r_k) = \sum_h \overline{A}_h S(r_k \leftarrow r_h). \quad (47.19)$$

For α and β radiation and a huge volume of tissue, all of the emitted energy would be absorbed within the source region. Therefore the fraction $\phi_i = 1$ for the source region and 0 for any other region outside the source region for all radiation types i , and dose calculations become simple. For penetrating radiation (γ -rays) and the human body, only a fraction of the energy emitted in a source organ is absorbed in that organ, and some of the energy will escape from the body completely. It means that for all targets, $0 < \phi_i < 1$ and ϕ_i depends on the energy of the radiation, volumes and localization of the tissues, and some other parameters characteristic of the body.

To determine absorbed fractions (ϕ_i) for photons, an anatomic model approximating the human body (more generally, the living system being investigated) must be developed. Sizes and shapes that resemble the organs and tissues are defined by mathematical expressions. The volumes and distances of the organs are usually taken into consideration by the age, body weight, sex, and other characteristics of man as represented by the Reference Man initially developed by Snyder (Snyder et al. 1969).

► **Table 47.4** lists examples of absorbed fractions for liver as the source organ. For determination of the absorbed dose by the form (► 47.18) additionally the equilibrium dose constant (Δ_i) is to be used. The constant depends on the γ -yield and -energy emitted by the radionuclide and the value of ^{99m}Tc takes $\Delta = 7.2 \times 10^{-5} \text{ Gy h}^{-1} \text{ per MBq kg}^{-1}$.

The formalism given can be extended to an inhomogeneously distributed source volume, which may be important in radionuclide therapies with markedly nonuniform, spatially accumulated activity within different organs. Radiation dosimetry of sufficient accuracy and precision for radionuclide therapy must be customized to the specific patient being treated, however. Therefore, additional parameters are introduced taking into account the inhomogeneity, including metastases, to be determined by nuclear medicine imaging, transmission computer tomography, etc.

With inhomogeneous energy deposition at the cellular level, it is necessary to consider microdosimetric dose estimates for treatment planning. The total dose from a radionuclide with γ -rays of very different energies is the sum of the separately assessed doses for all the γ energies.

► **Table 47.4**

Absorbed fractions (ϕ) from a uniform γ -ray source in liver to various target organs of reference man (Watson 1994)

Gamma energy	$\phi, \rightarrow \text{liver}$	$\phi, \rightarrow \text{kidney}$	$\phi, \rightarrow \text{lungs}$	$\phi, \rightarrow \text{marrow}$	$\phi, \rightarrow \text{whole body}$
100 keV	0.165	0.0044	0.010	0.021	0.45
140 keV	0.162	0.0042	0.0096	0.017	0.43
200 keV	0.158	0.0039	0.0092	0.013	0.42
500 keV	0.157	0.0039	0.0084	0.011	0.41
1,000 keV	0.144	0.0034	0.0083	0.0094	0.38

47.4.3 Intervention and Action to Reduce Exposures

During an accident or emergency, a source is often out of human control. This necessitates prompt action to mitigate a hazard or to prevent adverse consequences for human health and safety, quality of life, and condition of the environment. In addition, protective action should be taken in some chronic exposures. Intervention and action levels support the decisions regarding the introduction of different preventive procedures.

47.4.3.1 Factors to Reduce Exposure from External Sources

According to the mathematical formulae of external expositions, the exposition time, the distance from the radiation source, and the shielding have important effect on the individual dose. Naturally, the dose is linearly proportional to the intensity of radiation or radioactivity of the source.

- *Time.* The total radiation exposure to an individual is directly proportional to the duration of his/her exposure to the radiation source. The longer the exposure, the higher is the radiation dose. Therefore, it is wise to spend no more time than necessary near sources or in a radiation field.
- *Distance.* The intensity of radiation, and hence the radiation exposure, varies inversely as the square of the distance from the source to the point of exposure. It is recommended that an individual should keep as far away as possible from a radiation source.
- *Shielding.* Because the ranges of α - and low energy β -particles are short in matter, air and clothing provide adequate shielding for these radiation types. Most gamma-radiations, however, are highly penetrating, and therefore highly absorbing material (usually Pb) should be used for shielding. Special shielding is to be used for neutron radiation. Neutrons of high energy (ranges of keV – MeV) are first to be moderated to low energy by absorbers of low atomic number (e.g., water or wax) and then absorbed by nuclear reaction of large cross section, for example, by a Cd plate.

47.4.3.2 Factors to Reduce Exposure from Internal Sources

The most effective way of reducing internal contamination is reducing the intakes of radionuclides through inhalation and ingestion. Less effective and only in special conditions useable procedures are based on the increased excretion of radionuclides by the gastrointestinal and renal systems.

The most frequently used procedure is the iodine prophylaxis. It is based on the zero order absorption of iodine by the thyroid gland from the blood plasma and on the first order kinetics of renal clearance. Therefore, the stable iodine – if administered shortly before the intake of the radioactive one – reduces the radioactive iodine absorption to the thyroid, and most of it is excreted by urine. Depending on the administration time and metabolic parameters of the human body, the effectiveness of reducing might reach 50–90%. Iodine prophylaxis can be an effective method in the early phase of airborne ^{131}I -release from a nuclear installation. In most cases, it is expected that the exposure through ingestion can be avoided or reduced by a proper change on consumption habits, while exposure through inhalation cannot.

47.5 System of Radiological Protection of Humans

For practical control of exposures, the ICRP defines different types of exposure situations and different categories of exposure. Depending on the exposure situations and categories, the control, limitation, and other activities may be different.

47.5.1 Types of Exposure Situations

The ICRP Recommendation is to be applied to all sources and to individuals exposed to radiation but distinguishes three different types of exposure situations.

In the *planned situation*, the sources are under human control. In simple words, it means planned (normal) work with radiation. In the former recommendation, it was named as practice.

The *emergency situation* may occur during normal operation due to malicious act or from any other unexpected situation and require urgent action in order to avoid or reduce undesirable consequences.

The *existing exposure situation* exists when a decision on control and/or protected action has to be taken, including prolonged exposure situations after contamination. A typical example appears during remediation of the close environment after U-mining activity.

Especially in the last two situations, the optimization with respect to the averted dose (risk) and cost of actions should be analyzed.

47.5.2 Categories of Exposures

In the practice of radiation protection, three categories of exposures are generally distinguished: occupational exposure, medical exposure, and public (or environmental) exposure. Regulations, including dose limits, monitoring of the radiation relations, and technical managing can differ in the three categories.

47.5.2.1 Occupational Radiation Protection

Artificial sources of radiation are commonly used in industry, research, medicine, nuclear power plants (NPP), etc. Some workers are exposed to natural sources, for example, in mines and other conditions where the radon concentration in air might be higher than in normal cases. Relatively high dose rates are measured during air travel due to the elevated levels of cosmic rays at high altitudes. This means that many people are exposed in their work. Some of them are monitored individually, for example, by a small photographic film, thermoluminescent material, or portable electronic devices. These types of detectors on the body register the dose due to the external sources and yield an estimate of the dose received by the wearer.

Worldwide there are nearly one million workers in industry and over two million workers in medicine who are exposed by use of nuclear technology or ionizing radiation, including X-rays.

Personnel Monitoring

Personnel monitoring is usually required when (1) workers are likely to receive in 1 year 10% of the annual limit of exposure from the external radiation source, and (2) individuals enter high

radiation areas. Monitoring for occupational intake of radioactive material (e.g., in a nuclear medicine laboratory, in the operations hall of a nuclear power plant, or by production and separation of radioisotopes) is also required if the annual intake by an individual is likely to exceed 10% of the value derived from the annual dose limit.

The most commonly used devices to monitor the personal dose include film badges, thermoluminescent (TL) badges, and pocket-type electronic tools (► Fig. 47.5). The workers should wear the devices only at work, in order to exclude background doses received at home or at other sites.

To monitor the intake, a whole body counter (► Fig. 47.6) can be used to measure the γ -radiation outside the body. Due to the internal contamination by isotopes of pure α - and β -radiation, excreta samples (usually urine) are to be analyzed.

The plastic holder of the film and TL discs are equipped with filters of different metals (aluminum, copper, and cadmium) inside the holder, in front of the film and TL to differentiate exposure from radiations of different types and energies.

Film badges are usually changed monthly for each worker and the exposure duration should be no longer than about 2 months, due to the effects on the film of humidity and other factors. The exposition to TL-discs might be longer. The TL-material can be reused many times after proper reading by thermo heating.

The principle and use of detector materials based on optically stimulated luminescence (OSL) are similar to those of the TL ones, but the reading does not destroy the stored information.

Radon Dosimeter

An organic plate as a track detector is in a domed holder, which allows radon gas to enter but excludes dirt, moisture, and radon decay products (e.g., ^{218}Po , ^{214}Bi) attached to aerosol particles in air (► Fig. 47.5). The number of tracks is proportional to the radon gas concentration in the building. Tracks due to the α -particles from radon are counted by a scanning microscope. Detectors are usually exposed for 1–6 months.

The personal portable (pocket) dosimeter usually contains a gas-filled or a semiconductor radiation detector (e.g., a G-M tube) tailored with an electronic device and a dedicated

► Fig. 47.5

Film badge holder, thermoluminescent (TL) dosimeters (in the form of discs and rings), electronic and radon dosimeters

■ Fig. 47.6

Whole-body counter with external detectors for γ -ray determination

computer. It measures the dose rate continually, and time integration is provided by the computer, which is equipped with alarm levels and visual and audible signals. The integrated dose can be read any time, and the device can be used as an “operative dosimeter” in an emergency situation.

Whole-Body Counter

The whole-body counter is used to provide measured data on levels of radionuclides in the whole body and/or in organs. Therefore, radiation detectors (scintillation or semiconductor types) facing the whole body or the organs of interest are used in either stable or scanning geometry to determine the intensity of γ -radiation from the radionuclides inside the body. The detectors identify the radionuclides by their γ -energy radiated and the measured intensities can be transferred to dose rates in the body and/or different organs, tissues, by using proper computer software. ● Figure 47.6 shows a scheme of a body counter with two detectors.

Hand-Foot Contamination Monitor

This monitor is designed to monitor radioactive material deposited on clothes, shoes, and body surfaces of a worker in an isotope laboratory. Therefore, the device contains foot and hand detectors. It is usually posted at the exit of the laboratory. The purpose of the monitor is to avoid the spread of radioactive substances and to discover any internal contamination.

Monitoring at Workplaces

Devices equipped with detectors and radiation level monitors are posted inside rooms of a workplace. They usually measure the external radiation continuously. Their alarm levels are

put slightly higher than the background in the laboratory. Any alarm signal of the monitor is to be investigated and interpreted (e.g., due to the opening of a radioisotope container). Contamination of the air and surfaces of furniture is to be controlled by determination of the radioactivity of air filters and rubbed samples.

Transportation of Radioactive Material

Transportation of radioactive material is governed by regulations, with guidelines for packaging, for example, types of packaging material, limits of radioactivity in a package, exposure limits outside the package, and labels on the packages. Employees who ship radioactive material must have proper training, and a record of training must be kept.

Exposure of Workers

Exposures of workers due to various sources are 3–5 mSv yearly, as reported by the United Nations Scientific Committee on the Effects of Atomic Radiation (UNSCEAR). According to the report in 2000, the average annual effective doses of the most exposed groups in different fields are shown in Fig. 47.7.

The last two groups are exposed to natural sources: in metal mining mainly to radon, the aircrew to cosmic rays. With the exception of mining, the average annual doses from most types of occupational exposure due to artificial sources, including the nuclear industry, are below 2 mSv. Doses have been reduced in recent decades primarily because of the widespread introduction of the ICRP recommendations and control by appropriate authorities.

47.5.2.2 Medical Radiation Protection

The terms “medical exposure” and “medical radiation protection” refer to patients. In addition, members of the family and close friends either in the hospital or at home, who may come close to the patients following administration of radiopharmaceuticals, plus volunteers in biomedical research studies, belong to this category of exposure. The exposure of doctors and

Fig. 47.7
Average annual doses in different highly exposed occupations (UNSCEAR 2000)

other workers, and the proper requirements for their work in the medical stations belong to the occupational category of radiation protection.

The exposed people, the patients, are directly interested in getting better diagnostic results and directed to improved therapy; therefore, the benefits of exposure are realized individually, and public anxiety is less than that due, for example, to a nuclear facility built near a living site. The worldwide average of the number of medical examinations per 1,000 people per year is 330. The annual effective dose is 0.4 mSv per examination. The spread of these data is high. Where the population per physician is less than 1,000, both the frequency and the annual dose are about three times higher than the world averages, mainly due to the often-used CT (computed tomography).

Medical X-Ray Imaging

The average dose contribution from artificial sources is mostly attributable to medical diagnostics by radiographic imaging, including CT. A conventional X-ray investigation produces nearly 0.2 mSv and the CT 1–10 mSv external effective dose, while dental imaging and screening mammography produce less than 0.1 mSv. Although mammography-screening exposures will increase the radiation risk, the potential benefit for women who carry an undetected breast cancer is much higher than the associated risk from radiation.

A relatively high patient dose (10–100 mGy local tissue dose) can be provided by interventional radiology, for example, a series of X-ray imaging during a surgical procedure. In some cases, the doses are high enough to cause deterministic effects; therefore, these procedures should be carefully controlled and optimized.

Nuclear Medicine

Medical procedures involving intake of radioisotopes (e.g., in vivo tests in nuclear medicine for functional and morphological investigations, such as uptake metabolism of tissues, gamma camera, Positron Emission Tomography – PET, etc.) are less frequently used than X-ray imaging. Depending on the type of test, organ investigated, and radioisotope used, the internal dose from a single investigation involves 0.5–5 mSv effective dose to the patient.

Radiotherapy

Radiation of high intensity and dose is used to kill cancerous cells and tumor tissues. Using external radiation, the beam from an external source is directed to the tumor, while sparing the surrounding healthy tissues. Especially for deeply placed tumors, the protection of healthy tissues is incomplete, and the radiation may possibly cause cancer in other tissues. The aim of planning radiotherapy involves maximizing the effectiveness of treatment while minimizing the adverse side effects.

