During glacial episodes mutually antagonistic and different processes affected the atmospheric levels of radiocarbon and carbon dioxide and these include reduction in radiocarbon atmosphere–ocean exchange caused by a lowered sea-level and increased ice cover, less downward advection due to a reduced rate of bottom water formation in the Atlantic and a concomitant reduction in the global rate of upwellings bringing less carbon-14-deficient water to the surface plus changes in the biological productivity of high-latitude surface waters. The first two of these considerations indicate a higher atmospheric carbon-14 level, but downward eddy diffusion transport of the radioisotope over the oceanic thermocline increases during glacial episodes because oceanic thermal gradients are less. Changes in atmospheric carbon dioxide content and $\Delta^{14}\text{C}$ are interrelated. A 100 ppm decrease in the former during the previous glacial would have caused a 2.5% increase in atmospheric $\Delta^{14}\text{C}$ if all other global reservoirs stayed constant. And this would suggest an estimated 7% reduction of $\delta^{14}\text{C}$ in deep oceans because of a 7% increase in inactive oceanic carbon-12 during glacial times. Such a change in carbon content would take place if the concept of phosphorus extraction on continental shelves is correct.

The missing carbon concept arose because radiocarbon-calibrated carbon cycle models predict that the quantity of carbon remaining in the atmosphere after fossil fuel release should exceed that suggested by the direct observation of rising concentrations of carbon dioxide. Three solutions have been proposed. One is that current ocean models cannot be adequately calibrated using radiocarbon. A second is that the biosphere currently acts as a sink for carbon. The third is that the biosphere has been a net source of carbon in the past.

16.5 O–H–C Isotopes in Trees and Seas

The early work of Emiliani (1955) reflected his belief that the isotopic record related to variations in sea surface temperatures, but it was later suggested that ice volume changes were more influential and the isotopic record actually records mainly the changes in continental volumes of ice (Shackleton 1967). Later work provided support from equatorial Pacific Ocean Core V28-238 (stated to have an accumulation rate of about 1.5 cm per 1,000 years). An original 16 isotopic stages were extended to 22 and similar isotopic fluctuations both for planktonic and benthic foraminifera were noted. If temperature had been the main factor controlling the isotopic values, the isotope record of the benthic forms should have showed low variability since bottom water temperatures are relatively stable. In fact, however, they showed great variability that might imply a significant contribution from changes in the water chemistry. Later, core work was extended back to the Plio-Pleistocene Boundary to provide a complete record of Quaternary climatic changes. Also, the Brunhes/Matuyama Boundary and the Jaramillo and Olduvai events were recognized. From these data, an average rate of accumulation of 1 cm per 1,000 years was inferred. However, the Brunhes Chron showed steadier accumulation rates, these being sufficiently reliable for it to be taken as the Later Pleistocene stratotype.

The above-mentioned researches demonstrate that Urey's confident assertions have been realized, albeit in a slightly different form as regards glacial episodes in the history of the Earth. Oxygen isotope ratios can be interpreted in terms of the changing chemistry of both oceans and atmosphere in accordance with the growth and decline of the polar and subpolar ice sheets.

Actually, they provide the standard stratigraphic framework into which Pleistocene climatic events can be placed. In this respect, radiometric dating has been invaluable in establishing an absolute stratigraphy for the past 800,000 years. A model was developed in which the isotope is envisaged as a response of a single exponential system induced by variations in obliquity and precession of the orbit of the Earth (Imbrie et al. 1984).

Stable isotope investigations were made on plants and tree-rings. Variations in the widths of annual growth rings in many temperate and subpolar tree species are valuable proxy indicators of past climatic fluctuations and led to the science of dendrology. Progress has led to the creation of a parallel research field, that of dendroclimatology.

Apropos tree-ring isotope chemistry, the important isotopes are oxygen-16, 17, and 18; hydrogen-1 and 2 (deuterium); and carbon-12, 13, and 14 (radiocarbon). Again it was Urey who first suggested in 1947 that the carbon-13 content of plant material might be related to temperature and subsequently, it was shown that the $^{13}\text{C}/^{12}\text{C}$ ratio of atmospheric carbon dioxide is a function of temperature-dependent exchange reactions with the oceans (Craig 1954). It is interesting that oak $\delta^{13}\text{C}$ values were proposed as potential paleo-rain gauges and paleo-thermometers (Tans, Unpublished Dissertation).

16.6 Orbital Frequency Rhythms in the ^{18}O Records

The oceanic core isotope record can be fitted to a timescale of planetary orbital changes so as to construct an accurate chronology of first-order climatic variations over the past hundred million years that confirmed the significance of orbital-frequency rhythms in this record and made small, but crucial, adjustments in the timescale of the last 400,000 years (Hayes et al. 1976). The consequent power spectrum of the $\delta^{18}\text{O}$ signal indicated a dominance of 100,000-year power with lesser 41,000- and 23,000-year responses. Also, it has been observed that the $\delta^{18}\text{O}$ signal from the high-latitude planktonic species *Globigerina bulloides* resembles other signals of this type known to be subject to the effects of ice volume. Probably this species changed its season and/or depth of occurrence chronologically so as to observe a narrow temperature regime despite localized climatic changes (► Fig. 16.3).

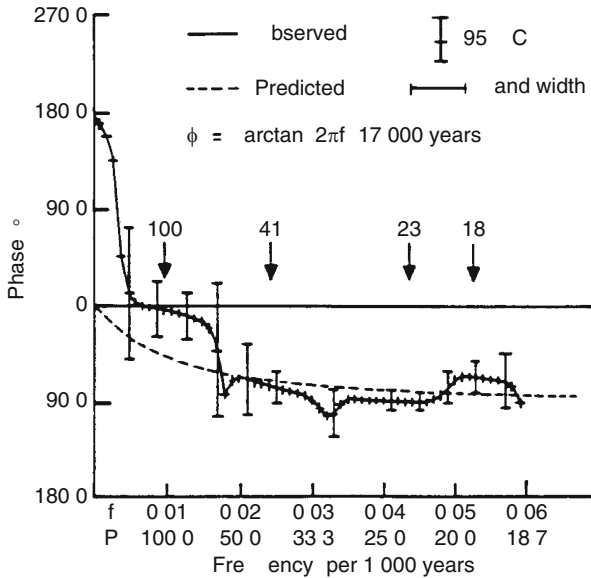

16.6.1 Modeling Pleistocene Climatic Response

This takes into account the hypotheses of Milankovitch and J. Croll requiring that the Earth's climate must respond to orbital forcing (Imbrie 1985). Suitable models include spectral and cross-spectral, gain-and-phase, and dynamic, but cannot be discussed here. However, the first involved four of the main Milankovitch frequencies, i.e., at 100,000, 41,000, 23,000, and 19,000 years, the second including two attempts. One aimed at simulating the entire 782,000-year record, again using the Milankovitch four, which are 100,000 = eccentricity, 41,000 = obliquity, 23,000 and 19,000 = precessional factors (► Fig. 16.4).

A second treated younger and older data separately with the boundary between the two placed at 400,000 years B.P. Dynamic models are useful in showing how strong or weak a response is elicited by any given forcing function. Variations in climate in other frequency bands have also been considered. Over the decadal band, there is evidence to show that Alpine glaciers altered greatly in size through periodic volcanic explosions and solar activity and lunisolar tides affected regional patterns of precipitation and temperature. On the millennial

■ Fig. 16.3

Theoretical and observed phase spectra relating $\delta^{18}\text{O}$ and orbital variation over the past 782,000 years. The *dashed line* represents the predicted phase response of a single-exponential system with a time constant of 17,000 years (From Imbrie et al. 1984)

■ Fig. 16.4

This is a model of $\delta^{18}\text{O}$ variation over the past 782,000 years. The model curve is the sum of four components, each being an orbital curve multiplied by an appropriate gain and shifted by an appropriate phase. The difference from others is due to the incorporation of these frequency components, namely the 100,000 year one of eccentricity, the obliquity signal (variance concentrated near to 41,000 years) and the 23,000 and 19,000 year components of precession. The result is the model that has a correlation of 0.71 with the data and a pattern of residuals in time (not included) suggesting a change in the response characteristics of the system about 400,000 years ago. A spectrum of these residuals indicates model failures near 59,000 years and at periods rather longer than 100,000 years (From Imbrie et al. 1985)

band, mountain glaciers probably expanded and contracted during the Holocene and the periphery of the Laurentide ice sheet must have fluctuated during the late Pleistocene. Indeed, orbital variations may well have initiated Pleistocene ice episodes. They were pre-Pleistocene glacial episodes also, for instance in the Middle Oligocene about 30 million years ago when small glaciers were widespread in Antarctica and at the end of the Eocene about 38 million years ago. These events constitute the Late Cenozoic Glacial Age commencing about 10 million years ago and culminating in the Pliocene. A similar extensive event, the Permo-Carboniferous Glaciation, occurred about 300 million years ago and there were even earlier ones, for instance during the Late Devonian to Late Permian and glacial deposits have been found in Africa near the Ordovician/Silurian Boundary. This probably indicates a glaciation and it is interesting that glaciations appear to have been more the norm than the exception in the Paleozoic and may even have synchronized with relatively “warm” oceans. Over 700 million years ago, early in the Precambrian, glaciations lasting from 10 to 20 million years took place in the Early and Late Proterozoic and could have coexisted with “hot” ($>60^{\circ}\text{C}$) oceans. Modeling arrays, transformations, multivariate procedures, and climate forcing are all entailed regarding the reconstruction of past climates as a multivariate function of time and space, relating them to frequency domains (Imbrie 1985). Some remarks on using multivariate statistical methods on biological and geological information as well as transfer functions were made above in ▶ Sect. 16.3.2. Transforming and condensing numerous observations into estimates of small sets of climatic indices are not just paleoclimatologically exclusive but also applicable to modern climatology, oceanography, and meteorology. This has been done in an attempt to understand the climatic anomalies known as ENSO (see ▶ Sect. 16.4 above). The relevant transformations comprised conversions of sets of observations about climate at a particular time and in a particular place into a smaller number of informational indices such as assessments of salinity or air-mass frequency.

16.6.2 Simulating the Ice Age

Several models have been presented. All have to recognize the complicated interrelationships and interactions of the many terrestrial components such as the atmosphere, the cryosphere, the oceans, and land. Simpler ones can be used to compute the spatial distribution at equilibrium of any one key climatic parameter, e.g., temperature as a function of latitude. Such models facilitate understanding changes in gross climatic conditions occurring when the near equilibrium between energy gain and loss of the relevant climatic system is changed to another equilibrium state. More elegant models reflect the development of general circulation models (GCMs) that can be used not merely to simulate ice age conditions, but also to predict future developments of terrestrial climates, e.g., how continued rise in the carbon dioxide levels in the atmosphere are likely to change it. Of course, all models are simplifications of the real world because the complex processes of the existing climatic system are far from being fully understood. The results of using GCMs to simulate February and August paleoclimates for 18,000 years B.P. on the basis of CLIMAP data utilized at the National Center of Atmospheric Research, the Geophysical Fluid Dynamics Laboratory, and Oregon State University have been described (Heath 1979). Later, final CLIMAP data were used in conjunction with a new simulation. Ice age conditions used were a sea-level drop of 150 m and a drop in the carbon dioxide content of the atmosphere from 320 to 220 ppm. The carbon dioxide decline was based on observations of levels for this gas assessed from ice cores (Neftel et al. 1982).

The ice simulation showed both in February and August a zonally averaged cooling of the surface air temperatures at all latitudes with a maximum effect at about 10°N. Averaged cooling was approximately 3.4°C globally and, in tropical regions, the average temperature change was about 2°C. Rates of precipitation during the ice age altered at most latitudes from 3% in February to 9% in August and there was a narrowing of the subtropical dry zone near 14°N accompanied by a southward displacement of the zonally averaged midlatitude precipitation maximum from 34°N to 26°N. All this revealed the ice age as cooler and dryer over much of the Earth. Earlier in the history of the Earth, plate tectonics provide a unified model that can explain such variations over the past several hundreds of millions of years at least. It is clear that plate tectonic movements produced alterations in the distribution of land and seas together with changes in the relative percentages of each. These profoundly affected past climates. A zonally averaged energy-balanced model (EBM) was used to examine possible mechanisms determining the warm equable climate of the Middle Cretaceous 100 million years ago (Thompson and Schneider 1981; Barron et al. 1979). The implication is that such geographical changes were highly significant. However, it must be remembered that **EBMs** are usually one-dimensional and employ only simplified relationships. But, *faute de mieux*, they are widely used (Crowley and North 1985). The atmosphere/ocean/cryosphere system now has been discussed, particularly as regards its significance in controlling simulations of the climate under altered external forcing systems. An optimal approach entails formulation of a Newtonian mechanics problem for geophysical fluids and integration of the system of differential equations forward in time to be followed by assembling of statistics. The technique is feasible because of the availability of the digital computer and the installation of a global network of observational stations originated by the **IAEA** and World Meteorological Organization (**WMO**) termed the **Global Network for Isotopes in Precipitation** (GNIP) that can initialize the problem and verify the numerical solutions. Over 30 years' experience with **GCMs** of the global atmosphere showed their value in weather prediction and such huge numerical models could be valuable in generating climatic experiments. The output ought to include a complete description of the present model climate, but the problem is more complex because the equations are nonlinear and their interrelationships are so very complicated that they become mathematically unstable. Hence, small errors amplify with integration to cause a degradational effect in effective determinations that may explain why meteorologists cannot provide good weather forecasts 2 weeks ahead. Obviously, there is still a very long way to go in modeling Pleistocene and earlier climatic changes with large scale models.

16.6.3 Pleistocene/Holocene Climatic Changes

The last ice age caused reductions in the diversity of terrestrial vertebrate faunas in most continents and many islands at the end of the Pleistocene and the start of the Holocene. Such extinctions were not random because species of large body size were more severely affected than those with body masses under 25–50 kg. Human predation played a part as well. However, if environmental fluctuations are offered in order to explain Late Pleistocene extinctions, why did similar ones not occur during previous glacial/interglacial cycles of which there have been a minimum of 22 during the past 870,000 years? The unsolved question is whether the Pleistocene/Holocene change was triggered by some factor or factors which were fundamentally different from other environmental fluctuations and if so what were they.

Similar extinctions took place on a much larger scale at the end of the Cretaceous about 66.5 million years ago when dinosaurs, ammonites, and many other plant and animal groups declined and often disappeared. This is evidenced by the accumulation of deposits containing anomalous iridium accumulations of up to 160 times the background level. A similar iridium anomaly was recorded in the Lower to Middle Jurassic of the Venetian area of northern Italy. These earlier extinction episodes cannot be related to human hunters, but rather to astronomical and other forcing factors. Ice ages must have been important also and they too were influenced by these same factors.

Some ambiguity has arisen. Recent US Geological Survey work at Devil's Hole, Nevada, at a site where water flowing in from a large catchment area, deposited a calcite vein over the last 250,000 years. Calculation of ages was effected layer by layer by measuring $^{230}\text{Th}/^{234}\text{U}$ or $^{234}\text{U}/^{238}\text{U}$ ratios, and the oxygen isotope record was also examined. Results from both approaches did not accord with those from deep-sea cores and air bubbles trapped in ice sheets, although a similar pattern was apparent. It was inferred that the previous interglacial episode may have started as long ago as 163,000 years B.P., although conventional techniques put it at its warmest about 122,000 years ago. This agrees with changes in the angle of obliquity of the Earth and its precession implying that, in the northern hemisphere, summers were especially warm about 125,000 years B.P. Despite this seeming disparity between the Milankovitch model and these data, the latter do not undermine the former. In fact, the model is claimed as inadequate to account for the timing of several major paleoclimatic events that occurred during the time interval from 100,000 to 300,000 years ago. Additionally, there are $\delta^{18}\text{O}$ records from deep-sea sediments (Core CH73-1390 from the Rockall Plateau, northeast Atlantic Ocean) showing relatively slow glacial buildup, the end of the ice age occurring rapidly in about 10,000 years.

16.7 Quantifying Isotopic Chronostratigraphy

The method has been used in the Gulf of Mexico and improved stratigraphic resolution across a basin in an effort to improve hydrocarbon prediction (Williams and Trainor 1986). It was extended globally and each isotope record was regarded as a time series, common analyses being used to develop criteria about the identification of common events in records and how accurately these can be recognized and interpreted (McKenna et al. 1988). The limiting factors include insufficient knowledge on the paleo-evolutionary behavior of foraminifera, inadequate data on oceans, not enough information on isotope processes with time, nonlinearity in the atmosphere/ocean climate system and diagenetic effects. These combine to cause a “noise” effect in every record, that is to say they introduce a factor with no discernible relationship to any geological process of interest. Sampling is another problem because this may be carried out at a set of discrete times over a finite geological interval and may be fine in depth at some point in time and coarser at another. Established methods based on information theory were used for the signal processing strategy. Initial quantitative analysis of Plio-Pleistocene $\delta^{18}\text{O}$ records necessitated using interpolative filters, semblance and coherence analyses, autocorrelation and cross-correlation, and non-minimization filters. Two sections were involved. One was a formulation of a $\delta^{18}\text{O}$ -type record for the Plio-Pleistocene and the second compared this with other $\delta^{18}\text{O}$ records for the same time range. In the first, a high-quality $\delta^{18}\text{O}$ record from **DSDP** piston-core V-28-239 was transformed into the TYPE record that had a lower noise level than the original. In the second, the TYPE record was compared with $\delta^{18}\text{O}$ records from **DSDP** sites 502B, 504, and 522A. Because much of the isotope signal represents global isotopic

changes in ocean chemistry induced by the volume of Pleistocene ice sheets in the northern hemisphere, a common global signal in the Plio-Pleistocene $\delta^{18}\text{O}$ must exist. If such a global signal is subtracted from an individual record, what remains must reflect other constituents in the $\delta^{18}\text{O}$ signal, e.g., temperature, melt-water impulses, the disturbance of sediments, etc. A common signal is recorded in the behavior of similar record types at different locations as the latter merge so that the record types reflect a degree of coherence. Coherent events are spread through some time range.

Here the concept of semblance can be introduced. This is derived from geophysics and functions to provide a more meaningful measure of coherent signals. Semblance can detect small timescale correlations (high semblance) over a few datum points in each record when a small window is used and long-term correlatable trends when a large window is used. On the other hand, uncorrelated or anti-correlated events appear as low semblance areas and the range and/or strength of a correlated or uncorrelated event is determinable by high- or low-semblance contours closing as the window width increases around a given time.

A **TYPE** record can be made for the Pleistocene $\delta^{18}\text{O}$ signal with time and can be used as a template against which other Plio-Pleistocene isotope records can be compared. To select a **TYPE** record entails meeting certain requirements. One is a relatively fine, continuously sampled record with depth and a second is a rate of sediment accumulation that preserves isotopic shifts at specific times in preference to small thicknesses of sediment covering large time spans. Thirdly, a relative abundance of biostratigraphic and paleomagnetic time horizons should be included. Lastly, the core sample should have simple structure and stratigraphy. Piston core V28-239 from an open ocean area fulfills all these desiderata relative to most other Pleistocene records and so it was selected as the initial **TYPE** section. The $\delta^{18}\text{O}$ record from another sample, core 522A, came from benthic foraminifera, data from other sites from planktonic ones. No attempt was made to normalize the benthic information to the planktonic data due to $\delta^{18}\text{O}$ -temperature fractionation. The $\delta^{18}\text{O}$ depth record of V-28-239 was converted to time using suitable time horizons and assuming constant rates of sedimentation between the “known” time horizons. The so-constructed time record was sampled at 5,000-year intervals to produce a $\delta^{18}\text{O}$ time series with a time range of 5,000–1,870,000 years. This $\delta^{18}\text{O}$ record contains the basic input data for ensuing analyses. It showed a marked break at about 930,000 years, the younger part comprising broad peaks and troughs and the older part narrower ones. The top of the record (5,000–935,000 years) was designated V28-239T and the bottom part (940,000–1,870,000 years) was designated V28-239B. Application of a Wiener filter revealed increased high-frequency structures and the Fourier transformation of the two pre- and post-Wiener filter sets from the time to the frequency domain enabled determination of the power at discrete frequencies in the records from power spectra to be made. There are 94 harmonics in them with harmonic spacing equal to $1/T$, where T is the total length of the record (930,000 years). The zeroth was suppressed so as to obtain scaling clarity and some dominant peaks were labeled in thousands of years. There was a roughly constant low power above harmonic 44, this being the “noise” power extracted by the Wiener filter. Noise is defined as all frequency components above harmonic 44 (period of 21,000 years). This destroys a component of the precession signal interpreted by some, but provides objective data analysis. Removing “noise” from raw data showed that most of the basic characteristics in the input record were preserved and exactly the same procedure was applied to the older part of the Plio-Pleistocene record. In this way, it was possible to create a noise-free $\delta^{18}\text{O}$ record with time from 5,000 to 1,870,000 years together with a reconstructed record designated **TYPE** used for the rest of the analyses.

A common periodic signal of $95,000 \pm 30,000$ years in **TYPE**, 502B, 552A, and 504 was identified, this being close to that derived from the orbital eccentricity parameter by Milankovitch in 1930 and also by others (Berger 1976; Kominz et al. 1979). In addition, this periodicity was reflected in power spectra, cross-spectra versus **TYPE** and spectral coherency versus **TYPE** within resolution limits. Other global periodicities of about 1,355,000, 41,000 \pm 2,000, and 24,000 \pm 3,000 years were noted in the average (global) spectral coherency. The relevant work introduced a new dimension into both correlative and interpretive researches into isotope records.

16.8 Time's Arrow Reversed: Pliocene Paleoclimates

The Pliocene embraced a thermal optimum, which, through a new technique termed climostratigraphy that includes micropaleontological, isotopic, “radiological,” and paleomagnetic data, facilitated subdividing the Epoch, identifying datum planes and global paleoclimatic events (climathems). An accuracy of 50,000–100,000 years has been claimed and such events grouped into superclimathems (SCTs) and hyperclimathems (HCTs), the first containing 100,000–300,000-year episodes and the second longer time intervals of which 30 were diagnosed between 7.3 and 1.2 million years ago. Through this latter (which extends into the Late Miocene), both types were observed, for instance the Messinian salinity crisis correlated with the seventh hyperclimathem and a warm, dry time interval in the Mediterranean and seven climathems in the Black Sea. SCTs were numbered from the present to the past, the first spanning Stages 1–7 of the deep-sea cores scale, the second Stages 8–10, the third Stages 16–20, and the fifth Stages 21–25. The sixth is the Late Cenozoic climate boundary connected with the first continental ice sheet glaciation in Europe, the maximum glaciation in North America and in Patagonia (Zubakov and Borsenkova 1988). It really marked the onset of the Pleistocene. SCTs and HCTs probably relate to variations in orbital parameters, mostly in the eccentricity. The so-called Climatic Optimum of the Pliocene occurred between 4.4 and 3.3 million years ago, and during it the atmosphere may have contained about twice as much carbon dioxide as now. This may be an analog of anticipated climatic conditions in the middle of the twenty-first century if the supposed and probably actual greenhouse conditions continue that long.

A curve has been postulated describing variations in the strontium isotope composition of seawater in the Late Neogene 9–2 million years ago, these based on $^{87}\text{Sr}/^{86}\text{Sr}$ analyses of marine carbonate at the five DSDP sites 502, 519, 588, 590, and 593 (Hodell et al. 1989). The strontium isotope contents of the oceans rose during the time interval, but from 9 to 5.5 million years ago these ratios were practically constant at about 0.708925. Between 5.5 and 4.5 million years ago, they increased monotonically at a rate of about 1×10^{-4} per million years. The steep slope then could serve to facilitate high-resolution strontium isotope stratigraphy across the Miocene/Pliocene Boundary. The rate of change in the isotope ratios decreased almost to zero again during the time interval 4.5 to 2.5 million years ago and ratios averaged 0.709025. The relatively rapid increase between 5.5 and 4.5 million years ago could be connected with changes in flux of average $^{87}\text{Sr}/^{86}\text{Sr}$ ratios of the major inputs of strontium to the oceans. Quantitative modeling of these inputs implies that the increase may have been caused by an increase in the dissolved riverine flux of strontium into the oceans or an increase in the average $^{87}\text{Sr}/^{86}\text{Sr}$ composition of the river water or maybe by a combination of both of these factors. On the other hand, the 5.5–4.5-million-years age period can be modeled as a simple transition from one steady state to another if the oceanic residence time of strontium was eight times less than

the currently accepted value of 4 million years. During the time interval when the strontium isotope ratios steeply increased, sediment accumulation rates may have risen too and there might have been a drop in the calcite compensation depth (CCD) together with a decrease in the $\delta^{13}\text{C}$ of dissolved bicarbonate. Hodell and his coworkers thought that the simplest mechanism to explain all this would have been an increase in chemical fluxes carried by rivers to the oceans, reflecting increased chemical denudation of continents and shelves in the Late Neogene. Increased chemical weathering rates could be due to increased exposure of continents and shelves as a result of eustatic regression accompanied by intensified glacial/interglacial cycles and accelerated rates of global tectonism during the latest Miocene. Today the intra-continental shields of North America, Eurasia, and Antarctica mostly comprise Precambrian basement with high $^{87}\text{Sr}/^{86}\text{Sr}$ ratios. For the latest Miocene, evidence exists implying a cooling episode and pulsed ice sheet expansion with oxygen isotope records suggesting a magnitude for glacial/interglacial episodes of about one third of the ice volume changes of the late Pleistocene.

16.8.1 Middle Tertiary Paleoceanographic Changes

The analyses of Oligocene and Miocene planktonic and benthonic foraminifera and calcareous nannofossils (unicellular algae) from DSDP Site 354 in the equatorial Atlantic led to the taking of the isotopic composition of *Cibicidoides pseudoungerianus* as representative of bottom water changes, the $\delta^{18}\text{O}$ deviating in isotopic composition about 0.4‰ from that of *Uvigerina* (Biolzi 1983). In the older part of the section analyzed, the isotopic composition remained constant at about +1.6‰, but toward the top of the Oligocene two minor fluctuations in $\delta^{18}\text{O}$ values occurred and were followed by a positive shift reaching a maximum of +2‰. Until the end of the Early Miocene, the oxygen-18 values for *Cibicidoides* ranged between +1.6‰ and +1.7‰. Then came a hiatus, but succeeding that was an increase of 0.5‰ to reach +2‰. The genus was benthic and so to estimate pelagic water conditions, planktonic foraminifera were used. These showed a general trend toward higher $\delta^{18}\text{O}$ values and *Globigerina venezuelana* was selected as a reference for these conditions from the Oligocene into the Miocene. Its oxygen isotope composition increased from about -1.5‰ in the Middle Oligocene to about +0.5‰ in the Middle Miocene. If this represents temperature changes, then there must have been a marked cooling in the Middle Oligocene about 30 million years ago. There is supportive evidence of small glaciers at that time. The associated ice age culminated in the Pliocene after the Middle Miocene accumulation of the Antarctic ice sheet. Further confirmation of this pre-Pleistocene ice age came from the deuterium contents of interstitial waters of cores as part of the **Joint Oceanographic Institutions Deep Earth Sampling (JOIDES)** work. It was estimated that allowing for diffusion effects, there was an increase of 10‰ in δD (corresponding to a $\delta^{18}\text{O}$ change of about 1.2‰) between the Early and Late Miocene. A similar analysis of Pleistocene to Holocene changes showed a δD increase of 8‰ during the time of maximum continental ice (corresponding to a $\delta^{18}\text{O}$ increase of about 1‰). It was thought that there was no change in the parameter from the Cretaceous to the Tertiary.

16.8.2 The Eocene Ocean

In the Early Tertiary, the Earth experienced rather warm conditions as shown by benthic foraminifera from deep-sea sediments. With planktonic ones, there is the problem that it is very difficult to be sure whether the species in question actually lived at the sea surface and so

would have recorded the relevant temperature. Analyses of foraminiferal species from the Paleocene were affected and results from the ones consistently registering higher temperatures, i.e., with the isotopically lightest oxygen isotope composition, used. This was justified by reference to the carbon isotope composition (Shackleton and Boersma 1981).

The important vertical carbon isotope gradient in the upper part of the ocean water column results from the photosynthetic removal of isotopically light carbon from the dissolved inorganic carbon in the photic zone. The return of this carbon to the oceanic carbon reservoir occurs in deep water. The difference between the carbon-13 content of surface and deep water is about 2‰ and parallels that between *Globigerinoides sacculifera* and species of *Uvigerina*. However, a much greater difference was observed (sometimes as much as 4‰) between planktonic and benthonic species in the Late Paleocene and through much of the Eocene from carbon and oxygen isotope variations in at **DSDP** Site 384. While not all samples were synchronous, they were plotted on a global reconstruction representing 50 million years ago at those localities where it was thought they occurred. Paleolatitudes were similarly estimated. Temperatures were calculated on the basis of an oceanic isotopic composition of -1.2‰ versus PDB (which refers to the time interval prior to the Middle Miocene accumulation of the Antarctic ice sheet). Some interesting conclusions were drawn. The overall range of surface water temperatures turned out to be lower than is the case now. This compares favorably with previous deep sediment work, but not with the anomalously high apparent temperature derived from the isotopic analyses of mollusks in the North Sea Basin (Burchardt 1978). This may have been the result of localized and salinity-related isotopic anomalies or represent diagenetic changes. In the North Atlantic and, to a lesser extent, the South Atlantic also, there appeared to have been strong Western Boundary currents and the east–west temperature gradient across the latter has been reported consistently. However, in the North Atlantic, there has been found an anomalous temperature estimate in its north-eastern part (Vergnaud-Grazzini et al. 1978). If the surface- and deep-water temperatures estimated for each sample are plotted as a function of paleolatitude and compared with the average temperature distribution in existing oceans as a function of latitude, it is clear that more measurements are necessary before an accurate estimate of the global average surface temperature can be made. However, if the available data are considered, they are adequate for averaging over 10° bands of paleolatitudes and an average temperature of 18°C weighted according to area has been proposed. This compares with about 16°C in the oceans today. Therefore, on the scale of global average, the difference between then and now is about 2°C despite the tremendous changes that occurred in some regions, e.g., tropical vegetation grew in the Early Eocene where London is now. By the end of the epoch, sea ice probably formed around Antarctica. In this regard, it is interesting that the difference between the last glacial and now was also of the order of 2°C when averaged. To a first approximation, the latitudinal temperature gradient in the last glacial was similar to the present one, so heat transport mechanisms must have operated in the same way as now. But the latitudinal temperature gradient of the Eocene Ocean was less than half of its present value, thus the transportation of solar energy from high to low attitudes must have proceeded differently. Maybe much of this was through the oceans because of the inability of the atmosphere to transport heat through the reduced temperature gradient. But the way in which heat could have been transported effectively when temperature gradients were as low as they were during the Eocene remains unclear.

A major climatic event occurred near the end of the Eocene, namely the development of the psychrosphere, the deep and very cold waters of the world ocean. This was first detected at the Eocene/Oligocene Boundary as a major reorganization of deep water ostracodan faunas. Also,

oxygen isotope measurements demonstrated a dramatic drop of almost 5°C during the Late Eocene (foraminiferal Zones P15 to P16) in the Atlantic. A similar phenomenon was recorded in the equatorial Pacific. Also, there was a parallel decrease in bottom water temperatures found in samples from the earliest Oligocene of the Campbell Plateau south of New Zealand. All may signal the start of Antarctic bottom water formation at near-freezing temperatures. Stratigraphic problems arising from the time-regressive nature of stratigraphic zones between temperate and tropical regions have been invoked to explain the appearance of cold water in the south-western Pacific, but there is a possibility that the time lag is real.