Radiotherapeutical procedures can also be provided by internal sources. Thyroid tumors that are hyperfunctioning are cured by intake of ^{131}I (200–1,000 MBq). The iodine is accumulated nearly 100% in the tumor tissue, and the β -radiation kills the cells within 1–2 mm. The penetrating γ -radiation simultaneously emitted from ^{131}I provides a dose to the healthy tissues, to the whole body, and even to people in the vicinity of the patient.

Release of Patients Administered a Radiopharmaceutical

The decision to hospitalize or release a patient after administration of radiopharmaceuticals should be made on an individual basis, considering the residual activity in the patient, patient's wishes, family considerations (particularly the presence of children at home), environmental

factors, and national regulations. The international recommendation for caregivers and comforters of the patient advises a dose constraint of 5 mSv per episode. Written instructions must be given to the patient on his staying at home (maintain distances from others, have sole use of the bathroom, limit visits by others, drink plenty of water, etc.).

Guidance Level of Medical Exposure

The decision whether to prescribe an X-ray or other radiological examination is a matter of medical judgment made in the best interest of the patient. In medical practice, so-called guidance levels, rather than dose limits, are used. The radiologist locally has to balance the exposure against the advantages of the radiological procedure. The dose contribution to the patient has to be in the range of or less than the guidance level established for the specific procedure or technique by professional bodies. It means that the medical doctor has some flexibility based on the clinical situation and the techniques used. The guidance levels are to be revised as technology and techniques improve. Examples of guidance levels in diagnostic radiography for a chest PA (posterior-anterior) examination is 0.4 mSv, for a lumbar spine AP (anterior-posterior) examination, 10 mSv. Guidance levels of activity for procedures in nuclear medicine are listed in ➤ [Table 47.5](#).

47.5.2.3 Environmental Radiation Protection

Ionizing radiation in the environment arises from both natural and artificial sources. Natural sources include cosmic rays and γ -rays from Earth; artificial sources include X-rays in medicine and discharges of radioactive waste from the nuclear industry. Sometimes the separation between natural and artificial sources involves difficulties; for example, the radionuclides ^3H and ^{14}C in the air can result from both cosmic rays and the nuclear industry.

The dose in the environment – the delivered dose to a human body – depends on many factors, namely, on the spatial distribution of radionuclides (in soils or in the atmosphere), the characteristics of the radiation (energy, type, etc.), the living site of individuals (at sea level or high elevation, indoors or outdoors), including the incorporation of radionuclides into the body through inhalation and food intake. With high local variation, the worldwide average annual effective dose is about 4 mSv, nearly 3 mSv of it from natural sources and 1 mSv from artificial sources (➤ [Table 47.6](#)).

Radon in the Atmosphere

The largest component of the natural dose comes from inhalation of the daughter nuclides of ^{222}Rn ($T_{1/2} = 3.8$ days). The radionuclide ^{222}Rn is an intermediate member in the uranium

■ Table 47.5

Examples of guidance levels in nuclear medicine, for a typical adult patient

Test	Radionuclide	Chemical form	Activity (MBq)
Bone imaging by single-photon emission tomography	Tc-99m	Phosphate compounds	800
Liver and spleen imaging	Tc-99m	Labeled colloid	80
Tumor or abscess imaging	Ga-67	Citrate	300
Lung ventilation study	Xe-133	Gas	400

■ Table 47.6

Worldwide average annual doses in the environment (dose to the human body). The ranges correspond to about a 90% confidence interval

Components or sources	Mean dose and range (mSv)
Natural sources	
Cosmic rays, external effective dose	0.38 (0.3–1.0)
Cosmogenic radionuclides due to inhalation and ingestion (internal, committed effective dose)	0.012 (0.008–0.02)
Terrestrial, external effective dose:	
Outdoor	0.45 (0.3–0.6)
Indoor	0.55 (0.4–0.8)
Terrestrial due to intake (except radon daughters) (internal, committed effective dose)	0.27 (0.2–0.5)
Terrestrial from radon and its daughters (internal, committed effective dose)	1.2 (0.5–5.0)
Terrestrial from radon and its daughters to lungs (internal, equivalent dose of lung tissue)	10
Artificial sources	
Medicine, external (mainly due to X-ray diagnosis)	1.5 (0.1–5)
Nuclear power plant (within 1–5 km)	0.01 (–0.1)
Nuclear weapon in Hiroshima and Nagasaki (in the area of the cities)	100–5,000
Nuclear weapons tests:	
Northern hemisphere	0.1–2
Southern hemisphere	<0.01
Chernobyl nuclear accident:	
In the $r \approx 30$ km circle	1–20
In Middle and West Europe	0.1–2.0
In North America	0.01
In Japan	0.01
In the southern hemisphere	<0.01

decay series (from ^{238}U to the stable ^{206}Pb) and emanates directly from ^{226}Ra in the soil due to α -decay, into a form of noble gas. Most of the radon atoms decay in the soil, but, primarily from the upper 20–50 cm layer, part of them are exhaled into the atmosphere and are distributed in the lower 200–300 m of air to an activity concentration of 5–8 Bq/m³ (the density of the radon is a bit higher than that of air). The ^{222}Rn nuclide decays into radionuclides of ^{218}Po , ^{214}Pb , etc., by α - and β -decays over a short time (in minutes), and the metallic elements of Po, Pb, and Bi are attached to aerosol particles in air very quickly. There is essentially no deposition of inhaled radon atoms – as a noble gas – into the lungs; therefore, the α -radiation due to the decay of ^{222}Rn has no contribution to the body dose. In contrast, the daughter atoms of Po, Pb, and Bi are attached to aerosols, and vapor drops are efficiently deposited into the lung tissues, where they are metabolized by the individual; therefore, a relatively large dose contribution might be provided from the radiation of short-lived

daughters such as ^{218}Po , ^{214}Pb , ^{214}Bi , and ^{214}Po . One daughter element in the series, ^{210}Pb , has a longer half-life ($T_{1/2} = 22$ years); therefore, most of the radioactive ^{210}Pb atoms are already excreted from the body before the decay and emission of radiation; less than 10% is incorporated into the bones, where it stays for a long while.

The radionuclide ^{220}Rn ($T_{1/2} = 56$ s) is an intermediate of the thorium decay series (from ^{232}Th to ^{208}Pb); this radionuclide (another isotope of the *element* radon besides its most common isotope ^{222}Rn) has the special name of thoron. Due to the short half-life, the exhalation rate of ^{220}Th from minerals to the atmosphere is small, and the concentration in air is about 10 times less than that of ^{222}Rn , at equilibrium. Therefore, the dose contribution is negligible, except in the atmosphere where the upper soils are rich in thorium content. The actinium series (from ^{235}U to ^{207}Pb) involves the intermediate of ^{219}Rn ($T_{1/2} = 4$ s). Due to the very short half-life of ^{219}Rn , its exhalation from soil is very small, as is the dose contribution.

Indoor and Outdoor Doses

Because most building materials are extracted from the Earth, walls made from bricks, stones, etc., contribute to the dose received by a person staying in the building, while the external dose from an outside source might be reduced due to the shielding of the γ -radiation by the walls. The external dose, after reduction by shielding, is usually less than the increased dose from the materials in walls.

Indoors, the building material contributes to the radon originating from the soil. In a closed space, with little ventilation, dilution with outside air is less effective, and the radon concentration at equilibrium might be 10–100 times higher than outdoors, causing activity concentrations as high as 100–1,000 Bq/m³. Elevated radon concentrations in air might also be observed in other closed spaces, such as mines, caves, and closed thermal springs.

Due to the inhomogeneous distribution of uranium, thorium, and other radionuclides in materials in the Earth's crust, the doses to humans are affected both by the geological formations of the area and the structure of the buildings in which they live. The world-average dose due to inhalation of radon daughters (annual effective dose, 1.3 mSv; see [Table 47.6](#)) is derived mainly by staying indoors (occupancy: ~80%). This is especially so in temperate and subarctic zones where the isolation that helps maintaining a comfortable temperature inside a building results in an enclosed space for radon. The contribution to dose in winter is usually higher than that in summer, due to the difference in building ventilation rates.

In dwellings, the main source of radon is the soil below the building due to the flux of radon through gaps in the ground. Therefore, the rooms on the ground floor are usually more contaminated than the ones on the upper floors.

Technologically-Enhanced Natural Exposures

Usually, the deeper soil layers contain heavy metals at higher concentrations than the surface layers. By mining and other soil shifting, including replacing coal slag – in other words, by technology – the minerals with higher U and Th contents can come closer to humans, even into the ground and building materials of houses. This kind of technology results in an enhanced exposure to people from natural radionuclides.

Actions to Reduce the Radon Dose in Dwellings

To prevent enhanced radon concentrations in the living spaces of buildings, ground soils and building materials should be tested before their use. To mitigate the radon concentration in an existing house, two main actions can be introduced: (1) increasing the ventilation in rooms that

are occupied, and (2) aspiration of the soil layer under the building. Naturally, the exchange of highly active ground soil is an effective action, but usually it is not a cost-effective procedure.

47.5.3 Limitation of Exposure to Ionizing Radiation

Ionizing radiation and radioactive substances are natural and permanent features of life on the Earth, and thus the risks associated with the radiation can only be restricted, not eliminated. Additionally, sources of ionizing radiation become essential to human practice: in energy supplying, in modern health care including X-ray diagnostics and radiation therapy, etc. The use of artificial radiation is widespread.

The acceptance by society of risk associated with radiation is conditional on the benefits to be gained from using the radiation. Nonetheless, the risk must be restricted and protected against by the application of radiation safety standards established by the national authority that take into account a desirable international consensus.

The general principles of radiological protection recommended by the ICRP (1991) are the following.

1. No practice involving exposures to radiation should be adopted unless it produces sufficient benefit to the exposed individual or to society to offset the radiation detriment it causes. (Justification of a practice.)
2. In relation to any particular source, the magnitude of individual doses, the number of people exposed, and the likelihood of incurring exposures where these are not certain to be received should all be kept as low as reasonably achievable, economic and social factors being taken into account. (Optimization of protection.)
3. The exposure of individuals resulting from the combination of all the relevant practices should be subject to dose limits, or to some control of risk in the case of potential exposures. No individual is exposed to radiation risks that are judged to be unacceptable from these practices in any normal circumstances. (Individual dose and risk limitation.)

Any system of protection should include an overall assessment of its effectiveness in practice. The international standards (IBSS 1996) established on the bases of the ICRP recommendations specify the basic requirements for protection of people against exposure to ionizing radiation and for the safety of radiation sources. In addition to the viewpoints of protection and safety in radiation, the technical developments, economics, and social situations are to be included in the general requirements of the system. Therefore:

1. Any exposure whose magnitude or likelihood is impossible to control is deemed to be excluded from the standards (e.g., the exposure caused by ^{40}K in the body or by cosmic radiation on the surface of the earth).
2. Procedures with and sources of ionizing radiation may be exempted from the requirements of the standards, for example, due to the very low activity and activity concentrations of radionuclides in the material, radiation risk to individuals caused by the exempted practice or source being sufficiently low as to be of no regulatory concern.

The standards for protection and safety differentiate the following circumstances: exemption, practices (formerly referred to as planned impact), and intervention. For exemption, most of the regulative requirements and standards are not applicable; in practices, they are to be applied. The intervention situations to which the standards apply are emergency exposures

requiring protective action to reduce or avert temporary or chronic exposures, including accidents and remediation of contaminated areas.

The requirements for the practices to which the standards shall apply include dose limits recommended by the ICRP and accepted by most of the international, regional, and national organizations; these dose limits are listed in ▶ [Table 47.7](#).

The limits apply to the sum of the relevant doses from the external exposure in the specified period and the 50- (for children 70-) year committed dose from intakes in the same period. The limitation on the effective dose to the public provides sufficient protection for the extremities (hands and feet) against stochastic effects; therefore, no limitations are established for them .

For students 16–18 years of age who are required to use radiation sources in their training and studies, the occupational exposure shall be controlled, and the following annual limits must not be exceeded: effective dose of 6 mSv, equivalent dose of 50 mSv to the lens of the eye, and equivalent dose of 150 mSv to the extremities or the skin.

Additionally, some special circumstances with respect to the regulations and monitoring of the doses are also recommended. Among them, for radon (^{222}Rn) in workplaces, the yearly average activity concentration should be less than $1,000 \text{ Bq m}^{-3}$ in air, as an action level. The ICRP derived radon conversion coefficient based on epidemiological determinations corresponds to $6 \text{ nSv (Bq h m}^{-3})^{-1}$.

Dose limits are to be applied to occupational and public exposures but not to medical exposures to a patient. Medical exposures should be justified by weighing the diagnostic or therapeutic benefits they produce against the radiation detriment they might cause. The medical practitioners are assigned the primary task and obligation of ensuring overall patient protection and safety in the prescription of medical exposure. Medical decisions with respect to potential exposures are supported by guidance levels concerned with different procedures (IBSS 1996). The limits of dose contributions listed in ▶ [Table 47.7](#) may be compared to various sources in planned and other situations.

The world average annual impact from natural sources results in 2–3 mSv effective dose; half of that dose derives from the radon component, due to the inhalation of radon daughters (UNSCEAR 2000). The contribution of cosmic rays to the natural background can be assessed at 0.35 mSv per year. The dose consequence of a transmission computer tomography for a typical adult patient is about 50 mGy of absorbed dose in the head, and the average individual dose due to an in vivo diagnostic test in nuclear medicine involves 2–5 mSv effective dose.

■ **Table 47.7**
Dose limits recommended by the ICRP (2007)

Application		Annual limits	
		Occupational	Public
Effective dose		20 mSv averaged over 5 years, but 50 mSv in any single year	1 mSv
Equivalent dose in	• the lens of the eye	150 mSv	15 mSv
	• the skin	500 mSv	50 mSv
	• the hands and feet	500 mSv	–

In an emergency situation, the intervention dose level recommended for acute exposure is between 10 and 50 mSv effective dose to individual members of the public.