16.8.3 Oxygen and Carbon Isotopic Variations in Foraminifera Across the Cretaceous/Tertiary (K/T) Boundary

Species of *Rugoglobigerina* or *Pseudoguembelina* were used for the Maastrichtian and species of *Guembelitra*, *Acarinina*, and *Morozovella* for the Paleocene as having lived nearest to the ocean surface (Boersma 1970). Then the situation was unusual because of the apparent dominance of heterohelids in the surface zone. Several species showed anomalously negative carbon isotope values. However, during the Paleocene, the heterohelids adopted deep-dwelling habits and other surface-dwelling species gave more positive carbon isotope values. As regards surface water carbon isotope values, problems exist apropos interpreting them in the *Globigerina eugubina* Zone and early Zone P1 since the planktonic foraminiferal species, which registered the warmest temperatures consistently gave more negative carbon values than cooler living species. It appears that through most of the Tertiary and in recent times also many of the warmest living species record more positive carbon isotope values while deeper (i.e., cooler water) dwellers have more negative (i.e., isotopically lighter) carbon isotope ratios. The carbon isotope difference recorded between recent *Globigerinoides sacculifera* and the average recent benthic foraminifera is roughly equal to the recorded gradient in the water column. There is as yet no satisfactory explanation for these anomalous carbon isotope profiles in the Early Paleocene. Boersma selected the highest carbon values in samples from this time interval, although the surface carbon isotope values are sufficiently alike to be treated together. Those from the latest Campanian Age through the Early and Middle Maastrichtian Age cluster around +2‰, the values rising through the Late Maastrichtian to reach +2.3–2.6‰ in the *Abathomphalus mayaroensis* Zone just below the Cretaceous/Tertiary Boundary. Across this boundary, there was a significant excursion everywhere, carbon isotope ratios becoming more negative by 1–1.5‰ in the earliest *Globigerina eugubina* Zone. Measurement of bulk carbonates gave values at Sites 384 and 152 that showed similar drops across the boundary. In sum, it can be inferred that a temperature drop of 5–6°C took place from the Late Cretaceous to the Early Tertiary.

16.8.4 Isotopes and Mass Extinctions

As well as around the K/T Boundary, there were earlier ones, for instance at the Permian/Triassic (P/T) Boundary about 248 million years ago. When the former took place, there may have been an alteration in sea-floor spreading rates and a drop in the carbonate compensation depth (CCD) in the Atlantic, succeeded by a rise. Another such drop occurred in the Early Tertiary and may have been the result of a supernova. Four episodes were recognized in the

evolution of the stable isotope and carbonate records across the K/T Boundary and in the Early Paleocene at **DSDP** Site 577 (Zachos et al. 1989).

Event I at 66.5 million years ago preceded the boundary and showed an enrichment in planktonic and benthonic microfossil carbon records together with a decrease in the barium accumulation rate. The $\delta^{13}\text{C}$ rise may reflect a change in that of the oceanic total dissolved carbonate reservoir caused by increased organic carbon burial on continental margins (or decreased carbon fluxes from weathering) triggered by the latest Cretaceous transgression commencing 66.5 Ma ago.

Event II was the main plankton extinction and productivity crisis connected to the rapid collapse of the surface-to-deep water carbon isotope gradient and drops in barium and carbonate accumulation rates. Curiously, there was a hundredfold increase in the concentration of foraminifera relative to total carbonate. It could be due to intensified deep circulation with winnowing of the fine fraction. Or possibly to better the preservation of the dissolution-prone planktonic forms through deepening of the **CCD** and/or lowered rates of in situ dissolution caused by decreased decay of organic carbon in sediment pore waters. There is support for this idea from the fact that coccoliths tend to be more dissolution-resistant than foraminifera, also from calcite dissolution above the calcite saturation horizon is driven mainly by titration by metabolic carbon dioxide derived from organic carbon decay at or near the sediment–water interface.

Event III (65.9 Ma ago) entailed the gradual return of the surface-to-deep water carbon isotope signal, a slight increase in barium accumulation rates and a gradual decline in planktonic foraminiferal accumulations. This implies that surface water productivity started rising about 0.5 Ma after the Cretaceous/Tertiary Boundary event. Temperature fluctuations of several degrees Celsius are inferred from variations in nannofossil and foraminiferal $\delta^{18}\text{O}$ values.

Event IV (65.3 Ma ago) expressed the surface-to-deep water carbon isotope gradient associated with a decrease in planktonic foraminiferal concentrations to more normal levels. Aluminum accumulation rates rose and, since they probably reflect a flux of eolian debris to the site, may mirror a climatic change together with an increase in wind strength. Environmental stability is indicated by a practically constant $\delta^{13}\text{C}$ gradient, relatively stable $\delta^{18}\text{O}$ values and low rates of change of accumulation of planktonic foraminifera. An abrupt extinction of phytoplankton and zooplankton plus the disappearance of the carbon isotope gradient took place, probably within 10,000 years or so. Only such a rapid environmental change could have triggered such a drastic collapse of the marine ecosystem. A bolide encounter could have triggered an “instantaneous” environmental stress factor that went on to engender the collapse of primary productivity, but could not have done so for long. It is possible that the 500,000 years “**Strangelove**” **Ocean** might have existed just long enough to provide the recovery time for the biosphere regarded as normal after such a mass extinction period. A Strangelove Ocean is one in which the dissolved carbon dioxide became enriched due to reduced plankton lasting at least a 1,000 years and followed by increased productivity of plankton.

16.8.5 Isotopes as Mesozoic Climate Indicators

Ice-free oceans are involved. Not much information is available from deep-sea cores at more than a 100 sites from **DSDP** Legs 1–75 penetrating the Cretaceous and yielding foraminifera. A temperature maximum based on $\delta^{18}\text{O}$ values from belemnites at paleolatitudes considered to

have been tropical appears to have occurred in the Albian Age. If a mean $\delta^{18}\text{O}$ of -1‰ for ocean water on an ice-free Earth be assumed, the planktonic foraminifera analyzed recorded paleotemperatures ranging from 25°C to 27°C and this agrees closely with belemnite results. If neither was altered diagenetically, then the surface temperatures in Cretaceous tropical oceans were hotter than today. Of course, if the mean value for ocean water differs from that cited above, these values might be shifted by a couple of degrees either way. As regards diagenetic alteration, this induces a shift in the measured $\delta^{18}\text{O}$ in an isotopically lighter, i.e., negative, direction and thus produces a paleotemperature which is too high. Luckily belemnites are usually translucent and so diagenetic changes are optically visible. Isotopic paleotemperature data are very numerous and suggest that much more equable climates existed during the Mesozoic than was the case in the Tertiary.

Oxygen isotope data from Pacific-cores foraminifera and belemnites showed that low-latitude bottom water temperatures fell from $>15^{\circ}\text{C}$ to about $10\text{--}12^{\circ}\text{C}$ at the end of the Cretaceous. A Cretaceous maximum occurred in the Albian (Teis et al. 1969). This did not agree with other data indicating a climatic temperature maximum in the Coniacian/Santonian almost 11 million years later. The disparity might have been due to a different $^{16}\text{O}/^{18}\text{O}$ ratio in the Teis Group standards, also its specimens came from isolated Santonian waters so that temperatures calculated from their belemnites were lower than the usual ones. There is general agreement that there was an Aptian temperature minimum preceding Albian and continuing an earlier Hauterivian one.

Toward the end of the Jurassic, a low-latitude arid zone extended northwards into much of Europe and south central Asia and caused replacement of corals and limestones by evaporates together with a spreading of limestones at the expense of siliclastics. The transition into the Cretaceous produced humid conditions again with seasonal rains over a vast area including North America, Europe, North Africa, and the Middle East, although southeast Asia stayed dry. This is shown by the abrupt replacing of shallow marine limestones by coarse siliclastics. Large deposits of bauxite and coal relate to such humid conditions and an equatorial humid zone is shown by coals and ironstones in Nigeria and Colombia. Huge salt deposits record Early Cretaceous aridity in the low-latitude South Atlantic region. Isotope data confirm the expansion of the humid zones in the Late Cretaceous as against their extent in the Late Jurassic. Evidence came from strontium isotope ratios in marine carbonates that are believed to reflect seawater values accurately. The $^{87}\text{Sr}/^{86}\text{Sr}$ ratios correlate with the amount of continental run-off that depends on the extent of land and quantity of precipitation falling on it. Allowing for the regional spread of epicontinental seas, the ratio is significantly higher in the Late Cretaceous than it was in the Lower Jurassic. This is the opposite of what happened in the Neogene Ocean. Such changes are due to alterations in the flux of changes in the flux of average $^{87}\text{Sr}/^{86}\text{Sr}$ ratios of the major inputs of strontium to the oceans.

16.8.6 The Permo/Triassic (P/Tr) Boundary

Data from a geochemical record at the P/Tr Boundary recorded in a core, GK-1, in the Carnic Alps, Austria, that started in the Muschelkalk Conglomerate (Middle Triassic) and ended in the lowermost part of the Triassic (as evidenced by the presence of the conodont species *Hindeodus parvus*) are very interesting (Holser et al. 1989). The paleomagnetic record of this core showed several polarity reversals and a carbon isotope profile showed $\delta^{13}\text{C}$ -enriched values of about $+3 \pm 0.3\text{‰}$, a drop occurring in the younger parts of the core. The $\delta^{18}\text{O}$ values also showed

consistent variations at certain intervals with a marked depletion across the P/Tr Boundary that is interpreted as showing a temperature rise of possibly 5°C. A smooth decrease in $\delta^{13}\text{C}$ in Unit 1B (Upper Bellerophon Formation) continued through Unit 2 (the Tesero Horizon, including the P/Tr Boundary) at an accelerating rate, the drop signaling the inception of a zone of low $\delta^{13}\text{C}$ values and chemical changes, e.g., the first and third of three carbon minima are marked by high concentrations of pyrite. The group found two peaks in iridium data that are well above background, but an order of magnitude lower (at least) than the iridium spike at the K/T Boundary. The drop in $\delta^{13}\text{C}$ started in the core at about 50 m below the P/Tr Boundary and showed a net oxidation of the world reservoir of organic carbon as sea level fell to expose paralic and shallow shelves to erosion. The Holser Group claimed that the $\delta^{13}\text{C}$ profile confirmed an accelerated organic carbon oxidation as the boundary is approached and a similar situation was found at Tesero in Italy. An abrupt change to anoxic conditions shown by a rise in Ce^*/La^* and high S/C ratios plus the appearance of pyrite at the top of Unit 2. If this is the case and the $\delta^{13}\text{C}$ dropped through zero for the first time, anomalous concentrations of iridium and other metals may have resulted. The Holser Group took the maximum of the anoxic zone to correspond with the initial minimum of the $\delta^{13}\text{C}$ and claimed that a similar sequence is repeated during a later $\delta^{13}\text{C}$ minimum at the top of Unit 3A and that this was, again, accompanied by high concentrations of metals and sulfides. Actually a single minimum zone of $\delta^{13}\text{C}$ at the base of the Triassic has been validated globally. The interesting question is why many of the above-mentioned changes occurred so fast after the primary global longer-term shifts of the carbon cycle. It is possible that all were the result of the same sea-level regression that first exposed organic carbon to oxidation and finally created anoxic conditions to precipitate metals at least in this part of the Tethys Ocean. This would agree with increased erosion of elevated red beds of the underlying Gröden Formation and precipitated at the oxidation–reduction interface (compare the metal-rich shales of the Kupferschiefer that include platinum group elements). Metal accumulation may have been assisted by algae, as is perhaps shown by observed lamellar texture. If the anoxia and metal concentrations turn out to be localized in the Bellerophon Basin, the cause might be an estuarine-type top flow of freshwater from the lands to the west during the maximum regress of the Tethys Ocean. Alternatively, on a larger scale, a last phase of a deep-sea oxygen minimum zone believed to have existed during much of the Paleozoic Era may have been involved after having been brought near to the surface during the maximum regress event. A prevalent incidence of freshwater eroding continental rocks during this regression is shown by the high values of $^{87}\text{Sr}/^{86}\text{Sr}$ compared with those of the earlier Permian.

The above-mentioned considerations make it clear that the P/Tr Boundary was a very significant event associated with what may well have been the greatest of all mass extinctions. The carbon and oxygen isotope values recorded a drop in $\delta^{13}\text{C}$ values and a depletion in $\delta^{18}\text{O}$ values with a related temperature rise of about 5°C. These phenomena are apparent in other regions, for instance West Spitsbergen where a number of non-allochthonous brachiopods were analyzed. These were Late Permian in age and selected because they do not fractionate carbon and oxygen isotopes significantly. Associated conodonts suggested that the range reached the end of the Permian. The lower part of the carbon isotope curve scattered round a $\delta^{13}\text{C}$ value of +4‰, which is globally typical of Permian rocks. However, there is marked decline of more than 10‰ in the upper part to produce very negative values and it is thought to have taken place over a few million years. The oxygen isotope curve parallels the carbon one. The most startling feature of the data is the size of the carbon shifts that imply that the Late Permian Ocean was first relatively impoverished and later enriched in carbon-12. Is it possible that this reflects a diminished uptake of the light isotope by the biosphere? Or does it mirror an

increased input of the light isotope to the system in the form of organic carbon from land ($\delta^{13}\text{C} = -25\text{‰}$), marine deposits ($\delta^{13}\text{C} = -15\text{‰}$ to -20‰), or juvenile carbon dioxide ($\delta^{13}\text{C} = -5\text{‰}$)? Some prefer the idea that the global process demonstrated by the carbon isotope measurements are attributable to an increased burial of organic matter (spike) succeeded by its oxidation (drop). This would be consistent with the oxygen isotope curve because oxidation of organic matter must lead through kinetic fractionation processes to a decline in the $\delta^{18}\text{O}$ values as measured in all species of dissolved carbon. Such processes may have occurred in the ocean rather than in another carbon reservoir and a similar phenomenon may have taken place at the Precambrian/Cambrian Transition.

16.8.7 Oxygen and Carbon Isotopic Paleozoic Ocean Data

The $\delta^{18}\text{O}$ values of marine chemical sediments tend to decrease with age not just in carbonates but also in cherts, phosphorites, and glauconites. Of course, this could be due to postdepositional equilibrium with oxygen-18-depleted meteoric waters, such equilibration increasing with increasing age. On the other hand, it is possible that it indicates a higher overall temperature for ancient oceans with Archean and Early Proterozoic waters having values exceeding 60°C , although this must be regarded as inherently improbable. Then again, the oxygen isotope composition of the oceans changed through geological time, becoming depleted in the heavy stable isotope. This trend is said to have occurred in carbonates, but to a lesser extent in the Cenozoic and Mesozoic compared to the Paleozoic and Precambrian (Veizer and Hoefs 1976). In the Late Paleozoic, there may have been a major step in the $\delta^{18}\text{O}$ age curve, which, if postdepositional alteration were the sole cause of the secular trend recorded, may be significant in understanding the diagenetic evolution of (bio)chemical sediments.

Secular oscillations have been detected in the $\delta^{13}\text{C}$ of marine bicarbonates. On timescales of 10^7 years, the $\delta^{13}\text{C}_{\text{carbonate}}$ correlates negatively with $\delta^{34}\text{S}_{\text{sulphate}}$ and both correlate with $^{87}\text{Sr}/^{86}\text{Sr}_{\text{carbonate}}$ and the Phanerozoic “sea-level stands.” It seems that the inverse S–C isotopic relationship probably implies oxygen transfer and hence a redox balance between sulfur and oxygen exogenic cycles.

16.8.8 The Precambrian Eons

The Precambrian is extremely long and includes two eons, i.e., the earlier Archean and the later Proterozoic, starting about 4.4 Ga ago and ending with the onset of the Cambrian Period initiating the Paleozoic Era about 570 million years ago. Large-scale ice ages occurred in the Precambrian (Salop 1983). Thus, rock sequences show wide fluctuations in paleoclimates and in many ways similarly to such changes in the Phanerozoic. There was an ice age, the Vendian, in the Eocambrian (570–650 Ma B.P.) and this is indicated by the last Precambrian “tillites,” assuming that these really are tillites and really do show a glaciation situation. This led to the suggestion of a major Varangian global ice age between 630 and 670 Ma ago (Harland 1964). Contrary evidence comes from associated dolomites and/or red beds typical of tropical conditions as well as from paleomagnetic data, poor but indicative of a low-latitude situation. It has been suggested that the tillites were indeed glacial, but the paleomagnetic information is incorrect either because the geomagnetic field was not a dipole of the type found through the

rest of Earth history or the data are too poor in quality. If the tillites were in fact polar, very fast polar wandering would be necessary to account for their apparently widespread distribution, i.e., if distances 30° from the poles were involved. Clearly there is a potential problem in distinguishing paleopolar tillites from the rest. For instance, 47 tillite-like beds have been recorded in the 750 m thick Garvallack sequence of the Late Precambrian of Scotland and claimed to represent at least 17 separate glacial advances (Spencer 1971). These might have been the result of an ecliptic-type wobble that brought ice to the equator every few score thousand years to produce alternation between glacial facies with tropical oxidation and dolomitization. Such wobble-induced ice could have been the mechanism that eroded laterites and tills in their turn would have been oxidized and dolomitized. The requisite time interval has been estimated as 40,000 years. The association of red beds and dolomites with tillites has been accepted and a very different tilt of the Earth's spin axis with respect to the orbital plane could have produced this intimate mixture of hot and cold facies (Williams 1975). The tilt would have varied between $21\frac{1}{2}^\circ$ and $24\frac{1}{2}^\circ$ in the Milankovitch model, but the potential range is clearly between 0° and 90° . The inference is that the Earth formed from a solar prominence with the spin axis in the plane of the planetary orbit, i.e., with an obliquity of the ecliptic of 90° .

Say a change of 1° occurred in 7 million years, then a complete cycle of the spin axis through 360° with respect to the orbital plane would take place every 2.5 Ga. If the polar axis were to lie near or actually in the plane of the Earth's orbit, equatorial latitudes would on average be colder than polar ones. An ecliptic obliquity of 54° would represent an intermediate stage between average hotter pole and average hotter equator. In this state, the Earth would have practically no climatic zonations, hence the climate would effectively be the same everywhere. Such a tilt would fit with the concept of a global glaciation. The area of the planet lying within $20\text{--}30^\circ$ of the equator is much greater than that within $20\text{--}30^\circ$ of the poles, therefore the geological record is biased toward low-latitude phenomena. It was proposed that such a drastic tilt of the terrestrial spin axis could not have been a short-term episode, but rather a much longer one. If so, geological evidence below and above the Varangian glacial deposits showing signs of low-latitude deposition and hot conditions argues against the proposed tilt. The main advantages of Williams' major obliquity hypotheses are that it would associate minimum obliquity with warm or equable climates in the Late Phanerozoic Era and maximum obliquity times would include the Early and Late Proterozoic. However, the Witwatersrand glacial sequence in South Africa constitutes an objection to this because it falls in the middle of a supposedly non-glacial time interval. In this case, if the Williams hypothesis is true, the relevant ice would have had to have been at high latitude. An even more telling argument against Williams is that the Milankovitch wobble of a mere $2\text{--}3^\circ$ caused a marked climatic effect much later in Earth history and this implies that the Williams ecliptic megacycle incorporating major changes in the obliquity of the ecliptic should have had much greater effects on paleoclimates than those actually observed.

16.8.8.1 Archean/Proterozoic Transition

Metasedimentary rocks formed in these two eons extending from 590 to 4,000 Ma B.P., but differ both in lithological abundances and geochemistry, for instance their $^{87}\text{Sr}/^{86}\text{Sr}$ ratios in carbonates are <0.703 for the Archean and <0.704 for the post-Archean. As might be expected almost all such rocks have undergone extensive metamorphism. Carbonates have been used to evaluate the history of the isotopic composition of seawater. As postdepositional alteration is

believed to have been more likely to have increased rather than diminished this ratio, the lowest $^{87}\text{Sr}/^{86}\text{Sr}$ values for a given suite of samples is taken as the best available estimate for strontium isotope composition in their contemporary oceans. The Transition was investigated by examining the geochemistry of rocks from Guyana and Montana (Gibbs et al. 1986). The Guyana material came from the greenstone belts of the Guyana Shield. Metapelites and volcanoclastic metagreywackes of the Early Proterozoic proved similar to many Archean greenstone belts in rare earth elements, trace and major element compositions. Other Archean continental basin sediments turned out to resemble their post-Archean counterparts, implying that the upper continental crusts of the relevant time intervals did not differ to any great extent. Dolomitic limestone from a greenstone belt in northern Guyana has an anomalously low $^{87}\text{Sr}/^{86}\text{Sr}$ ratio of 0.7007, which may mirror the local influence of mantle-derived volcanics during carbonate deposition, diagenesis, or metamorphism. Gibbs and his associates thought that their results made a reconsideration of the Archean/Proterozoic Transition necessary with regard to its attributes of substantial increases in continental area, changes in weathering and erosion together with alterations to the average isotope compositions of upper continental crust.

If it can be shown that the Archean/Proterozoic Transition is an artifact, Archean epicontinental basins and Proterozoic greenstone belts must have been more important than has been previously recognized. The greenstone belts may have formed in some pre-cratonic stage and later comprised part of the basement. Hence they are found at deeper crustal levels than continental sedimentary basins and must have been less vulnerable to erosion or involvement in the internal zones of collision orogens. The transitional event has been interpreted as diachronous so that comparisons of 2–2.5 Ga with 2.7 Ga old metasediments can be regarded as another demonstration of this. But similarly consistent associations of geochemical compositions and geological settings have been reported from both older and younger rocks as well as from modern sediments. Both pre-cratonic and cratonic crust apparently coexisted through Earth history, and change from one to the other probably proceeded throughout as well.

Abstract: This chapter provides a necessarily brief summary of radioactive dating techniques, which can produce dates (“ages”) ranging from tens to thousands through millions to billions of years often with assumptions not universally accepted, especially those involving the assessments of half-lives and radioactive decay constants.

17.1 Introduction

Radioactive dating methods involve use of radioactive isotopes of various elements. Of the more than 1,500 presently known nuclides, over four fifths are unstable although most do not occur naturally on Earth, because of their very rapid rates of radioactive decay. To date, rocks, minerals, and naturally occurring radioisotopes are used that continued to exist long after the so-called Big Bang because of their extremely slow rates of radioactive decay. These include uranium-238, uranium-235, thorium-232, rubidium-87, and potassium-40. Some result from the radioactive decay of long-lived, naturally occurring radioactive parents, and among these are uranium-234, thorium-230, and radium-226. Others may have been created by natural nuclear reactions, and these include radiocarbon (carbon-14) and tritium (hydrogen-3). Today, artificial radionuclides have been introduced into the environment as a result of thermonuclear testing and the operation of nuclear fission reactors and particle accelerators.

Whatever its sources, radioactivity is significant as regards geochronology and radioactive dating began in an attempt to determine the age of the Earth once the phenomenon was discovered and uranium and thorium minerals were found to emit radiation. Two new elements were identified, namely polonium and radium, and the word “radioactivity” was derived from the latter. Ever accelerating progress has been made in determining the ages of minerals, rocks, archeological and historical objects, and so on to such an extent that numerous approaches have become routine. Major methods for achieving these data are presented alphabetically in abbreviated form in order to provide a brief but useful perspective of what is in fact a vast and continuously expanding subject. The techniques include four radiation damage techniques, namely electron spin resonance (ESR), fission track dating (FTD), pleochroic haloes, and thermoluminescence.

Great advances resulted from Hans Oeschger’s development of the *Oeschger Counter* that has a lower background than other such instruments. It became the leading instrument for measuring the activity of a variety of naturally occurring radionuclides such as tritium, radiocarbon, aluminium-26, argon-37, argon-39, krypton-81, and krypton-85. Using this method, Oeschger and his team were able to quantify exchange processes between different components of the Earth System. There is a final caveat to make here, and this refers to the words “assuming,” “presuming,” “implying,” and “inferring” appearing occasionally in the text regarding certain dating methods, and in a number of cases, dubiety apropos half-lives and radioactive decay constants are mentioned. From this, it is apparent that there is still some way to go to improve and, if possible, perfect many of the relevant techniques.

In this chapter, the following shorthand notation is used. $[^AX]$ denotes the number of atoms/concentration of nuclide AX , where X stands for the chemical symbol of some element and A is the mass number of one of its isotopes. (^AX) is the activity (either absolute or specific) of nuclide AX . Symbols such as $[^AX/^BY]$ actually mean atomic ratios of nuclides AX and BY ; i.e., they represent the ratio $[^AX]/[^BY]$. Similarly, the ratio of activities $(^AX)/(^BY)$ will be abbreviated sometimes as $(^AX/^BY)$. An asterisk as a right superscript such as $^AX^*$ or $[^AX]^*$ is to stress that the nuclide in question or the specified number of them is of radiogenic origin.

17.2 Argon/Argon

For a better understanding of the argon/argon method, it is recommended that ▶ Sect. 17.15 on potassium/argon dating be read first. The method presented below can be considered as a special variant of the K/Ar method in which the potassium content is monitored by an argon isotope that is readily formed by the neutron irradiation of potassium.

The argon/argon method is partly based on the formation of argon-39 by irradiation of potassium-bearing samples using both thermal and fast neutrons in a nuclear reactor. The relevant reaction is

Argon-39 is radioactive, decaying by beta emission with a half-life of 269 years, a fact that makes it stable in terms of the relatively insignificant analytical times involved in research. A counting technique for the assessment of argon-39 was superseded in the middle 1960s by mass spectrometric determination of the $^{40}\text{Ar}/^{39}\text{Ar}$ ratio. It is assumed that all argon-40 in the irradiated sample is either radiogenic or atmospheric in origin and that argon-39 is produced by the (n,p) reaction as shown by ▶ Eq. (17.1).

During the irradiation process, reactions that involve potassium, calcium, and chlorine occur, but the only one of interest is that cited above. The number of radiogenic $^{40}\text{Ar}^*$ atoms present in a sample due to the radioactive decay of potassium-40 during its geological history is given by

$$[^{40}\text{Ar}^*] = \frac{\lambda_{\text{EC}}}{\lambda} [^{40}\text{K}] (e^{\lambda t} - 1), \quad (17.2)$$

where λ_{EC} is the decay constant of potassium-40 for electron capture, λ is the total decay constant of potassium-40 (including β^- decay):

$$\lambda = \lambda_{\text{EC}} + \lambda_{\beta} \quad (17.3)$$

and t is the age. For the decay scheme of ^{40}K , see ▶ Eq. (7.22) in Chap. 7, Vol. 1, presented as an example for branching decays.

After the neutron irradiation process, the $^{40}\text{Ar}/^{39}\text{Ar}$ ratio can be determined and compared with the $^{40}\text{Ar}/^{39}\text{Ar}_{\text{fm}}$ ratio of a flux monitor the age of which is known. Various mineral concentrates can be used as flux monitors. One is MMHb-1. It is assumed that all argon-40 in the irradiated sample derives either from a radiogenic or an atmospheric origin, argon-36 is purely atmospheric, and also that all argon-39 is produced by the (n,p) reaction shown in ▶ Eq. (17.1).

Several corrections have to be introduced, especially as regards younger samples ($\sim 10^6$ years) and those having $[\text{K}/\text{Ca}] < 1.0$. Particularly important are interfering reactions involving calcium isotopes. For instance, argon-36 is produced by the reaction

and removed by the reaction

both reactions interfering with the correction for atmospheric air, which is based on argon-36.

In addition, an atmospheric argon-40 correction is relevant both to conventional potassium/argon and to $^{40}\text{Ar}/^{39}\text{Ar}$ dating methods. The assumption is made that argon-36 is of

atmospheric origin and that the ratio $[^{40}\text{Ar}/^{36}\text{Ar}]$ in the atmosphere is 295.5. However, both argon-40 and argon-36 may become incorporated into minerals when they crystallize so that the $[^{40}\text{Ar}/^{36}\text{Ar}]$ ratio of this argon may differ significantly from that of atmospheric argon today. Consequently, the observed quantity of argon-36 in a mineral or rock may not allow an accurate correction to be made for the presence of non-radiogenic argon-40. Where the $[^{40}\text{Ar}/^{36}\text{Ar}]$ ratio of the inherited argon exceeds 295.5, an apparent excess of radiogenic argon will result. But if the value of this ratio is below 295.5, an apparent deficiency of radiogenic argon will result. This latter result might mistakenly be attributed to a partial loss of argon-40.

It is possible to calculate a date from the $[^{40}\text{Ar}/^{39}\text{Ar}]$ ratio of a sample that has been irradiated by neutrons and so a set of such dates can be obtained for the sample if argon is liberated from it in steps following temperature increases. If the sample was a closed system for both argon and potassium since it first cooled, the dates obtained from each step should be constant. However, if some loss of radiogenic argon occurred and took place in regard to some, but not all, crystallographic sites, the $[^{40}\text{Ar}/^{36}\text{Ar}]$ ratios of the gas released at different temperatures will vary and a range of dates will result. From this result, the time elapsed since initial cooling can be derived.

It has been indicated that the $^{40}\text{Ar}/^{39}\text{Ar}$ approach has several advantages over potassium/argon method of which perhaps the greatest is that only ratios of argon isotopes have to be measured in order to calculate an age rather than absolute quantities. Hence, it is not necessary to extract all radiogenic argon from a mineral to derive an accurate age, thus mitigating a problem inherent in the potassium/argon dating of sanidine, which is that K/Ar ages for this mineral tend to be anomalously young since the melt usually forms a viscous mass, which retains some radiogenic argon under ultrahigh vacuum. Even at maximum attainable temperatures in standard induction heaters and resistance furnaces, 5–10% of the gas can stay trapped in such viscous sanidine melts. The problem was obviated by using a $^{40}\text{Ar}/^{39}\text{Ar}$ analytical system (Dalrymple 1989).

17.2.1 Incremental Heating

The concept of stepwise heating (Merrihue and Turner 1966) was incorporated into a model used to forecast the $[^{40}\text{Ar}^*/^{39}\text{Ar}]$ spectrum of a potassium-bearing mineral grain that underwent a partial loss of radiogenic argon-40 (i.e., $^{40}\text{Ar}^*$) caused by heating during a metamorphic event. A mineral grain that underwent partial loss of argon-40 may become a closed system again when the relevant metamorphic event ended. If uniformly sized grains of a particular potassium-bearing mineral with such a geological history is incrementally heated, the $[^{40}\text{Ar}^*/^{39}\text{Ar}]$ ratios of the gas fractions liberated at different temperatures will vary systematically. The first will emerge at the lowest temperature and come from grain surfaces with a low ratio. This reflects the time interval elapsed since the accumulation of radiogenic argon-40 recommenced after the metamorphic event. Succeeding fractions released through rising temperatures will have progressively higher $[^{40}\text{Ar}^*/^{39}\text{Ar}]$ ratios representing the removal of the gas from increasingly retentive locations, which lost ever smaller fractions of the argon-40 during the event. Finally, the $[^{40}\text{Ar}^*/^{39}\text{Ar}]$ ratios may reach a plateau that corresponds to a date approaching the time, which has passed subsequently to the original cooling of the mineral.