47.5.3.1 Action Levels for Radon Concentrations

To avoid an unacceptably high exposure from radon, many countries have introduced limitations on the radon concentration in dwellings for chronic exposures. Action levels have been designated above which protective actions should be carried out to decrease chronic exposure. In most countries, action levels for dwellings are established between 200 and 600 Bq m⁻³ for the annual average radon concentration, based on representative measurements and other parameters.

Formerly, the principal objective of radiation protection was to achieve appropriately safe conditions for all human individuals engaged in activities involving exposures. This concept has been expressed by “if man is adequately protected, then other living things are also likely to be sufficiently protected.” Recently, it has been recognized that this statement might not apply under all conditions, such as situations where humans are absent. Therefore, new approaches are being developed to specify dose quantities, criteria, standards, and guidance to extend the scope of radiation protection to protect nonhuman biota, ecosystems, or the whole environment with respect to radiation exposure (IAEA-TECDOC 1999; UNSCEAR 2008).

47.6 Health Hazards of Radiation Exposure

The biological effects of ionizing radiation appear in several ways. They depend on the absorbed dose, various dose modifying factors, physical conditions of radiation, and endogenous and exogenous chemical-biochemical-biological circumstances. The possible range of doses of biological-medical interest covers several orders of magnitude.  *Figure 47.8* demonstrates these wide possibilities indicating the average natural level, the dose levels that induce cytogenetic effects detectable by chromosome aberration analyses being one of the most sensitive assays to reveal injuries in cells.

Even higher dose levels induce radiation injuries and illnesses. Below the natural level, a few examples are indicated for population exposure (e.g., normal operation of a nuclear power station with pressurized power reactors and air traveling at about 10–12,000 m). Below the indicated level of inducing chromosome aberrations, only epidemiological investigations are available to score somatic effects like occurrences and frequencies of malignant tumors, that is, cancers. Accordingly,  *Fig. 47.8* indicates that there are differences of several orders of magnitude (approximately 6–7) between doses provoking radiation illnesses and those raising the probability of carcinogenesis.

47.6.1 Deterministic Effects

With respect to radiation protection and radiation hygiene, the biological effects of ionizing radiation are categorized into two groups according to the features of their dose–effect

■ Fig. 47.8

Comparison of dose levels above the natural background provoking radiation injuries and below that population exposure from flying in an airplane or living near a nuclear power plant

relationships, that is, the deterministic and stochastic effects. The deterministic effects appear only above a certain threshold dose, and then the severity increases with dose. This dose–effect relationship is shown in ▶ Fig. 47.9. A few threshold dose-values based on ICRP1984 are shown in ▶ Table 47.8.

Tissue and organ injuries, local injuries, the various syndromes of acute radiation sickness like the bone marrow syndrome, the gastro-intestinal syndrome, the vascular-nervous syndrome, and any other combinations with local radiation burns are the syndromes of deterministic effects (Barabanova et al. 2008).

The deterministic effects develop as consequences of injuries or deaths of many cells. Their appearances and severities depend on the radiation sensitivities of the cell components of exposed tissues. The cellular injuries or the radiation-induced functional alterations might serve for the assessment of absorbed doses, too. These parameters are called biological indicators or dosimeters of radiation injury. The radiation sensitivity like mortality of cells can be determined.

For high-LET radiation, the dose-response curve may be exponential, that is, linear on a semi-logarithmic plot. It may be characterized by the slope, which is usually represented by its reciprocal, the dose (D_0) required to reduce survival to 37%.

In the mammalian (including the human) organism, the most sensitive cells are the circulating small lymphocytes and the internal layer of vessels, the endothelial cells. Tissues in decreasing order of radiation sensitivities are the lymphatic tissue, bone marrow, epithelia of stomach and intestines, the gonad cells, the basal layer of skin, the glandular tissues, liver, the connective tissue, muscle, and the nervous tissue.

■ Fig. 47.9

Schematic dose-response curves for the stochastic and deterministic effects of ionizing radiation

47.6.2 Stochastic (Somatic and Genetic) Effects

The stochastic effects are characterized by a linear dose-response without threshold (LNT model) where the probability of the effect is increasing with the dose (see ▶ Fig. 47.9). Accordingly, a certain risk can be attributed to the very low doses, too. The validity of the LNT theory is under wide international debate. The stochastic effects include the carcinogenesis and the hereditary alterations. Hereditary effects, however, in human population could not be shown. Not even on two generations from the survivors of atomic bombing. Hereditary effects exist as demonstrated from radiation biology experiments from lower (microbes) up to higher organisms (plants, mammals). The fortunate lack of effects in human population is probably due to the fact that the injured gonad cells either male or female will not be able to serve as starting points for embryonic developments. It is also possible to consider that the mutations induced by radiation exposure in a population might be rather quickly repaired. Of course, genetic alterations in humans cannot be excluded, though rather large population would be needed for statistically significant evaluation. The nominal risk coefficients for stochastic effects according to ICRP103 are shown in ▶ Table 47.9.

The values for carcinogenesis are average values. The risk of development and lethality of various types of cancers might be different from these average values. In general, the risk of leukemia, lung and breast cancers are 3–5 times larger than that of throat or thyroid. The latency periods are also different: for leukemia, it is approximately 5 years, while for pharyngeal cancer, it is approximately 27 years. Among the survivors in Japan, the leukemia cumulated between 5 and 20 years with an average of 14 years, while for solid cancers, the latency periods were, on average, 25 years.

Table 47.8
Examples of threshold doses for deterministic effects

Tissue and effect	Threshold values for		
	Total equivalent dose received in a single brief exposure (Sv)	Total equivalent dose received in highly fractionated or protracted exposures (Sv)	Annual dose rate if received yearly on highly fractionated or protracted exposures for many years (Sv a ⁻¹)
<i>Testes</i>			
Temporary sterility	0.15	NA ^a	0.4
Permanent sterility	3.5–6.0	NA ^a	2.0
<i>Ovaries</i>			
Sterility	2.5–6.0	6.0	>0.2
<i>Lens</i>			
Detectable opacities	0.5–2.0	5	>0.1
Visual impairment (cataract)	5.0	>8	>0.15
<i>Bone marrow</i>			
Depression of hematopoiesis	0.5	NA ^a	>0.4

^aNA denotes *Not Applicable*, since the threshold is dependent on dose rate rather than on total dose.

Table 47.9
Nominal risk coefficients (10⁻² Sv⁻¹) for stochastic effects

Exposed population	Cancer	Heritable effects	Total
Adult	4.1	0.1	4.2
Whole	5.5	0.2	5.7

Ionizing radiation might induce various types of cancers, and these cannot be distinguished histologically from those induced by other carcinogen exposures. The frequencies depend on genetic factors, the ages of exposed persons, and population groups. The probabilities of cancer induction might be modified by physical and chemical factors either increasing or decreasing it. Among the physical factors, the type of radiation and the dose rates are relevant (the less the dose rate the lower the probability). At high-LET radiation like alpha-radiation the probability of hitting sensitive targets is higher than for low-LET radiation. Among the chemical factors, the presence of sensitizers or protective compounds like antioxidants during irradiation might modify the radiation effect.

47.7 Diagnostic Procedures for Radiation Injuries (Biological Dosimetry)

The biological indicators or biological dosimeters are based on radiation-induced alterations at various levels of biological organization from molecular through subcellular, cellular, tissue, organ to organism level. As there are “protective mechanisms” built-in against all levels of injury, the balance between the injury and biological response will determine the nature and severity of the detectable endpoint. Therefore, the detection of the deterministic effects above the threshold dose and its severity are the main interests for medical points of view in accidental exposures for dose assessment.

The “dose-assessing” function of biological indicators or dosimeters has important roles in the following cases:

1. When physical dose measurement data are not available (e.g., because the injured person has not worn a personal dosimeter).
2. When the dose has been detected and recorded by the personal dosimeter but its reading is not reliable (e.g., due to the nonuniform exposure of the body, the dosimeter was outside the main beam of radiation).
3. When the physical dosimeter was irradiated tentatively or accidentally without the exposure of its owner.
4. When the follow-up is needed in radiation-induced process, including the regeneration. In addition, biological indicators are needed to follow the conditions of radiation-therapy patients.
5. When the compliance has to be assessed for dose limits of radiological protection system for occupational and population categories.

Based on these needs, the general requirements for the indicators are

- Sensitivity to indicate overexposures from acute irradiation in the dose range from dose limits of occupational exposure (>20 mSv) up to accidental overexposures of several grays.
- Proportionality of its changes with the dose absorbed by the cells, tissues, and organisms.
- Ability to react mostly to electromagnetic or particle radiations, that is, possibly no other physical, chemical, or biological factors might provoke the change of the indicator.
- Early appearances of changes – within hours or days – and long duration of signal after irradiation.
- Partial-body exposure should be detectable, preferably with exact localization.
- The method should be applicable to fractionated and chronic exposures.
- All the different radiation qualities should be covered by the method; in particular, exposure due to internal emitters should be measurable.
- The biological material that shows the effect must be readily accessible without extensive invasive methods.
- Evaluation should be either easy and rapid or transferable to machines.
- It has to be easily performable without any further serious burden to the patient.

Until now, however, no such an assay has been developed, that can fulfill all these requirements. Depending on the actual level of scientific knowledge in biology and radiobiology, there were always efforts to use various radiobiological phenomena as biological indicators and it is still an important practical task of radiation biology. It is supposed that no

single indicator will be ever found that will be able to mark the various phases of the complex radiation-induced processes. The solution of the problem probably lies in various observations, tests, and the complex evaluation of several biological signs and symptoms. Therefore, the indicators already existing and those to be developed will form a system for analysis.

In the followings, a brief summary of the presently available techniques is presented.

➤ **Table 47.10** demonstrates the main groups of methods, the combination of which is necessary, as most of them have limited information if alone.

47.7.1 Hematological Indicators

The changes of blood cell counts as hematological indicators in the peripheral blood following irradiation have been studied for many years. The early phase after radiation accident is usually

■ **Table 47.10**
Main groups of biological indicators and dosimeters of radiation effects.

Group	
Hematology	
	Peripheral depletion of cells in the peripheral blood (lymphocytes, granulocytes, platelets, erythrocytes)
	Depletion of cells in the bone marrow
Cytogenetic	
	Development of metaphase chromosome aberrations (dicentrics, rings)
	Increase of numerical aberrations
	Development of interphase aberrations like micronuclei
	Detection of premature chromosome condensation PCC
	Detection of chromosome aberrations by fluorescent in situ hybridization (FISH)
Cytological – molecular	
	Detection of DNA breaks by gel electrophoresis “comet assay”
	Detection of membrane-related phenomena
	● Cell electrophoresis
	● Binding alterations, e.g., lectins
	Detection of loss of gene expressions at glycophorin A locus on erythrocytes
	Detection of altered
	● cellular functions
	● cellular morphology
	● cellular density
	● reproductive capacity

characterized by an initial and temporary granulocyte peak and the early fall in the lymphocyte count. These signs might appear between 0.5 and 1 Gy of low LET irradiation. The sharper the slope of the fall of lymphocyte number and the lower the value of the minimum, the more severe the exposure is. The number of platelets also decreases after about 1 Gy, but this process is more protracted than the decrease of lymphocyte counts. These events, however, can be followed only by rather frequent blood sampling and the dose-dependency shows great differences in various individuals. The hematological data allow judging the individual reactivity both in the acute phase and in the phase of regeneration. The main advantage of blood cell count is that it gives an immediate impression on the severity of an accident particularly during the first 2 days, when no other commonly applicable techniques are available.

47.7.2 Cytogenetic Assays

The chromosome aberration analysis of peripheral blood lymphocytes is a widely recognized tool for assessing the dose (IAEA-TRS 2001). It is especially important to note that at an equivalent dose lower than 1 Sv, the chromosome aberration analysis might be the only possible biological indicator of exposure. It is influenced by the background level of aberrations in the human population and the number of cells that are analyzed per case. Depending on the expertise of the laboratory personnel, sufficiently reliable dose estimates can be made above 0.1–0.15 Gy of low LET radiations or 0.01 Gy fission spectrum neutrons. One of the most important drawbacks of this test is that it is rather time-consuming and due to the need for cell-culturing and scoring, it requires about 3 days to get a result about a person.

47.7.2.1 Lymphocyte Metaphase Chromosomes

The dose–response curve for low-LET induced dicentrics will be a combination of one- and two-track events, with the former being more frequent at low doses and the latter much more frequent at high doses. The dose–response curve is generally assumed to fit the equation

$$Y = A + \alpha D + \beta D^2,$$

where Y is the yield of dicentrics, D is the dose, A is the control background frequency, α is the linear coefficient, and β is the dose squared coefficient. The ratio of α/β of the two coefficients is equal to the dose at which the linear and the quadratic components contribute equally to the formation of dicentrics.

In the further development of chromosome aberration analysis, new results were obtained like the fluorescent in situ hybridization (FISH) technique. Its great potential arises from its unique ability to combine cytological information about chromosome with molecular information about DNA sequence structure. In situ hybridization enables the localization of any particular DNA sequence along metaphase chromosomes. While staining only two or three chromosomes, linear-quadratic dose–effect relationships could be found for stable as well as for unstable chromosome aberrations like translocations and dicentric chromosomes (dicentrics), respectively, in circulating lymphocytes gamma-irradiated in vitro. The main advantage of this new staining technique is that the stable aberrations can be detected long after the irradiation. The yield after a given dose was found to be between 1.5 and 2 times higher than that of dicentrics. Certain limitation of the application might be

that the base value of the population is approximately an order of magnitude higher than that for dicentrics.

47.7.2.2 Lymphocyte Micronuclei

In recent years, a large number of references has been accumulated indicating the scoring of human lymphocytic micronuclei as a source of information for cytogenetic injury following ionizing radiations, as well as chemical toxicants. Well-reproducible dose–effect relationships could be established, which were found to be linear-quadratic in a dose range of 0.25–4 Gy. The data on the base line values in the population are cumulating also, accordingly, the dose assessments are getting more reliable. The relatively simple performance of the test could assist in testing combined effects and it gives a hope to assess individual radiosensitivities.

47.7.2.3 Premature Chromosome Condensation (PCC)

Lymphocytes isolated from irradiated peripheral blood are fused with mitotic Chinese hamster ovary cells using polyethylene glycol. The damage in their prematurely condensed chromosomes is shown to be a sensitive indicator of exposure. Radiation effects manifest themselves as fragments, that is, chromatid material in excess of 46 chromatid chromosomes is counted and used to estimate the cytogenetic damage. PCC can be used as a biodosimeter in non-stimulated human lymphocytes, thus avoiding complication arising from cell cycle delays and interphase death at high doses. The technique is rather efficient to detect proportion of undamaged cells. The initial damage can be determined immediately after exposure. Linear-quadratic dose–effect relationship could be found. A further step was introduced in painting the chromosomes when the FISH technique was combined with PCC. The dose–response curve for fragment induction was linear within a couple of hours after exposure. Later, it became linear-quadratic. The approach indicates that painting the prematurely condensed chromosomes might be useful for biological dosimetry.

There are several other assays in development, which might become in the future proper biological indicators or dosimeters in radiation accidents. These are, for instance, various gene expression profiles, cytological and molecular biomarkers, and clustered DNA lesions.

47.8 Management of Overexposures

The early recognition and a quick initial response to an accidental radiation injury are important in diagnosis, in treatment planning, and assessing the prognosis (🔗 [Table 47.11](#)).

For all of these tasks, properly prepared personnel as well as medical facilities are necessary. The exposure can be

- External to the body, in which case it may affect the whole body or may be limited to a part of the body, or
- Internal due to contamination with radioactive materials, if ingested, inhaled, or deposited in wounds.

■ Table 47.11

Guide for the management of radiation injuries based on early symptoms (IAEA-SRS2 1998)

Clinical signs		Corresponding dose (Gy)		Decision
WBE	LE	WBE	LE	
No vomiting	No early erythema	<1	<10	Outpatient with 5 week surveillance period (blood, skin)
Vomiting 2–3 h after exposure	Early erythema or abnormal sensation 12–24 h after exposure	1–2	8–15	Surveillance in a general hospital (or outpatient for 3 weeks followed by hospitalization if necessary)
Vomiting 1–2 h after exposure	Early erythema or abnormal sensation 8–15 h after exposure	2–4	15–30	Hospitalization in a haematological or surgical (burns) department
Vomiting earlier than 1 h after exposure and/or other severe symptoms, e.g., hypotension	Early erythema, within the first 3–6 h (or less) after exposure of skin and/or mucosa with oedema	>4	>30	Hospitalization in a well equipped haematological or surgical department with transfer to a specialized center for radiopathology

WBE: whole body exposure. LE: local exposure.

Exposure can be acute, protracted, or fractionated. It can occur alone, or be combined with other injury, such as trauma, thermal burn, and toxic effects.

Recognizing radiation injuries can be performed by clinical manifestations and laboratory assays. (For the latter, see the chapter on biological indicators.)

Following a high-level accidental exposure to radiation, injuries evolve over time in distinct phases. The length and time of the occurrences of the phases depend on the dose. Low doses like below 0.2 Gy do not produce observable effects.

A typical course following a whole body exposure to a source of penetrating radiation involves an initial prodromal phase with symptoms such as nausea, vomiting, fatigue, and possibly fever and diarrhoea, followed by a latent period of varying lengths. A period of illness follows, characterized by infection, bleeding, and gastrointestinal symptoms. Problems in this period are due to a deficiency of cells of the haematopoietic system, and with higher doses, to loss of cells lining the gastrointestinal tract.

A local exposure, depending on dose, can produce signs and symptoms in the exposed area such as erythema, oedema, dry and wet desquamation, blistering, pain, necrosis, gangrene, or epilation. Local skin injuries evolve slowly over time – usually weeks to months – may become very painful, and are difficult to treat by usual dermatological methods. Approximately above 20 Gy of local dose, irreversible alterations might occur; below this dose healing can be expected. Partial body exposures result in a combination of varying symptoms as mentioned above, the type and severity of which depend on the dose and volume of the exposed part of the body.

Additional symptoms may be related to location of the tissues and organs involved. There are usually no early symptoms associated with internal contamination unless the intake has been very high, which is extremely rare. If this has occurred, it will normally be obvious to the person concerned.

There are a few important rules to be considered in case of an accident when radiation injury is suspected as follows:

- If the person involved has a conventional injury or illness, save his/her life and treat him/her as normally required. Note that radiation does not produce life threatening early symptoms.
- Be aware that a radiation-injured person does not present a health risk to the personnel handling him/her.
- If contamination is suspected, avoid spread of material by using isolation procedures. The level and contamination should be monitored.
- Do a prompt complete blood count, repeated in 4–6 h within the first day.
- Look for a decrease in the absolute lymphocyte count if exposure was recent. If at the same time, the initial white blood cell and platelet counts are abnormally low, consider the possibility of an exposure 3–4 weeks earlier. Additional daily blood counts will be needed. The cytogenetic biological dosimetry through chromosome aberration analyses should be done as early as possible. A careful differential diagnosis is the task of the physician based on the anamnesis, physical dosimetry data, clinical observation on the patient, and laboratory assays.

An important point in the preparedness is to have satisfactory information on the name, address, and phone number of proper health institution to be called as soon as possible. The main procedures in the therapy (🔗 [Table 47.12](#)) involve antibiotic treatment against bacteria, viruses, and fungi; provision of blood preparations for platelets, red blood cells; application of cytokines for stimulation of blood formation; isolation of the person under aseptic conditions; and feeding the person with sterilized food and water. Provide proper care to the body and soul.

47.9 Dose–Response Relationships

For radiation protection purposes, the biological effects of ionizing radiation are grouped into two main categories, the stochastic and deterministic effects. In both cases, the effects are related to the absorbed doses. Therefore, the knowledge on the dose–response relationships is essential for risk assessment.

47.9.1 Biological Effects of Low Radiation Doses

The effects of low doses are considered by observations in epidemiology, cellular radiation biology, and microdosimetry. The levels according to these views are demonstrated in 🔗 [Table 47.13](#).

Based on epidemiological data of radiation-induced cancer occurrences, various authors agree that low dose is below 200 mGy as under this level the statistical evaluation of data becomes more and more uncertain.

■ Table 47.12

Principal therapeutic measures for acute radiation syndrome (ARS) according to degree of severity (IAEA-SRS2 1998)

Whole body dose (Gy)	1–2	2–4	4–6	6–8	>8			
Degree of severity of ARS	Mild	Moderate	Severe	Very severe	Lethal			
Medical management and treatment	Outpatient observation for maximum of 1 month	Hospitalization						
		Isolation, as early as possible						
		G-CSF or GM-CSF as early as possible (or within the first week)	IL-3 and GM-CSF					
		Antibiotics of broad spectrum activity (from the end of the latent period) Antifungal and antiviral preparations (when necessary)						
		Blood components transfusion: platelets, erythrocytes (when necessary)						
			Complete parenteral nutrition (first week)					
			Metabolism correction, detoxication (when necessary)					
			Plasmapheresis (second or third week)					
			Prophylaxis of disseminated intravascular coagulation (second week)					
				HLA-identical allogene BMT (first week)	Symptomatic therapy only			

BMT: bone marrow transplantation; G-CSF: granulocyte-colony stimulating factor; GM-CSF: granulocyte macrophage-colony stimulating factor; IL-3: interleukin.

Certain cellular reactions like enzyme inductions, DNA-repair processes, adaptive responses, chromosome aberrations, etc., could already be observed between 10 and 100 mGy by various sensitive assay techniques (🔗 Table 47.14). However, this dose range is considered low. In general, the doses causing fully recoverable cellular damages or alterations might be considered low doses in the cell biology. In microdosimetry, the low dose is defined when 20% of targets, that is, cells in tissue are hit.

Among the low dose radiation-induced cellular alterations, special interest has been focused recently toward the hormesis and adaptive responses. Although these phenomena, that is, inducing stimulatory or beneficial effects are more and more targets for research, no direct evidence is available for their possible impact on human radiation protection.

It is also worth mentioning that when individual radiosensitivity of persons was studied through the frequencies of radiation-induced lymphocytic micronuclei following in vitro irradiation of individual blood samples, below 200 mGy the responses were found to be

Table 47.13
Dose ranges considered low by various approaches to biological effects of ionizing radiation

Approaches	mGy, mSv
For stochastic effects as carcinogenicity	200
For gamma and X-rays	200
For neutrons	50
For cellular reactions	10–100
By microdosimetrical consideration	When less than 20% of gross sensitive volume – GSV – will be hit once
For comparison:	
The average natural background	
In a year	3
In the lifetime of a person	50–200
“Insignificant individual dose”	0.01
“De minimis” dose	0.01

unrelated to the absorbed dose. These data suggest the importance of other factors in individual sensitivity besides the dose. On the other hand, the data point to the existence of dose–effect modifying biological factors, making the response statistics uncertain like in epidemiology below the same dose range.

In the foregoing, the dose range was given in mGy. It has to be recalled that the natural background from cosmic and terrestrial sources is approximately 3 mGy on world average. This level means one hit per cell per year for a person. For comparison of considerations on low doses, it has to be noted that earlier the opinion was that 10 μ Sv for an individual is an “insignificant dose.” In other words, 10 μ Sv is a “*de minimis* dose.” The expression comes from the language of jurisprudence, that is, “*De minimis non curat lex*,” – the law does not care about minimal causes or effects. At dose levels when “the collective dose committed by one year of performance of the practice is no more than about 1 man-sievert, or an assessment for the optimization of protection shows that exemption is the optimum option,” the risk assessments based on the collective dose is not justified (IBSS 1996).

47.9.2 The LNT Theory and Its Critical Review

The biological effects of ionizing radiation for radiation protection considerations are grouped into two categories: the deterministic and the stochastic ones (► Fig. 47.9).

The deterministic effects occur when above a certain “threshold”, an appropriately high dose (above 500–1,000 mSv) is absorbed in the tissues and organs to cause the death of a large number of cells and consequently to impair tissue or organ functions early after exposure. The severity of injury depending on the absorbed dose according to an s-shaped dose–response curve might be manifested in the various syndromes of radiation illness, that is, the bone

■ Table 47.14

Examples for cellular responses and alterations provoked by low doses

Response/alteration	Dose-range (mGy)
Free radicals	
Increases of production of granulocyte oxidant	0.1–1
Increases of superoxide dismutase	100
Increases of oxidative stress	50
Cellular responses	
Lymphocyte mitogenic stimulation by lectins increases	10–40
Thymidin kinase activity increases	10
Prospholipase C, increases	
Adenylatecyclase increases	2.5
Spleen colony formation stimulation	6
Mutagenic alternations	
Lymphoblast 6-thioguanin resistance (6-TGr) formation increases	10
Nuclear structure	
Chromatin conformation alteration	40–250
Cytogenetic alterations:	
Increases of micronucleus formation	>100
Increases of dicentric aberrations	
Cell membrane structure and function	
Lipid composition changes	10–100
Antioxidant capacity decreases	10–100
Micromorphological alterations	250
Adaptive response develops	5–10

marrow, the gastro-intestinal, and the central nervous system-vascular syndromes. The effects can be detected by laboratory and clinical techniques.

The stochastic effects might occur following low doses (below several tens or 100–200 mSv). The probability of consequences increases with the dose and the relationship between dose and effect is assumed linear. Accordingly, not having a “threshold” dose a certain risk – albeit very small – can be attributed to any low dose.

Such late effects might be the development of malignant (cancerous) diseases and of the hereditary consequences. Here, it has to be mentioned that in human populations, hereditary effects could not be detected even in the offspring of the large population of A-bomb survivors in the first two generations. The possibility of hereditary alterations is known only from experimental observations in radiation biology.

The model for assessing the detrimental health effects used for the deterministic effects is the nonlinear-threshold (NLT) model, while for the stochastic effects the linear-non-threshold “LNT” model. In the low-dose dilemma, the problem raised is whether the use of the LNT model is justified to attach any health risks to low doses.

The arguments of those who oppose the LNT model can be summarized as follows, though not necessarily including all the available reasoning:

- Below 200 mSv, no cancer cases were found in a significantly increased frequency among the A-bomb survivors.
- No higher risk could be detected at high natural background areas though they might be 3–10 times higher than the average level.
- The carcinogenesis is not a first order kinetic process, that is, the hit of cellular genes at sensitive sites or the malignant transformation of one or a few cells does not lead necessarily to the clinical manifestation of a malignant disease.
- Repairing a few single strand breaks (SSB) or double strand breaks (DSB) following a damage in the DNA caused by low doses does not overload the repair capacity of a cell: the metabolism of cellular DNA and the repair of damages induced by other endogenous or exogenous factors are running with much higher intensity.
- A real threshold might appear when the latency period is long enough compared with the life time of an individual by low dose exposures no detectable biological or health effects are provoked, the LNT model is for regulatory purposes, as a tool for risk assessment, but it is not verified scientifically or statistically in epidemiology.

The arguments of those who are in favor of keeping this model further as valid for the risk assessment are mainly the followings:

- The linearity is known and it has a great tradition in radiation biology since the detection of the genetic effects on *Drosophila*.
- For stochastic effects, the LNT model is recommended by the ICRP and it is widely used in assessment of health detriment.
- In cellular radiation biology including observations on the survival of cells in culture, formation of cytogenetic aberrations and mutations, many results can be fitted to a linear dose–response relationship or linear-quadratic one when the investigations are extended to higher doses, that is, approximately above 1 Gy.
- Recent data indicate significant increase of risk for thyroid cancer, breast cancer, and malignancy following in utero irradiations also in the range between 50 and 100 mGy.
- Even among the A-bomb survivors, the risk of cancer increased already above 50 mGy significantly, though it is obvious that the risk below 100 mGy is really small.
- Among the “liquidators” of the Chernobyl, accident site increases of malignant tumors of the digestive system were observed up to 1995. The average dose of the studied cohort was 108 mGy.
- It is also repeatedly mentioned that the consequences of DSB if not repaired are more serious than the consequences of SSB-s.