The stepwise heating procedure applied to a mineral sample, which underwent partial loss of radiogenic argon, permits a set of dates to be calculated, and this procedure ideally includes

the actual time of the metamorphic event (low temperature release). This is advantageous because a date can be derived which nears, if sometimes underestimating, the original cooling age of potassium-bearing minerals in rocks, which suffered partial loss of radiogenic argon in the course of a metamorphic event.

17.2.2 Stony Meteorites

Investigations have been made on stony meteorites including severely shocked chondrites. Also, the effect of implanting argon isotopes during a similar shock metamorphism on $^{40}\text{Ar}^*/^{39}\text{Ar}$ dates of both terrestrial and lunar rocks has been examined. Many data have been obtained from samples derived from metamorphic terranes on Earth, for instance Barberton Mountain komatiites, extrusive igneous rocks of peridotitic composition with much higher melting temperatures than basalts.

The validity of the technique was scrutinized by dating minerals and rocks with ages already known from alternative isotope methods. Whole-rock samples of diabase with excess radiogenic argon from dykes in western Libya were analyzed in order to assess the stepwise approach. Results showed that minerals from slowly cooled metamorphic and intrusive igneous rocks normally yield $^{40}\text{Ar}^*/^{39}\text{Ar}$ ages younger than their real crystallization ages because radiogenic argon-40 continues to escape from the mineral crystals in appreciable amounts until they cool below some critical temperature range (► Fig. 17.1). Such loss is a volume diffusion process. The integrated closure temperature corresponding to the temperature of the mineral at the time conforming to its apparent integrated age can be regarded as a function of the diffusivity of argon-40 in the mineral, a dimension over which diffusive loss occurs and the rate of cooling.

17.2.3 Argon Losses

Argon-39 may be lost or relocated in a sample because of its recoil arising from the emission of a proton during the (n,p) nuclear reaction shown in ► Eq. (17.1). If much is lost from an irradiated sample, the $[^{40}\text{Ar}/^{39}\text{Ar}]$ ratio will increase proportionally and so the total release date will exceed the real geological age. Loss of argon-39 from a potassium-bearing mineral grain may occur from a surface layer 0.08 μm thick and the effect of such recoil-induced loss is related to the particle size of the mineral, i.e., fractured or fine-grained minerals lose more of the isotope during irradiation than do coarse-grained ones. The implication is that the $^{40}\text{Ar}/^{39}\text{Ar}$ method may be unsuitable if applied to the dating of potassium-rich clay minerals of the glauconite type, which normally comprise green pellets made of aggregates of platy crystals about a micrometer thick. Of course, recoil loss from potassium-rich mineral grains may entail gas entering adjacent grains of potassium-poor minerals. Then the $[^{40}\text{Ar}/^{39}\text{Ar}]$ ratio of the former would increase and that of the latter would decrease. The amount of increase would depend on grain sizes, namely the surface-to-volume ratio of the relevant grains. Where this ratio is large, that is to say where the grains are small, there will be a larger increase in the $[^{40}\text{Ar}/^{39}\text{Ar}]$ ratio due to the argon-39 recoil loss than in a similar sample with larger grains of potassium-bearing minerals. Potassium-depleted minerals taking up expelled argon-39 include pyroxene and they are more retentive as a rule than potassium-rich minerals. Therefore, argon freed at high temperatures may have lower $[^{40}\text{Ar}/^{39}\text{Ar}]$ ratios because it is derived from pyroxenes containing argon-39 expelled from potassium-bearing minerals during

■ Fig. 17.1

(a) Uniform distribution of the radiogenic $[^{40}\text{Ar}^*/^{40}\text{K}]$ ratio in a spherical mineral grain closed since crystallization, (b) partial loss of radiogenic $^{40}\text{Ar}^*$ through diffusion induced by heating, which reduced the relevant ratio to zero at the surface of the grain while leaving it unaltered at the center, (c) distribution of the $[^{40}\text{Ar}^*/^{40}\text{K}]$ ratio at a time after partial argon loss after the system again became closed to $^{40}\text{Ar}^*$. The value of the $[^{40}\text{Ar}^*/^{40}\text{K}]$ ratio on the surface of the grain is a function of that time, which elapsed subsequently to partial outgassing, and at the center of the grain, it corresponds to the age of the mineral sample

neutron irradiation of the sample. This may explain why the stepwise release spectra of some lunar rocks showed a decrease of this ratio at the highest gas release temperatures.

The $^{40}\text{Ar}/^{39}\text{Ar}$ age spectra of a whole-rock sample and mineral concentrates can be altered by the occurrence of minerals, which may lose argon at a continuous rate even at low temperatures and perhaps also of minerals younger than the main minerals. These latter can be produced by thermal metamorphic episodes involving low temperatures. Alternatively, they may exist as inclusions in the main minerals. Either way, it is hard to separate them and, since they are characterized by their inability to retain argon, their presence in irradiated samples contributes to low dates commonly derived from low temperature-derived gas fractions freed by incremental heating. The problem has been approached using a precisely focused laser beam to release gas from individual grains of retentive minerals. In one experiment, a pulsed ruby laser melted less than a $1\ \mu\text{g}$ sample of the neutron-irradiated sample to create a pit $10\text{--}100\ \mu\text{m}$ wide, the beam being focused through a petrographic microscope on to a polished surface of the sample sealed in a vacuum chamber on the stage. The gas was collected on charcoal at the temperature of liquid nitrogen and later a gas source mass spectrometer used to obtain the required $[^{40}\text{Ar}/^{39}\text{Ar}]$ ratio. Another technique involved applying continuous argon-ion lasers to melt individual mineral grains previously irradiated by fast neutrons. Dates were obtained from biotite, hornblende, and muscovite of Precambrian age and could not be distinguished from total release dates resulting from fusion of the relevant minerals by radio frequency

induction. Using lasers is valuable because individual mineral grains can be dated so that their inclusions and any alteration products can be excluded.

The laser method has been used to study the occurrence of argon in lunar rocks from the Mare Serenitatis, but there were drawbacks. They resulted from the fact that the date obtained was a total release that could underestimate the ages of samples, which lost argon-40 after crystallization. Also, the laser beam may stimulate the release of argon from other minerals when penetrating the target material. However, it was claimed that less than 1% of the gas freed from pits comes from an area exceeding 10 μm from their peripheries.

Dating sulfide minerals is complicated because they lack radioactive elements such as uranium, thorium, and rubidium. However, some contain potassium, e.g., the mineral rasvumite, KFe_2S_3 . Samples of this mineral were collected from an alkali-rich igneous rock at Coyote Peak near Arcata, northern California, and they gave a date of 26.5 ± 0.5 Ma, while associated phlogopite mica yielded a total release date from $^{40}\text{Ar}/^{39}\text{Ar}$ measurements of 28.3 ± 0.4 Ma. This confirms that potassium-bearing sulfide minerals can be dated on the basis of the radioactive decay scheme

17.2.4 Some Important Applications

K/Ar ages and paleomagnetic data from geological mapping of the Jemez Mountains in northern Mexico were used as a basis for recognition of the Jaramillo Normal Subchron (JNS) and obtaining calibration points near the Matuyama/Brunhes Boundary (MBB). Sanidine and obsidian were used. The isotopic ages of volcanic rocks significant both for the JNS and MBB were reported following $^{40}\text{K}/^{40}\text{Ar}$ and $^{40}\text{Ar}/^{39}\text{Ar}$ analyses of rhyolite domes of the Valles caldera, which formed just prior to the MBB. New information was obtained by measuring $^{40}\text{Ar}/^{39}\text{Ar}$ ages of basalt flow extruded during the Matuyama/Brunhes magnetic field reversal. The age of the MBB was further constrained by dating of sanidine from the reversely magnetized Oldest Toba Tuff in Sumatra.

Other applications of the $^{40}\text{Ar}/^{39}\text{Ar}$ technique include a Burdigalian (Miocene 1) age for extensional ductile tectonics in the Edough Massif, Kabylies, Algeria, a preliminary $^{40}\text{Ar}/^{39}\text{Ar}$ age spectrum and laser probe dating of the Manson Impact Structure (MI core), a Cretaceous/Tertiary (K/T) Boundary crater candidate, use of the $^{40}\text{Ar}/^{39}\text{Ar}$ technique to date mylonitic deformation associated with the regionally extensive Norumbega fault zone in south-central Maine, USA, meteorites (acapulcoites and lodranites, also dating shock-melted phases of the Chico chondrite as well as an argon isotope study of lunar meteorite Asuka 881757. Also studied were diamonds some of which are known to be 2–3 Ga old, the formation of which from the Earth's mantle might have entailed incorporating large quantities of “excess” radiogenic argon in association with potassium. If this is true, the dating projects may turn into studies of the ancient mantle fluids.

17.3 Cesium

The natural isotope ^{133}Cs is stable, but two radioactive isotopes are of interest. These are ^{135}Cs and ^{137}Cs . Both are radioactive with half-lives of 2.3 Ma and 30 a, respectively. They are produced with equal yields of about 6–7% in binary fission of actinide nuclides. The nuclei

enter the environment through atmospheric testing of nuclear devices and release from the nuclear industries. ^{137}Cs is a well-known radiotracer and time marker while ^{135}C has been neglected because its much longer half-life precludes detection by counting. In addition, in conventional mass spectrometers, the tail from the stable ^{133}Ca swamps its signal (since its abundance is typically 10^{-9} smaller). The first measurement of the relevant isotopes was made using two coastal sediment samples and a thermal ionization mass spectrometer equipped with a retarding potential quadrupole lens filter. The $[^{135}\text{Ca}/^{133}\text{Cs}]$ ratio was about 1×10^{-9} , and the $[^{137}\text{Cs}/^{135}\text{Cs}]$ ratio was about five due to the decay occurring through the past 30 years from their production ratio of about one. It was noted that this appeared to be the first detection of fallout ^{135}Cs in nature and it may be inferred that the isotope ratio $[^{137}\text{Cs}/^{135}\text{Cs}]$ is much more powerful as a tracer than ^{137}Cs alone. Two models were given to illustrate how the ratio may be used in order to quantify estimates of recent sedimentation and rates of erosion (Lee et al. 1993).

17.4 Cosmogenic Radionuclides

17.4.1 Aluminum-26

This radionuclide enters the oceans in ionic form and mixes with stable aluminium-27, later becoming adsorbed on various particles. Its concentration rises with depth and its half-life is 0.716×10^6 years. Its residence time was estimated as 1,400 years and that makes it valuable for dating authigenic minerals, although detecting it is not easy. It has been employed to determine the rates of growth of manganese nodules of which one estimate is 2.3 mm Ma^{-1} . When it is measured with beryllium-10 from the same sample, the ratio of their respective rates of radioactive decay decreases with time. The geochronometer is useful because the time-dependent variations in the rates of production and the geochemical paths of the two tend to annul each other (Lal and Somanyajulu 1984). The Oeschger Counter has been a valuable asset in measuring this radionuclide.

17.4.2 Argon-39

This radionuclide forms in the atmosphere through the nuclear reaction

and decays by beta emission to ^{39}K with a half-life of 269 years.

Its contribution to atmospheric radioactivity is about $1.87 \pm 0.17 \text{ Bq m}^{-3}$ and of this, less than 5% is due to thermonuclear testing. It has a long residence time that damps down fluctuations in its production rate and contributes to probable constancy of its concentration in terms of time and latitude. This makes it valuable for dating glacial ice and groundwaters. At about 70 m depth, névé (also called firn) is converted to glacial ice and air bubbles become trapped and can be analyzed to assess disintegration rates for ^{39}Ar as well as for radiocarbon and krypton-81. The main problem in using it is that it is chemically inert and so does not interact with solids (unlike radiocarbon, silicon-32, and chlorine-36). Also, because it and other inert gases occur mostly in the atmosphere, concentrations in groundwater depend on the time elapsed since the water was in contact with the atmosphere. In addition, analyzing

argon-39 entails collecting very large volumes of water as with silicon-32. Finally, excess argon-39 may arise from potassium-39 as shown in ► Eq. (17.1), i.e., through the (n,p) reaction

in rocks containing measurable amounts of uranium and thorium.

17.4.3 Beryllium-7

Beryllium-7 occurs naturally and is radioactive with a half-life of 53.29 days, after which it decays to lithium-7 by electron capture. It is a cosmogenic product of various high-energy spallation reactions between cosmic-ray neutrons and nitrogen in the atmosphere about 1.5 km above the surface of the Earth. It forms BeO molecules, which diffuse until encountering dust particles to which they adhere, most forming cloud nuclei with their beryllium-7 incorporating into atmospheric precipitation. Once deposited on the terrestrial surface, it enters the geochemical cycle of beryllium. Although it has low production rate, it is easy to detect because it is found practically carrier-free in the atmosphere. Years ago, it was suggested that beryllium-7 might be useful in dating and its rapid radioactive decay facilitates examining various atmospheric processes, surface water in the oceans, and the mixing of sediments in offshore marine and lake environments.

17.4.4 Beryllium-10

As with beryllium-7, this is a spallation product formed by cosmic rays in the atmosphere, and it descends in precipitation to reach sea-bottom sediments and continental ice sheets. Its half-life is 1.5×10^6 years and its global production rate has been estimated as between 1.5×10^{-2} and 3×10^{-2} atoms $\text{cm}^2 \text{s}^{-1}$, although a lower value has been claimed for Antarctic snow. Like aluminium-26 and beryllium-7, it is introduced into seas in ionic form and mixes with the stable isotopes such as beryllium-9 and aluminium-27. Having high ionic potentials, they may become adsorbed on both organic and inorganic particles. Seawater has a very low concentration of beryllium-10 compared to river waters and lower concentrations at the surface than in deep waters. The residence has been calculated as being about 1,600 years, and so it is useful for dating authigenic minerals, which take it up in ionic solution in the oceans. But there are difficulties because of its low level of activity and its disintegration rate varies sporadically with depth in cores (associated abundances depending not just on the time elapsed since deposition, but on the rate of deposition and secular variations in the production rates). It cannot be assumed that the rates of sedimentation in oceans at any particular place were constant for geologically significant time intervals of ~ 1 Ma. As well as sediment dating in oceans, beryllium-10 concentrations on land, for instance in soils, can be examined. However, few data are available again due to the low activities involved.

Beryllium-10 gave a rate of growth for the manganese nodule (alluded to above in aluminium-26) of about $2.8 \pm 0.06 \text{ mm Ma}^{-1}$. Tektites of various origins were analyzed and it has been concluded that the beryllium-10 arose from sediments on the Earth's surface. It may be noted that a pair of older tektites (moldavites) about 15 million years old had a content of less than 2×10^6 atoms of $^{10}\text{Be g}^{-1}$ that could mean that decay occurred after their formation as

a consequence of meteoritic impact on the Earth and so a terrestrial origin is confirmed (Pal et al. 1982).

17.4.5 Chlorine-36

This radionuclide is produced in the atmosphere through the nuclear reaction

mostly in the stratosphere and its formation is latitude-dependent because of the effects of terrestrial magnetism on cosmic-ray intensities. Mixing there is rapid and the concentration of chlorine-36 is constant. Its atoms attach to atmospheric aerosols in the submicron range and these are progressively removed by precipitation from the lower troposphere. Entry from the stratosphere into the troposphere varies seasonally, and the fallout rate is greater in middle latitudes than it is at the poles or equator. This rate was determined at 57° N latitude at Stripa, Sweden, as about 14 ± 3 atoms $\text{m}^{-2} \text{s}^{-1}$ (Lal and Peters 1967). Its half-life is 3.01×10^5 years. This makes it useful for dating glacial, groundwater, etc. Neutron irradiation of oceanic aerosols following thermonuclear testing at low altitudes induced increased fallout through the nuclear reaction $^{35}\text{Cl}(n, \gamma)^{36}\text{Cl}$, an effect rising from 1953 to a 1964 maximum of 70,000 atoms $\text{m}^{-2} \text{s}^{-1}$ (Bentley et al. 1986). Because such tests began earlier over oceans, the chlorine-36 bomb-peak predated that of tritium by about 10 years. A residence time in the atmosphere for chlorine ions as less than 3 years has been proposed, which may be why the bomb pulse of chlorine-36 was transient with fallout rates returning to normal by the early 1970s when low altitude testing was terminated (Elmore et al. 1982). This bomb pulse was used to study the migration of water through the unsaturated zone into groundwater aquifers and also the stratification of waters in unconfined aquifers.

There is subterranean production of chlorine-36 and the world average chlorine contents of granite and basalt have been given as around 50 and 200 ppm, respectively. Sedimentary rocks have variable contents ranging from 10 ppm in sandstones to 20,000 ppm in deep-sea limestones. Rock outcrops are exposed to the cosmic neutron flux so that some chlorine-36 results from neutron capture by chlorine-35, but, below a few meters, it is ineffectual. Nonetheless, some chlorine-36 results from an in situ neutron flux in rock matrices caused by (α, n) reactions triggered by alpha particles from uranium and thorium radioactive decay systems. This flux may be of the order of $10^{-4} \text{ cm}^{-2} \text{s}^{-1}$ (Kuhn et al. 1984).

At Stripa, efforts were made to use data to obtain generalized groundwater regimes. These regimes were presented as “A,” “B,” and “C.” “A” showed groundwater evolution in a granite where salinity arises from interaction with the rock matrix, the [$^{36}\text{Cl}/\text{Cl}$] atomic ratio of the dissolved chloride characterizing the rock. “B” had the groundwater recharging a formation with lower content of radionuclides (thus lower neutron flux) than the granite so that a lower [$^{36}\text{Cl}/\text{Cl}$] atomic ratio resulted as chlorinity rose. If chlorinity evolution stopped before this groundwater reached the granite, the ratio would increase with increasing residence time in the granite and the length of this could be estimated from the extra ^{36}Cl in-growth in the granite. “C” assumed chlorinity to derive from a source with a low [$^{36}\text{Cl}/\text{Cl}$] ratio (possibly an evaporite). Later infiltration into a formation with a higher content of radionuclides will produce ^{36}Cl in-growth in the dissolved chloride and, if the groundwater resides long enough, the chloride will reach the saturation ratio for the in situ neutron flux. Subsequent flow into a granite fracture system would induce a further time-dependent rise in the [$^{36}\text{Cl}/\text{Cl}$] atomic

ratio if no additional matrix chloride was dissolved. Chlorine-36 deposits in snow on the Greenland ice sheets and in Antarctica can be used to date ice or detect variations in production rates in the atmosphere.

17.4.6 Krypton-81 and Krypton-85

Krypton-81 resembles both argon-39 and the short-lived argon-37 in that it is a cosmogenic radionuclide occurring in the atmosphere, in groundwater that has been in contact with the atmosphere and in air occluded in glacial ice. Both ^{81}Kr and ^{85}Kr result from spallation reactions involving protons and also from (n,γ) reactions from the stable ^{80}Kr and unstable ^{84}Kr . Krypton-81 has a half-life of 2.13×10^5 years and undergoes radioactive decay by electron capture to the stable bromine-81. It is not a fission product and has an activity of 0.067 ± 0.003 dpm L^{-1} . This value exceeds expectations by a factor of up to two that might imply an extraterrestrial influence of some sort (Kuzimov and Pomansky 1980). Krypton-81 has been used to date glacial ice.

Krypton-85 is a fission product continuously being released into the atmosphere during the reprocessing of spent nuclear fuel. Because major reprocessing plants are located in the northern hemisphere, krypton-85 concentrations in the southern hemisphere are systematically lower. In addition, part of the krypton-85 released at mid-northern latitudes decays before it can be transported to the southern hemisphere. It has a half-life of 10.76 years and decays to the stable nuclide rubidium-85 by beta emission. The specific activity of anthropogenic krypton-85 has been reported as about 3×10^4 dpm L^{-1} (Alburger et al. 1986). Both krypton-81 and krypton-85 have been investigated using the Oeschger Counter.

17.4.7 Silicon-32

Silicon-32 is produced by the cosmic-ray spallation of argon in the upper atmosphere from whence it descends to mix with surface water so that, as a radiotracer, it may be applied to measuring ocean water mixing and currents, glacier formation, the accumulation of sediments, and the stability of groundwater over centuries. However, there is a problem with the half-life of which estimates range from 60 to 700 years or more. A fairly recent value was 172 ± 4 years (Alburger et al. 1986). Of course, this constrains its utility, and another disadvantage is that its extremely low concentration in planetary waters requires using relatively enormous samples of around 10 t of water for analytical purposes.

17.5 Electron Spin Resonance (ESR)

When dielectric (paramagnetic) solids meet ionizing radiation, metastable electrons occur and are detectable. Measuring them is feasible using electron spin resonance (ESR) spectrometers that can sense the adsorption of microwave radiation by the trapped electrons when these are subjected to a strong magnetic field. Splitting of the energies of unpaired electrons is promoted and how this happens depends on whether their magnetic moments are aligned parallel to or opposite to the applied field. ESR-dating is based on such measurements of unpaired electrons trapped in crystal defects. Such quasi-“free” electrons are produced through geological time by

natural radiation arising from the decay of radioactive atoms and also from cosmic radiation. Paramagnetic centers in crystals revealed by ESR can be used to date samples of animal or human bones, fossil shells, corals, stalactites, quartz grains in fault gauges, etc., in the Quaternary Era (Ikeya and Miki 1980). Also, early Pleistocene volcanic rocks have been dated using quartz (Shimokawa et al. 1984). However, it has been shown that defects in quartz may have lasted for at least 1.5 Ga and, since quartz is the most abundant mineral in the Earth's crust, this may have laid the foundation for a greatly extended ESR geochronometer capable of dating numerous geological features over practically the last third of the history of the Earth (Odom and Rink 1988).

Some matters still have to be resolved. The relevant centers can be attributed to *Schottky–Frenkel defects* in the crystal lattice of quartz and measuring their number is difficult because of the fact that the characteristic ESR lines are frequently small and close to the background signal. Extreme spectrum accumulation has been proposed as a remedy. Also, the defects were created by elastic collisions of recoiling α -emitting nuclei with silicon and oxygen atoms and the precise amount of α -particle emitting nuclides have to be determined. They belong to the uranium and thorium decay chains, but normally have concentrations in quartz in the ppb range that makes them very hard to assess. In addition, the number of centers per unit of radioactive nuclides can vary as a function of the type of quartz examined.

17.6 Fission Track Dating

Energy is transferred from charged particles passing through a solid to its atoms and a damage trail is left behind. Such tracks were noted during the examination of irradiated solids using an electron microscope with high magnification ($\times 50,000$). Later it was found that such tracks could be both enlarged and made visible under the optical microscope by etching with an appropriate chemical solution, this reflecting the preferential solubility of the damaged areas. Tracks have dimensions of about 10 μm and are created by spontaneous fission fragments of uranium-238. These tracks not only have a large individual mass each but also release a large quantity of energy amounting to some 200 MeV during the process. It was proposed that track densities might be used for dating various types of mica. Natural minerals such as biotite and muscovite may have track densities up to $5,000\text{ cm}^{-2}$. The actual numbers relate to the time interval during which they accumulated and the uranium concentration in the samples. Any selected sample must have enough uranium content to produce a track density greater than 10 tracks/cm^2 during the time interval from cooling of the sample until now. And the tracks must be stable at ordinary temperatures for periods of time comparable to the age being measured. Tracks can be created artificially by induced fission of uranium-235 through irradiation of a sample using thermal neutrons in a nuclear reactor, this procedure being termed the “zeta” method of calibrating fission track dating (FTD) against other radiometric techniques (Hurford and Green 1983). Clearly, fission tracks must be reasonably free of defects and lattice ruptures so that they can be counted after etching and also the distribution of uranium in a sample must be close to uniform in order to permit the concentration to be determined from the density of induced tracks. Obviously, weathering is adverse to fission tracks and interestingly can reduce the assessed date of apatite while having little or no effect on zircon or sphene. However, the apparent reduction of the assessed date may have resulted from difficulty in identifying tracks in corroded crystals and perhaps also because they may have partially faded through the action of groundwater.

An age equation has been proposed, bearing in mind that the vast majority of tracks is due to the spontaneous fission of uranium-238 so that the effects of uranium-235 and thorium-232 can be neglected as can those due to decay by spontaneous of naturally occurring radionuclides of high atomic numbers. It is also assumed that induced ^{235}U fission resulting from the adsorption of thermal neutrons arising from the spontaneous fission of ^{238}U is insignificant unless the mineral, being dated, was embedded in uranium ore. The radioactive decay constant for the spontaneous fission of uranium-238, λ_6 , is uncertain, but it could be $(8.46 \pm 0.06) \times 10^{-17} \text{ a}^{-1}$.

With the usual assumptions, the relevant dating equation is as follows:

$$t = 6.446 \times 10^9 \ln \left(1 + 7.715 \times 10^{-18} \frac{\rho_s}{\rho_i} \Phi \right) \quad (17.10)$$

where ρ_s is the area density of spontaneous fission tracks on the surface of the mineral that is being analyzed and ρ_i is the area density of the induced tracks. The time t can be derived after measurement of ρ_s/ρ_i and the relevant dose from the monitor, Φ . Zeta calibration became necessary because of systematic errors arising from uncertainty regarding the value of λ_6 , these possibly affecting FTD dates.

17.7 Iodine/Xenon

In all, iodine has 33 isotopes, of which 16 are radioactive. The one of interest is iodine-129 with a half-life of 15.7×10^7 years. Common iodine is iodine-127. Xenon is an inert gas present in the atmosphere in minute amounts of around 0.006 ppm. It has 36 isotopes, of which the one of interest is xenon-129 produced by iodine-129 via β^- decay. This has an abundance in the naturally occurring element of 26.4 atom %. The I/Xe system could be a potentially precise geochronometer, especially of events in the solar system.

17.8 Lanthanum/Cerium

Both these elements are lanthanides (rare earths) and, like all members of that group have properties resembling those of aluminum. Cerium is a member of the inner transition elements. The lanthanum/cerium geochronometer is based on ^{138}La with a natural abundance of 0.09%, which undergoes branched radioactive decay by negatron emission to produce stable ^{138}Ce and by electron capture to yield the stable isotope barium-138. The initial values for partial half-lives have been given as $(2.69 \pm 0.24) \times 10^{11} \text{ a}$ (beta decay) and $(1.51 \pm 0.10) \times 10^{11} \text{ a}$ (electron capture), respectively. It became apparent that both of the radioactive decay constants had to be refined before the technique could be used. The Oeschger Counter was useful in promoting it.

Constraints on the ^{138}La β -decay half-life must be discussed. It was recognized that the La/Ce isotope scheme could be a powerful adjunct to the samarium/neodymium approach for petrogenetic studies. However, counting of the β -decay half-life of lanthanum gave $3.02 \times 10^{11} \text{ a}^{-1}$ and this did not accord with the geological half-life determinations from lanthanum/cerium and samarium/neodymium mineral isochrons (Dickin 1987). Further examination of this matter led to a six-point La/Ce isochron on whole-rock samples of Lewisian granulite facies of Archean gneiss from northwest Scotland. Based on the

above-mentioned half-life, a La/Ce age of 2.99 ± 0.4 Ga (2σ) resulted and this came within the error of a whole-rock samarium/neodymium date from Lewisian granulites of 2.895 ± 0.1 Ga (2σ). The above-mentioned half-life is equivalent to a La β -decay constant of $2.30 \times 10^{-12} \text{ a}^{-1}$ and it can be recommended for geological application of the method.

17.9 Lutetium/Hafnium

As with rhenium/osmium and potassium/calcium, this depends on the β decay of a naturally occurring radioactive isotope and all three techniques can be applied to rocks and minerals that cannot be dated by other conventional methods. Also, studying their radiogenic daughters gives information about the terrestrial mantle as well as about the accreting of continental crust. For a long time, it was not possible to use the Lu/Hf approach because of the difficulty in determining the half-life of ^{178}Lu by dating appropriate minerals of which the age was known from other methods. Another problem was that of separating pure hafnium from other elements, but this has been overcome (Patchett and Tatsumoto 1980). Thereafter great progress has been made with dating both minerals and rocks.

Lutetium-176 is radioactive and subject to branched decay by β emission, mostly to ^{176}Hf , though approximately $3 \pm 1\%$ decays to ^{176}Yb . However, the latter can be disregarded because of the long half-life of ^{176}Lu . Thus, the decay scheme of interest is

which leads to an excited state of hafnium-176 first that “decays” to the ground state by γ emission.

Two approaches were used to determine the half-life of lutetium-176. These were analysis of lutetium-bearing minerals with known ages and direct counting. Variable results range from 2 to 7×10^{10} years and a calculation from the slope of a Lu/Hf isochron formed by ten achondrites (eucrites) with an age of 4.55×10^9 years gave a value of $(3.53 \pm 0.14) \times 10^9$ years. This value accords with a recent estimate of 3.8×10^9 years.

Hafnium is a dispersed element found in many minerals where it replaces zirconium and to a lesser extent titanium. In lutetium-bearing rocks, the radioactive decay of ^{176}Lu means that the abundance of ^{176}Hf increases as a function of time. To assess the age of a mineral or rock sample, the concentrations of lutetium and hafnium have to be measured and also the $[^{176}\text{Hf}/^{177}\text{Hf}]$ ratio after which an appropriate age equation can be applied. If a suite of samples has a common age, but differing $[^{176}\text{Lu}/^{177}\text{Hf}]$ ratios with the same initial $[^{176}\text{Hf}/^{177}\text{Hf}]_i$ ratio, all its members will lie on a straight-line isochron in the graph of $[^{176}\text{Hf}/^{177}\text{Hf}]$ vs. $[^{176}\text{Lu}/^{177}\text{Hf}]$, its slope being a monotonic function of their age (which, for relatively short ages, simplifies to proportionality) and its intercept being the initial $[^{176}\text{Hf}/^{177}\text{Hf}]_i$ ratio. (For a similar case, see [Sect. 17.16](#).) Data have been published on a suite of whole-rock samples and separated zircons from the Amitsoq gneiss, West Greenland, and the relevant isochron gave an age of 3.59 ± 0.22 Ga and an initial ratio of 0.280482 ± 0.000033 (Pettingell et al. 1981). This result agreed closely with others obtained using the rubidium/strontium method and quite well with uranium, thorium, and lead dating as well. Therefore, this date is probably a very reasonable estimate of the time elapsed since the sources of the Amitsoq gneiss were transferred up from the mantle.

From the Murchison chondrite meteorite, the $[\text{Lu}/\text{Hf}]$ ratio was taken as 0.24 and, assuming that the age of the chondritic reservoir is 4.55 Ga, the present value of the

[$^{176}\text{Hf}/^{177}\text{Hf}$] ratio would be 0.2828, taking into account the corresponding [$^{176}\text{Lu}/^{177}\text{Hf}$] ratio of this chondrite, which is 0.0334. These data define a hafnium growth curve valuable as a reference for the isotopic composition of hafnium in terrestrial rocks and minerals. In basalts from mid-oceanic ridges (MORB) and oceanic islands (OIB), the [$^{176}\text{Hf}/^{177}\text{Hf}$] ratio ranged from the above-mentioned 0.2828 to 0.2835 and usually exceeded the present ratio in the chondritic reservoir. It may be inferred that such basalts derived from mantle sources depleted in hafnium relative to lutetium during earlier episodes of partial melting, therefore having higher [Lu/Hf] ratios than do chondrites. Curiously, the [$^{176}\text{Hf}/^{177}\text{Hf}$] ratios of oceanic basalts correlate negatively with [$^{87}\text{Sr}/^{86}\text{Sr}$] ratios, but positively with [$^{143}\text{Nd}/^{144}\text{Nd}$] ratios (Patchett and Tatsumoto 1980).