It is foreseen that the multisided debate will be continued but at this stage some views can be delineated as *conclusions*: Further research and investigations, on the cell biological as well as on the epidemiological aspects of health consequences of low doses are necessary.

It has to be realized that a biological response itself experienced following rather low doses does not mean detrimental health consequences. The LNT model might be too conservative and unjustified, but at present it seems to be safe enough to ensure the safe application and uses of ionizing radiation and nuclear energy. The rejection of the LNT model and the acceptance of a threshold in cases of stochastic effects would raise many questions concerning the regulatory action. These foreseen questions like the safe thresholds

for late effects, for different population groups, for various practices, etc., are hardly answerable at the moment. It seems to be easier, however, to reach an agreement on the level of acceptable risk instead of the risk threshold dose.

Abstract: Most radiation related to nuclear properties is outside the visible part of the electromagnetic spectrum or involves submicroscopic particles, hence is invisible. Detectors – devices to sense the radiation, and perhaps measure its properties – are essential. The emphasis in research has moved from the characterization of radioactivity, through simple nuclear reactions, to explorations of the extremes of nuclear matter, but the central importance of suitable radiation detectors has persisted. This chapter emphasizes detectors associated with measurements of radioactivity, as opposed to nuclear reactions. Thus, much of the current creative work is excluded, but otherwise the scope of these volumes would at least double. Detectors are classified broadly as based on ionization of gases, conduction in semiconductors, or scintillation. The concluding section is an introduction to systems based on two or more components of one of these basic types.

48.1 Introduction

Radiation detectors have played and continue to play an essential role in the study and use of nuclear transformations. The goal of this chapter is to describe the general characteristics of radiation detectors with emphasis on detectors for radiations associated with radioactive decay. These radiations include photons, electrons (both negative and positive), and energetic atomic ions (primarily, but not exclusively, α particles). The detectors can be classed according to the physical form of the detector (gas, liquid, solid), the nature of the signal (ions, current, light), or the purpose (simple detection, spectroscopy, or diverse other roles).

The relevant part of the energy spectrum (for photons and electrons) extends from low energies of a few keV to high energies of about 10 MeV. The upper value is related to alternatives available to excited nuclei. When excitation energies are greater than nuclear binding energies, it is more likely for the nucleus to come apart than for a photon or β particle to be created. The lower value is also related to alternative deexcitation mechanisms. Photon emission is retarded when the size (wavelength) of the photon is large compared with the size of the radiator (nucleus). Electron and neutrino emission are retarded when the momentum phase space is severely limited. There is an effective lower limit for α particles because of the nuclear Coulomb barrier.

For the user, the primary questions may be what radiation to detect and what properties to measure. Is it sufficient to measure the amount of radiation without regard to type? Is it desired to discriminate among types? Is it important to measure the energy of the radiation? Is time dependence important?

Radioactivity was discovered by detecting the radiations emitted by samples of uranium. The detector was photographic film, and the radiations were primarily electrons (β rays) emitted, not by uranium, but by $^{234\text{m}}\text{Pa}$ in equilibrium with ^{234}Th , in turn in equilibrium with the decay of ^{238}U . It is unlikely that these facts would have been discovered without improved detectors – first electroscopes and then Geiger-Müller (GM) detectors. Each of these detectors is still in common use. Electroscopes are used as personal dosimetry devices, such as for a visitor to a facility where exposure to radiation is possible. GM detectors are used to measure ambient radiation levels and to locate surface contamination resulting from radiochemical work. Although new detectors, combinations of detectors, large arrays, on-board logic, etc. are what have carried investigations of nuclear matter to the extreme, they must be understood in terms of basic, simple types. That understanding is the object of this chapter.

Two types of information sources have been used: textbooks, and manufacturers' catalogs and specification sheets. The textbooks include Glenn Knoll's *Radiation Detection and Measurement*, 3rd edn (Knoll 2000) and Debertin and Helmer's *Gamma- and X-ray Spectrometry with Semiconductor Detectors* (Debertin and Helmer 1988). The former describes detectors and their principles so that one might design or modify detectors for specific purposes, as well as use them intelligently; check for a 4th edn. The latter gives the principles and procedures for state-of-the-art metrology with available detector systems. Current manufacturer information should be consulted to find out "what is available." Properties of individual nuclides are taken from current compilations (Browne et al. 1986; Firestone et al. 1996; Baum et al. 2002).

48.2 General Properties of Detectors

A typical detection system consists of the following parts.

Detector. This is the "transducer" that converts the nuclear radiation, such as an energetic α particle, into, for example, a number of electron-hole pairs in a semiconductor. It may also include shields, collimators, spacers, etc.

Power supply. This permits the detection event to trigger the release of a larger, perhaps proportional, amount of energy. In the example of an α particle detected in a semiconductor (Si diode), a voltage is used to sweep out the electrons and holes before they can recombine.

Additional mode converters. These convert current into voltage, step functions into pulses, voltage into a binary number, etc. They include preamplifiers, amplifiers, discriminators, and analog-to-digital converters (ADCs).

Recorder. This might be the product of a chemical reaction, an image on paper, or a complex file of data.

Another way to understand radiation detection is by a case method and the factors that influence the quality of the result. In general, the factors are the following.

Attenuation. If a measurement seeks to identify radionuclides and measure how much of each is present, it is important to know what fraction of the initial radiation reaches the sensitive volume of the detector. This also includes attenuation in the source, the outer parts of the detector system, and the medium between source and detector.

Uncertainties in position. In most cases, nuclear radiation is emitted in all directions from the source, and the fraction reaching the detector depends on relative positions.

Statistics. If each detection event leads to a "count," and the measurement as a whole depends on the relation between a sample and the larger population, precision requires large numbers of events.

Efficiency calibration. What fraction of the radiation would lead to a count if there were no uncertainties in absorption or position?

Dead time. Does the detector ever miss counts, perhaps because it is "busy" processing another event?

Coincidence summing. Some radioactive materials emit two or more radiations in rapid succession, and the detector misses the parts and sees the whole. The missing parts must be accounted for.

Pile-up. When the count rates are high, by chance two radiations may be sensed as one. Again, corrections for the missing parts, and perhaps the unexpected whole, must be made.

In the following sections, various types of detectors are described, and in a few cases the detailed considerations required for accurate quantitative work are given.

48.3 Detectors Based on Gas Ionization

Most nuclear radiation is classified as “ionizing radiation” because interaction with individual atoms or molecules generally transfers enough energy to exceed the ionization potential of the absorber. Some of the earliest replacements of photographic detectors were based on this ionization process, and developments continue.

The main subclasses of detectors depend on how the ions are collected and measured. If a modest voltage gradient is imposed on the gas, some of the electrons and ions produced by radiation will be swept out, and some will recombine and ultimately produce heat. As the gradient is increased, recombination will diminish and the ion current will increase. If and when recombination is negligible and the current approaches an asymptote, the system functions as an ionization chamber.

If the gradient becomes large enough that an electron gains enough energy between collisions with gas molecules to ionize the struck molecule, the number of ions will increase. Under appropriate conditions, the increase will be approximately the same for all initially formed ions, and the system functions as a proportional counter. In this region, an increase in gradient will increase the multiplication factor while maintaining proportionality.

At higher gradients, the proportionality will be lost. This will certainly be the case if there is an electric discharge, a spark. However, some combinations of electrode geometry and gas composition lead to propagation of the discharge so that a nearly constant pulse is produced, regardless of the amount of original ionization. This is the Geiger (or Geiger-Müller) region of operation.

Detectors based on ionization continue to be developed, and they do not always fit these simple categories, but these categories provide a foundation for selecting and using modern ionization detectors.

48.3.1 Ionization Chambers

There are few restrictions on the geometry of the gas and electrodes in ionization chambers, but they are less likely to be operated in pulse mode than are the other types. In effect, one measures the electrical resistance of the gas under conditions of saturation current.

This saturation collection current finds two important applications – measurement of high radiation fields without paralysis and measurement of intensities of extended photon emitters. A GM detector (see next section) is a useful survey meter for modest levels of radiation, but in high radiation fields a GM detector becomes paralyzed. Ionization chambers based on continuous current do not have this deficiency and even benefit from the more robust current.

A therapeutic dose of a radiopharmaceutical is too active to count individual decays, but quite sufficient to produce robust continuous ionization current. It is important that amount of radioactive material be known quite accurately. ➤ *Figure 48.1* shows the geometry of an ionization chamber designed to measure the activities of, for example, batches of radioactive material packaged in a standard way. Although the detector can be stable over long periods of time, variations in absorption in the samples must be minimized. The system must be calibrated for each radionuclide and each geometry of container and contents.

■ Fig. 48.1

Schematic of ionization chamber used to measure packaged doses. The textured area shows the volume sensitive to ionization events. The graph shows detection efficiency versus sample position (From Weiss 1973; used by permission of Elsevier)

48.3.2 Geiger-Müller

If the electric field in a cylindrical chamber (see ► Fig. 48.2) is high enough and the gas has appropriate properties (not discussed here), each ionization event in the sensitive volume will lead to discharge the entire length of the anode. The advantage is that a large signal is produced. It can be registered with a simple electronic circuit. The disadvantage is that the discharge in effect enlarges the anode and changes the voltage gradient so that these large discharges cannot occur until the slow positive ions migrate toward the cathode. There is a rather long time ($\gg 10 \mu\text{s}$) during which the detector is dead. This dead time is “paralyzable.” If such a detector is in a very high radiation field, counting can cease entirely – not a good thing if the device is intended to warn of dangerous radiation conditions. However, when used with discretion, GM detectors are inexpensive, effective devices.

48.3.3 Proportional Counters

The development of proportional counters accelerated when electronic instrumentation permitted realization of the advantages (energy proportionality, fast response, negligible dead time) of these devices. Two (of many) implementations are given in ► Figs. 48.3 and ► 48.4.

Many radioactive materials in the natural decay series and in the nuclear fuel cycle are α emitters for which very little radiation escapes a macroscopic sample. If radiochemistry is used to isolate a particular element, and its mass is small, the solid can be deposited on a metal planchet (e.g., by evaporating a small volume of liquid containing the purified material) and counted with the planchet forming the bottom of the gas chamber such as shown in ► Fig. 48.3. Under these conditions, the α detection efficiency can be about 52% and the β detection efficiency about 80%. (Some β particles that are emitted toward the planchet are scattered into the gas volume.)

■ Fig. 48.2

Cylindrical geometry for detector based on gas ionization. (This type of design is used both in Geiger-Müller and proportional counters.) The cross section on the left defines the size of the inner and outer electrodes. When a is quite small compared with b , avalanches can be confined to a small volume around the central, positive electrode. Most of the interactions with radiation take place outside this volume, and the primary electrons are swept into the region, where they are subject to the same degree of multiplication, an important property of proportional counters. Hence, at moderate voltages and using an appropriate filling gas, most of the pulse heights are proportional to the number of primary ions. A simplified diagram of the power supply (V_0), detector (capacitor C), and the development of signals (voltage V_R developed when current flows through the detector) is given on the right (From Knoll 2000; used by permission of Wiley)

■ Fig. 48.3

Proportional counter with 2π geometry. The electric field near the anode is not as uniform as it could be, and energy resolution is modest. However, effective discrimination between α particles, which deposit most of their considerable energy in the sensitive volume, and γ or β rays can be obtained (From Knoll 2000; used by permission of Wiley)

■ Fig. 48.4

Proportional counter with 4π geometry (From Knoll 2000; used by permission of Wiley)

When it is important to know the total disintegration rate of a sample accurately and the material can be obtained in a thin deposit, it can be counted in a 4π geometry with a detection efficiency close to 100%. This type of detector is shown in ► Fig. 48.4.

Proportional counters filled with BF_3 or ^3He can be used to detect low-energy neutrons. The reaction $^{10}\text{B}(\text{n},\alpha)^7\text{Li}$ has a large cross section for thermal neutrons, and the charged reaction products produce a large, distinctive pulse. The cross section drops as energy increases, but it remains useful to keV neutron energies. Similarly, the $^3\text{He}(\text{n},\text{p})^3\text{H}$ reaction has a large cross section, produces a distinctive pulse, and can be used for spectroscopy.

48.3.4 Avalanche Detectors

Arrays of proportional counters can be used to measure position as well as energy. Such an array is shown in ► Fig. 48.5. More limited, but useful, amounts of gain can be obtained with the uniform electric field between parallel plates. These PPAC's (parallel plate avalanche counters) are used to detect and time individual particles in beams at accelerators. In this geometry, as usual, the avalanches involve electrons. The gain depends on where the primary electron was created. In typical applications, all particles pass through the gas and have the same path length, so the pulses are proportional to the energy deposited, albeit weighted by the deposits near the cathode.

48.4 Semiconductors

The motivation to produce transistors and integrated circuits led to improvements in semiconductor materials, which led to improved detectors. Semiconductors might be considered

■ Fig. 48.5

Multi-wire proportional counter for energy and 2D spatial resolution (From Sauli 1994)

“solid state ionization chambers” with several advantages over gas devices. The energy required to produce an electron–hole pair in a semiconductor is about a tenth that required to produce an ion pair in a gas. This increase in number of carriers leads to improved statistics and better energy resolution.¹ The efficiency of energy to carrier conversion constrains the relative variation in the number of carriers for a given energy deposit. The absence of windows to contain a gas or of a gas supply is also advantageous.