Zircon crystals may contain detrital cores with ages preceding the crystallization of the igneous rocks that contain them and also they can acquire overgrowths during the metamorphism of their host. In such zircons, the hafnium may well have a wide range of isotopic compositions that produces a scattering of data points about the isochron and introduces systematic errors into the derived ages. However, zircons have low [Lu/Hf] ratios and so can be used to extend the [Lu/Hf] ratios of data points on isochrons as well as to calculate the initial [$^{176}\text{Hf}/^{177}\text{Hf}$]_i ratios of igneous rocks by using their ages after these ratios have been determined by alternative methods.

17.10 Manganese

Manganese has a naturally occurring stable isotope, ^{55}Mn , and 12 radioactive isotopes. The one of interest is ^{53}Mn that has a half-life of 3.7×10^6 years and decays by K-capture into the stable ^{53}Cr . It may be possible to use it in assessing the terrestrial ages of meteorites and extraterrestrial dust abundances in ice and sediments.

17.11 Nickel

Nickel has 5 stable and 11 unstable isotopes. The one of interest is ^{59}Ni with a half-life of 7.5×10^4 years. It decays by electron capture and is the longest-lived of the unstable isotopes. It has been employed to assess the terrestrial ages of meteorites and extraterrestrial dust abundances in ice and sediments.

17.12 Osmium/Osmium

Since negative thermal ion mass spectrometry (N-TIMS) for rhenium/osmium dating (see [Sect. 17.18](#)) was developed about 1990, not too much work has been published. This is probably due to the high rhenium blanks from the current generation of “clean” platinum filaments and to problems in achieving isotopic exchange and equilibrium between sample and spike for osmium. Another drawback is the non-homogeneity of samples. Because of this, rhenium and osmium concentrations may vary by up to 40% in the same sample.

Obviating such difficulties may be possible using “Os/Os,” that is to say $^{187}\text{Os}/^{186}\text{Os}$ and $^{187}\text{Os}/^{188}\text{Os}$, dating (Yin et al. 1993). The approach is a high-precision one, and its use with a molybdenite sample implied that it can become a geochronological tool even capable

of dating such minerals from meteorites. Irradiating a rhenium-bearing sample with thermal neutrons in a nuclear reactor enriches ^{186}Os and ^{188}Os proportionally to the neutron flux and the Re/Os ratio of the relevant sample. After free decay (i.e., after a short “cooling” period during which short-lived intermediate nuclides decay), the increments of ^{186}Os and ^{188}Os contents caused by thermal neutrons can be measured. (The relevant branching ratio is 0.922.)

Although very difficult to use, Os/Os dating could eliminate problems characteristic of conventional rhenium/osmium analyses and enable both the Re/Os ratio and the osmium isotopic composition to be derived from a single measurement. It is clear that the precision of age determination will reflect the instrumental precision of osmium isotope ratio measurements using N-TIMS. The method may offer the possibility of dating open systems, i.e., to say of obtaining age spectra by selective leaching or by in situ measurement of irradiated samples. However, the analytical procedure must be further refined, particularly as regards the flux monitor. Obviously establishing and certifying an appropriate monitor would facilitate extending the Os/Os method. And, since ^{186}Os , ^{187}Os , and ^{188}Os are variable and for ^{189}Os , there is significant ^{188}Os interference, e.g., in molybdenites; only $^{190}\text{Os}/^{192}\text{Os}$ can be used for the fractionation correction in all Os/Os dating measurements. MPI-Os is an available standard.

17.13 Pleochroic Haloes

These are bands or zones of discoloration surrounding uranium- and thorium-bearing inclusions in minerals, which show such radiation damage effects as a result of the interaction of α particles with atoms in the relevant crystal lattices to produce either displacement of the atoms or their electrons from their equilibrium positions. Such phenomena occur not only in colored minerals, but also in such colorless ones as muscovite and fluorite. The inclusions involved are centrally located with respect to the haloes and commonly comprise zircon, apatite, or sphene. Correlation with radioactivity was established as long ago as 1907. Pleochroic haloes are composed of concentric rings with radii ranging from 20 to 50 μm . They are produced by specific α particles emitted by the radionuclides occurring in the central inclusions. The radii record the kinetic energies of the corresponding α particles. Rings form because the ionizing power of such α particles maximize near the end of their ranges in particular media. (See the Bragg curve in [Fig. 8.5 in Chap. 8, Vol. 1.](#)) Probably the optimal mineral in which to examine them is biotite because of its perfect cleavage and also because radiation damage discoloration is easily observed. Although numerous attempts have been made to identify which radioisotope is responsible for which ring with any specific radius, in biotite, the matter is not yet completely solved. Controversy exists regarding giant haloes with diameters that may reach 110 μm . Some are caused by energetic α particles emitted for instance by polonium isotopes. Some have radii of about 54 μm and derive from uncommon 10.5 MeV α particles of ^{212}Po , a daughter of thorium.

The origin of haloes with greater radii is speculative. They may come from the diffusion of radioactive daughters of uranium and thorium. Otherwise, they could be due to the occurrence of residual primordial ^{244}Pu , which emits α particles with energies far exceeding 15 MeV during spontaneous fission. Another suggestion is that such giant haloes are produced by the radioactive decay of superheavy elements (SHEs) with atomic numbers up to 127. (See [Sect. 21.2.1, Chap. 21 in this Volume.](#))

Pleochroic haloes have been used to date minerals and rocks. The method depends on the fact that the intensity of their colors increases with the alpha dose to which they have been exposed. The relationship between the two may fall into any one of three categories. In the first place, a normal stage exists in which color increases linearly with radiation dose. Secondly, there is a saturated stage in which the color reaches a maximum density and does not show any further increase with increasing radiation dose. Thirdly, there is an inversion stage in which coloration actually decreases with the intensity of the radiation dose – this is caused by extreme radiation damage. Only those from the first category are used for age determinations.

A number of assumptions have to be made. One is that the coloration really is a linear function of the received alpha dose. A second is that concentrations of radionuclides emitting alpha particles have not altered except through radioactive decay processes. Consequently, to date a mineral using this method entails measuring the alpha activity of the inclusion at the center of the pleochroic halo as well as assessing the intensity of color of this feature. Also, it is essential to know the relationship between the alpha dose and the intensity of color in the mineral to be dated. This latter can be established experimentally by irradiation of the mineral sample with alpha particles from an artificial source or by examining haloes in other samples of the same mineral with known ages.

Mineral dating using pleochroic haloes is possible, but drawbacks must be noted. One is that the haloes are to some extent erased by heating of the mineral during metamorphism (Fowler and Lang 1977; Hashemi-Nezhad et al. 1979). Secondly, the alpha activities in the inclusions are hard to measure. Finally, there is some ambiguity surrounding the exact relationship between the alpha dose and coloration in biotite, which is the best mineral for use in age determinations using pleochroic haloes.

17.14 Polonium/Lead

Polonium is a radioactive element with 27 isotopes, of which the longest-lived has a half-life of 103 years. The isotope of interest in this new geochronometer is ^{210}Po found in some uranium ores to the extent of one part in 10^{10} . It is a member of the uranium-238 series (see Fig. 7.6 in Chap. 7, Vol. 1) of which the most relevant steps are as follows:

In an undisturbed (closed) system, that is to say one at secular or radioactive equilibrium, ^{210}Po has the same activity as other radionuclides in this series. Preceded by ^{210}Bi , its immediate parent (half-life 5.013 days), fractionation occurs, and it equilibrates with its “grandparent,” namely ^{210}Pb .

The method described here has been suggested to date glassy eruption products within a few years after eruption (Rubin et al. 1994). The method is based on the fact that during eruption degassing occurs, which affects not only the obvious ^{222}Rn , but also ^{210}Po as its compounds (e.g., its halogenides) are rather volatile (even the pure metal has a fairly low boiling point of 962°C). So it is thought to be completely gaseous in volcanic eruptions at about 400°C . Due to the very short half-lives between ^{222}Rn and ^{210}Pb , equilibrium gets reestablished again within a few weeks all the way down to ^{210}Pb , so that the activity of the latter can be considered constant.

The calculation was based on a simplified form of the Bateman equation – see [Eq. \(7.42\) in Chap. 7, Vol. 1](#) – for closed system radioactive decay to describe the ^{210}Po content of degassed lavas as a function of time. Using appropriate initial conditions for solving [Eq. \(7.36\) in Chap. 7, Vol. 1](#), one obtains the following relationship for the activities:

$$(^{210}\text{Po}) \equiv (^{210}\text{Po})_t = (^{210}\text{Po})_0 e^{-\lambda t} + (^{210}\text{Pb})(1 - e^{-\lambda t}) \quad (17.13)$$

where t is the time elapsed since the eruption and λ is the decay constant of ^{210}Po .

For the numbers of atoms there is a slightly more complicated formula involving the decay constant λ_{Pb} of ^{210}Pb :

$$[^{210}\text{Po}] \equiv [^{210}\text{Po}]_t = [^{210}\text{Po}]_0 e^{-\lambda t} + [^{210}\text{Pb}] \frac{\lambda_{\text{Pb}}}{\lambda} (1 - e^{-\lambda t}). \quad (17.14)$$

To calculate t from one measurement of (^{210}Po), it is necessary to know both (^{210}Pb) and (^{210}Po)₀. While for a totally degassed lava, the latter term would be zero, it is probable that only partial degassing may take place in the case of submarine lavas, which erupted under high hydrostatic pressure. However, it is feasible to calculate a unique maximum value to t by assuming that total degassing occurred and fitting an exponential function to a set of measurements made on a sample as ^{210}Po grows into equilibrium with ^{210}Pb (Rubin et al. 1994). The maximum age corresponds to (^{210}Po)₀ = 0 on the best fit growth curve. The approach was applied to East Pacific Rise (EPR) lavas and repeated measurements of (^{210}Po) over several years were made on aliquots of each sample together with in-growth curves having the functional form of the above equation. They were fitted to the data using the time interval between sequential measurements in order to constrain t . The regression results gave a function for (^{210}Po) and the known analysis times linked the results to calendar time.

If degassing was not complete at eruption, the eruption time cannot be accurately ascertained, but is bracketed in every case by the “window” between collection of sample and calculated maximum age. Such “windows” (eruption dates) are most accurately determinable for samples either having the lowest (^{210}Po) when collected or for which the initial (^{210}Po)₀ can be estimated independently. Samples have been obtained from mid-ocean ridge basalts (MORBs), and these have similar chemical compositions and were erupted at the same water depth, both factors possibly affecting the efficiency of degassing. Hence, it can be anticipated that all will have more or less the same initial (^{210}Po)₀. But the degassing content may not be as high as the subaerial value of 100%. Two samples were analyzed by Rubin et al. (1994) and had the same ^{210}Po contents at the time of collection, which were only about 25% of the secular equilibrium value (25.1% and 25.6%, respectively), implying that all samples were minimally 75% degassed in the course of the eruption.

Best-estimate “windows” are about 2 months long and allow investigation of MORB eruption chronology on a much finer scale than was hitherto possible. If Po degassing turns out usually to be larger than the “conservative” minimum estimate of 75%, the resolution of the process may improve although such improvement would require analyses of ^{210}Po in a number of young MORBs having eruption dates, which are well-known so that the normal degree of degassing could be established. It was proposed that making remote observations of potential eruption indicators such as seismicity or mega-plumes that fall within an eruption “window” could also be valuable in constraining eruption dates and the range of initial (^{210}Po)₀ in MORBs.

17.15 Potassium/Argon

Potassium has 18 isotopes, of which the majority are unstable. The naturally occurring unstable one is potassium-40 and this undergoes branched radioactive decay to calcium-40 and argon-40 so that argon-40 abundance in the atmosphere is orders of magnitude greater than would be expected by comparison with abundances of the other inert gases. Hence, excess ^{40}Ar should occur in ancient potassium-bearing minerals, and once this was found to be the case, the foundation of the K/Ar dating method was laid. The relative abundances of the three significant potassium isotopes are ^{39}K 93.2581%, ^{40}K 0.1167%, and ^{41}K 6.7302%. Those of the interesting argon isotopes are ^{36}Ar 0.337%, ^{38}Ar 0.063%, and ^{40}Ar 99.6%.

Radioactive decay of potassium-40 to stable argon-40 takes place by electron capture (and also by positron decay) with the emission of γ quanta (energy 1.51 MeV). (See the decay scheme in [Eq. \(7.22\) in Chap. 7, Vol. 1.](#)) Eleven percent of the potassium-40 decays by electron capture to an excited state of argon-40 that de-excites by emitting a gamma ray. About 0.16% of the decays take a more direct route by electron capture straight to the ground state of argon-40. Positron decay is rare, taking place only about 0.001% of the time with an E_{max} of 0.49 MeV. It is followed by two annihilation gamma rays with a combined energy of 1.02 MeV.

Negatron (β^-) decay to stable calcium-40 involves most of the potassium-40 atoms and in fact only 11% of them decay to ^{40}Ar . In a potassium-bearing system closed to all external influences through geological time, the growth of radiogenic argon-40 and calcium-40 can be represented as

$$[^{40}\text{Ar}] + [^{40}\text{Ca}] = [^{40}\text{K}](e^{\lambda t} - 1) \quad (17.15)$$

where $\lambda = \lambda_{\text{EC}} + \lambda_{\beta}$ is the total decay constant of potassium-40, and all numbers of atoms including that of ^{40}K refer to the same moment t .

Each branch of the decay mode has its own decay constant and these are as follows. For ^{40}K to ^{40}Ar , it is $\lambda_{\text{EC}} = 0.581 \times 10^{-10} \text{ a}^{-1}$, and for ^{40}K to ^{40}Ca , it is $\lambda_{\beta} = 4.962 \times 10^{-10} \text{ a}^{-1}$. Summing gives a value for λ of $5.543 \times 10^{-10} \text{ a}^{-1}$ and the corresponding half-life is 1.25×10^9 years. The branching ratio is about 0.11. It should be added that there are other, slightly different, values for the decay constants in the literature.

The growth of radiogenic ^{40}Ar atoms in potassium-bearing minerals is given by

$$[^{40}\text{Ar}] = \frac{\lambda_{\text{EC}}}{\lambda} [^{40}\text{K}](e^{\lambda t} - 1) \quad (17.16)$$

where λ_{EC} is the decay constant for the decay of ^{40}K to ^{40}Ar .

The total number of argon-40 atoms will be the sum of the radiogenic ones and those that were present when the mineral formed. It is assumed that none was present initially and if this is the case, then, if the ^{40}Ar concentration and the amount of accumulated radiogenic argon-40 in a mineral are known, its age t can be derived from

$$t = \frac{1}{\lambda} \ln \left(1 + \frac{\lambda}{\lambda_{\text{EC}}} \frac{[^{40}\text{Ar}]}{[^{40}\text{K}]} \right). \quad (17.17)$$

Some other assumptions have to be made in order to derive values for t from various minerals. One is that none of the radiogenic ^{40}Ar arising from the radioactive decay of ^{40}K in the mineral during its geological history has escaped by diffusion. Another is that the mineral closed to ^{40}Ar soon after crystallization, hence rapid cooling must have occurred.

It is implicit in the method that no excess ^{40}Ar became incorporated in the mineral when it crystallized or during any subsequent metamorphic episodes. Finally, it is assumed that the mineral remained closed to potassium throughout its geological history so that the isotopic composition of the potassium in it must have altered solely through radioactive decay of the ^{40}K originally present and no isotopic fractionation took place. A correction is necessary for the presence of atmospheric ^{40}Ar . Also, the potentially disturbing effects of argon being overpressurized in extremely old basement rocks have to be considered because the gas might be released during metamorphism (Roddick 1983). However, it has been claimed that this may not always happen because analyses of Alpine muscovites in granites from the Helvetic basement (Aar Massif) in the central Swiss Alps showed that no argon overpressure, either of radiogenic or atmospheric origins, existed (Dempster 1986).

If argon loss occurred in a mineral, it happened usually because of metamorphism, this phenomenon showing the inability of argon to bond with other atoms in a crystal lattice. In fact, minerals have difficulty in retaining the gas even at quite low temperatures and at atmospheric pressure. So it is not surprising that the concept of closure temperatures below which, when minerals formed, crystallization ages were recorded, has been increasingly criticized. In the western Alps and Norway, old ages were retained despite later metamorphic temperatures believed to have exceeded the supposed closure temperatures (Chopin and Maluski 1980; Verschure et al. 1980). Clearly, other factors such as chemical weathering, deformation, ex-solution, and recrystallization may affect mineral age relationships. Naturally, only potassium-bearing minerals, rocks, and minerals able to resist as many as possible of these adverse influences are appropriate for dating by the K/Ar method. In fact, such rocks and minerals are quite common and, among igneous rock, include volcanics, although those containing devitrified glass must be avoided, as also should those containing such secondary minerals as xenocrysts. Basaltic glass can retain argon well, but hydrated glass cannot, especially if devitrified. Devitrified glass data revealed a lowering of K/Ar dates. Xenocrysts may produce the opposite effect if they possess excess radiogenic argon-40.

Such excess radiogenic argon-40 may occur in some potassium-bearing minerals, and its effects on K/Ar ages are most marked in young minerals or those with low potassium content. However, while beryl, cordierite, and tourmaline often contain such excess radiogenic argon-40, other minerals do not. The excess gas can result from the relevant minerals having been exposed to high partial pressure of the gas during an episode of regional metamorphism when pegmatites crystallize or kimberlite pipes are emplaced. In addition, it may diffuse into minerals as a result of the outgassing of older potassium-bearing minerals in the crust and mantle of the Earth or from older xenoliths or xenocrysts. Whenever it happens, K/Ar ages are increased and therefore give overestimates for the ages of minerals containing it. Minerals used in such dating have different blocking temperatures, e.g., that of biotite is lower than that of hornblende in deep-seated plutons and so the K/Ar “clock” of the hornblende starts before that of biotite since cooling is in progress. If temperature decrease was smooth and both minerals constituted closed systems since crystallization, the hornblende will register an older date than the biotite. If two such different dates are obtained, they can be used to infer the cooling rate.

Discordant K/Ar dates from coexisting minerals have been recorded in metamorphic rock samples from metamorphic rocks having two separate temperature histories. In such cases, either all the minerals were totally degassed during the metamorphic episode and slow cooling followed or the degassing process did not go to completion and the fraction of argon lost from a particular mineral will relate to the retentivity of that mineral for the gas.

17.15.1 The Metamorphic Veil Concept

Many biotites from granitic gneisses and schists of Precambrian age shields and orogenic belts have been dated by the method and results often reflected times elapsed after cooling through blocking temperatures rather than real ages. If such dates are plotted on a map, they form a conceptual surface termed the metamorphic veil (Armstrong 1966). The meaning of this is that the K/Ar dates veil the real ages of the host rocks and show only the metamorphic episode and the later cooling histories of the rocks. Regional homogeneity for such dates in shields and orogens implies that large parts of the continental crust may have undergone metamorphism, later cooling in large-scale systematic patterns perhaps induced by the uplifting of vast cratonic blocks bordered by extensive fracture zones extending far below the surface. Perhaps the K/Ar dates from an individual mineral of such a cratonic block might represent the time interval that elapsed since rocks now exposed at the surface were upthrust across the isotherm corresponding to the blocking temperature. Contours drawn to represent equal times since cooling through blocking temperatures have been termed thermochrons or chronochrons. In the Grenville Province, Canada, they run roughly parallel to the Grenville Front to form a southeasterly dipping surface. Rocks that are now exposed were uplifted through the blocking temperature isotherm between 850 Ma and 1.125 Ga ago, and the western edge of the Grenville craton was uplifted before the eastern. However, if the lower dates along the eastern edge are a result of argon loss induced thermally during the Appalachian orogeny, this would be an alternative explanation. Data from the Canadian shield cluster around certain values may relate to the presumed ages of orogenies, of which there were at least four for which the timescale was determined using K/Ar dating as well as whole-rock Rb/Sr and U/Th (Stockwell 1982). In association with this, eight structural provinces have been recognized on this shield and each stabilized at the end of a particular orogeny as is shown by the clustering of K/Ar mica dates around a so-called magic number. But the metamorphic veiling must be remembered – it conceals the real ages so that, for instance, the Grenville Province has rocks formed much earlier than the Grenville orogeny. A similar timescale has been constructed for the USA.

Coexisting minerals with the same presumed initial $[\text{}^{40}\text{Ar}/\text{}^{36}\text{Ar}]_i$ ratio and the same age can be represented by points defining a straight line in coordinates of the measured $[\text{}^{40}\text{Ar}/\text{}^{36}\text{Ar}]$ and $[\text{}^{40}\text{K}/\text{}^{36}\text{Ar}]$ ratios, this constituting an isochron. The slope of such an isochron, m , can be used to derive an equation for calculating relevant ages, which is as follows:

$$t = \frac{1}{\lambda} \ln \left(m \frac{\lambda}{\lambda_{\text{EC}}} + 1 \right) \quad (17.18)$$

where t is the time elapsed since crystallization.

Such K/Ar isochrons have been used extensively and clearly, they only form when all the samples involved are closed systems with respect to potassium and argon, this ensuring that the data points define the relevant slopes satisfactorily. The isochron approach is probably more advantageous than conventional K/Ar dating because the degree of good fit of such data points to a straight line expresses the degree of closure of the samples analyzed through geological time as well as the similarity or concordance of their initial $[\text{}^{40}\text{Ar}/\text{}^{36}\text{Ar}]_i$ isotopic ratios.

17.16 Potassium/Calcium

Calcium has six stable isotopes, the commonest being calcium-40 with an abundance of 96.98215%. The isotopic composition in minerals and rocks varies through the formation of

^{40}Ca by the negatron decay of ^{40}K (along one path of branched decay, the other leading to ^{40}Ar) and also because of the fractionation of calcium isotopes during several physicochemical processes. The possibility of calcium isotopes fractionating is great because of the considerable difference in their masses (about 20% of ^{48}Ca relative to ^{40}Ca). The decay constant for the decay of ^{40}K to ^{40}Ca is about $\lambda_\beta = 4.962 \times 10^{-10} \text{ a}^{-1}$. Co-genetic rocks or minerals with the same initial $[^{40}\text{Ca}/^{42}\text{Ca}]_i$ ratio and of the same age lie on an isochron in coordinates of $[^{40}\text{Ca}/^{42}\text{Ca}]$ and $[^{40}\text{K}/^{42}\text{Ca}]$ with a slope, m , of

$$m = \frac{\lambda_\beta}{\lambda} (e^{\lambda t} - 1) \quad (17.19)$$

and an intercept b equal to the original $[^{40}\text{Ca}/^{42}\text{Ca}]_i$ ratio. High precision values for this ratio relative to $[^{42}\text{Ca}/^{44}\text{Ca}]$ were about 0.31221, a useful reference for making fractionation corrections. The Pikes Peak batholith, Colorado, USA, was dated at $1.041 \pm 0.032 \text{ Ga}$ by isochron and this agreed closely with results from other isotopic geochronometers (Marshall and DePaolo 1982). The initial $[^{40}\text{Ca}/^{42}\text{Ca}]_i$ ratio was 151.024 ± 0.016 , and this is almost the same as that obtained from two stony meteorites and three mantle-derived rocks and minerals.

17.17 Radiocarbon (Carbon-14)

Radiocarbon is produced in the atmosphere through the impact of cosmic-ray neutrons on a small proportion of nitrogen-14 atoms in the following manner:

It then becomes incorporated into molecules of carbon dioxide by reaction with oxygen or by exchange with stable carbon isotopes in molecules of carbon dioxide or monoxide. Molecules of $^{14}\text{CO}_2$ mix rapidly into the atmosphere and hydrosphere as well as living organisms to attain a constant level of concentration representing a steady-state equilibrium maintained because of the continuous production of ^{14}C and its on-going radioactive decay; hence,

The Q -value of the above decay is only $Q = 0.156 \text{ MeV}$, and the ground state of nitrogen-14 is reached directly without γ emission. Thus, the result is a rather “soft” β radiation with $E_{\text{max}} = 156 \text{ keV}$.

Radiocarbon dating can be performed on objects made from once-living organisms such as wood or the remnants of such organisms. The idea behind the method is that the steady-state equilibrium stops between the organism and its environment as soon as it stops living. From that moment on, the specific activity of ^{14}C incorporated by the organism starts to decline (due to the above decay) according to the exponential law with a half-life of $5,730 \pm 40 \text{ years}$ (see [Chap. 7 in Vol. 1](#) as well as [Fig. 17.2](#) and [Eq. \(17.22\)](#) later on).

A multi-wire counter was used by Libby to measure the radiocarbon content in archeological artifacts. The first sample he dated was a piece of acacia wood from furniture in Pharaoh Zoser's tomb at Saqqara, Egypt. About 20 g were used, and the date determined was $2,030 \pm 350 \text{ years BC}$. The technique developed rapidly, and only 10 mg of the same sample were dated in 1992 in the new National Ocean Sciences Accelerator mass spectrometry facility at Woods Hole Oceanographic Institution and gave an age of $4,115 \pm 34 \text{ years}$, i.e., within one σ error of the first (Libby) analysis. The Oeschger Counter is another indispensable tool on

■ Fig. 17.2

The radioactive decay of radiocarbon in plant or animal tissues originally in equilibrium with atmospheric or hydrospheric $^{14}\text{CO}_2$ molecules. Exchange ceases after the deaths of the organism involved. The radioactivity diminishes as a function of time (half-life of ^{14}C is 5730 ± 40 years). When the residual radiocarbon activity is measured, the age of the sample is obtainable from this graph

measuring the activity of the naturally occurring radioisotope (carbon-14). Oeschger, together with F. T. Houtermans (Bern), built the first Radiocarbon Dating Laboratory in Switzerland and was the first to date the “age” of Pacific deep water. The Oeschger Counter facilitated the application of the ^{14}C method to geophysical problems.

17.17.1 Conversion of Radiocarbon Years to Calendar Years

To do this conversion, it requires corrections accounting for fluctuations of radiocarbon content in atmospheric carbon dioxide in the past. These are based on measurements of radiocarbon concentrations in a series of tree rings dated using dendrochronological techniques. The tree ring calibrated age for the modern carbon-14 AMS equipment analysis of the Zoser wood gives two solutions with a 95% degree of confidence: 2877–2800 BC and 2780–2580 BC. This fact accords with archeological estimates. However, a marked step in the calibration curve during Zoser’s reign precludes a high precision calibrated age estimate for this particular material.

17.17.2 Atmospheric Radiocarbon in the Past

There have been systematic variations in the radiocarbon content of the atmosphere in the past, which cause inaccuracies where dating is concerned. One reason for such variations is that the rate of formation by the (n,p) reaction shown by [Eq. \(17.20\)](#) depends mostly on the density of the cosmic-ray-produced neutron flux (see [Eq. \(7.68\)](#) in Chap. 7, Vol. 1), which increases

with altitude to attain a maximum between 12,000 and 15,000 m above the surface of the Earth. Also, the flux is greater by a factor of four in the polar regions. Consequently, the rate of production of radiocarbon there should mean that living tissues in that region ought to have more radiocarbon in them than those at the equator. However, it has been shown that specific ^{14}C activity may be independent of location probably because of rapid mixing in the upper atmosphere, a process believed to last less than 2 years. The effect of this may well tend to produce uniformity at the surface of the Earth. In addition, the neutron flux will vary as the intensity of the solar proton flux does, so that the ^{14}C content of the atmosphere doubtless varied with time in conjunction with alternating solar activity. Additionally, the cosmic-ray flux may be modified by changes in the Earth's magnetic field during the past 40,000 years or so, although data have been published implying that the initial radiocarbon in a set of archeologically dated samples was compatible with present day values (Arnold and Libby 1949).

17.17.3 Radiocarbon in Dead Animals and Plants

The radioactivity of a carbon sample from a plant or animal tissue, which died t years ago is given by $A = A_0 e^{-\lambda t}$, where A is the specific activity now and A_0 is the specific activity of ^{14}C in the same sample when death occurred. A value for the estimated specific activity of ^{14}C was 226 ± 1.2 Bq/kg and the half-life, $T_{1/2}$, was given as $5,730 \pm 40$ years with a decay constant of 1.209×10^{-4} . A “dead” sample containing carbon can be considered no longer in equilibrium with the ^{14}C of the atmosphere.

From the exponential law of decay applied to (specific) activities one obtains

$$t = \frac{1}{\lambda} \ln \left(\frac{A_0}{A} \right) \quad (17.22)$$

which, substituting the value of λ , gives

$$t = 8271.3 \ln \left(\frac{A_0}{A} \right) \text{ years.} \quad (17.23)$$

The initial activity is a known constant through the past 70,000 years independent of passing time and with a value independent of geographical location and the species of dead plant or animal from which the relevant tissues are taken. It is assumed that the sample to be dated was not contaminated by modern radiocarbon and that its observed activity is unaffected by radioactive impurities. Research has shown that the initial carbon-14 activity of modern plant and animal tissues is constant to a first approximation and also that the radiocarbon activity in archeological materials of known age is measurable with sufficient precision to provide radiocarbon dates that agree satisfactorily with the known historical ages.

Materials suitable for radiocarbon dating include charcoal, peat, wood, grains and seeds, ivory, burnt bones, collagen, cloth, inorganic and organic carbon in shells, lake marls, lake and deep-sea sediments, pottery, and iron. Amounts needed for analysis vary from about 25 g for wood to 5,000 g for iron. To measure the radiocarbon contents, liquid scintillation has been used and is adequate for dates <30,000 years old. Ultrasensitive high-voltage tandem mass spectrometers offer direct counting of ^{14}C ions, but the technique is expensive.

17.17.4 The De Vries Effect

It has been shown that the radiocarbon content of the atmosphere varied systematically in the past so that the radiocarbon activity around 1,500 and 1,700 was approximately 2% higher than it was during the nineteenth century. This phenomenon has been termed the De Vries effect, and another such effect (called the Suess effect) has been observed in twentieth century activity and is ascribed to the introduction of “dead” CO₂ into the atmosphere through the combustion of fossil fuels after the start of the Industrial Revolution (De Vries 1958).

17.17.5 Bomb, Reactor, and Accelerator Radiocarbon in the Environment

Larger effects came from atmospheric thermonuclear explosions then and later by the operation of nuclear reactor and particle accelerators. Bomb-produced radiocarbon is detectable in the oceans and also in the biosphere. To narrow uncertainty of estimates of fossil fuel, anthropogenic carbon dioxide uptake by the oceans is important in quantifying the contemporary carbon budget. Using ocean general circulation models (OGCMs) may be the best way of tackling this problem, but first the model has to be calibrated with the distribution of bomb-produced radiocarbon in the ocean. Natural, i.e., cosmic ray-produced, radiocarbon is most sensitive to processes operating over century timescales, whereas anthropogenic (i.e., bomb testing-produced) radiocarbon is most sensitive to processes operating over 10-year periods. If the bomb-produced radiocarbon is not separated from the natural radiocarbon, it will not be possible to determine whether the disagreements between model and observation reflect the deficiencies in the model's simulation of the steady-state distribution of natural radiocarbon or in its simulation of the distribution of the bomb radiocarbon transient. Therefore, the separation of bomb-produced radiocarbon from the natural radiocarbon in the overall radiocarbon measurements is essential if radiocarbon distribution is to be used to constrain the ocean models.