The most common, and therefore important, semiconductors are silicon and germanium. These materials have good mobilities of carriers, very similar mobilities for electrons and holes, and low trapping. They are chemically stable and can be fabricated in a variety of shapes, including very thin sheets (most commonly for silicon) and large crystals (mainly germanium).

48.4.1 Si for Alphas

Spectroscopy of α particles is used for detecting, identifying, and quantifying components in a mixture of α emitting nuclides. Note that, in contrast to γ -ray detection, α spectroscopy with silicon detectors requires thin sources, which usually involves radiochemical purifications. However, for suitable sources, impressive results can be obtained. Figure 48.6 shows the spectrum obtained for ^{241}Am . Note that the weak 5,512 keV α is resolved from the major peak only 26 keV away. There are many weak α groups with energies below 5,389 keV. Some of them would be discernable with longer counting times; others would require α – γ coincidence measurements.

For use with radioactive samples, relevant parameters of Si detectors are depletion depth (100 μm is sufficient for normal α energies), area (geometrical efficiency), and ruggedness (some electrodes can be damaged by exposure to chemicals and vapors). The decay of heavy elements may include spontaneous fission. The ranges of fission fragments are comparable to the ranges of α ’s from decay, and the same detector criteria apply. However, fission fragments produce many more electron–hole pairs per unit path length, and the high density of carriers

■ Fig. 48.6

Spectrum of α 's emitted by a thin source of ^{241}Am measured with a Si detector (Chanda and Deal 1970)

leads to significant recombination (the pulse height defect). For this and other reasons, one need not specify the best energy resolution (at higher cost for the detector) for fission fragments or for α spectroscopy of relatively thick sources.

48.4.2 Si for Photons

The dominant interaction of high-energy photons (>100 keV) with silicon is Compton scattering. For these energies, silicon is not attractive for spectroscopy, which depends on

■ Fig. 48.7

Energy dependence of detection efficiency for photons in a Si(Li) detector (Used by permission of Canberra)

events in which all of the energy is deposited in the detector volume. Below about 50 keV, photoelectric absorption is significant, and silicon can be quite useful. ➤ Figure 48.7 shows the energy dependence of full energy absorption as a function of detector characteristics and of photon energy.

➤ Figure 48.8 shows the low-energy photon spectrum of ^{241}Am . Note that in terms of photons emitted by the source, the intensity of the 59 keV γ ray is more than 15 times that of the 26 keV γ ray. That the peak areas in the spectrum are about the same shows the drop in full energy efficiency of silicon above ~ 50 keV. However, the energy resolution in the range for which the detector is useful is very good. In contrast to silicon, germanium, which can be used in the same energy region, produces a large escape peak about 10 keV (the energy of a Ge K X-ray) below the main peak.

48.4.3 Ge for Photons

All Ge detectors operate at low temperature, generally that of liquid nitrogen. When the first Ge detectors were made, even the purest available material had significant amounts of p-type impurities. These impurities were compensated by diffusing and drifting lithium atoms into the crystal. Unfortunately, the lithium in these Ge(Li) detectors would migrate and the detector characteristics would be destroyed if the crystal warmed to room temperature. Currently, high purity (“intrinsic”) Ge is used, and the lithium compensation is not required. These detectors can be stored at room temperature.

Photon spectrometers fabricated from germanium are available from several manufacturers with a variety of specifications. The technology is highly developed, and it is unlikely that any user would attempt to construct one from raw materials. Some of the available shapes and electrode geometries are shown in ➤ Fig. 48.9. Corresponding detection efficiencies are given

Fig. 48.8

Photon spectrum for ^{241}Am observed in a Si(Li) detector (From Gehrke and Lokken 1971; used by permission of Elsevier)

Fig. 48.9

Shapes of Ge detectors. The thick boundaries are thick electrodes that attenuate low-energy radiation (Used by permission of Canberra)

in Fig. 48.10, and resolutions are given in Fig. 48.11. It is apparent from the trends in resolution that small detectors can have superior energy resolution. As shown in Fig. 48.10, these small detectors have low efficiency at high energies.

Figure 48.12 shows the spectrum of L and K X-rays (from ^{207}Bi) observed with a small Ge detector. The efficiency within the display range is nearly constant (except for increasing Ge K X-ray escape at lower energies; see Fig. 48.10). The high resolution results from low electrical capacitance of the small crystal.

Fig. 48.10

Detection efficiencies for various configurations of Ge. Circled numbers refer to types ①, REGe; ②, 10 cm² LEGe; ③, 2 cm² LEGe; and ④, 10% Coaxial Ge (See Fig. 48.9)

Fig. 48.11

Resolution for various types (See Fig. 48.9) of commercial Ge systems (Used by permission of Canberra)

■ Fig. 48.12

Spectra for Pb L and K X-rays observed in the small, thin-window Ge detector. The region labeled M is more likely to be escape peaks than easily absorbed M X-rays (From Debertin and Helmer 1988; used by permission of the author)

The probability for photoelectric absorption drops below that for Compton scattering at about 150 keV in germanium. That large crystals can be used for energies of many MeV is due to multiple interactions with photons and a sufficient size to absorb the energetic secondary electrons. At energies well above the 1,022 keV threshold, production of electron–positron pairs becomes important.

It is normal to treat empirically the complex mixture of interactions that lead to full energy deposit and to the spectral peak corresponding to that full energy. The trends in spectral features are shown in Fig. 48.13. At energies below about 200 keV the full energy peak is the dominant feature; most of the γ rays that enter the sensitive volume of the detector deposit all of their energy. At higher energies, the Compton continuum (broad plateau extending from 0 to about 250 keV below the peak) becomes more important, in accord with the decreasing probability for photoelectric interaction.

At still higher energies (above 1,022 keV), pair production becomes significant, and there are escape peaks resulting from annihilation of positrons.

The processes that form the escape peaks are as follows. Some of the original, high-energy photons that entered the Ge crystal produced an electron pair (e^+ and e^-) in the first interaction. The electrons were created with, between them, kinetic energies equal to the photon energy less the energy (1,022 keV) required to create two electrons. Unless the process takes place near the surface of the crystal, the electrons are likely to deposit all of their kinetic energies in the crystal. The negative electron is no longer of interest, but the positron is not finished. When the positron reaches approximately thermal energies, it finds an electron and, most often, the matter/antimatter pair annihilates into a pair of photons, each with the energy (511 keV) derived from the mass of an electron. Depending on how much more energy the annihilation quanta deposit, three peaks and additions to the continuum result. (See response functions for high-energy γ rays in Fig. 48.13.)

Real spectra corresponding to intermediate and high-energy γ rays are shown in Fig. 48.14. The upper part shows the spectrum for ^{137}Cs . This source emits β rays and

■ Fig. 48.13

Calculated response functions for monoenergetic γ rays in a Ge crystal. The *bottom row of peaks* shows full-energy peak (FP) when the total γ energy is absorbed by the Ge crystal. The top and the middle rows show double-escape (DE) and single-escape (SE) peaks, respectively. See text for more details (From Meixner 1974; used by permission of Elsevier)

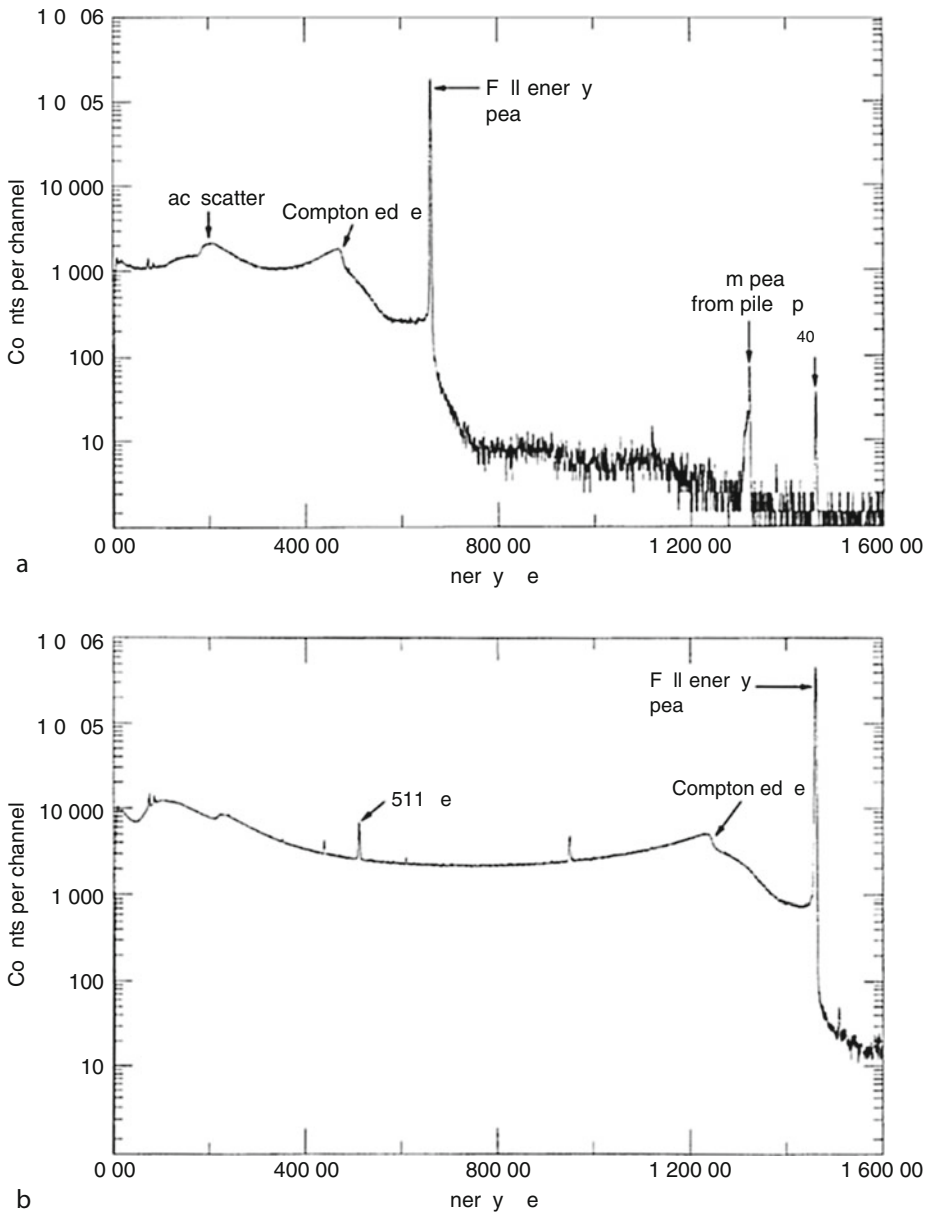

conversion electrons that are almost always absorbed before reaching the sensitive Ge volume. There are also Ba X-rays and 661.6 keV γ rays. Whether the X-rays reach the detector depends on the specific type of electrodes used in the detector. In this case, the p-type high-purity Ge crystal has a thick absorbing layer, and most of the Ba X-rays are absorbed. More energetic Pb K X-rays (from the shield) are detected. The backscatter peak arises from 662 keV γ rays that Compton scatter from electrons in the surroundings. The peak is broad because of the range in scattering angles. The Compton edge shows a rather sharp maximum in the energy transferred to electrons in the Ge crystal. Note that the backscatter peak and the Compton edge are complementary.² Sometimes, two γ rays from separate decays enter the detector at about the same time and give rise to a sum peak.

The lower part shows the spectrum of 1460.8 keV γ rays emitted in the decay of ^{40}K . (Note that a weak ^{40}K γ -ray peak occurs in the upper spectrum due to potassium in materials outside the detector and shield.) Interactions of the γ rays with the detector give annihilation escape peaks (SE for single escape, DE for double escape) in addition to the components seen for the lower energy ^{137}Cs γ ray. The 511 keV peak results from pair production followed by annihilation in the surroundings, most likely in the Pb of the shield. Note again the Pb K X-rays (~ 74 and ~ 85 keV).

■ Fig. 48.14

Spectra for monoenergetic γ rays in a large Ge crystal. The radiation source is ^{137}Cs for the upper and ^{40}K for the lower spectrum (Courtesy of the ORTEC Products Group, Oak Ridge, TN)

Real applications generally involve a mixture of radioactive materials, each with many γ rays. ➤ [Figure 48.15](#) shows a spectrum of intermediate complexity from a source of neutron-activated silver. The source is dominated by $^{110\text{m}}\text{Ag}$ but includes a small amount of $^{108\text{m}}\text{Ag}$. The $^{108\text{m}}\text{Ag}$ has a relatively simple spectrum with the major peaks showing up at

■ **Figure 48.15**

Typical spectra for multi-gamma sources with NaI(Tl) and Ge. Energies are in keV. Most of the peaks arise from $^{110\text{m}}\text{Ag}$. A few originate from $^{108\text{m}}\text{Ag}$ (From Philippot 1970; © 1970 IEEE)

79.5, 433.6, 614.1, and 722.7 keV. The upper trace shows the spectrum obtained with a low resolution detector (NaI(Tl); see ▶ Sect. 48.4.1), which cannot detect $^{108\text{m}}\text{Ag}$ under these conditions. The advantage of the Ge resolution is obvious.

If no $^{110\text{m}}\text{Ag}$ were present, it would be easy to detect the $^{108\text{m}}\text{Ag}$ in the sample, even with NaI(Tl). If there were very little radioactivity of any type in the sample, competition from background radiation would become important, particularly if some of the γ rays of interest in the sample also were in the background. ▶ Figure 48.16 shows various techniques for reducing the background spectrum for a γ -ray spectrometer.

■ Fig. 48.16

Background spectra for a large Ge detector under different conditions (From Brodzinski et al. 1987; used by permission of Elsevier)

In some cases, the amount of a radioactive material can be determined by comparison with a standard amount of that same material. Details of the detector are unimportant. More often, it is inconvenient to obtain such a standard, and the absolute efficiency of the detector for the relevant energies must be known. (Also, the absolute intensities of the γ rays must be known.)