17.17.6 Separating Bomb-Produced ¹⁴C from Natural Radiocarbon

A method of achieving such a separation has been developed. It involves the strong correlation between natural radiocarbon and dissolved silica. For global coverage, radiocarbon measurements made on samples collected during the Geochemical Ocean Sections Study (GEOSECS) in 1972–1978 were analyzed for bomb radiocarbon inventory in the ocean. Later measurements made in the Atlantic Ocean during Transient Tracers in the Ocean (TTO) in the early 1980s and South Atlantic Ventilation Experiment (SAVE) in the late 1980s were also analyzed for temporal variations in bomb radiocarbon inventory. Recent radiocarbon measurements on the NOAA/OACES 1993 cruise in the Atlantic have also been analyzed for bomb radiocarbon inventory. In the Pacific Ocean, radiocarbon measurements from samples collected in the WOCE program are gradually becoming available for bomb radiocarbon inventory analysis. Continuing efforts in analyzing WOCE data have been proposed.

Comparison of results between GEOSECS and TTO/SAVE shows that the bomb radiocarbon inventory has increased by 36% for the region north of 10° N, by 69% for the equatorial region and by 71% for the region south of 10° S. These data reflect the radiocarbon uptake for the Atlantic Ocean between 1973 (GEOSECS) and 1985 (TTO/SAVE). Along with global bomb radiocarbon distribution, this information provides crucial constraints for the carbon cycle in the ocean. Preliminary results from CGC-91, one of the WOCE cruises, show that the observed increase in bomb radiocarbon inventory from 1974 to 1991 in the northern Pacific Ocean is consistent with the first-order prediction from a box-diffusion ocean model.

17.17.7 Variation of Bomb Radiocarbon in Oceans

Variation of bomb radiocarbon in oceans has been applied to the analysis of banded corals and so to lower latitudes. A shell-derived chronological history of bomb ^{14}C on Georges Bank and its Labrador Sea implications offered high latitude data resulting from the analysis of a 54-year-old mollusk (age assessed from annual growth bands) using accelerator mass spectrometry. This finding gave a time history from 1939 to 1990 and so widened the scope of such investigations. Other significant information came from the southern Great Barrier Reef in Australia (Druffel and Griffin 1993). Radiocarbon and stable isotope ($\delta^{18}\text{O}$ and $\delta^{13}\text{C}$) data for biannual samples were obtained from a 323 years banded coral series collected from the region. The high precision $\Delta^{14}\text{C}$ record showed variations on an interannual timescale that were especially large from 1,680 to 1,730. This observation may have nothing to do with atmospheric changes, but perhaps involved in vertical mixing and large-scale advective changes of source waters to the western Coral Sea. Low values from 1,935 to 1,875 may relate to El Niño/Southern Oscillation (ENSO) events in the eastern tropical Pacific. But these values cannot explain all the variations, especially those from 1,875 to 1,920 characterized by high $\Delta^{14}\text{C}$ values. The time interval 1,635 to 1,795 appears to embody a 6-year periodicity, a coherency later lost. It may be inferred that secular changes take place in the nature and properties of the ENSO as manifested in the southwestern Pacific. Interestingly, no trace of the Suess effect was found from the coral record.

17.17.8 Dendrochronology and Radiocarbon

Further to previous remarks regarding Zoser's tomb and the converting of radiocarbon years to calendar ones, analyzing old trees facilitated investigation of the secular variations of the radiocarbon content of the atmosphere. Such trees can be dated using tree rings, annual accretions of woody tissue to the circumferences of their trunks.

Layers deposited earlier cannot receive radiocarbon from the atmosphere anymore so that their radiocarbon contents decrease by radioactive decay. Two tree species that have been used are *Pinus aristato* (bristlewood pine) and *Sequoia gigantea* (sequoia). Combining dendrochronology with isotopic investigations enables age-corrected deviations of the radiocarbon contents of such trees to be used in calculating corrections applicable to conventional radiocarbon dates (► Fig. 17.3). The drawback is that the technique is valid only back about 12,000 years into the past. However, examination of varve chronologies of sediments deposited in glacial lakes extends the approach further back. The researches imply that the radiocarbon content of the atmosphere varied by about $\pm 10\%$ of the nineteenth century value.

■ Fig. 17.3

The graph gives the corrections that have to be added to radiocarbon dates so as to bring them into agreement with tree ring dates based on 143 analyses of the wood of bristlecone pine (*Pinus aristata*) and sequoia (*Sequoia gigantea*), which gave dendrochronological dates

17.17.9 Radiocarbon and Dating Groundwaters

Radiocarbon is important for dating groundwaters on the basis that the soil-zone carbon dioxide is of biogenic origin resulting from the respiration of plant roots and also from the decay of plants. So, indirectly, it contains radiocarbon from the atmosphere. The actual content of the radioisotope decays steadily since the gas is no longer in contact with the atmosphere and the fraction of the original content remaining is a measure of the time elapsed since this happened through infiltration. The time since this occurred, t , is given by

$$t = 8,720 \ln \left(\frac{C_0}{C} \right) \text{ years} \quad (17.24)$$

where 8,270 is the mean life of radiocarbon in years, C_0 is the initial concentration of the radiocarbon, and C is the concentration recorded in the sample.

Since radiocarbon is measured relative to the total carbon content of the sample, the origin of the stable carbon present must be examined as well. Not all of it is similar in origin to the atmospheric radiocarbon since infiltrating water contains carbon dioxide dissolved out of the soil zone, which dissolves carbonate minerals in the soil. However, water from limestone contains no radiocarbon and therefore that which reaches the water table contains dissolved carbon in the chemical forms H_2CO_3 , HCO_3^- and CO_3^{2-} with a radiocarbon content lower than that occurring in the soil (biogenic) carbon dioxide. The evaluation of the dilution of soil carbon dioxide originally containing 100% modern radiocarbon with radiocarbon-free (“dead”) carbonate in order to estimate the initial radiocarbon concentration in recharge water reaching the water table is one of the most difficult problems of radiocarbon age determination.

An interesting study of the frequency distribution of radiocarbon ages in groundwater samples collected in the Sahara has appeared (IAEA 2002). It has been known for at least a century that large reserves of groundwater lie beneath the Sahara, the largest desert in the world. Radiocarbon dating made it possible to estimate the age of these groundwaters. From a graph based on 350 samples collected in Algeria, Libya, Egypt, and the Southern Sahara, it was shown that aquifers in Northern Africa were recharged mainly during the pluvial periods of the Holocene and during the interstadials of the last glacial period. A well-marked minimum in the distribution curve ranging from approximately 12 to 20,000 years B.P. reflects the time interval

of maximum aridity in Northern Africa. This estimate of the groundwater age is critical in exploiting this groundwater resource, all the more so since absence of tritium and low concentrations of radiocarbon strongly imply that the aquifer in question is not being replenished at present.

17.17.10 Fractionation of Carbon Isotopes in Nature

Fractionation of the carbon isotopes in nature entails small systematic errors in radiocarbon dates that can be eliminated when the isotopic composition of stable carbon to be dated can be assessed using a mass spectrometer. The value is expressed as $\delta^{13}\text{C}\%$. Such fractionation during photosynthesis alters the abundances of the stable isotopes ^{12}C and ^{13}C from those prevailing in the atmosphere and plants usually become enriched in ^{12}C and depleted both in ^{13}C and ^{14}C .

17.18 Rhenium/Osmium

The beta decay scheme of rhenium-187 to osmium-187 may be applied to the study of sulfide minerals of molybdenum and osmium-rich minerals such as iridosmine. Together with rubidium/strontium, samarium/neodymium, lutetium/hafnium, and uranium/lead methods, it has been used to examine mantle differentiation and the accretion of continental crust. In molybdenites, rhenium concentrations vary from a few ppm to as much as 1.88%. The element has two naturally occurring isotopes, and these are the stable rhenium-185 with a relative abundance of 37.398% and the radioactive rhenium-187 with a relative abundance of 62.602%. This decays as follows:

with a Q-value about 2.5 keV. This makes it difficult to determine its half-life by direct counting, but it is about 4.56 Ga and its decay constant is about $(1.64 \pm 0.05) \times 10^{-11} \text{ a}^{-1}$.

The growth of osmium in a rhenium-bearing system is expressible as

$$\left[\frac{^{187}\text{Os}}{^{186}\text{Os}} \right] = \left[\frac{^{187}\text{Os}}{^{186}\text{Os}} \right]_i + \left[\frac{^{187}\text{Re}}{^{186}\text{Os}} \right] (e^{\lambda t} - 1). \quad (17.26)$$

The first term is the isotope ratio of the isotopes now, the second that which prevailed initially when the system closed to both elements, and the third includes the present ratio of rhenium-187 to osmium-186, λ being the decay constant of ^{187}Re . Of course, the second term must necessarily be an assumption. This equation is applicable to a suite of samples with a common age and presumably, the same initial $[^{187}\text{Os}/^{186}\text{Os}]_i$ ratio and these form an isochron in coordinates of $[^{187}\text{Os}/^{186}\text{Os}]$ and $[^{187}\text{Re}/^{186}\text{Os}]$ of which the relevant slope is proportional to their age. Taylor expansion of the exponential expression in [Eq. \(17.26\)](#), namely, yields the following approximation for relatively short ages:

$$\left[\frac{^{187}\text{Os}}{^{186}\text{Os}} \right] \approx \left[\frac{^{187}\text{Os}}{^{186}\text{Os}} \right]_i + \left[\frac{^{187}\text{Re}}{^{186}\text{Os}} \right] \lambda t \quad (17.27)$$

where the zero intercept of the isochron will give the initial $[^{187}\text{Os}/^{186}\text{Os}]_i$ ratio.

The concentrations of both elements have been determined in iron meteorites and these plus the metallic grains of chondrules were found to fit the same isochron, implying that they formed from the solar nebula (thought to have contained isotopically homogeneous osmium) in a very short time interval estimated to be about 90 Ma. The primordial $^{187}\text{Os}/^{186}\text{Os}$ ratio has been given as 0.807 ± 0.006 . And the isotopic compositions of both rhenium and osmium in meteorites are compatible with terrestrial sample values.

17.18.1 Rhenium/Osmium in Meteorites and the Mantle

Molybdenites are particularly suitable for rhenium/osmium dating because their $[\text{Re}/\text{Os}]$ ratio is very high. The rhenium contents of molybdenites have been recorded as ranging from 2 to 230 ppm in 19 samples. From these samples, ages ranging from 105 Ma to 2.54 Ga were obtained. Osmium-bearing minerals may record the isotopic evolution of the element in the mantle as is implied by the genetic association of iridosmine with ultramafic rocks. Data have been published on measurements of $^{187}\text{Os}/^{186}\text{Os}$ ratios from iridosamine samples with known ages and, when shown in coordinates of $^{187}\text{Os}/^{186}\text{Os}$ and time t , fitted a straight line with slope m .

The collinearity of these data points indicates that the mantle sources of these samples probably had a homogeneous $[\text{Re}/\text{Os}]$ ratio (Luck et al. 1980) that changed solely through the decay of rhenium-187. The value of this ratio was calculated from the slope of the osmium-development line shown by [Eq. \(17.27\)](#):

$$\left[\frac{^{187}\text{Re}}{^{186}\text{Os}} \right] = \frac{m}{\lambda}. \quad (17.28)$$

Considering this equation and the concrete value determined for m , if $\lambda = 1.52 \times 10^{-11} \text{ a}^{-1}$, then the $^{187}\text{Re}/^{186}\text{Os}$ ratio in the mantle is 3.34 ± 0.14 and the corresponding $[\text{Re}/\text{Os}]$ ratio is about 0.085. The intercept of the osmium-development line gives a value for the $^{187}\text{Os}/^{186}\text{Os}$ ratio in the mantle at present, i.e., at $t = 0$, of 1.040 ± 0.01 . Both ratios in the mantle fit the Re/Os isochron for meteorites and the agreement suggests that the Earth and the parental bodies of the meteorites formed at about the same time from a primordial source containing rhenium and osmium, both with a homogeneous isotopic composition. Since a unique osmium-development line exists, it can be inferred that, despite internal magmatic activity accompanying the formation of the crust, the mantle is homogeneous as regards its rhenium/osmium ratio. Granites, ultrabasics, and basalts have similar concentrations; therefore, the element Re was not appreciably partitioned during partial melting and fractional crystallization, the geochemical differentiation of the mantle not having changed its rhenium concentration much. As osmium is depleted in granites and basalts compared to ultra-mafics, it could be that only a small fraction of mantle osmium has been transferred into the crust. Hence, while the $[\text{Re}/\text{Os}]$ ratio appears to have been rather stable through geological time, the crust appears to have undergone more variation with respect to it. Thus, its variability could be a useful indicator of crustal contamination of magma.

17.19 Rubidium/Strontium

Rubidium has an ionic radius sufficiently close to that of potassium that it can substitute for the latter in all potassium-bearing minerals, and hence it occurs as a dispersed element forming

measurable parts of micas, potassium feldspar, some clay minerals, and evaporites. Two isotopes occur in nature, namely rubidium-85 and the radioactive rubidium-87 with isotopic abundances of 72.17% and 27.83%, respectively. Rubidium-87 undergoes decays by negatron emission to strontium-87 with a half-life, $T_{1/2}$, of 4.8×10^{10} years. Regarding this, other values have been proposed, which affect the value of the decay constant, although $1.49 \times 10^{-11} \text{ a}^{-1}$ must be close to the true figure.

The decay process is

where $Q = 275 \text{ keV}$.

Strontium has four naturally occurring isotopes, strontium-87 having a relative abundance of 7% and a metastable state with a γ energy of 388 keV for the isomeric transition. This decays by electron capture in a time interval determined by the half-life of 2.81 h. The abundance varies reflecting the formation of radiogenic ^{87}Sr by the decay of ^{87}Rb . Therefore, the precise isotopic composition of strontium in a mineral or rock containing rubidium depends on the age and the $[\text{Rb}/\text{Sr}]$ ratio of either.

The growth of radiogenic ^{87}Sr in a rubidium-enriched mineral over a time interval t is given by the following expression:

$$[^{87}\text{Sr}] = [^{87}\text{Sr}]_0 + [^{87}\text{Rb}](e^{\lambda t} - 1) \quad (17.30)$$

where $[^{87}\text{Sr}]$ and $[^{87}\text{Rb}]$ are the total numbers of atoms of the respective isotopes in a unit mass of the mineral now and $[^{87}\text{Sr}]_0$ is the amount of ^{87}Sr incorporated in it when crystallized, λ is the decay constant of ^{87}Rb , and t is the age of the mineral sample.

An equation for age determination has been presented and based on real isochrons. A rubidium/strontium three-isotope plot (see [Fig. 17.4](#)) is constructed involving $[^{87}\text{Sr}/^{86}\text{Sr}]$ against $[^{87}\text{Rb}/^{86}\text{Sr}]$. When a rock cools, all of its minerals have the same ratio of strontium-87 to strontium-86 though they will have varying amounts of rubidium. As the rock ages, rubidium decreases by changing to strontium-87. For any given age, the composition can be represented by a line through the points, and this line can be extrapolated back to zero to

■ Fig. 17.4

A rubidium/strontium “three-isotope” diagram showing the time-dependent isotopic evolution of rock systems after they crystallize from a homogeneous magma

obtain the initial $[^{87}\text{Sr}/^{86}\text{Sr}]_0$ ratio. This ratio is about 0.70775, but for the K/T Boundary it is 0.70790, a rise attributed to acid rain. Values at this boundary have been given as 1.6 for Denmark, 1.3 for Colorado, and 1.1 for New Zealand. The age of the rock is determinable from the slope of the isochron. This slope is a monotonic function of the age of the rock and the older the rock, the steeper the line. If the slope of the line is m , the age t is given by

$$t = \frac{1}{\lambda} \ln(m + 1) = \frac{T_{1/2}}{\ln 2} \ln(m + 1). \quad (17.31)$$

Measuring rubidium and strontium concentrations in suitable minerals can be effected using standard chemical and mass-spectrometric procedures, X-ray fluorescence, or isotope dilution.

Real isochrons may be altered through metamorphism when heat causes minerals to deviate from the whole-rock isochron and each acquires its own isochron. Also, new minerals may form, and existing minerals may recrystallize. The entire situation is one of mobility entailing ionic diffusion. Metasomatism may occur and involve both the bulk chemical composition and the trace element composition. The phenomenon can affect the parent/daughter relationships of all naturally occurring radioactive element systems in a particular rock. A suitable age equation for t is available and, to implement it, the best rocks to utilize are igneous acidic ones such as granite because they contain both micas and potassium feldspars. However, both concordant and discordant results may be obtained. The latter results are due to gain or loss of radiogenic ^{87}Sr caused by geological events usually connected to metamorphism. And when forming, such igneous rocks undergo fractional crystallization of magna involving the separation of crystals from an ever-diminishing liquid magma so that suites of comagmatic igneous rocks have different chemical compositions. However, if it is assumed that the strontium in such a magma stayed isotopically homogeneous through the cooling process, all the various suites formed will have the same initial $[^{87}\text{Sr}/^{86}\text{Sr}]_0$ ratio. It is reasonable to assume that all rocks formed will have about the same age because cooling and crystallization times are negligible compared to the age of the event. In this way, the age equation may be regarded as relating to a set of suites and creating a group of straight lines on a plot having a slope intercept such that

$$y = b + mx. \quad (17.32)$$

All rock samples from a comagmatic suite plot as points on a straight line in coordinates of $[^{87}\text{Sr}/^{86}\text{Sr}]$ (y) and $[^{87}\text{Rb}/^{86}\text{Sr}]$ (x), that is to say that they form an isochron. Its slope is related to t as

$$m = e^{\lambda t} - 1 \quad (17.33)$$

and the value of the initial $[^{87}\text{Sr}/^{86}\text{Sr}]_0$ ratio may be provided by the y -intercept b .

17.19.1 Fictitious Isochrons in the Rift Valley

Fictitious isochrons have slopes devoid of any geochronological significance. If a set of samples resulted from the mixing of two components with different $[^{87}\text{Rb}/^{86}\text{Sr}]$ and $[^{87}\text{Sr}/^{86}\text{Sr}]$ ratios, they will fall on a straight line, which links the end members in coordinates of these ratios. The result is a fictitious isochron, which may have a positive or a negative slope depending on the relative values of the end members. An instance was obtained from potassic lava flows found in

volcanic centers lying along the western Great Rift Valley north of Lake Tanzania and west of Lake Victoria, these centers being about 160 km apart (Bell and Powell 1969). Identified as Pliocene to Recent in age, their volcanic activity is believed to have continued into historical times so there is no doubt that the relevant rocks are young and ought to give an isochron with practically zero slope. However, a significant positive correlation between the average $[^{87}\text{Sr}/^{86}\text{Sr}]$ and the $[^{87}\text{Rb}/^{86}\text{Sr}]$ ratios of the rock types was found and the straight line drawn through the data points was not an isochron, rather a mixing line. It had a slope yielding a fictitious age of 773 Ma because the $[^{87}\text{Sr}/^{86}\text{Sr}]$ ratios of the rocks resulted from mixing and do not relate to the radioactive decay of rubidium-87 in them after crystallization took place.

17.19.2 Meteorites, BABI, LUNI, and FUN

Rubidium/strontium analyses of chondritic meteorites gave an average age of about 4.49 Ga as did those of achondrites and it was suggested that crystallization occurred fast and that they had similar initial $[^{87}\text{Sr}/^{86}\text{Sr}]_0$ ratios. Basaltic achondrite analyses gave the value for the primordial $[^{87}\text{Sr}/^{86}\text{Sr}]_p$ ratio of 0.6987 ± 0.00003 and this is termed BABI (Basic Achondrite Best Initial). Isotope anomalies in meteorites imply that the solar nebula could not have been isotopically homogeneous with respect to some elements. The concert of Fractionation and Unknown effects as possible causes produced the term FUN (Papanastassiou and Wasserburg 1969). The Rb/Sr method was used to help in unveiling the seismological history of the Moon and an age for the satellite of about 4.5 Ga was obtained. BABI is paralleled by LUNI of which a value has been given as 0.69892 ± 0.00009 (Nyquist 1977).

17.19.3 Some Caveats

It must be added that there is a number of things that can present difficulties for the Rb/Sr dating method and include the following. One is the case where a rock contains some minerals that are older than the main part of the rock. Occasionally, magma inside the Earth will take up unmelted minerals from the surrounding rock as it moves through a magma chamber. Normally, such “xenoliths” are distinguishable from the younger minerals surrounding them. If they are not used for dating the rock, the points represented by these minerals will be off the line made by the rest of the points. Another problem arises if a rock has suffered metamorphism during which it became extremely hot but not sufficiently hot to completely remelt the rock. Then, dates will be confused and not lie along a line. Some minerals will have completely melted others not at all. Thereafter, some minerals will try to give the igneous age, while some others will try to give the metamorphic age. In such cases, there will not be a straight line and no valid date is determined.

In some rare cases, the Rb/Sr method gave straight lines giving wrong ages. This may result when the rock being dated was formed from a magma that was not well mixed and had two separate batches of rubidium and strontium. One magma batch had rubidium and strontium compositions near the upper end of a line and one batch had compositions near the lower end of the line. Then, the minerals received a mixture of both batches and the resulting composition ended near a line *between* the two batches. Such a state of affairs is termed a two-component

mixing line. Among tens of thousands of rubidium/strontium dates, at least 30 cases have been documented. Of course, if a two-component mixture is suspected, a second dating method must be employed in order to either confirm or disprove the rubidium/strontium date. In general, it may be stated that agreement between several dating methods is by far the best way to date rocks.

17.20 Samarium/Neodymium

Both of these elements are lanthanides (rare earth elements), and each has 26 isotopes, of which seven occur naturally. Samarium-147 is radioactive and decays by α emission to a stable isotope of neodymium, ^{143}Nd :

The half-life of ^{147}Nd is 1.06×10^{11} a with a corresponding decay constant of $6.54 \times 10^{-12} \text{ a}^{-1}$, and the decay scheme is applicable to dating terrestrial rocks, stony meteorites, and lunar materials.

Samarium, neodymium, and the other rare earth elements occur in high concentrations in minerals such as monazite (CePO_4) and as trace elements in common rock-forming ones such as biotite and plagioclase feldspar. The atomic $[\text{Sm}/\text{Nd}]$ ratio on Earth varies from 0.1 to 0.5 and the relative abundances are 15% for ^{147}Sm and 12.18% for ^{143}Nd . It has been suggested that neodymium is more concentrated than samarium during the fractional crystallization of magma and that crustal rocks usually have lower $[\text{Sm}/\text{Nd}]$ ratios than rocks originating from the upper mantle such as oceanic tholeiites. Also, during the formation of silicate liquids by partial melting of rocks in the crust or mantle of the Earth, the liquid phase may enrich in neodymium relative to samarium. This may be because Nd^{3+} has a larger ionic radius than samarium, which gives it a lower ionic potential as a result of which it forms weaker ionic bonds that can be more easily ruptured than those involving Sm^{3+} .

The growth of radiogenic ^{147}Nd due to the decay of ^{147}Sm can be given as

$$\left[\frac{^{143}\text{Nd}}{^{144}\text{Nd}} \right] = \left[\frac{^{143}\text{Nd}}{^{144}\text{Nd}} \right]_0 + \left[\frac{^{147}\text{Sm}}{^{144}\text{Nd}} \right] (e^{\lambda t} - 1) \quad (17.35)$$

where ^{144}Nd acts as the reference since the number of its atoms in a unit quantity of any given sample remains constant so long as the host system remains closed to neodymium. The decay constant of ^{147}Sm , λ , is taken to be $6.54 \times 10^{-12} \text{ a}^{-1}$.

Determination of ages by the Sm/Nd method entails analyzing either individual minerals or cogenetic rock suites in which the ratios between the two are sufficiently different to define the slope of an isochron in coordinates of $[^{143}\text{Nd}/^{144}\text{Nd}]$ and $[^{147}\text{Sm}/^{144}\text{Nd}]$. The method is especially suitable for mafic and ultramafic rocks, cf. the Rb/Sr method, which is best suited for acidic and intermediate igneous rocks enriched in rubidium and depleted in strontium. Since the rare earth elements are less mobile than the alkali metals and the alkaline earths, phenomena such as regional metamorphism have less effect on them. Hence, suitable rocks can be dated by the Sm/Nd method even if they have lost or gained rubidium and strontium and this makes the Sm/Nd method a useful complement to the R/Sr method.

17.20.1 Apollo-12, ADOR, and CHUR

Volcanics from the Onverwacht Group, Swaziland and South Africa, comprise the basal part of the Early Precambrian Barberton greenstone belt found both in Swaziland and the Transvaal. Data from them gave an age of about 3.54 Ga calculated using an initial $^{143}\text{Nd}/^{144}\text{Nd}$ ratio of 0.50809 ± 0.0004 (Hamilton et al. 1979). The strontium and neodymium isotopic record of *Apollo-12 basalts* from the Moon were examined. Isochrons were derived for an achondrite (eucrite) and another meteorite and gave ages of about 4.58 and 4.562 Ga, respectively, with primordial $^{143}\text{Nd}/^{144}\text{Nd}$ ratios of 0.50684 ± 0.00008 and 0.506664 . An initial $^{87}\text{Sr}/^{86}\text{Sr}$ ratio was termed *ADOR*. The isotopic evolution of neodymium in the Earth has been described by means of a model termed *CHUR* (CHondritic Uniform Reservoir). And the present value of the $^{143}\text{Nd}/^{144}\text{Nd}$ ratio is 0.512638 relative to a $^{146}\text{Nd}/^{144}\text{Nd}$ ratio of 0.7219. The present value of the $^{147}\text{Sm}/^{144}\text{Nd}$ ratio of CHUR is 0.1967, which permits calculation of $^{143}\text{Nd}/^{144}\text{Nd}$ ratio in any past time interval.

17.21 Thermoluminescence (TL)

This is a phenomenon occurring as a result of increase in temperature of a body and it takes place when electrons trapped in crystal defects are released by heat. When ionizing radiation impinges on a dielectric solid, electrons may be stripped off and so become trapped in metastable states associated with the said defects. Heat frees this energy as light emissions when the trapped electrons resume their stable ground states. Such light emissions are independent of the normal incandescence shown by thermally activated solids and increase linearly with the radiation dose until saturation is reached. Once electron traps are drained by heating, thermoluminescence disappears unless the sample is irradiated again. In TL dating, a sample is heated at increasing temperatures and its light output recorded as a glow curve, the area underneath this measures the radiation dose to which the sample was subjected since it was last heated to about 450°C . The annual radiation dosage can be assessed from the concentrations of uranium, thorium, and potassium in the rock sample and the time elapsed since the last heating, t , is given by accumulated radiation dose/annual radiation dose. The accumulated radiation dose is given by the glow curve. In the 1950s, it was suggested that the method could be used in order to date geological materials and shown that TL can be induced by pressure and the recrystallization of solids.

Later, archeological materials and even Pleistocene sediments have been analyzed and yielded important data. TL dates have been obtained from loess deposits above and below the Old Crow tephra at the Halfway House near Fairbanks, Alaska, and its age restricted to 86 ± 8 ka, which accorded with radiocarbon records from wood and peat less than 6 m above the tephra that gave an age of more than 60 ka. Emission spectra of meteorites showed that neither trapping levels at 170 and 350°C nor the luminescence centers were significantly perturbed by either their shock or thermal histories. A tentative assignment of the luminescence producing the low-temperature broad emission feature was made to Mn^{2+} ions in the oligoclase feldspar (Strain et al. 1986). Interestingly, it has been suggested that induced thermoluminescence may prove to be valuable in terms of understanding metamorphism in chondrites (Batchelor and Sears 1991). Their feldspar has a novel origin and history. Induced thermoluminescence and the thermal history of plagioclase feldspars have been examined (Kim et al. 1995). On the other hand, eucrites were regarded as igneous rocks resembling

terrestrial and lunar basalt. The success of induced TL studies could be used for many types of basalt in which dry, low-level metamorphism took place.

17.22 Tritium

Tritium, ^3H , the radioactive isotope of hydrogen, is produced in the atmosphere by the interaction of cosmic ray-produced neutrons with nitrogen, hence

and also

with a production rate of $0.5 \pm 0.3 \text{ atoms cm}^{-2} \text{ s}^{-1}$.

It also results from solar emissions, the operation of nuclear reactors and particle accelerators on the Earth together with diminishing quantities originating from earlier atmospheric testing of thermonuclear devices. These later added “bomb tritium” and practically eliminated natural tritium as a tracer. However, it offered a new tool, namely the use of the bomb tritium peak as a “dye” that is delivered to natural water systems from the atmosphere on local to global scales. But there are natural limits to the method because tritium decay and dispersion make it increasingly hard to identify the bomb peak in groundwater. A way round this has been presented and this involves using tritium with its decay product ^3He ($^3\text{He}_{\text{trit}}$). This is discussed in detail below. Tritium in the environment from this source reached a prominent peak in the Northern Hemisphere in 1963, thereafter steadily declining. The radioisotope undergoes beta decay,

with $Q = E_{\text{max}} = 18.6 \text{ keV}$ and the half-life is 12.43 years.

As to the inventory, tritium (also denoted by the symbol T) is measured in tritium units. By definition, the abundance of ^3H is 1 TU when the atomic ratio $[^3\text{H}/^1\text{H}]$ equals 1×10^{-18} . In terms of specific activity $1 \text{ TU} = 3.2 \text{ pCi/kg H}_2\text{O} = 0.12 \text{ Bq/kg H}_2\text{O}$, the natural level in precipitation being $\sim 5 \text{ TU}$ as compared to “bomb tritium” maximum levels of $\sim 1,000$ – $2,000 \text{ TU}$ and more. In 1973, natural tritium represented $\sim 2.5\%$, nuclear power plants 0.02% , bombs 97.5% of the total.

Tritium can be assessed mass spectrometrically but results from this approach were improved using the Oeschger Counter, which measures weak radioactivity. Oeschger began determining the tritium content of firn and ice, using them as archives of environmental information. His participation in various expeditions to Greenland and Antarctica from 1964 to 1992 provided his laboratory with direct access to polar ice cores. The analytical methods and drilling technology developed from this access facilitated an unprecedented reconstruction of climatic changes of the last 150,000 years.

Once tritium is formed in the atmosphere, it becomes rapidly incorporated into water molecules and resides in the lower stratosphere for anything between 1 and 10 years. Later such molecules enter the lower troposphere and rainout of the tritiated water (HTO) occurs within five and twenty days. This is how HTO enters the hydrological cycle where it constitutes a radiotracer for water that has been in the atmosphere for the past 35 years. However, as the bomb component diminishes, so does the radio-tracing value.

17.22.1 Dating Using Tritium and Tritogenic ^3He

To compensate for the decline of bomb tritium input into the environment and continue to use tritium as a dating tool for water in aquifers, rivers, springs, etc., the following approach was proposed. Simultaneous measurement of tritium and tritogenic ^3He permits identification of the tritium peak as the sum of $[^3\text{H}]$ and $[^3\text{He}_{\text{trit}}]$, even if most of the tritium has decayed, and also allows direct calculation of age from the radioactivity of mother per quantity of daughter ratio (tritium/ ^3He age). Extensive studies of this methodology and the applicability of tritium/ ^3He dating were commenced in the middle to late 1980s and early 1990s.

Determination of the tritium/ ^3He age of groundwater is straightforward:

$$t = \frac{T_{1/2}}{\ln 2} \ln \left(1 + \frac{[^3\text{He}_{\text{trit}}]}{[^3\text{H}]} \right). \quad (17.39)$$

The hardest step in determining the tritium/ ^3He age is the separating of the $^3\text{He}_{\text{trit}}$ from the total ^3He dissolved in a groundwater. The total ^3He concentration, $[^3\text{He}_{\text{tot}}]$, has a number of sources noted as follows:

$$[^3\text{He}_{\text{tot}}] = [^3\text{He}_{\text{eq}}] + [^3\text{He}_{\text{exc}}] + [^3\text{He}_{\text{terr}}] \quad (17.40)$$

where $^3\text{He}_{\text{eq}} = ^3\text{He}$ in solubility equilibrium with the atmosphere, $^3\text{He}_{\text{exc}} = ^3\text{He}$ due to excess air, and $^3\text{He}_{\text{terr}} =$ terrigenous ^3He (nucleogenic ^3He together with mantle ^3He). Only $^3\text{He}_{\text{tot}}$ and $^3\text{He}_{\text{eq}}$ are determined through measurements. $^3\text{He}_{\text{exc}}$ and $^3\text{He}_{\text{terr}}$ (if they are present in a sample) must be determined by using measurements of ^4He and Ne ($^3\text{He}_{\text{terr}}$).

The total ^4He concentration measured in a groundwater sample, $[^4\text{He}_{\text{tot}}]$, can be presented as

$$[^4\text{He}_{\text{tot}}] = [^4\text{He}_{\text{eq}}] + [^4\text{He}_{\text{exc}}] + [^4\text{He}_{\text{terr}}] \quad (17.41)$$

where $[^4\text{He}_{\text{eq}}] = ^4\text{He}$ concentration equilibrium with the atmosphere, $[^4\text{He}_{\text{exc}}] = ^4\text{He}$ concentration caused by excess air, and $[^4\text{He}_{\text{terr}}] =$ terrigenous ^4He concentration (radiogenic ^4He together with mantle ^4He). If no terrigenous helium is contained in the groundwater sample, $[^3\text{He}_{\text{trit}}]$ can be calculated using the following equation:

$$[^3\text{He}_{\text{trit}}] = [^4\text{He}_{\text{tot}}](R_{\text{tot}} - R_{\text{atm}}) + [^4\text{He}_{\text{eq}}]R_{\text{atm}}(1 - \alpha) \quad (17.42)$$

where $R_{\text{tot}} =$ measured $[^3\text{He}/^4\text{He}]$ ratio of the sample, $R_{\text{atm}} = [^3\text{He}/^4\text{He}]$ ratio of air (1.384×10^{-6}), and α is the solubility isotope effect (about 0.983).

The conversion factor κ by which one has to multiply the above $[^3\text{He}_{\text{trit}}]$ value to switch from $\text{cm}^3 \text{ STP g}^{-1}$ to TU is

$$\kappa = \frac{4.021 \times 10^{14}}{1 - s/1000} \frac{\text{TU}}{\text{cm}^3 \text{ STP g}^{-1}} \quad (17.43)$$

where s is the salinity in ‰.

For the separation of terrigenous helium, neon measurements have to be employed. Two assumptions are (1) that the neon comes only from the atmosphere and also (2) that $[\text{Ne}/^4\text{He}]_{\text{eq}} = [\text{Ne}/^4\text{He}]_{\text{air}}$. The terrigenous ^4He component will then become

$$[^4\text{He}_{\text{terr}}] = [^4\text{He}_{\text{tot}}] - ([\text{Ne}_{\text{tot}}] - [\text{Ne}_{\text{eq}}]) \frac{[^4\text{He}_{\text{atm}}]}{[\text{Ne}_{\text{atm}}]} - [^4\text{He}_{\text{eq}}] \quad (17.44)$$

where $[Ne_{tot}]$ is the measured concentration of neon in the sample, $[^4He_{atm}/Ne_{atm}]$ is atmospheric $[He/Ne]$ ratio (0.288), and $[Ne_{tot}] - [Ne_{eq}] = [Ne_{exc}]$ is the neon concentration originating from excess air.

$[^3He]$ is calculated by multiplying the $[^4He_{terr}]$ calculated from the above equation by the $[^3He/^4He]$ ratio of the terrigenous helium component, which can be radiogenic helium, mantle helium, or a mixture of both.

The best approach to determine R_{terr} is to measure it in groundwater samples from the same aquifer that are free of tritium. If there is no tritium-free groundwater in the relevant aquifer, then an estimate can be obtained in the majority of such cases by plotting $[^3He]$ versus $[^4He]$, such a plot offering quite good clues regarding the origin of the terrigenous helium.

The concentration of the atmospheric $^3He_{atm}$ component may be expressed as follows:

$$[^3He_{atm}] = R_{atm} \{ [^4He_{tot}] - [^4He_{terr}] - [^4He_{eq}](1 - \alpha) \}. \quad (17.45)$$

Other appropriate equations are also available, which will facilitate attaining the concentration of $^3He_{trit}$. Observations have been made on the nonlinearity of the tritium/ 3He age. This age, calculated from [Eq. \(17.39\)](#), is apparently independent of the initial tritium concentration of the water sample, this comprising an advantage since it removes the need to establish the precise time-dependent tritium delivery to the aquifer. Of course, there is always the possibility that mixing and dispersive factors may affect the tritium/ 3He age because this is typically biased toward the age of the water component with the higher tritium concentration. For quantitative studies, it is usual to rule out mixing as a significant influence or try to account for it in the final evaluation of the relevant data.

There are important differences between the apparent tritium/ 3He ages and the real water ages and, as a rule, these occur near the location of the bomb peak. The validity of this remark is ascribed to the high tritium and 3He concentration gradients near the bomb peak as well as the related increased transport of both tracers by dispersive processes. The effect also sets the usual life period over which tritium/ 3He dating is typically applicable. In many aquifers, the tritium/ 3He balance below the bomb tritium peak is dominated by the downwardly directed dispersion of bomb tritium and $^3He_{trit}$ as a result of its radioactive decay. Hence, in cases like these the tritium/ 3He age distribution is constant over a depth of a few to several tens of meters below the location of the bomb peak. It may be added that in aquifers with very low dispersion rates, meaningful tritium/ 3He ages can be provided for periods that precede the bomb peak.

3He is a gas; therefore, using the tritium/ 3He method for the dating of groundwaters is dependent on the extent of confinement of $^3He_{trit}$ in the groundwater, which is primarily determined by the ratio of advection to dispersion in the water parcels moving away from the water table. In aquifers with reasonably high recharge rates and related vertical flow velocities near the water table, loss of $^3He_{trit}$ is smaller than approximately 10–20%.

17.22.2 A Danubian Application of the Tritium/ 3He Dating Method

This was effected using 3H , 3He , 4He , and Ne concentrations in samples from a shallow groundwater system being recharged by bank infiltration from the Danube River in the Szigetköz area, northwestern Hungary (Stute et al. 2002). The $^3H/^3He$ ages were found to increase linearly along the flow lines as a function of distance from the river. For the deeper groundwater (50–100 m below the surface), which is not affected by recharge from local

precipitation, a horizontal flow velocity of about 500 m annually was derived from the age gradient. Variation of ^3H plus ^3He ("initial tritium") groundwater data as a function of the $^3\text{H}/^3\text{He}$ age is consistent with the time series of tritium measurements in the Danube River for the past 30 years. This confirms the reliability of the derived residence times. Deviations between the measured Danube tritium data and ^3H and ^3He data from the aquifer are explicable as a result of dispersive mixing and also by interaction with local surficial recharge.

It is germane to add that the observed content of ^3He in meteorites has been used to determine their $^3\text{H}/^3\text{He}$ age and the method involved dividing the recorded total number of ^3He atoms by the number of ^3He atoms decaying per unit time and making a 30% correction for the directly produced ^3He . Results were dubious in part because of the need to assume that there was a constant ^3He content or a constant cosmic-ray flux at the meteoroid integrated over 25 years.

17.23 Uranium Series Disequilibrium

17.23.1 Ionium (^{230}Th)

Ionium (i.e., ^{230}Th) is a daughter of uranium-234 and produces radium-226 in the uranium-238 radioactive decay series. Its half-life is 7.52×10^4 years and the corresponding decay constant is $9.217 \times 10^{-6} \text{ a}^{-1}$. Differences in geochemical properties induce thorium isotopes to separate from uranium in the oceans, which is the basis for using ionium to date deep-sea sediments. In oxidizing conditions on the Earth's surface, uranium occurs as the uranyl ion, UO_2^{2-} , whereas thorium remains tetravalent and is rapidly abstracted from seawater by adsorption on solid surfaces and also by incorporation into authigenic minerals with uranium concentrating in the aqueous phase. Hence, the residence time of uranium in oceans is longer by orders of magnitude than that of thorium, namely ~ 0.5 million years compared to about 300 years. Most ionium in seawater is formed right there from dissolved ^{234}U , but about a quarter is thought to come from river inputs. The preferential removal of ionium from seawater separates the radionuclide from its parent and produces an excess of unsupported ionium in the sediments. This causes activity that falls off with time, this assuming that both locally formed and river-derived components are altogether removed from seawater.

A sample of sediment from a given depth below the water/sediment interface can be dated from its ($^{230}\text{Th}/^{232}\text{Th}$) activity ratio if this has stayed constant for at least several hundred thousand years in the water body next to the sediment in any given ocean basin and also if there was no migration of the isotopes in the sediments. In addition, their chemical speciation must have been the same in seawater with no isotopic fractionation between this and the mineral phases involving thorium in the sediment. Furthermore, the ionium and thorium found in detrital mineral particles must be excluded from the analysis. Assuming that the contribution made by uranium-supported ionium is negligible, the activity of a sample given as an activity ratio may be related to its age as

$$R = R_0 e^{-\lambda t} \quad (17.46)$$

where R is the ionium/thorium activity ratio of the leachable fraction of sediment obtained at a given depth below the top of a core, R_0 is the same ratio for the newly deposited sediment, λ is the decay constant of ionium, and t is the time elapsed since deposition occurred. R is measured and, if R_0 is known, then

$$t = \frac{1}{\lambda} \ln \left(\frac{R_0}{R} \right). \quad (17.47)$$

This approach has been used to determine the rate of sedimentation in oceans, and this varies greatly due to factors such as the quantity of debris introduced by rivers, the rates of melting of icebergs, and the number of particles transported through and deposited by the atmosphere. The ionium/thorium method covers a range from less than 0.5 mm/1,000 years to 50 mm/1,000 years on a carbonate and opal-free basis, the lower figures applying to the South Pacific and the higher ones to the Atlantic. This is paralleled by variation in ($^{230}\text{Th}/^{232}\text{Th}$) activity ratios at the surfaces from which it has been inferred that there is a greater input of ^{232}Th in the Atlantic. This may be due to the many large rivers that enter it. But an excess thorium-230 method may be applicable for separating ocean sediments into fractions, which form isochrons of which the intercepts decrease with depth in the core. However, the slope of the isochron in young samples was found not to be zero, as expected, but rather showed disequilibrium among the thorium isotopes in the sediment (Bernat and Allegre 1974).

17.23.2 Ionium/Protactinium

Protactinium is a radioactive element with over 20 isotopes, of which the one of interest is ^{231}Pa with a half-life of 32,480 years and a corresponding decay constant of $2.134 \times 10^{-5} \text{ a}^{-1}$. It is a daughter of ^{231}Th in the ^{235}U radioactive decay series. In oceans, its geochemical properties resemble those of thorium since the isotopes are removed from seawater either by adsorption on mineral grains or by incorporation into authigenic minerals. Hence, sediments deposited in oceans may contain not only excess unsupported ^{230}Th , but also unsupported ^{231}Pa . If both are removed from seawater equally efficiently, their activity ratios will change with time in a manner controlled by their decay constants.

The ratios of the activities of the unsupported ionium and ^{231}Pa increase with depth in cores and, if the sediment is deposited at a uniform rate, then the following expression below may be applicable:

$$\ln \left(\frac{^{230}\text{Th}}{^{231}\text{Pa}} \right) = \ln \left(\frac{^{230}\text{Th}}{^{231}\text{Pa}} \right)_0 + \frac{\lambda_{\text{Pa}} - \lambda_{\text{Th}}}{\alpha} h \quad (17.48)$$

where h is the depth in the core and $\alpha = h/t$ is the constant rate of sedimentation.

This is a straight-line equation in coordinates of h and $\ln(^{230}\text{Th}/^{231}\text{Pa})$. Its slope will be inversely proportional to the rate of sedimentation, and its intercept equals the logarithm of the initial value of the activity ratio of the relevant unsupported ionium and ^{231}Pa in the sediment, i.e., $\ln(^{230}\text{Th}/^{231}\text{Pa})_0$. The approach has been used to determine α for a core from the Arctic Ocean, and a value of 0.2 cm/1,000 years was derived (Baxter et al. 1981).

17.23.3 Lead-210

In the uranium series, a daughter of ^{238}U (namely ^{222}Rn) enters the atmosphere and later decays through several short-lived daughters to lead-210 with a half-life of 22.3 years (see also ▶ Sect. 17.14 on the polonium/lead method). This radionuclide is removed by precipitation with a residence time of about 10 days. Later, this may deposit on snow and ice in glaciers as

well as in lakes and coastal regions. The activity of unsupported lead-210 diminished thereafter as a function of time at a rate determined by its half-life. ^{210}Pb can be used to date materials containing it. Owing to the short half-life of ^{210}Pb , the dating range is only a few hundred years. The method has been used for measuring the rates of deposition of snow in Greenland and Antarctica as well as on Alpine glaciers. Lake sediments have been dated using the method, for instance some from Loch Lomond in Scotland.

In addition to the unsupported (excess) ^{210}Pb of atmospheric origin, this radionuclide is also found unsupported by its primary parent ^{238}U but supported by excess ^{226}Ra in sediment minerals, i.e., at equal activity to the latter through in situ production from ^{226}Ra . This component is controlled by sediment mineralogy and so gives no information about time-scales. The unsupported ^{210}Pb is quantified by subtracting the measured activity of supported ^{210}Pb from the total ^{210}Pb inventory at each depth in a core. ^{222}Rn activity is measured and the total inventory assessed by analysis of ^{210}Pb decay products ^{210}Bi or ^{210}Po . In all cases, secular equilibrium is assumed for the parent/daughter pairs. Thus, the conventional dating method is indirect and specialized, involving nuclear counting equipment and radiochemical expertise. A more practical alternative is afforded by a particle track approach, which depends on counting radiation damage tracks produced in selected plastic films by both alpha particles and fission products emitted from essentially in processed dried sediment. Supported ^{210}Pb is measured indirectly by ^{235}U analysis. Because the $[^{235}\text{U}/^{238}\text{U}]$ ratio does not vary significantly in nature, the ^{238}U content of a sample can be calculated and secular equilibrium with ^{210}Pb again invoked. The supported ^{210}Pb profile is then subtracted from the total alpha record and the assumption made that the resultant excess alpha-plot is dominated by the decay of unsupported ^{210}Pb (or ^{210}Po). Using this method depends on an idealized nonmigratory behavior for all other uranium series alpha-emitters and also on total constancy with depth of ^{232}Th and its decay products.

17.23.4 Snow, Ice, and Volcanoes

As regards snow and ice chronology, the time elapsed since a sample of snow deposited at a depth h from the surface can be calculated from the activity of ^{210}Pb if the initial activity of this radioisotope has remained constant so that

$$(^{210}\text{Pb}) = (^{210}\text{Pb})_0 e^{-\lambda t} \quad (17.49)$$

where the first term expresses the activity per unit mass of sample at depth h , $(^{210}\text{Pb})_0$ is the specific activity at the surface (where $h = 0$), λ is the decay constant of ^{210}Pb ($3.11 \times 10^{-2} \text{ a}^{-1}$), and t is the age of the snow sample. From this equation, the following may be derived:

$$t = \frac{1}{\lambda} \ln \left\{ \frac{(^{210}\text{Pb})_0}{(^{210}\text{Pb})} \right\}. \quad (17.50)$$

Excess ^{210}Pb unsupported by ^{238}U occurs in volcanic rocks and arises partly from the radioactive decay of excess ^{226}Ra (half-life 1,602 years). A sample from Mount Vesuvius showed enrichment in ^{226}Ra and so in ^{210}Pb also. There is a high ^{210}Pb activity in the mineral cotunnite (PbCl_2) that occurs as a sublimate in fumaroles around the volcano and its lead probably comes from the volcanization of basalts. Lead-210 activity in volcanic rocks increases through the radioactive decay of excess ^{226}Ra so that deviations in the $(^{210}\text{Pb}/^{238}\text{U})$ activity ratios cannot just be ascribed to elemental fractionation effects in the magma. In the oceans, ^{210}Pb

distribution was examined through the GEOSECS Program, particularly in the Pacific. Oceanic boundaries were envisaged as potential sinks for reactive metals in seawater. The lead-210 deficiency relative to its ancestral ^{226}Ra seemed to increase from oceanic interiors toward continental edges and sea floors where it is more intensively scavenged. Within about 100 m of the latter, a large amount of excess ^{222}Rn relative to ^{226}Ra has been recorded and attributed to supply by sediments through pore water diffusion. This ^{222}Rn decays to ^{210}Pb and so its effects on the distribution of the latter is manifest. However, some vertical profiles in the deep western North Pacific showed no significant variations with depth despite this excess ^{222}Rn . And the apparent box model residence time that is based on $(^{210}\text{Pb}/^{222}\text{Rn})$ activity ratios decreases from ~ 100 years in oceanic interiors to about 10 years near the bottom. The lead-210 data are explicable using a vertical-mixing and first-order scavenging model without enhanced scavenging near the sediment/water interface. This shows that the bottom excess ^{222}Rn can scarcely influence ^{210}Pb in the water and also that the short residence time mentioned may be an artifact not reflecting the chemical reactivity of lead. It may be inferred that the deficiency of ^{210}Pb through scavenging is best estimated using ^{226}Ra not ^{222}Rn . One caveat – the ^{210}Pb scavenging at the sediment/water interface inferred from the oceanic distribution of this radioisotope – appears difficult to detect from bottom ^{210}Pb profile measurements.

17.23.5 Thorium-230, Uranium-234, Uranium-238

Practically no thorium, but substantial amounts of uranium are contained in calcium carbonates deposited in saline lakes and also in the oceans where they sometimes reach 5 ppm. Hence, there is almost no initial ^{230}Th activity in newly deposited carbonates, but due to the radioactive decay of ^{234}U , the activity of ^{230}Th increases with time. Consideration of this lead to the setting up of a method, which has been used to date corals, for instance, those from the three lowest terraces in Barbados, an island apparently emerging from the sea at a uniform rate (Broecker 1963). Data from the $(^{230}\text{Th}/^{234}\text{U})$ activity ratios of coral samples gave dates of 122,000, 103,000, and 82,000 years. These coincide with predicted times of elevated summer radiation at 45° N latitude (Milankovitch 1920). In age determinations, it is necessary that initial activity ratios $(^{230}\text{Th}/^{234}\text{U})_0$ are close to zero, also the sample must have been a closed system as regards uranium and intermediates between ^{238}U and ^{230}Th . In addition, the initial activity ratios $(^{234}\text{U}/^{238}\text{U})_0$ must be known.

It is possible to relate the activity of ^{230}Th to that of its immediate parent, ^{234}U , since, if the ^{234}U is in secular equilibrium with ^{238}U , then the $(^{230}\text{Th}/^{234}\text{U})$ activity ratio is related to time, t , as follows:

$$\left(\frac{^{230}\text{Th}}{^{234}\text{U}}\right) = \left(\frac{^{230}\text{Th}}{^{234}\text{U}}\right)_0 e^{-\lambda t} + (1 - e^{-\lambda t}) \approx 1 - e^{-\lambda t} \quad (17.51)$$

where λ is the decay constant of ^{230}Th . Note that this equation does not take into account the possible presence of excess ^{234}U . This, however, may not make much difference.

17.23.6 The Uranium-234, Uranium-238 Geochronometer

Attainment of secular equilibrium in radioactive decay series starting with uranium-238, uranium-235, and thorium-232 depends on none of relevant daughters leaving or entering the systems concerned. Once this equilibrium is established, the decay rates of the daughters in

any particular system equal that of the parent: $\lambda_1 N_1 = \lambda_2 N_2 = \lambda_3 N_3 = \dots = \lambda_n N_n$ where $\lambda_1 N_1$ is the activity of the parent and the other terms represent those of the daughters. (See [Sect. 7.4 in Chap. 7, Vol. 1](#) on successive processes discussing the cases of equilibrium and nonequilibrium.) Under secular equilibrium conditions, the ratio between the decay rate of any daughter and its parent is equal to one. The production of uranium-234 from its parent proceeds as follows :

so that, where secular equilibrium exists, the rate of decay (i.e., the activity) of ^{234}U in a uranium-bearing mineral equals that of ^{238}U and the activity ratio ($^{234}\text{U}/^{238}\text{U}$) = 1. However, investigations from groundwater samples showed that such secular equilibrium does not exist there and was also absent from minerals deposited from the said groundwater (Thurber 1962). In fact, the value of the ratio usually exceeds unity because the ^{234}U is enriched by such processes as the radioactive decay of its parent dissolved in groundwater. The alpha decay of the parent, namely, damages the crystal lattice and permits the daughter to migrate through micro-capillaries in the mineral and oxidize to form uranyl ions, which dissolve in water and remove it into an aqueous phase. Uranium-238 occurs in stable lattice positions. Thorium-234 can be rejected from grain surfaces through recoil caused by alpha emission, and then it decays to uranium-234 through the short-lived protactinium-234. Generally, activity ratios ($^{234}\text{U}/^{238}\text{U}$) both in surface and groundwaters as well as in secondary minerals containing uranium on continents usually exceed unity and can reach values as high as ten. But the activity ratios of primary uranium minerals in chemically weathered rocks may be less than unity through the preferential removal of uranium-234.

If uranium occurs in solution in groundwaters, it may enter oceans and become isotopically homogenized, the relevant activity ratio ($^{234}\text{U}/^{238}\text{U}$) having a narrow spread of values with a mean around 1.15. The element uranium can be removed from oceans by incorporation into authigenic minerals such as calcium carbonate, also by adsorption on grain surfaces under reducing conditions. Once uranium has become isolated from seawater, ^{234}U decays to ^{230}Th until the activity ratio ($^{234}\text{U}/^{238}\text{U}$) approaches an equilibrium value. However, this is not useful as a dating method because of the possibility that uranium-234 migrated after deposition. Nevertheless, the radioactive decay of excess ^{234}U and the growth of its daughter ^{230}Th have been used for dating of marine and non-marine carbonates of Pleistocene age.

The geochronometer involves determination of γ_0 , the initial ($^{234}\text{U}/^{238}\text{U}$)₀ activity ratio and it has been applied to dating the calcium carbonate of biogenic and inorganic origin deposited both in marine and non-marine environments. The reliability of ages from the latter is restricted by uncertainty regarding the value of the initial ratio. In non-marine areas, this factor shows time-dependent variations since shells of some non-marine mollusks actually acquire uranium after the death of the organisms. However, since groundwater can enrich in uranium-238 relative to its parent, this enables its specific sources to be assessed. In addition, mixing of different water masses characterized by their individual ($^{234}\text{U}/^{238}\text{U}$) activity ratios can be determined (Kronfeld and Rosenthal 1981).

17.24 Uranium/Thorium/Lead

After radioactivity was identified in uranium and thorium minerals, it was used to date them, and methods included Pb/U, Pb/alpha, U/He, U/Th/Pb, and common lead of which the last

two are still utilized. Natural uranium comprises 99.28% ^{238}U with a half-life of 4.5×10^9 years, 0.71% ^{235}U with a half-life of 7.1×10^8 years, and 0.006% ^{234}U with a half-life of 2.5×10^5 years. The common radioactive isotope of thorium is ^{232}Th (half-life 1.4×10^{10} years) and its relative abundance in nature is 100%. From these data, the corresponding decay constants of these primordial radionuclides may be cited. For uranium-238, it is $1.55125 \times 10^{-10} \text{ a}^{-1}$, for uranium-235, $9.8485 \times 10^{-10} \text{ a}^{-1}$; for uranium-234, $2.806 \times 10^{-6} \text{ a}^{-1}$; and for thorium-232, $4.948 \times 10^{-11} \text{ a}^{-1}$. In fact, heavy radioactive elements can be grouped into four radioactive decay series that are designated as thorium ($4n$) series, neptunium ($4n+1$) series, uranium ($4n+2$) series, and actinium ($4n+3$) series. (See [▶ Chap. 7 in Vol. 1](#) and [▶ Chap. 13 in this Volume](#).) The numbers in brackets indicate that the parent and all members of a particular series have mass numbers exactly divisible by four or divisible by four with a remainder of one, two, or three. There is no natural cross-linkage between the series, though this can be achieved artificially. The uranium, thorium, and actinium series occur naturally and each element is the parent of its own series and has the longest half-life of the relevant series. They all decay to lead and all have alpha-decay modes. The neptunium series was added to the list after the discovery of the artificial transuranic elements. Neptunium is a by-product of the manufacture of plutonium in nuclear reactors. The neptunium series ends with ^{209}Bi .

17.24.1 Radioactive Series

The radioactive decay of uranium-238 initiates the uranium series ($A = 4n+2$). This includes ^{234}U as a daughter and ends in stable ^{206}Pb . This series is expressible as follows:

where $Q = 47.4 \text{ MeV}$ per ^{238}U atom.

Thus, each atom of ^{238}U undergoing radioactive decay eventually produces one atom of ^{206}Pb as the result of cumulative emissions of eight α particles (i.e., $^4\text{He}^{2+}$ ions) and six β^- particles (i.e., “normal” electrons with negative electric charge, also called negatrons, as opposed to positrons that are positive). This assumes that the radioactive decay occurred in a closed system as regards uranium, lead, and all intermediate daughters, and Q represents all the associated decay energies of the series. Some intermediate daughters undergo branched decay entailing the emissions of either α particles or β^- particles. However, stable ^{206}Pb remains as the end product of all possible decay paths. (See [▶ Fig. 7.6 in Chap. 7, Vol. 1](#).)

The radioactive decay of ^{235}U produces stable lead-207 after the emissions of seven α particles and four β^- particles and constitutes the actinium series ($A = 4n+3$). The process may be represented as

where $Q = 45.2 \text{ MeV}$ per ^{235}U atom. (See [▶ Fig. 7.7 in Chap. 7, Vol. 1](#).)

The radioactive decay of ^{232}Th produces stable ^{208}Pb after the emissions of six α particles and four β^- particles and constitutes the thorium series ($A = 4n$). The following expression summarizes these data:

where $Q = 39.8 \text{ MeV per } ^{232}\text{Th atom}$. Branched decay again occurs. (See [Fig. 7.4 in Chap. 7, Vol. 1.](#))

The artificial neptunium series has the formula $A = 4n+1$. (See [Fig. 7.5 in Chap. 7, Vol. 1.](#))

Altogether 42 nuclides representing 12 elements are formed as intermediate daughters in the three naturally occurring radioactive decay series, but none is a member of more than one series so that each of the series terminates in specific isotopes of lead. The half-lives of the respective parents are longer by orders of magnitude than those of the various daughters; hence, the decay series fulfill the requirements for the establishment of secular equilibrium, and the decay rates of the intermediate daughters are equal to those of the respective parents.

If the mineral used is a closed system and secular equilibrium exists, the rate of production of the stable daughter at the end of a particular decay series is equal to the rate of decay of the relevant parent. Hence, it is feasible to regard the radioactive decay of the uranium and thorium isotopes in minerals as if it went directly to the respective lead isotopes. This consideration simplifies the equations required to describe the growth of radiogenic lead in uranium- and thorium-bearing minerals. Four naturally occurring lead isotopes are ^{204}Pb , ^{206}Pb , ^{207}Pb , and ^{208}Pb . Their relative abundances are 52.4% for lead-208, 22.1% for lead-207, 24.1% for lead-206, and 1.4% for lead-204. Otherwise, lead has a total of 32 isotopes, the remaining 28 being radioactive and extremely short-lived. Actually, ^{204}Pb is also very slightly radioactive, but can be regarded as practically stable because of its enormously long half-life of 1.4×10^{17} years.

The isotopic composition of lead is determinable mass spectrometrically. An expression for the age, t , of a suitable mineral in the case of uranium-238 is shown in the following expression:

$$t = \frac{1}{\lambda_{238}} \ln \left\{ \frac{[\frac{^{206}\text{Pb}}{^{204}\text{Pb}}] - [\frac{^{206}\text{Pb}}{^{204}\text{Pb}}]_i}{[\frac{^{238}\text{U}}{^{204}\text{Pb}}]} + 1 \right\} \quad (17.56)$$

where $[\frac{^{206}\text{Pb}}{^{204}\text{Pb}}]_i$ is the initial atomic ratio of ^{206}Pb (i.e., the final product of the ^{238}U series) to ^{204}Pb (the non-radiogenic lead isotope used as an inner reference); and λ_{238} is the decay constant of ^{238}U , the primary parent of the series assumed to be in equilibrium with all of its radioactive daughters.

There are also similar equations for both uranium-235 and thorium-232. Results embody three independent ages referring to the three decay series involved and ideally should agree. However, they will only do so if the mineral samples analyzed stayed closed throughout their geological history and also if the isotopic compositions of uranium and thorium were not modified in any way, for instance by fractionation. It is assumed that the values used for the initial lead isotopes are accurate and that no analytical or systematic errors occurred. The ratio $[\frac{^{235}\text{U}}{^{238}\text{U}}]$ is 1/137.88 for uranium of normal composition found in terrestrial minerals, lunar rocks, and meteorites. That this is known is important because it enables a “207/206” date to be obtained without the necessity to know the uranium concentration in the relevant mineral. It is possible, namely, to derive a formula, which contains the ratio $[\frac{^{207}\text{Pb}}{^{206}\text{Pb}}]$ as the only parameter to be measured for a uranium-bearing sample in order to get its age. There are tables from which the age t can be interpolated.

Although uranium and thorium are found in many minerals, only a few of these minerals are suitable for dating using the uranium, thorium, lead method. These comprise those that can retain these elements adequately and probably the most retentive mineral is zircon. In sedimentary rocks, zircon derived from sources underlain by igneous or metamorphic complexes embodies a record both of the orogenic and magmatic histories of these sources. In

zircons, the concentrations of uranium and thorium average 1,330 and 560 ppm respectively, but in pegmatites greater concentrations occur. Uranium and thorium are present in zircons through the isomorphous replacement of Zr^{4+} (ionic radius 0.087 nm) by U^{4+} (ionic radius 0.105 nm) and also through the presence of thorite inclusions. Such substitution is restricted by differences in the ionic radii and Pb^{2+} is excluded altogether because its ionic radius is 0.132 nm. In addition, it carries a lower charge. Therefore, zircon does not contain much lead when it crystallizes and has very high ratios for $[\text{U}/\text{Pb}]$ and $[\text{Th}/\text{Pb}]$ that makes it an invaluable geochronometer. Hydrothermal decomposition in a sealed pressure vessel has been used to extract lead and uranium from zircons.