For precision work ($<10\%$ uncertainties), the detection efficiency for each spectroscopy system must be measured under the conditions of use. ➤ Figure 48.17 shows a (unusually

■ Fig. 48.17

Experimental detection efficiencies for a large Ge detector (From Kis et al. 1998; used by permission of Elsevier)

detailed) calibration curve for a specific detector. The efficiency is maximum at ~ 120 keV; its value reflects the solid angle subtended by the detector from the source position.

The drop in efficiency for lower energies reflects absorption (in the source or parts of the detector system between the source and the active Ge volume). For higher energies, an increasing fraction of interactions fail to deposit all of the energy of the photon in the detector, and the full energy efficiency drops. At the very highest energies, the ranges of the secondary electrons become significant compared to the size of the crystal; efficiency drops more steeply.

Note that in the energy range for common γ rays from radioactive sources (200–3,000 keV) the logarithms of the efficiency and the energy are nearly linearly related.

It is important that the calibration be made under the conditions of use. Choosing those conditions requires balancing many factors. Placing the sources close to the detector increases count rates and peak areas, which reduces statistical uncertainties. Unfortunately, some systematic uncertainties may increase.

Consider what might happen after a given γ ray has deposited all of its energy in the detector. There is nothing to prevent additional radiations from adding energy to the detector and removing the event from the range of pulse heights that would be interpreted as the full energy of the γ ray. If that radiation comes from the decay of the same atom, the effect is called “coincidence summing,” and can be understood in terms of cascade relations (shown by the decay scheme) and detection probabilities. If the radiation is from the decay of another atom, the effect is called “pileup” or “random summing.” These two effects are quite different.

Pileup is a function of the total count rate, the time constants of the amplifier, and (weakly) the energies of the γ rays. Reducing the count rate (at the expense of statistics) or shortening the time constants (at the expense of energy resolution) can reduce pileup.

Coincidence summing depends on the details of the relevant decay scheme. Each nuclide must be evaluated on the basis of its unique scheme. Consider the decay of ^{207}Bi .³ The most likely decay path is (1) electron capture to the 1,633 keV level of ^{207}Pb , the stable end-product of

the $4n+3$ series, (2) delayed emission of a 1,064 keV γ ray, and (3) almost immediately after the 1,064 keV γ ray, emission of a 570 keV γ ray. The 1,064 keV γ ray is emitted in 74.5% of the decays. Perhaps, this transition has been chosen as an indicator for ^{207}Bi , and the sample has been counted in a geometry for which both peak and total detection efficiencies are well known. The effective detection efficiency for the 1,064 keV γ ray is the probability that it will deposit all of its energy in the detector times the probability that no other radiation will be detected at the same time. Because of the delay following electron capture, the atomic transitions associated with the vacancy following capture are unlikely to occur at the same time. (The probability of γ -ray emission to occur within 10 μs of the capture is $\sim 7.7 \times 10^{-6}$.) However, any interaction by the 570 keV γ ray will prevent recording a count in the 1,064 keV peak.

The coincidence summing effect is shown in [Fig. 48.18](#). The calibration points were obtained with a mixed source containing, among others, ^{60}Co , ^{88}Y , and ^{152}Eu . Each of these decays has strong cascades for which the apparent efficiencies are considerably below the true efficiencies for individual γ rays of those energies.

Beta detection should not be ignored. Beta rays do not produce features as distinctive as those produced by photons (bremsstrahlung excepted), but if they reach the sensitive volume of the detector they are equally effective in removing a full-energy event from its spectral peak. For many detectors, such as p-type intrinsic Ge detectors, the layer of dead Ge may be sufficient

Fig. 48.18

Coincidence losses in a Ge detector (From Debertin and Helmer 1988; used by permission of the author)

to prevent β detection. A p-type detector might have a dead layer of $\sim 0.3 \text{ g cm}^{-2}$, which is range for $\sim 750 \text{ keV}$ electrons. On the other hand, detectors that are designed for detecting low-energy photons are also sensitive to intermediate energy (several hundred keV) electrons.

48.4.4 Other Semiconductors

The favorable characteristics of Si and Ge notwithstanding, both have low atomic number (hence low photoelectric absorption) and Ge requires cooling. Diamond can function as a detector and has been used, but it is expensive and has even lower atomic number. The most common alternatives to Si and Ge are the compound semiconductors $\text{Cd}_{1-x}\text{Zn}_x\text{Te}$ (CZT, or just CdTe when $x = 0$) and HgI_2 . Their band gaps are sufficiently large for operation at or slightly below room temperature. Interested readers should consult specifications of available commercial devices.

48.5 Scintillators

There are many materials that scintillate – give off visible light when excited by radiation, including the ionizing radiation of interest in nuclear studies. Only a few will be described, but they all depend on some device to convert the light into an electrical signal. Most commonly, a photomultiplier is used. The structure of a typical tube is shown in [Fig. 48.19](#).

An external source of high voltage (perhaps 1–3 kV, depending on the number of stages of amplification) provides the force to draw electrons from the photocathode, which converts the scintillation light into a very small current, down the series of intermediate electrodes called dynodes, increasing the current at each stage.⁴ The composition of the photocathode is chosen to match the spectral characteristics of the scintillator. This matching is illustrated in [Fig. 48.20](#).

The scintillators are chosen based on the type of radiation to be detected and the desired geometry. For spectroscopy of γ rays, it is generally desirable to have a scintillator with high average atomic number. This enhances the probability of photoelectric absorption, which leads to a full energy deposit. This application is illustrated by thallium-activated sodium iodide – NaI(Tl) . There are scintillators with higher effective atomic number, such as *bismuth germanate* (BGO), but they are slower, much more expensive, or have poorer resolution than NaI(Tl) . Plastics are easy to form into complex shapes that may be needed for a given application. They generally have slightly lower light output than NaI(Tl) , but the emission is generally much faster. Although semiconductors have largely replaced scintillators in many applications, the liquid scintillation spectrometer remains the most important detector for tracers that are pure β emitters.

The mechanisms whereby energy deposited by nuclear radiation is converted into light are quite diverse. Although inorganic scintillators are generally slow (time constants of $\sim 1 \mu\text{s}$) compared with organics, some of the light emitted by BaF_2 is very fast ($< 1 \text{ ns}$). Unfortunately, the yield is low and the emission is in the UV part of the spectrum, requiring special (e.g., quartz) windows and light pipes.

Some materials, such as properly doped salt crystals, store the energy deposited by radiation until they are stimulated (e.g., by warming) to release the energy by emitting light. These TLDs (thermoluminescent dosimeters) have largely replaced film for monitoring

■ Fig. 48.19

Cross section of a typical photomultiplier tube (PMT) (From Knoll 2000; used by permission of Wiley)

accumulated dose over weeks or months.⁵ There is considerable variation in response among individual chips of salt, but each chip can be characterized and then used many times.

In spite of the variety of scintillators, they are unusual materials. There is a mechanism for emission of light that is quite general for certain types of nuclear radiation. Charged particles moving through a transparent medium (e.g., water or glass) at a speed greater than the speed of light in that medium emit light – Cherenkov radiation. This is the blue glow emitted from the water surrounding the core of an operating reactor. The requirements that the incident radiation be charged and exceed the speed of light in the medium limits application, in the context of radioactive decay, to high-energy β emitters (see ▶ Sect. 48.4.3).

■ Fig. 48.20

Response functions of two photocathode materials used in PMT construction (*left scale*) to spectral characteristics of four inorganic scintillators (*right scale*). See text for details (From Knoll 2000; used by permission of Wiley)

48.5.1 NaI(Tl)

For many years, a “3 × 3 NaI” detector was the standard for routine measurements of γ -active materials. The detector consisted of a cylindrical piece of thallium-activated NaI 7.6 cm (i.e., 3 in.) in diameter and 7.6 cm in height. The hygroscopic crystal was enclosed in an aluminum can (with a glass window on one end) to protect it from moisture. These crystals could be manufactured sufficiently reproducibly that efficiencies could be taken from tabulations. Another useful geometry was similar except for a coaxial well where small samples could be counted at nearly 100% detection efficiency.

All of the details involved in obtaining precision results from γ -ray spectroscopy with Ge detectors apply to NaI(Tl). In fact, the methods were developed with NaI(Tl) and later applied to Ge. NaI(Tl) is superior to Ge in effective atomic number (total energy absorption), operation at room temperature, and size (up to 25 cm linear dimensions for the scintillator). But the vastly superior resolution of Ge dominates all other characteristics for most users. At about 1,000 keV, the energy resolution of a Ge detector is about 1.5 keV, and that of NaI(Tl) is about 60 keV (Fig. 48.15).⁶ Whereas Ge spectra can be analyzed in terms of individual peaks and their areas, NaI(Tl) spectra are usually analyzed in terms of the overall, somewhat indistinct pattern each nuclide produces under the conditions of the measurement. When conditions change and effects such as summing and pileup change, the patterns change.

In spite of these shortcomings, a shielded NaI(Tl) detector, perhaps in a “well” geometry with several external counting positions, is a valuable tool for tracking laboratory processing of radioactive materials.

48.5.2 Plastics

Plastic scintillators can generally be used in any application for which a gas detector might be considered, except where physical damage to the plastic might occur. Plastic can be formed into more complex shapes than can gas chambers with collection electrodes, but shapes are limited by the need to collect the light at the photocathode of a photomultiplier. The material itself is relatively inexpensive, so it is attractive for large volume detectors. Many plastic scintillators emit light on a nanosecond time scale – much faster than most inorganic scintillators.

48.5.3 Liquid Scintillators

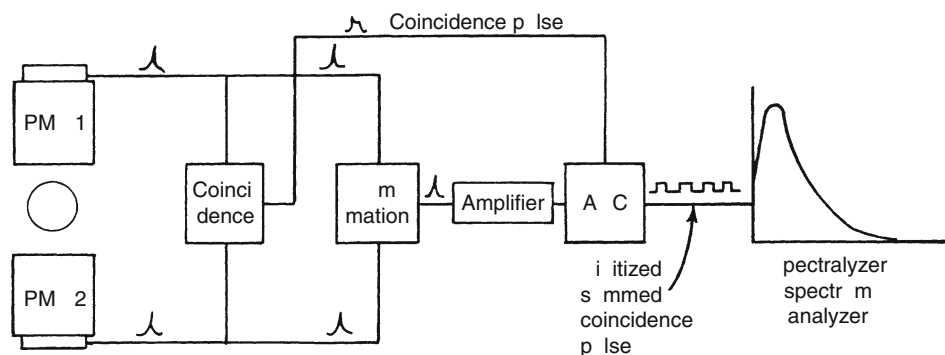

The largest use of radioactive materials is in the life sciences, and most of the nuclides used are pure β emitters. These nuclides include $12.3\text{ y }^3\text{H}$ (18.6 keV), $5,715\text{ y }^{14}\text{C}$ (156 keV), $14.3\text{ d }^{32}\text{P}$ (1,711 keV), $87.2\text{ d }^{35}\text{S}$ (167 keV), and $163\text{ d }^{45}\text{Ca}$ (257 keV; very weak 12.4 keV γ). Users generally are not interested in detectors per se; they just want to measure the amounts of these tracers, sometimes with more than one tracer used at a time. Manufacturers have met their needs with sophisticated systems and explicit protocols based on liquid scintillators into which the sample is dissolved.

► **Figure 48.21** shows the components of a *liquid scintillation spectrometer*. Two photomultipliers are used in coincidence to reduce the counts due to pmt noise. The noise from separate tubes is not correlated in time, but the light from a decay in the sample is. The energy corresponding to the triggers can be low, which reduces the loss of true events from low-energy decays. Once the coincidence condition has been met, the height of the sum of the two pulses is measured in an ADC. After the spectrum is stored, it can be analyzed and reanalyzed for the contributions from the nuclides present.

Light is produced, and sometimes quenched, by processes illustrated in ► **Fig. 48.22**. Since the sample is dissolved in the scintillator, there is no attenuation of the radiation on the way to the detector. Unfortunately, having the sample in the detector may interfere with scintillation. Most commercial systems can sense and correct for this quenching. Typically, a small pellet

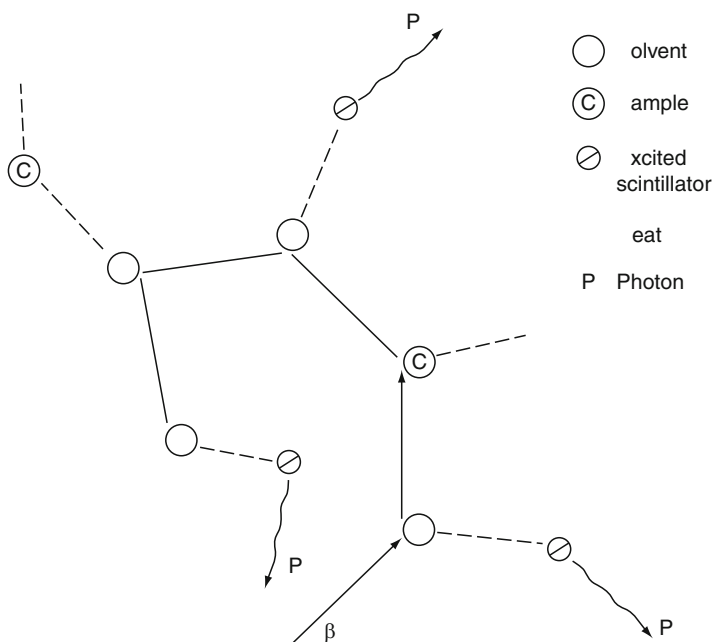

► **Fig. 48.21**

Components of a modern liquid scintillation spectrometer (From Kessler 1989; used by permission of Perkin Elmer)

■ Fig. 48.22

The scintillation process in an organic liquid scintillator (From Kessler 1989; used by permission of Perkin Elmer)