17.24.2 Concordia and Discordia

The concept of two independent geochronometers arose from consideration of the radioactive decay of the naturally occurring radionuclides of uranium, i.e., ^{238}U and ^{235}U . For the atomic ratio of ^{206}Pb to ^{238}U , one can write

$$\left[\frac{^{206}\text{Pb}}{^{238}\text{U}} \right] = \exp(\lambda_{238}t) - 1 \quad (17.57)$$

where the ^{206}Pb is assumed to be in equilibrium with its primary parent ^{238}U all along the period t . On the other hand, using [Eq. \(17.56\)](#), one can also express the above ratio as a function of time as follows:

$$\left[\frac{^{206}\text{Pb}}{^{238}\text{U}} \right] = \frac{\left[\frac{^{206}\text{Pb}}{^{204}\text{Pb}} \right] - \left[\frac{^{206}\text{Pb}}{^{204}\text{Pb}} \right]_i}{\left[\frac{^{238}\text{U}}{^{204}\text{Pb}} \right]} = \exp(\lambda_{238}t) - 1. \quad (17.58)$$

The other decay series can be treated similarly. Such equations give concordant dates if a uranium-bearing mineral that satisfies the necessary assumptions regarding closed systems is analyzed. The expression(s) appearing on the left-hand side of the above equations and the equivalents for the actinium series are connected through the same parameter t that appears in the exponential expression on the right-hand side. Due to the parametric relationship, there is a particular curve representing the loci of all concordant U/Pb systems, this curve being termed the Concordia (see [Fig. 17.5](#)). In other words, the pairs of atomic ratios $[^{206}\text{Pb}/^{238}\text{U}]$ and $[^{207}\text{Pb}/^{235}\text{U}]$ determined from all samples having concordant dates – samples that do not represent episodic lead losses – must plot on this curve. If all radiogenic lead accumulated up to such a lead loss episode is lost during that episode, the system responds in such a manner that those coordinate points that represent it return to the origin and the U/Pb geochronometer restarts; i.e., the geological “clock” is reset. Of course, when this happens, all trace of the earlier geological history of the relevant system disappears. If only some radiogenic lead is lost, points move part way along a chord comprising systems with discordant dates, in other words a discordia.

Concordia plots allow the interpretation of the geological histories of uranium/lead systems and provide information on the past disturbances of these systems. Several concordia models have been developed in order to interpret the discordancy of the U/Pb dates of uranium-bearing minerals.

One is the *dilatancy model* (Goldich and Mudrey 1972). Minerals undergo radiation damage through the alpha decay of uranium, thorium, and their daughters, and the extent

■ Fig. 17.5

Concordia diagram showing the effects of lead loss or uranium gain on U/Pb systems. t_{cryst} is the time elapsed since original crystallization, t_{clos} is the time elapsed since closure of the system after lead loss or uranium gain. λ_{235} and λ_{238} are the decay constants of the respective primary parents ^{235}U and ^{238}U

of this increases with increasing age as well as with the uranium and thorium contents of the relevant minerals. Such damage produces micro-capillaries allowing water to enter crystals. This is retained until uplift and erosion release the pressures on minerals, such consequent dilation of zircons being accompanied by the escape of water and dissolved radiogenic lead. Loss of radiogenic lead probably occurred during the uplift and erosion of crystalline basement complexes in Precambrian shields. Investigations showed that “207/206” dates from these often approximate the true ages of uranium-bearing minerals. Such minerals from different continents may have lost radiogenic lead 500–600 Ma ago as a result of the Pan-African Event and parallel happenings in other parts of Gondwana such as the Brazilian Event.

A second model relates to chemical weathering that affects almost all minerals and rocks that outcrop. A third is a continuous diffusion one in which radiogenic lead diffused from crystals at a rate governed by a diffusion coefficient, D , an effective radius a , and a concentration gradient of $[^{206}\text{Pb}/^{238}\text{U}]$ (ordinate) against $[^{207}\text{Pb}/^{235}\text{U}]$ (abscissa). The crystals are assumed to be spherical and it is also assumed that there has been either no or negligible diffusion of uranium and intermediates. Also, it is assumed that the radiogenic lead diffusion followed Fick’s Law. The appropriate expression for the ^{206}Pb – ^{238}U pair, for instance, describes the change in lead concentration with time for any radial volume element in a sphere as follows:

$$\frac{\partial [^{206}\text{Pb}]}{\partial t} = D \frac{\partial^2 [^{206}\text{Pb}]}{\partial r^2} + \frac{2}{r} \frac{\partial [^{206}\text{Pb}]}{\partial r} + [^{238}\text{U}]_i \exp(-\lambda_{238}t) \quad (17.59)$$

where $[^{206}\text{Pb}]$ is the atom concentration of lead daughter, $[^{238}\text{U}]_i$ is the initial concentration of uranium parental atoms, λ_{238} is the decay constant of the parental uranium, and t is

the time elapsed since crystallization took place. The relevant boundary condition is $[^{206}\text{Pb}] = 0$ at $t = 0$.

17.24.3 Common Lead

Common lead (i.e., lead that had long lost any association with the decay series discussed above) is found in many minerals such as galena (lead sulfide) and cerussite (lead carbonate), which are constituents of ore-forming bodies. Also, it occurs as a trace element in minerals where associated uranium and thorium contents are low as well as in rock-forming minerals such as feldspars. The atomic weight of common lead is less than that of lead associated with uranium. The difference is due to the increased presence of radiogenic lead-206 in the latter. Common lead, namely, contains isotopes of the element with mass numbers 204, 206, 207, and 208. Lead-204 is not the decay product of a radioactive series, but the other three derive from the radioactive series initiated by uranium-238, uranium-235, and thorium-232, respectively. The relevant atom number ratios are denoted as follows:

$$\alpha = \left[\frac{^{206}\text{Pb}}{^{204}\text{Pb}} \right], \quad \beta = \left[\frac{^{207}\text{Pb}}{^{204}\text{Pb}} \right], \quad \gamma = \left[\frac{^{208}\text{Pb}}{^{204}\text{Pb}} \right]. \quad (17.60)$$

Every lead contains a measurable quantity of lead-204 and can be represented by a three-dimensional diagram of the variables α , β , and γ . There are large variations in the isotopic composition of common lead from different sources. Understanding this was initially difficult because earlier observations implied that common lead had a constant average atomic mass. It soon became clear that this supposed constancy was fortuitous and reflected the fact that the increase in the $[^{206}\text{Pb}/^{204}\text{Pb}]$ atomic ratio is often accompanied by a comparable rise in the $[^{208}\text{Pb}/^{204}\text{Pb}]$ ratio. Efforts were made to construct quantitative models for the isotopic evolution in the Earth from which its age and also that of common lead could be derived (Holmes 1946; Houtermans 1946). They supposed that the Earth was originally both fluid and homogeneous with uranium, thorium, and lead uniformly distributed and with primeval lead having the same isotopic composition everywhere. Later the Earth rigidified so that small regional differences in the $[\text{U}/\text{Pb}]$ ratio arose. In any given region, this may have changed only through the radioactive decay of uranium to lead. It was assumed that when a common lead mineral crystallized, the lead separated from uranium and thorium with its isotopic composition thereafter remaining constant. A Holmes/Houtermans model was developed and this facilitated understanding differences in the above-mentioned α , β , and γ parameters for various types of common lead and allowed calculations to be made of the time elapsed since the formation of the Earth's crust and the time when common lead became incorporated into an ore. Most of the lead in the accessible parts of the crust occurs in igneous and sedimentary rocks with contents ranging from a few tenths to say 500 ppm of lead. Only a tiny proportion of crustal lead is in minerals or ore bodies comprising more than 0.1% of lead and this is true for crustal uranium and thorium as well. Hence, the incorporation of lead into a lead mineral is a very rare event implying that the probability of the event occurring twice in the history of any given sample of lead is negligible.

In the source rock from which a sample of common lead is obtained, lead was related to given quantities of uranium and thorium. This relationship can be described by a chemical milieu index μ , the atom number of uranium-238 over lead-204 comprising that milieu from

which the sample of common lead came. As the ^{238}U decays with time, the content may be extrapolated to the present as if the original mother rock still existed. The chemical milieu index can then be defined as follows:

$$\mu = \left[\frac{^{238}\text{U}}{^{204}\text{Pb}} \right]_{\text{today}}. \quad (17.61)$$

In the same way, it is possible to define another chemical milieu index for the mother rock of a given sample of common lead by means of the ratio between the number of atoms of thorium-232 and the atom number of uranium-238 extrapolated to the present day, the following being appropriate:

$$x = \left[\frac{^{232}\text{Th}}{^{238}\text{U}} \right]_{\text{today}}. \quad (17.62)$$

Finally, the present atomic ratio of ^{235}U to ^{238}U is given as

$$\varepsilon = \left[\frac{^{235}\text{U}}{^{238}\text{U}} \right]_{\text{today}} = \frac{1}{139}. \quad (17.63)$$

17.24.4 The Holmes/Houtermans Model

This model assumed that all common lead had an isotopic composition explicable by the adding of radiogenic lead as decay products from uranium-238, uranium-235, and thorium-232 associated with a primeval lead at the time of formation of the Earth (Holmes 1946; Houtermans 1946). This primeval lead was characterized by the relative isotopic abundances α_w , β_w , and γ_w , w being the age of the Earth. It is taken for granted that the chemical milieu indices for a given sample of common lead remained constant from w up to a time p where p is the time elapsed since a given sample of lead became incorporated into a lead mineral to which a model age of p can be assigned. From the general equation of radioactive decay, it is clear that the lead sample changed its isotopic composition only by the addition of the isotopes lead-206, lead-207, and lead-208 from uranium and thorium with which it was linked in the mother rock during the time interval $w - p$.

A further impetus to researches came from the investigation of the isotopic compositions of minuscule amounts of lead in iron meteorites, particularly in the iron and troilite (FeS) phases of Catmon Diablo. The α and β values turned out to be far lower than those obtained from samples of terrestrial lead or lead from stony meteorites. The troilite phase, while containing lead, does not contain uranium and thorium and therefore the isotopic composition of the lead was regarded as practically constant since crystallization. Such lead is the least radiogenic available and may approach primeval lead in composition and the Catmon Diablo lead values may well approximate primeval lead ones initially incorporated into the Earth's crust and also into chondritic material. If the above values are assumed, the age of the Earth would be about 4.5 ± 0.05 Ga. All models of this type for the isotopic changes with time from the formation of the Earth's crust up to a time p of mineralization involve the hypothesis that the lead spent the entire time interval $(w - p)$ in a milieu with a constant value of μ . Interestingly, phenomena such as metamorphism that occurred often in geological history do not appear to have influenced the μ -values of the mother material of lead minerals to any great extent. However, there is a small dispersion in the x -values.

Serious problems arose with the Holmes/Houtermans model, and these problems came from anomalous lead as opposed to common lead that gave meaningful model dates. It is probable that the small number of ore deposits containing ordinary lead reflects the fact that the lead in most of these underwent a more complex history than that envisaged in the Holmes/Houtermans model. To conform with this model, the relevant lead must have had a single-stage history and this can be confirmed if the model dates agree reasonably well with isotopic data obtained for other minerals from the ore and if the isotopic ratios of lead from a particular deposit are constant within experimental error.

17.24.5 Anomalous Lead

The basic premise regarding the isotopic development of the isotopic composition of lead is the addition of radiogenic lead isotopes such as lead-206, lead-207, and lead-208 stemming from the radioactive decay of uranium and thorium and having values of μ and $x\mu$, which remained constant during the time interval $(w - p)$. Unfortunately, p does not always coincide with the actual time of mineralization as was shown by fossils in beds containing veins of lead ore. Indeed, some absurd results have been obtained that led to negative ages so that common lead ores now existing should form in the far future (up to 2 Ga later, see the last isotherm in [Fig. 17.6](#)).¹ Two types of anomalies are called “B” and “J.” “B” includes those anomalies in which the model age may exceed the geological age of the rock containing lead ores, and it is named after Bleiberg in Austria. Its causes include pneumatolysis, which can redistribute lead minerals in ore bodies or veins and so produce a condition where $g < p$, g being the geological age. J-type anomalies were called after leads at Joplin, Sudbury, Ontario, Canada, and for them, the application of the Holmes/Houtermans model gave negative model ages. However, there are instances of apparently normal leads belonging to this type and giving model ages more or less inferior to the age of mineralization. These are hard to identify, but can sometimes be recognized from their anomalous x -values. Explaining J-type anomalies is straightforward bearing in mind that a basic assumption of the method is that μ had a constant value during the time interval $(w - p)$. Obviously, this cannot be more than, at best, a first approximation of the actual history of a lead sample. So, if purely common lead mixed with a small amount of radiogenic lead, an isotopic composition resembling a J-type anomalous lead would be the result. Such an event could take place at any time during the time interval $(w - p)$ before the uranium and thorium contents of the lead sample dropped to zero.

A single analysis of an anomalous J-type lead gives little information about the date when radiogenic lead was added during the time interval $(w - p)$ or about the isotopic composition and hence the age. Better data are obtainable from a number of samples in a region. Three case histories were offered for three different regions containing lead ore deposits and these are Sudbury and Thunder Bay, Ontario, and Australia. Common leads and highly anomalous leads were used, the former following a lead development line without appreciable alteration in their μ and x values during the time interval $(w - p)$. They have model ages corresponding to the actual time of mineralization (Russell and Farquhar 1960). Of course, the isotopic data alone do not suffice to determine the time of addition of the radiogenic component of such anomalous J-type leads.

Alternatives to the Holmes/Houtermans model have been proposed. The Russell/Standton/Farquhar (RSF) and the Russell/Farquhar/Cumming (RFS) models were proposed based on the work of Alpher and Herman (1951). While the Holmes/Houtermans model presented a fan

■ Fig. 17.6

A graphic presentation of the Holmes/Houtermans model for common lead. The straight lines are isochrones (the p -values are given in million years, positive numbers refer to the past, the negative one to the future), the curved lines are Pb development lines. The relevant constants are as follows: $\alpha_w = 9.41$, $\beta_w = 10.27$, $w = 4.49$ Ga, $\lambda_{238} = 1.54 \times 10^{-10} \text{ a}^{-1}$, $\lambda_{235} = 9.80 \times 10^{-10} \text{ a}^{-1}$. The point (α_w, β_w) represents primeval lead. The extra radiogenic lead accumulated relative to the primeval lead composition during the time interval $(w - p)$ elapsed till crystallization can be represented this way: $\alpha - \alpha_w = \mu [\exp(\lambda_{238}w) - \exp(\lambda_{238}p)]$, $\beta - \beta_w = \mu \epsilon [\exp(\lambda_{235}w) - \exp(\lambda_{235}p)]$. Dividing the second equation by the first helps to eliminate the constant μ , thus $(\beta - \beta_w)/(\alpha - \alpha_w) = \epsilon \{[\exp(\lambda_{235}w) - \exp(\lambda_{235}p)]/[\exp(\lambda_{238}w) - \exp(\lambda_{238}p)]\}$, so that leaves only three constants to be assessed, i.e., α_w , β_w , and p . Hence from two pairs of α and β of known age p , the values for α_w and β_w can be extrapolated and the age of the Earth, w , evaluated

of lead development lines and isochrones starting from a point corresponding to primeval lead (α_w, β_w) or a similar α, γ diagram, both of the others assumed a single global source for all “ordinary” common leads, which could be in the upper mantle. A continuous growth model has been suggested and considered as more feasible since it is more probable that radiogenic contaminants were generated continuously during a time interval commencing with the formation of relevant rocks, for instance granites, and ending with the removal of radiogenic lead from them to mix with other lead prior to or in the course of the formation of a lead ore deposit.

17.24.6 Multistage Leads

Leads in igneous and metamorphic rocks have isotopic compositions determined by a multistage history in the majority of cases. Clearly, they will have past associations with

a number of systems possessing different [U/Pb] and [Th/Pb] ratios. In the complex situation of a sample of lead, which underwent transference through two uranium-bearing systems (at points p_1 and p_2 , respectively) characterized by different [$^{238}\text{U}/^{204}\text{Pb}$] ratios designated as μ_1 and μ_2 , the α -value of the sample is given by

$$\alpha = \alpha_w + \mu_1 [\exp(\lambda_{238} w) - \exp(\lambda_{238} p_1)] + \mu_2 [\exp(\lambda_{238} p_1) - \exp(\lambda_{238} p_2)]. \quad (17.64)$$

When lead is transferred from the first system to the second, this probably entails a physical process of removal, e.g., through the formation of magma in the mantle and its later emplacement in the crust of the Earth. Such a transition from system 1 to system 2 might occur without such a physical removal taking place, i.e., take place solely through changes in the U/Pb system of system 1. These changes would affect the [$^{238}\text{U}/^{204}\text{Pb}$] ratio and so the isotopic composition of the lead, which became incorporated in the ore deposit. A rarer possibility is that lead may be gained and its different isotopic composition would alter the isotopic composition of the final lead. It is clear that all of the above-mentioned considerations would apply to three or more stages also.

17.24.7 Whole-Rock Dating

Considering lead/lead isochrons of igneous and metamorphic rocks, if a magma volume involving homogeneous material crystallizes, a rock suite results, which contains different [U/Pb] and [Th/Pb] ratios. Alternatively, a volcanic rock assemblage might arise after a high-grade regional metamorphic episode and contain lead isotopically homogenized by the event. Either way the lead later evolved along a set of divergent and curved trajectories corresponding to different values of μ in each specimen. If such growth proceeds to the present uninterruptedly, the leads lie along an isochron if the rocks had the same initial isotope ratios of lead, formed at the same time and remained closed to uranium, thorium, and lead. Recent alterations in the concentrations of these elements are permissible if the isotopic composition of the lead is unaffected. An isochron equation can be derived of which the slope, s , is given by the following expression:

$$s = \frac{1}{137.88} \frac{\exp(\lambda_{235} t) - 1}{\exp(\lambda_{238} t) - 1}. \quad (17.65)$$

From this, the age of a rock suite can be obtained (Goldich and Mudrey 1972). A suite of metamorphic rocks from the Lewisian basement complex in northwestern Scotland was depleted in uranium compared to the crustal average. Uranium and lead concentrations were 0.24 and 7.9 ppm, respectively, and the average $^{238}\text{U}/^{204}\text{Pb}$ ratio was 1.76. The isotope ratios of lead scattered about a straight line interpreted as a secondary isochron. A date was found from the point of intersection of this with the primary lead growth curve, which had a value of 8.68 for μ , near to, but lower than the value for conformable lead ores. The result was an age of about 2.9 Ga that was taken to be the time of variable uranium losses during pyroxene/granulite metamorphism of the ancestral Lewisian rocks.

17.25 Uranium/Xenon, Uranium/Krypton

Uranium undergoes spontaneous fission as well as radioactive α decay and this produces fissionogenic xenon and krypton that accumulate in uranium-bearing minerals through

geological time. The determination of the ages of such minerals followed the discovery that xenon is produced by the spontaneous fission of ^{238}U in pitchblende (Khlopin et al. 1947). A U/Xe or U/Kr age may be calculated as follows:

$$t_{\text{U/Xe}} = \frac{1}{\lambda_{\alpha} + \lambda_{\text{sf}}} \ln \left\{ \frac{[^A\text{Xe}_{\text{sf}}](\lambda_{\alpha} + \lambda_{\text{sf}})}{[^{238}\text{U}]^A Y_{\text{sf}} \lambda_{\text{sf}}} + 1 \right\} \quad (17.66)$$

where λ_{α} is the decay constant of uranium-238 for alpha decay, λ_{sf} is the uranium-238 spontaneous fission decay constant, and $[^A\text{Xe}_{\text{sf}}]$ and $^A Y_{\text{sf}}$ are the concentration and mass yield, for the xenon isotope with mass number A resulting from spontaneous fission. Because $\lambda_{\alpha} \gg \lambda_{\text{sf}}$, the above can be reduced as follows (Eikenberg et al. 1993):

$$t_{\text{U/Xe}} = \frac{1}{\lambda_{\alpha}} \ln \left\{ \frac{[^A\text{Xe}_{\text{sf}}] \lambda_{\alpha}}{[^{238}\text{U}]^A Y_{\text{sf}} \lambda_{\text{sf}}} + 1 \right\}. \quad (17.67)$$

Similar equations can be derived for $t_{\text{U/Kr}}$ ages calculated from the concentration of and mass yield of suitable krypton isotopes such as ^{86}Kr .

The yield of the main ^{238}U spontaneous fission isotope ^{136}Xe is about 6% and, because the rate of production ratio $[^{136}\text{Xe}_{\text{sf}}/^{206}\text{Pb}_{\text{rad}}]$ is of the order of 4×10^{-8} , the U/Xe method was initially applied to uranium-rich minerals such as pitchblende, but later uranium-poorer accessory minerals such as monazites and zircons have been investigated as well.

17.25.1 Pitchblendes

Pitchblendes can be affected by geological events causing alteration or dissolution and the subsequent redistribution of uranium and its daughters so that reported U/Xe ages of pitchblendes are often lower than their formation ages. At one time, the disparity was attributed to gas losses by diffusion and it was inferred that pitchblende is unsuited for dating by the U/Xe method. But later work using U/Xe, U/Kr, and U/Pb systems plus electron microprobe analysis demonstrated that the fission gases in pitchblendes could well have survived even greenschist facies metamorphism so that studying them could aid in the interpretation of discordant isotope ages. Obviously, if geologically undisturbed pitchblendes gave concordant U/Pb ages and underwent no losses of fission gases, the U/Xe and U/Kr ages should both be identical and agree with the U/Pb ages if appropriate values for λ_{sf} , $^A Y_{\text{sf}}$, and $[^{136}\text{Xe}_{\text{sf}}/^{86}\text{Kr}_{\text{sf}}]$ are used. Where gas losses *did* take place, krypton seems always to be lost preferentially with respect to xenon and both fissiogenic xenon and lead losses ran almost parallel. When the $[^{136}\text{Xe}_{\text{sf}}/^{86}\text{Kr}_{\text{sf}}]$ atomic ratios are larger than 6.1 ± 0.1 , discordant fission gas ages clearly indicate perturbation of the U/Pb system. Extensive fractionation between xenon and krypton has been observed in pitchblendes.

To use the U/Xe/Kr dating method, the product ($\lambda_{\text{sf}} ^A Y_{\text{sf}}$) must be known and also the concentrations of spontaneous fission xenon and krypton, the relative xenon and krypton spontaneous fission yields, and the $[^{136}\text{Xe}/^{86}\text{Kr}]_{\text{sf}}$ ratio. Any contribution from uranium-238 that underwent fast neutron-induced fission can be neglected. Slow neutron-induced fission of ^{235}U , however, had to be taken into correction:

$$[^{136}\text{Xe}_{\text{sf}}] = [^{136}\text{Xe}_{\text{f}}] - [^{136}\text{Xe}_{\text{nif}}] \quad (17.68)$$

where the subscript “f” refers to all fission events resulting in ^{136}Xe , whereas “nif” stands for neutron-induced fission of ^{235}U .

Iteration was commenced using the following values: 6.39% for $^{136}\text{Y}_{\text{nif}}$ from the slow neutron-induced fission of ^{235}U and 6.3% for $^{136}\text{Y}_{\text{sf}}$ from the spontaneous fission of ^{238}U , both taken from earlier work (Eikenberg et al. 1993). For isotope pairs of Xe 136/131, 134/131, and 132/131, for which the differences between induced and spontaneous compositions are large, a mean value for a factor R was calculated for each sample, where R is the ratio of induced to spontaneous fission events.

Then $\text{U}/^A\text{Xe}$ and $\text{U}/^B\text{Kr}$ ages for each sample were calculated (where A and B are the respective mass numbers of Xe and Kr). While the former were only slightly different, there were significant differences between the $\text{U}/^{136}\text{Xe}$ and $\text{U}/^{86}\text{Kr}$ ages of geologically unaffected pitchblendes, a matter regarded as not surprising on the grounds that varying compositions of fission krypton from $^{238}\text{U}_{\text{sf}}$ have been reported. Keeping $^{136}\text{Y}_{\text{sf}}$ fixed, the $^A\text{Y}_{\text{sf}}$ and $^B\text{Y}_{\text{sf}}$ yields of the deviational $\text{U}/^A\text{Xe}$ and $\text{U}/^B\text{Kr}$ were changed to obtain agreement between all ages. The new yields were inserted into suitable equations so as to calculate a new set of ages, a procedure iterated until all ages agreed satisfactorily within analytical error. Most samples gave $[^{136}\text{Xe}/^{86}\text{Kr}]_{\text{sf}}$ values around 6.1. Back-up information showed that none of the samples was geologically disturbed. However, some of them had undergone xenon, krypton, and lead losses of up to 50%, but they were still suitable to determine the relative $^A\text{Xe}_{\text{sf}}$ and $^B\text{Kr}_{\text{sf}}$ isotopic ratios. This is because minute losses of inert gases have no detectable effect on the isotopic compositions of xenon and krypton. Regarding such geologically undisturbed samples, the product $(\lambda_{\text{sf}}^{136}\text{Y}_{\text{sf}})$ was obtained and required that the minerals assessed remained closed both to uranium and to the fission gases. Only samples with concordant U/Pb ages and the recrystallized pitchblendes (U/Pb discordant, but $\text{U}/\text{Xe}/\text{Kr}$ concordant) were examined, the latter having formation ages determinable from the intercept of the U/Pb discordia with the concordia and also from U/Pb microprobe analyses. All values of $(\lambda_{\text{sf}}^{136}\text{Y}_{\text{sf}})$ were around $5.7 \times 10^{-18} \text{ a}^{-1}$ and agreed within acceptable error. No fractionation between the heavier xenon and the lighter krypton was observed from which it was concluded that the selected minerals retained their fission xenon quantitatively.

Abstract: This chapter reviews the historical perspective of transuranium elements and the recent progress in the production and study of nuclear properties of transuranium nuclei. Exotic decay properties of heavy nuclei are also introduced. Chemical properties of transuranium elements in aqueous and solid states are summarized based on the actinide concept. For new application of studying transuranium elements, an X-ray absorption fine structure (XAFS) method and computational chemistry are surveyed.

18.1 Production of Transuranium Elements

18.1.1 Discovery of Transuranium Elements

The history of the discovery of transuranium elements is a fascinating story that has been described in several articles (e.g., Seaborg and Loveland 1990; Morss and Fuger 1992; Seaborg 1995; Hoffman et al. 2000).

There were at least two difficulties in the discovery of transuranium elements; the first one was the chemical behavior of transuranium elements. Before Seaborg's proposal of the actinide concept (Seaborg 1945), it was believed that thorium, protactinium, uranium, neptunium, plutonium, and the next elements 95 and 96 should be placed as the heavier members of groups 4 through 10. According to the actinide concept, it was expected that the new series should start with actinium as a prototype and end with the filling of the 5f electron shell at element 103, and that the heavier actinides would be trivalent homologs of the lanthanide series in which 4f orbitals were being filled. The second difficulty was the method of identification of transuranium isotopes produced in nuclear reactions. An isotope to be identified had to be isolated before it decayed from large quantities of impurities, especially from fission products.

18.1.1.1 Neptunium (Np)

The first man-made transuranium element, neptunium (Np), was discovered by McMillan and Abelson (1940) while studying the neutron-induced fission of uranium (U). The reaction used in the synthesis was

For separating fission products from the neutron capture products, a recoil technique was employed; fission products recoiling out of the target foil with high kinetic energies were removed from the target perse, and the neutron capture products together with the target material were subjected to chemical experiments. It was found that in the presence of the reducing agent, sulfur dioxide, SO₂, the 2.3-day half-life species produced in the growth from the 23-min uranium was quantitatively precipitated as a fluoride. This behavior chemically distinguished the product from uranium.

The later chemical study showed that neptunium was oxidized to hexavalent with the oxidizing agent, bromate ion BrO₃[−]; it resembled uranium, not rhenium (Re), contrary to the expectation from the periodic table at that time. The result was the first evidence that an inner electron shell (i.e., the 5f shell) is filled in the transuranium elements. The isotope of neptunium with the longest half-life ($T_{1/2} = 2.14 \times 10^6$ years) is ²³⁷Np, the mother nuclide of the

neptunium decay series produced in nuclear reactors. Neptunium was named after the planet Neptune, the next planet beyond Uranus.

18.1.1.2 Plutonium (Pu)

Plutonium (Pu), the second transuranium element, was discovered by Seaborg and coworkers (Seaborg et al. 1946). The first isotope of Pu was synthesized by using the 60 in. cyclotron for the deuteron bombardment of uranium at the University of California, Berkeley,

The α -emitting product was identified as a new element from the study of chemical behavior of this isotope. It was distinctly different from both uranium and neptunium in its redox properties; the 3+ and 4+ valence states were more stable. A second isotope of element 94, ^{239}Pu , with a half-life of 24,000 years was synthesized immediately as a daughter of β^- decay of ^{239}Np , which confirmed the presence of element 94. The isotope ^{239}Pu produced in appreciable amounts in nuclear reactors is of major importance, because of its large fission cross section with thermal neutrons. It was named after the planet Pluto in analogy to uranium and neptunium.

18.1.1.3 Americium (Am) and Curium (Cm)

Element 95, americium (Am), and element 96, curium (Cm) were synthesized by Seaborg et al. in 1944–1945 (Seaborg 1945) in bombardments of uranium and plutonium with α particles in a cyclotron:

The isotope ^{242}Cm was identified by observing the known isotope ^{238}Pu as the α -decay daughter of the new nuclide. It was found that successive neutron capture in ^{239}Pu produced ^{241}Am and ^{242}Cm in a reactor according to the following reactions (Ghiorso et al. 1950)

Americium and curium are quite similar to the rare earth elements in their chemical properties; a stable oxidation state is 3+. Thus, it was too difficult for the discovery team to chemically isolate the two elements from each other and from rare earth fission products. For their chemical separation, the development of the ion-exchange technique was required, which also made the separation and identification of subsequent transuranium elements. The identification of ^{241}Am was also confirmed by the volatility measurement of ^{241}Am produced from its parent ^{241}Pu . Element 95, americium, was named after the Americas in analogy with the naming of its rare earth homolog, europium, and curium was named after Marie and Pierre Curie in analogy with the naming of its homolog, gadolinium, that was named after the Finnish rare earth chemist Johann Gadolin.

18.1.1.4 Berkelium (Bk) and Californium (Cf)

The element with the atomic number 97, berkelium (Bk), was produced by irradiation of milligram amounts of ^{241}Am with α particles at Berkeley (Thompson et al. 1950a):

To identify the new nuclide, a rapid cation-exchange separation technique using ammonium citrate as an eluant was employed. Early experiments indicated that element 97 had two oxidation states 3+ and 4+. The actinide concept provided the guidance to search for these two oxidation states, by analogy with the homolog element, terbium (Tb). The chemically separated samples were subjected to the measurement of radiation. Characteristic Cm X-rays associated with the electron capture (EC) decay and low-intensity α particles with a half-life of 4.5 h were detected. Berkelium was named after the city of Berkeley, California where it was discovered, just as the name terbium derived from Ytterby, Sweden.

Californium was synthesized in 1950 by irradiation of a few micrograms of ^{242}Cm with α particles:

The identification of element 98 was accomplished with a total of only 5,000 atoms (Thompson et al. 1950b). The ion-exchange techniques were also used in the separation and identification of californium. Element 98 was eluted in the expected fraction, and the observed half-life and α -particle energy of the radioactivity were also in agreement with predictions. It was named after the state of its discovery, although the chemical analog of element 98 was dysprosium (Dy).