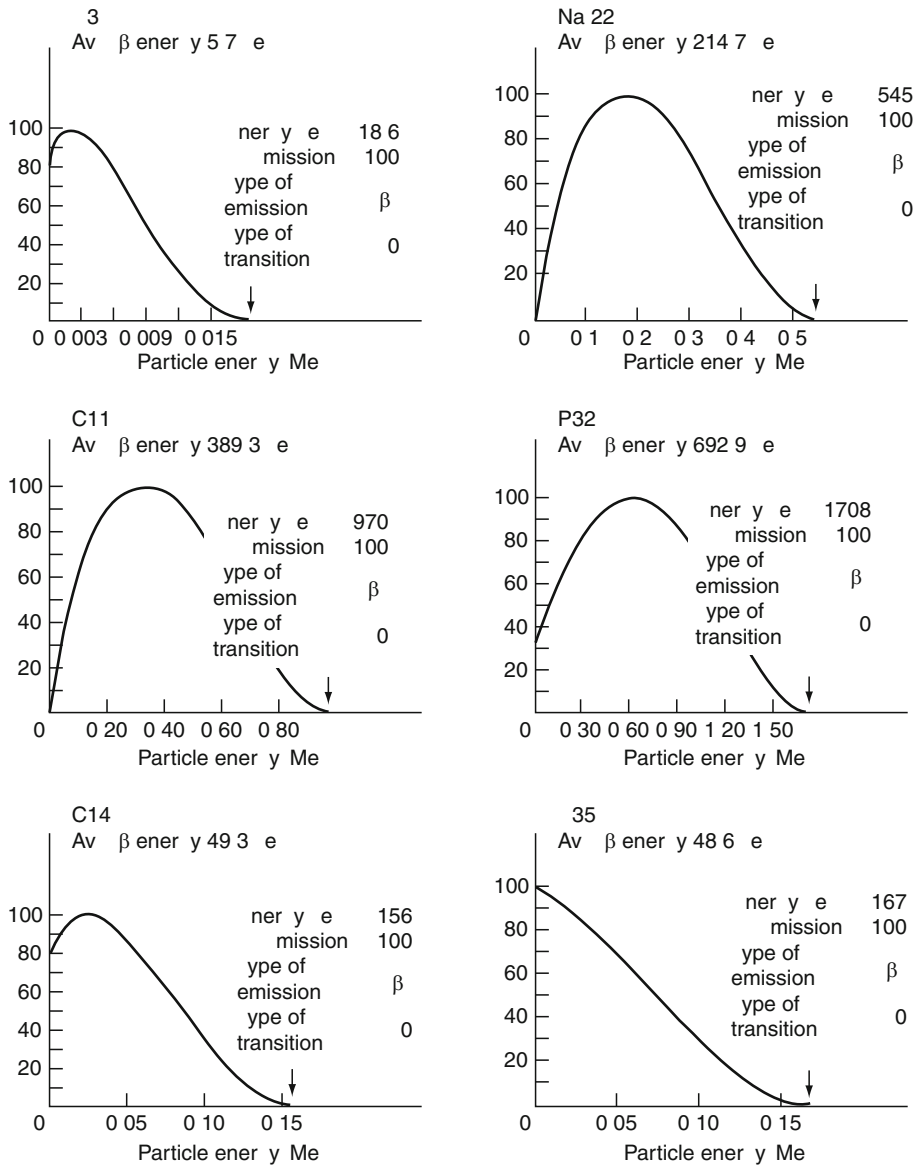

containing a γ emitter is pneumatically moved to the scintillation vial, and the shape of the Compton distribution is used to infer the degree of quenching. This information can be used to correct the energy scale and compensate for additional losses of low-energy events.

► Figure 48.23 shows the pulse height spectra for some commonly used tracers. The main features to note are the importance of very low pulse heights for tritium (^3H), and the smaller number of low pulse heights for positrons (e.g., ^{11}C) vs. negatrons (e.g., ^{14}C). This is explained by the simple fact that positrons (e^+) are accelerated as they leave the positive nucleus, the negatrons (e^-), on the other hand, are retarded. So, in the first case, the low-energy fraction decreases, while in the second it increases. The electrons emitted in β decay share energy with an unseen (anti)neutrino, which sometimes has almost all of the available energy.

Liquid scintillation is particularly attractive for α emitters if discrimination among nuclides is not required. The main advantage is avoiding the need to prepare thin sources or to correct for external absorption. The disadvantage is that only about 10% of the α energy is effective in producing scintillations. For typical systems not optimized for α detection, all α particles fall in a broad peak corresponding to about 500 keV electrons. ► Figure 48.24 show that if volumes are small, light collection is efficient, and quenching agents are avoided, modest α resolution can be obtained. Under these conditions, it is possible to use the shape of the scintillation pulse to distinguish α 's from electrons. Very low backgrounds for α counting can be obtained. Of course, if α decay leads to excited states which subsequently decay by internal conversion (electron emission), the resulting pulse is intermediate in shape. Pulse shape discrimination or α spectroscopy may not be applicable.

Fig. 48.23

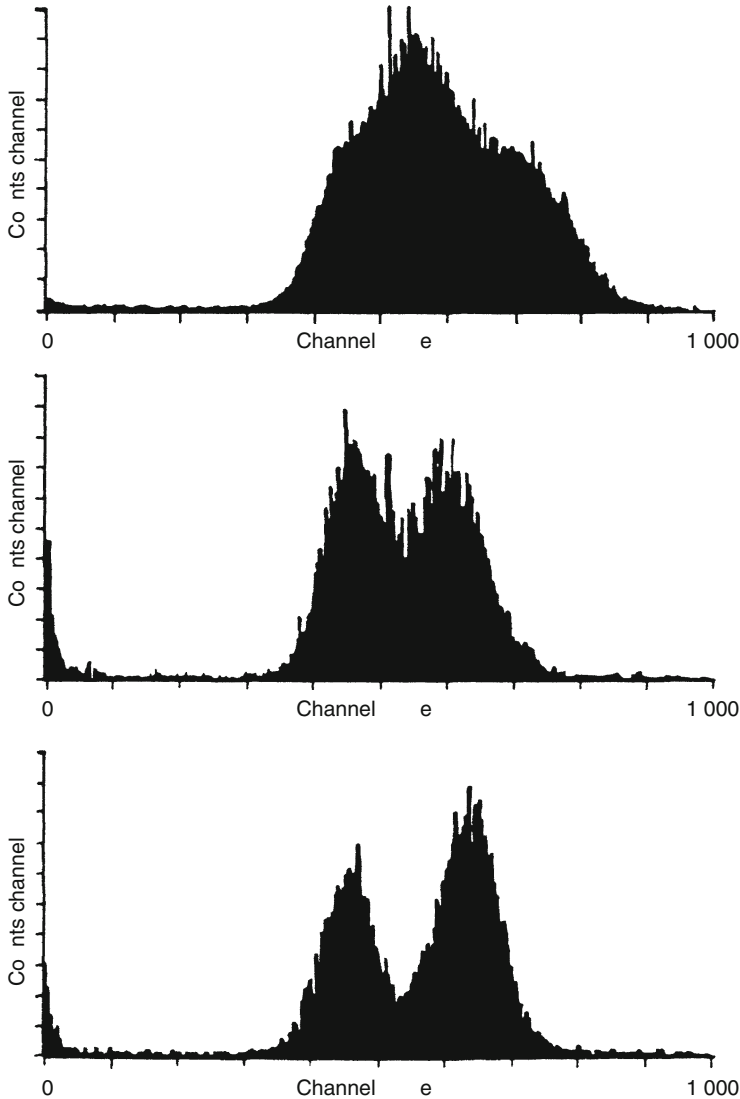

Spectra of typical β emitters (From Mantel 1972; reprinted with permission from Elsevier)

There are many choices among commercial scintillation fluids. Significant parameters include dissolving power (aqueous or organic), flammability, resistance to quenching, and environmental factors (“mixed” wastes containing hazardous chemicals and radioactivity are to be avoided). However, for detecting high-energy β decay by Cherenkov radiation (discussed together with transition radiation in [Sect. 8.3.6, Chap. 8, Vol. 1](#)), normal scintillation processes must be avoided. If water (index of refraction ~ 1.33) is used, Cherenkov radiation

■ Fig. 48.24

Spectra of α particles in liquid scintillators. Samples for the top two spectra contained ^{233}U (4.8 MeV) and ^{241}Am (5.5 MeV). A standard 20 mL vial was used for the top spectrum. A narrow tube, 6 mm in diameter, was used for the middle and bottom spectra. For the bottom spectrum ^{244}Cm (5.8 MeV) replaced ^{241}Am (From Kessler 1989; used by permission of Perkin Elmer)

will be emitted by electrons with speeds greater than $c/1.33$ where c denotes the speed of light in vacuum. This corresponds to energies greater than about 250 keV. These energetic decays can be detected in the presence of large amounts of low-energy β radiation. Note, however, that photons with energies greater than about 500 keV can produce Compton electrons above the Cherenkov threshold.

48.6 Neutrinos and Fission Fragments

Neutrinos are emitted in all β -decay processes and often carry away most of the decay energy. None of the detectors mentioned above is sensitive to neutrinos, which rarely interact with matter except by β interactions. For example, neutrinos (but *not* antineutrinos) with energies >0.82 MeV can react with ^{37}Cl to produce radioactive ^{37}Ar . The cross section is *very* small. In spite of the difficulty in detecting neutrinos, their spectroscopy is an active area of research.

Heavy ions, such as fission fragments, produce tracks of damage in absorbing materials. The damage makes the material more reactive chemically than it otherwise would be, and the tracks can be “developed” by suitable reagents. For example, glass containing damage tracks can be etched to reveal pits where the tracks reach the surface. When the etch conditions are carefully controlled and the absorbing material is uniform, the technique can reveal dE/dx along the path, hence the identity and energy of the particle causing the track⁷.

48.7 Composite Detectors

The possibility of constructing “composite” detectors which combine several individual detectors is open ended. Here, attention is limited to showing why combinations are desirable. In general, the motivation stems from the difference between analyzing small numbers of events directly as opposed to small differences in large numbers.

One of the earliest composites was designed to detect α particles in the presence of relatively large amounts of β and γ radiation. Two scintillators, the first thin and fast and the other thicker and slow, were mounted on a single phototube. Electronic filters were used to separate the fast and slow signals. Because of the short ranges of α particles, a fast signal without an appreciable slow component indicated an α particle, whereas a fast accompanied by a slow component indicated particles with longer ranges (electrons from Compton events, or β particles themselves). Note that the light emission from some scintillators includes more than one time constant and that different types of particles can give different ratios of these components. Similar circuitry (“pulse shape discrimination”) can be used to identify the particle type.

More commonly, the parts are operated separately and the signals are combined to achieve the desired results. For energies above a few 100 keV, relatively few γ -ray events in a Ge crystal lead to the full energy deposit that is required for the distinctive signal on which γ -ray spectroscopy is based. That loss of potential counts in the peak is not as serious as the production of counts at lower pulse heights where one might look for other signals. The height of the Compton continuum can be reduced significantly by nearly surrounding the Ge crystal with, for example, NaI(Tl) or BGO (see [Sect. 48.4](#)). The latter is quite compact and opaque to γ rays; the former is sensitive to low energies. If events in the Ge are accepted only if no photons are detected in the surrounding material, the Compton continuum can be suppressed by a factor of 5–10, except near the Compton edge, where the recoil photon exits along the same path the original photon entered to reach the Ge.

If the process to be studied involves the simultaneous emission of many γ rays (e.g., in-beam spectroscopy of high spin states), individual detectors should subtend small solid angles to avoid excessive coincidence summing. There is room for lots of these detectors, and some implementations include over a 100 Compton-suppressed Ge detectors in a geometry that approaches a “ball” of detectors (4π). Since thin plastic or silicon detectors for charged particles are relatively transparent to γ -rays, there can be a ball within a ball (8π), etc.

An extreme case for needing to select particular events to the exclusion of many others is the study of nuclides far from stability. Even with the availability of radioactive beams, nuclear reactions that lead to products at the extremes of stability have small probabilities compared to those that are more energetically favorable. A particular study might include several thin detectors to identify particles on an event-by-event basis (by dE/dx and time of flight) and track them along a beam.⁸ Individual particles might be caught in a detector with two-dimensional resolution; this detector could signal the arrival of a particle characterized by upstream detectors and its subsequent decay. That decay could be characterized by arrays of suitable detectors that surround the stopping point. And a needle could be found in the haystack.

48.8 Editors' Notes

1. See [Sect. 9.5.1.3 in Chap. 9 of Vol. 1](#) on Stochastics and Nuclear Measurements (p. 2266).
2. This means that the energies represented by them add up to the γ energy represented by the position of the full-energy peak along the horizontal pulse-height axis that is proportional to the energy absorbed. The reason is that the Compton edge represents the maximum of kinetic energy of an electron scattered in the crystal – see [Eq. 8.46 in Chap. 8, Vol. 1](#) – while the backscatter peak represents the minimum of energy of a γ photon scattered outside the crystal (p. 2272).
3. See the Appendix on the [Table of Nuclides in Vol. 2](#) (p. 2276).
4. The “multiplication” of a single photoelectron passing through a sequence of dynodes is represented by [Fig. 9.21 in Chap. 9, Vol. 1](#), as a stochastic process (p. 2278).
5. See [Sect. 49.3.2.2 in Chap. 49](#) of this volume for more details on TLDs (p. 2279).
6. In the case of soft γ radiation, one can make use of the fact that thinner scintillators have better resolution. [Figure 9.20, e.g., in Chap. 9, Vol. 1](#), shows the detector signal of a mere 0.1 mm thick NaI(Tl) scintillator at the 14.4 keV radiation produced by the first excited state of ^{57}Fe , the most common Mössbauer nuclide (p. 2280).
7. See the Bragg curve in [Fig. 8.5 and the related formulae in Chap. 8, Vol. 1](#), on the Interaction of Radiation with Matter (p. 2285).
8. See [Fig. 19.6 in Chap. 19, Vol. 2](#), on Production and Identification of Transactinide Elements (p. 2286).