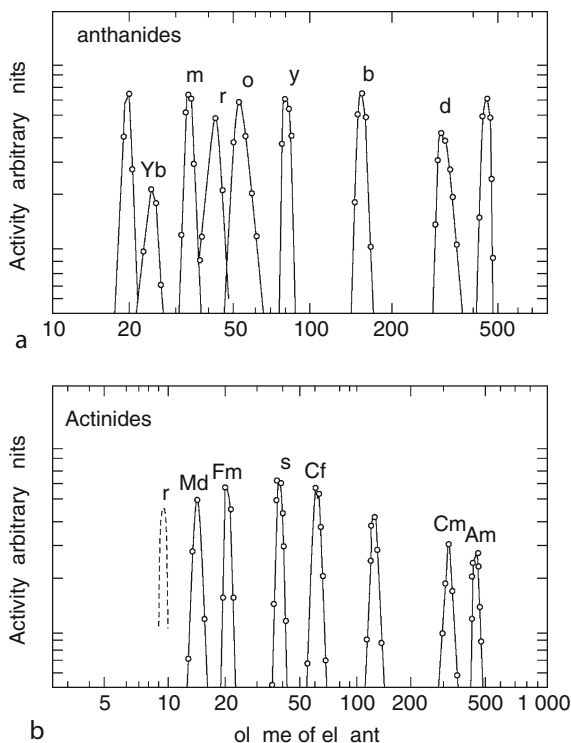

The last four actinides (Am, Cm, Bk, and Cf) have 3+ as their most stable valence state in solution, just as the rare earth elements. The similarity in solution has been commonly used for identification of a particular actinide. ▶ [Figure 18.1](#) shows elution curves for lanthanides and actinides from a cation-exchange column (cited from Katz et al. 1986). Ion-exchange properties of actinides are described in ▶ [Sect. 18.2.3.1](#).

18.1.1.5 Einsteinium (Es) and Fermium (Fm)

Einsteinium (Es) and fermium (Fm) were identified in 1952 in the radioactive debris from the “Mike” thermonuclear explosion that took place in the Pacific. Ion-exchange separation was applied, and the new elements, einsteinium and fermium, were isolated by processing larger amounts of the radioactive coral material (Ghiorso et al. 1955a). Chemical identification was made by ion-exchange separations, while isotopic assignments were made as the result of the corresponding decay sequences: $^{253}\text{Cf} \rightarrow ^{253}\text{99}$ and $^{255}\text{99} \rightarrow ^{255}\text{100}$. A 20-day activity emitting α particles of 6.6 MeV was identified as ^{253}Es and 7.1 MeV α activity with a half-life of 22 h was identified as ^{255}Fm . The elements Es and Fm were named in honor of Albert Einstein and Enrico Fermi. These discoveries confirmed that ^{238}U can suffer as many as 17 successive neutron captures and subsequent β^- decays if the neutron flux is large enough ($1 \times 10^{24} - 4 \times 10^{24} \text{ s}^{-1} \text{ cm}^{-2}$).

■ Fig. 18.1

Elution curves for 3+ lanthanide and actinide ions from Dowex-50 ion-exchange resin with ammonium α -hydroxyl isobutyrate eluant (Katz et al. 1986)

18.1.1.6 Mendelevium (Md)

Mendelevium (Md) was produced in 1955 by irradiation of ^{253}Es with α particles (Ghiorso et al. 1955b). The number of atoms of element 101, N_{101} , expected to be produced was calculated as $N_{101} = N_{\text{Es}} \phi_{\alpha} \sigma t \approx 1$ atom under the experimental conditions characterized by the following parameters. The number of the ^{253}Es target atoms was $N_{\text{Es}} \approx 10^9$ ($\sim 4 \times 10^{-13}$ g), the flux density of α particles was $\phi_{\alpha} \approx 10^{14}$ particles s^{-1} , the cross section was $\sigma \approx 1$ mb ($= 10^{-27}$ cm^2), and the irradiation time was $t \approx 10^4$ s. To detect these single atoms produced in 10^4 s, the recoil technique was applied. The einsteinium target was prepared by electrodeposition on a thin gold foil. The produced element 101, recoiling through a vacuum due to the momentum of the impinging α particles, could be caught on a catcher foil. After irradiation, the catcher foil containing recoiling mendelevium atoms was subjected to the chemical separation by the cation-exchange resin Dowex-50 with an eluant of ammonium α -hydroxy isobutyrate (► Fig. 18.1). The earliest experiments were confined to searching for short-lived α -emitting isotopes of element 101. No α activity, however, was observed that could be attributed to element 101. After longer bombardments, spontaneous fission (SF) events with a half-life of 3.5 h were observed in the fractions corresponding to elements 100 and 101. At that time, it

was assumed that the isotope $^{256}_{101}\text{Es}$ was produced in the $^{253}_{99}\text{Es}(\alpha, n)$ reaction that decayed by electron capture (EC) with a half-life of the order of half an hour to $^{256}_{100}\text{Fm}$, and that $^{256}_{100}\text{Fm}$ then decayed by spontaneous fission (SF) with a half-life of about 3.2 h. In fact, another experiment confirmed the SF decay of $^{256}_{100}\text{Fm}$ produced in the following neutron capture reaction:

Only 17 atoms of Md were detected by their EC decay into the spontaneously fissioning isotope $^{256}_{100}\text{Fm}$ that is presently known to have the half-life of 2.6 h:

The name mendelevium was suggested for the element, in honor of the Russian chemist, Dmitri Mendeleev.

18.1.1.7 Nobelium (No) and Lawrencium (Lr)

The first report of the discovery of element 102 came from the Nobel Institute, Stockholm, Sweden. The research group used the reaction of $^{244}_{98}\text{Cm} + ^{12}_6\text{C}$ in which they found a new α emitter with a half-life of about 10 min. However, experiments neither at Berkeley nor at the Kurchatov Institute in Moscow confirmed the above result. In 1958, Ghiorso et al. (1958) announced the positive identification of $^{254}_{102}\text{No}$ that was supposedly produced in the following reaction by use of the double recoil technique:

$^{250}_{100}\text{Fm}$, the daughter of the new element, was collected using the recoil technique, one atom at a time, and identified as Fm by their position in the cation-exchange elution curve. A half-life of ~ 3 s was assigned to $^{254}_{102}\text{No}$ at that time. However, it is now known that the 3 s radioactivity was $^{252}_{102}\text{No}$ produced in the $^{244}_{98}\text{Cm}(^{12}_6\text{C}, 4n)$ reaction; the used target contained 20 times more $^{244}_{98}\text{Cm}$ than $^{246}_{98}\text{Cm}$. $^{254}_{102}\text{No}$ is now known to have 55 s half-life. The errors in this experiment indicate the difficulty associated with one-atom-at-a-time studies. In subsequent chemical experiments, it was found that the most stable oxidation state of element 102 in solution was 2+. The element was named nobelium after Alfred Nobel.

The first identification of an isotope of element 103 was by the Berkeley group in 1961 (Ghiorso et al. 1961). The californium isotopes, $^{249,250,251,252}_{98}\text{Cf}$, were bombarded with boron beams:

Reaction products recoiling from the target were caught by a long-metallized Mylar tape, which was moved past a series of α -particle detectors. A new α -emitting nuclide with α energy of 8.6 MeV and a half-life of ~ 4 s was assigned to $^{257}_{103}\text{Lr}$. But later experiments indicated this activity was due to $^{258}_{103}\text{Lr}$. Subsequent identification of element 103 was made by the Russian group in 1965 using the double-recoil technique (Donets et al. 1965).

$^{256}_{103}\text{Lr}$, now known to have a half-life of ~ 30 s, was deduced from the genetic relation with the known $^{252}_{103}\text{Lr}$. Lr is the first actinide that was identified through a purely instrumental

method, because the half-life of the isotope was too short to allow any chemistry. Silva et al. later conducted the ion-exchange experiments of ^{256}Lr and confirmed that Lr exhibits a stable 3+ state in solution, as expected by the actinide concept (Silva et al. 1970). Lawrencium was named after Ernest O. Lawrence, the inventor of the cyclotron.

The discovery of elements 93 to 103 is summarized in [▶ Table 18.1](#). The names and symbols from element 101 through 103 were approved in 1992 by IUPAC (International Union of Pure and Applied Chemistry) based on the report of the Transfermium Working Group (TWG) (Barber et al. 1992), which consisted of scientists appointed by both IUPAP (International Union of Pure and Applied Physics) and IUPAC.

[▶ Figure 18.2](#) shows the year of discovery of the transuranium elements. Some of the important discoveries related to the transuranium elements are also shown in the figure.

18.1.2 Production of Transuranium Nuclides

There are two kinds of methods for production of transuranium elements as indicated in the previous [▶ Sect. 18.1.1](#): neutron capture reactions in nuclear reactors and charged-particle-induced reactions at accelerators.

18.1.2.1 Neutron Capture Reactions

The method is based on the concept that absorption of neutrons by nuclides with the atomic number Z leads to formation of neutron-rich nuclides that transmute by β^- decay into nuclides with the atomic number $Z + 1$.

[▶ Table 18.1](#)

Discovery of transuranium elements 93–103

Atomic number	Element	Symbol	Year of discovery	Production reaction
93	Neptunium	Np	1940	$^{238}\text{U} (\text{n}, \gamma) ^{239}\text{U} \rightarrow ^{239}\text{Np}$ (2.3 days)
94	Plutonium	Pu	1940–1941	$^{238}\text{U} (\text{d}, 2\text{n}) ^{238}\text{Np} \rightarrow ^{238}\text{Pu}$ (87.7 years)
95	Americium	Am	1944–1945	$^{238}\text{U} (\alpha, \text{n}) ^{241}\text{Pu} \rightarrow ^{241}\text{Am}$ (433 years)
96	Curium	Cm	1944	$^{239}\text{Pu} (\alpha, \text{n}) ^{242}\text{Cm}$ (163 days)
97	Berkelium	Bk	1949	$^{241}\text{Am} (\alpha, 2\text{n}) ^{243}\text{Bk}$ (4.5 h)
98	Californium	Cf	1950	$^{242}\text{Cm} (\alpha, \text{n}) ^{245}\text{Cf}$ (44 min)
99	Einsteinium	Es	1952	Thermonuclear explosion, ^{253}Es (20 days)
100	Fermium	Fm	1952	Thermonuclear explosion, ^{255}Fm (22 h)
101	Mendelevium	Md	1955	$^{253}\text{Es} (\alpha, \text{n}) ^{256}\text{Md}$ (1.3 h)
102	Nobelium	No	1958	$^{244}\text{Cm} (^{12}\text{C}, 4\text{n}) ^{252}\text{No}$ (~ 3 s)
103	Lawrencium	Lr	1961	$^{249-252}\text{Cf} (^{10,11}\text{B}, \text{xn}) ^{258}\text{Lr}$ (~ 4 s)

■ Fig. 18.2

Historical presentation of the discovery of transuranium elements. Some important discoveries related to the transuranium elements are also shown

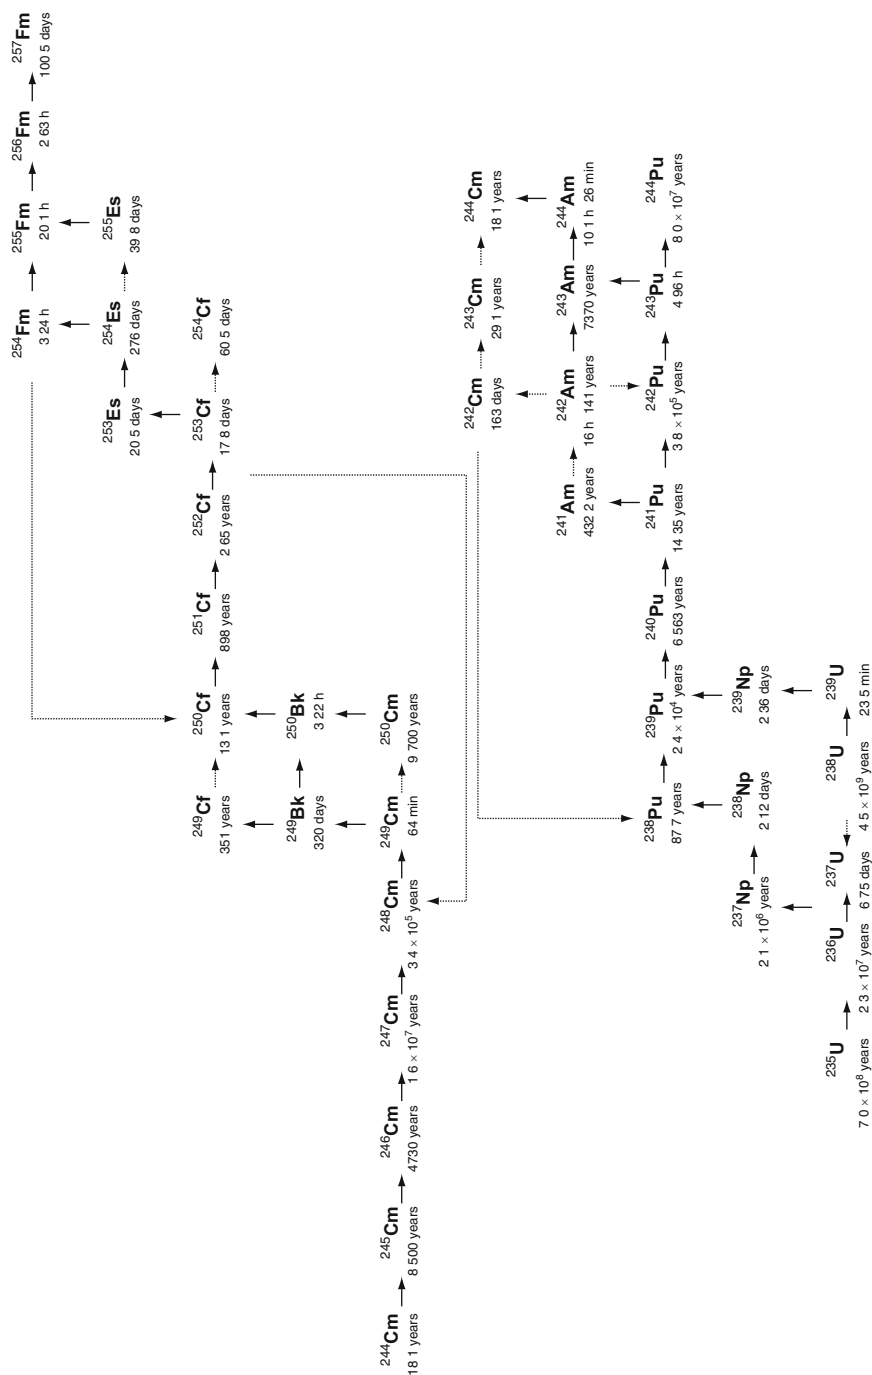

Four of the transuranium elements (Np, Am, Es, and Fm) were first produced using neutron capture reactions. In ▶ Fig. 18.3, the neutron capture paths used for production of transuranium nuclides in nuclear reactors are shown. Starting with ^{238}U , the main path goes to ^{239}Pu that undergoes multiple neutron captures to ^{243}Pu . ^{243}Pu decays to ^{243}Am that successively undergoes captures and decays to ^{244}Cm . Then ^{244}Cm can undergo multiple neutron captures to yield the Cm isotopes up to ^{249}Cm followed by subsequent captures and decays to ^{249}Bk , ^{250}Bk , ^{250}Cf , ^{252}Cf , and finally to ^{257}Fm . The chain ends at the 380 μs spontaneous fission (SF) of ^{258}Fm . As no appreciable amounts of nuclides above ^{244}Cm are produced in power reactors, one needs irradiations of heavy targets such as ^{244}Cm in a specific isotope production reactor for the production of heavier nuclides. As a typical facility for such irradiations, there is the High Flux Isotope Reactor (HFIR) at Oak Ridge National Laboratory, USA that accommodates 300 g of actinide target nuclides in a flux of 2×10^{15} – $5 \times 10^{15} \text{ n cm}^{-2} \text{ s}^{-1}$. Production of the heavier transuranium nuclides at HFIR is shown in ▶ Table 18.2 (cited from Hoffman 1986). Macroscopic quantities of some of these elements are available for studies of their nuclear and chemical properties and also serve as accelerator targets for preparation of other heavy element isotopes.

Successive neutron capture reactions (see ▶ Fig. 18.3) depend on the β -decay constant, λ , and the neutron capture cross section, σ , of each nuclide, as well as on the neutron flux ϕ . In other words, the competition between neutron capture and β^- -decay processes should be considered. The production rate of the i th nuclide with the number of atoms N_i is expressed as

$$\frac{dN_i}{dt} = N_{i-1}\sigma_{i-1}\phi - (\lambda_i + \sigma_i\phi)N_i. \quad (18.13)$$

Fig. 18.3

Neutron capture paths to produce transuranium nuclei in nuclear reactors. The horizontal arrows represent the neutron capture and the vertical ones pointing upward indicate β^- decay. The main paths are shown by the solid arrows

■ **Table 18.2**

Mainline High Flux Isotope Reactor (HFIR) production (elements 96–100) (cited from Hoffman 1986)

Isotope	Half-life (principal decay mode)	Production (amount/year)
Curium-248	3.397×10^5 years (α)	150 mg
Berkelium-249	320 days (β^-)	50 mg
Californium-249	350.6 years (α)	From ^{249}Bk decay
Californium-252	2.64 years (α) ^a	500 mg
Einsteinium-253	20.4 days (α)	2 mg
Einsteinium-254	275.7 days (α)	4 μg
Fermium-257	100.5 days (α)	1 pg

^a ^{252}Cf has neutron output from spontaneous fission (SF) of $2.3 \times 10^{12} \text{ n s}^{-1} \text{ g}^{-1}$.

In the case of $\lambda_i \gg \sigma_i \phi$, the nuclide transmutes by β^- decay into the nuclide with $Z + 1$, while in the case of $\lambda_i \ll \sigma_i \phi$ the nuclide undergoes neutron capture to produce the nuclide with the number of neutrons increased by one. When $\lambda_i \approx \sigma_i \phi$, two processes compete with each other. Assuming the following values, e.g., for the neutron flux and the neutron-absorption cross section of the i th nuclide $\phi = 1 \times 10^{15} \text{ n cm}^{-2} \text{ s}^{-1}$ and $\sigma_i = 10$ barns ($1 \times 10^{-23} \text{ cm}^2$), respectively, the competing processes become comparable if the β half-life of the nuclide is $T_{1/2} = 2.2$ years ($\lambda_i = 1 \times 10^{-8} \text{ s}^{-1}$).

Over a thousand tons of plutonium has been synthesized in commercial and military reactors; the annual global net production rate in nuclear power reactors is $\sim 100 \text{ tons y}^{-1}$, contained in the spent fuel elements. The accumulated amount of higher actinides within the European community is on the level of 1–3 tons for ^{237}Np , ^{238}Pu , and ^{241}Am and over 100 kg for ^{244}Cm ; the amounts in the USA and Russia are of the same magnitudes (Choppin et al. 1995).

For frontier research on both the chemical and nuclear properties of the heaviest elements, large quantities of heavy actinides with relatively long half-lives, such as ^{254}Es and $^{244,248}\text{Cm}$ are needed. In fact, the LEAP (Large Einsteinium Activation Program) project had been proposed by the US national laboratories to investigate the inorganic and nuclear chemistry of elements in the transfermium region and to search for superheavy elements (Hoffman 1986).

18.1.2.2 Charged-Particle-Induced Reactions

Compound nucleus reactions involving light incident charged particles were used for the first production of the transuranium elements Pu, Cm, Bk, Cf, and Md. However, for the production of transuranium nuclei far from the stability line, the emphasis has shifted from using light charged-particle-induced reactions to using heavy-ion-induced reactions. Recent developments in accelerator technology have made the use of high intensity heavy-ion beams as massive as ^{238}U . General description of the heavy-ion reactions appears in some references (see, e.g., Bock 1980; Bass 1980; Bromley 1984).

Successful production of fissionable nuclei, such as transuranium nuclides in nuclear reactions, depends mainly on two factors: fusion cross section, σ_{fusion} , and survival probability, P_{survival}

$$\sigma_{\text{production}} = \sigma_{\text{fusion}} P_{\text{survival}}. \quad (18.14)$$

The first term is the yield of compound nucleus formation or the fusion cross section used in the heavy-ion reaction, while the second term is the survival probability of the produced transuranium nucleus in the process of de-excitation. Fusion cross section can be approximated by the equation

$$\sigma_{\text{fusion}} = \pi \lambda^2 \sum (2l + 1) T_l P_{\text{cn}} \quad (18.15)$$

where λ is the de Broglie wavelength of the incident particle, l is the orbital angular momentum, and T_l indicates the transmission coefficient of the wave (for detailed explanation of nuclear reactions see [▶ Chap. 3 in Vol. 1](#)). P_{cn} is the probability of the compound nucleus formation. On the de-excitation process of transuranium nuclei, competition between the particle emission (mainly neutron) and fission that destroys transuranium nuclei, $\Gamma_{\text{n}}/\Gamma_{\text{f}}$, should be considered. $\Gamma_{\text{n}}/\Gamma_{\text{f}}$ is discussed in detail by Vandenbosch and Huizenga (1973) and the experimental values are compiled for various fissioning nuclei by Schmidt et al. (1980). The $\Gamma_{\text{n}}/\Gamma_{\text{f}}$ values averaged over evaporation of four neutrons are shown in [▶ Fig. 18.4](#) as a function of the neutron number N of the nucleus. It is found that the $\Gamma_{\text{n}}/\Gamma_{\text{f}}$ decreases with the atomic number Z of the nucleus and increases with N for each Z .

For the calculation of $\sigma_{\text{production}}$ via compound nucleus formation followed by the de-excitation process with $\Gamma_{\text{n}}/\Gamma_{\text{f}}$, some computer codes, such as ALICE (Plasil and Blann 1975; Blann 1984), PACE (Gavron 1980), and HIVAP (Reisdorf 1981) are widely used.

In the production of heavy transuranium nuclei with heavy ions, additional factors that enhance or decrease the yields of transuranium products should be considered. They are fusion enhancement at sub-barrier energy and dynamical hindrance to fusion.

The dynamical hindrance caused by the Coulomb repulsion between two fusing nuclei in heavy nuclear systems brings up a serious problem for heavy element production. A dramatic decrease in fusion probability occurs as the value of $Z_1 \times Z_2$ becomes 1,600–2,000, where Z_1 and Z_2 indicate the atomic numbers of the incident particle and target, respectively. The energy required to make the nuclei to touch is called the interaction barrier, while the extra radial energy above this barrier to make the two nuclei to fuse and form a compound nucleus is called the extra-push energy (Swiatecki 1982). For estimating the interaction barrier, the Bass barrier (Bass 1974) is generally used. Experimental data and recent interpretation of the dynamical fusion hindrance are summarized in the review articles by, e.g., Schmidt and Morawek, and Armbruster (Schmidt and Morawek 1991; Armbruster 1999).

The anomalous sub-barrier fusion of two massive nuclei is the phenomenon that is of several orders of magnitude larger than expected from the quantum tunneling through the interaction barrier. Various theoretical attempts have been made to understand the causes of this enhancement of fusion, such as static deformation of colliding nuclei, neck formation during fusion, vibrational excitation of nuclear surfaces, and nuclear structure effects. As a formal theoretical approach, the channel-coupling picture, the tunneling degree of freedom (entrance channel) coupled to the internal degree of freedom (inelastic channel) of the quantum many-body system (two nuclei), is suggested. The detailed description of the sub-barrier fusion appears in the reviews by Beckerman, Satchler, and Reisdorf (Beckerman 1988;

■ Fig. 18.4

Systematics of the Γ_n/Γ_f values averaged over evaporation of four neutrons. The symbols on the right side are the incident particles to produce heavy nuclei (Schmidt et al. 1980)

Satchler 1991; Reisdorf 1994). For the calculations of sub-barrier fusion cross sections, the computer code CCDEF (Fernandez-Niello et al. 1989) is widely used in which the influence of the static deformation of the colliding nuclei as well as the inelastic coupling to collective excited levels is considered.

Some experimental production cross sections of transuranium nuclides including transactinides in charged-particle-induced reactions of the U isotopes and ^{248}Cm targets are summarized in Table 18.3.

Some cross sections listed in Table 18.3 are plotted as a function of the atomic number Z of the product for various incident charged particles (CP) in Fig. 18.5. The decreasing trend of the cross section with increasing Z is obvious, and it is interesting to note that the slope for $^{238}\text{U}(\text{CP},5n)$ and $^{248}\text{Cm}(\text{CP},5n)$ are about the same, while the absolute values for the ^{248}Cm reactions are slightly larger than those for ^{238}U .

Neutron-rich nuclides are inaccessible via the compound nuclear reaction. To produce neutron-rich transuranium nuclides, heavy-ion-induced transfer reactions of actinide targets ranging from ^{238}U to ^{254}Es with a variety of incident particles ranging from ^{16}O to ^{238}U have been studied.

A typical example of such attempts was the study of the $^{238}\text{U} + ^{238}\text{U}$ reaction at GSI (GSI Helmholtzzentrum für Schwerionenforschung GmbH), Darmstadt, Germany. In Fig. 18.6, the production yields of transuranium isotopes for the reaction of 7.5 MeV/amu ^{238}U ions with thick ^{238}U targets are shown (Schädel et al. 1978). The yield distributions of the heavy actinides were found to show similar bell-shaped variations with the atomic number Z and mass number A as observed in the $^{136}\text{Xe} + ^{238}\text{U}$ reaction (Schädel et al. 1978). However, the yields of each isotope in the $^{238}\text{U} + ^{238}\text{U}$ reaction are much larger than those observed in the $^{136}\text{Xe} + ^{238}\text{U}$ reaction. Schädel et al. (1982) also measured the yields of heavy actinides in the reaction of ^{238}U with ^{248}Cm and the results showed that the shapes and centroids of the isotopic distributions are similar in all cases but the magnitudes of the yields are the greatest in the $^{238}\text{U} + ^{248}\text{Cm}$ reaction.

^a Maximum cross section σ_{\max} at the bombarding energy E_{\max} .

The availability of relatively large quantities of curium isotopes has made it possible to use them as target materials, both for the production of heavier elements and new neutron-rich nuclides. ^{248}Cm has been widely used as a target to make superheavy elements and isotopes in other heavy element studies because of its high neutron-to-proton ratio, its long half-life (3.4×10^5 years), its availability in milligram amounts, and its high isotopic purity, especially, if it is produced by milking from ^{252}Cf (e.g., Malmbeck et al. 2001). The transfer reactions for the production of heavy transuranium nuclides using various heavy ions on ^{248}Cm are summarized in ▶ Table 18.4.

Interesting results were reported for the bombardments of ^{248}Cm with the ^{40}Ca , ^{44}Ca , and ^{48}Ca projectiles. Production yields for elements through Fm are shown in ▶ Fig. 18.7a (Türler et al. 1992). Considerable difference is observed in the yields of the below-target elements with the highest yields observed for ^{48}Ca , while for the above-target elements the lowest yields were observed for the ^{48}Ca projectile. The most neutron-rich nuclides in the isotopic yield distribution were observed for the reactions with ^{48}Ca (Hoffman et al. 1985).

■ Fig. 18.5

Cross sections for transuranium elements produced in the charged-particle-induced reactions of ^{238}U and ^{248}Cm

The reactions of ^{40}Ar with ^{233}U , ^{235}U , and ^{238}U were studied at the energy of the Coulomb barrier (Scherer et al. 1990). Contrary to the above $\text{Ca} + ^{248}\text{Cm}$ reactions, the element yields below uranium are the same within the limits of errors for the three target isotopes, while the yields of the above-target elements are in the order of ^{238}U , ^{235}U , and ^{233}U as shown in

► Fig. 18.7b.

Neutron-rich isotopes of heavier actinides such as ^{262}No and $^{261,262}\text{Lr}$, were produced through transfer reactions by bombardments of highly radioactive ^{254}Es ($T_{1/2} = 275.7$ days) targets with heavy ions (Lougheed et al. 1989; Hulet 1990a). Most recently, it has been suggested that the nuclear shell structure may strongly influence the nucleon flow in the low-energy damped collisions of heavy ions (Zagrebaev et al. 2006; Zagrebaev and Greiner 2008). The production of neutron-rich heavy nuclei has been proposed (Zagrebaev et al. 2006) in the multi-nucleon transfer processes of low-energy heavy-ion collisions that are based on the dynamical multidimensional Langevin equation.

18.1.3 Experimental Techniques for Production and Identification of Short-Lived Transuranium Nuclei

In the study of the mechanism of heavy-ion reaction resulting in transuranium products and for investigating nuclear properties of transuranium nuclei, it is of great importance to isolate and uniquely identify the products by their atomic number Z , mass number A , and production cross sections. The claim to the discovery of a new element must present a clear evidence for unequivocal identification of Z , while that of a new isotope has to be made with the determination of both Z and A .

■ Fig. 18.6

Production cross sections of transuranium isotopes in the reactions $^{238}\text{U} + ^{238}\text{U}$ and $^{136}\text{Xe} + ^{238}\text{U}$ (Schädel et al. 1978)

A review of the experimental techniques is given in several articles (Herrmann and Trautmann 1982; Münzenberg 1988; Seaborg and Loveland 1990; Trautmann 1995). Table 18.5 presents a comparison of characteristics, such as separation time and total efficiency, of various methods generally used for isolating and identifying transuranium reaction products.

For studying fission properties such as mass-yield and total kinetic energy (TKE) distributions of very short-lived spontaneous fission (SF) isotopes, the SWAMI (spinning-wheel analyzer for millisecond isotopes) apparatus was constructed (Hulet et al. 1989). The schematic diagram is shown in Fig. 18.8.

A portion of the recoil products emerging from the target is stopped in $100 \mu\text{g}/\text{cm}^2$ Al foils in continuous band on the rotating disk. These foils rotate between four pairs of detectors that measure the energy deposited by correlated fission fragments when the product nuclei decay by SF. For example, SF properties of $1.2 \text{ ms } ^{258}\text{No}$ produced through the $^{248}\text{Cm}(^{13}\text{C}, 3n)$ reaction were studied with SWAMI. A similar rotating wheel technique was developed by Gäggeler et al. (1984) to measure SF of Fm isotopes.

A gas-jet transport method is conventionally used to identify and study short-lived transuranium nuclei. Nuclei recoiling out of a target are stopped in a volume of gas such as He, which is loaded with aerosols, such as KCl, PbI_2 , C clusters, and MoO_3 . The products

attached to the aerosols are swept out of a target recoil chamber with the He gas and are transported through a capillary to a detection system or other apparatuses.

To search for new transuranium nuclides and to study decay properties of these nuclei, a composite system consisting of the gas-jet transport apparatus and an online isotope separator (JAEA-ISOL) has been developed by Ichikawa et al. (2002). This system enables one to simultaneously determine the mass number via the isotope separator and the atomic number by the measurement of X-rays associated with the EC/ β^\pm decay of a nucleus. The experimental setup is schematically drawn in ► Fig. 18.9.

The reaction products recoiling out of targets are thermalized in the He gas loaded with PbI_2 aerosol clusters. The targets are mounted in the multiple target system. The products attached to the aerosols are swept out of the target chamber and transported to the thermal ion source of ISOL through the gas-jet. The transported nuclides are ionized, mass separated, and collected on an aluminum-coated Mylar tape in the tape transport system or in the rotating catcher foil apparatus. The new isotope ^{241}Bk produced in the $^{239}\text{Pu}(^6\text{Li},4n)$ reaction was identified by the measurement of the characteristic Cm X-rays associated with the electron capture (EC) decay of the nucleus separated for mass 241 (Asai et al. 2003). The other new isotope ^{233}Am produced in $^{233}\text{U}(^6\text{Li},6n)$ was identified through an α - α correlation analysis (Sakama et al. 2000).

The identification of new nuclides $^{243,244}\text{Np}$ with the gas-jet coupled rapid chemical separation method (Moody et al. 1987a) is described as follows. Two different chemical separation procedures were used to isolate Np from other reaction products in the

the SISAK experiment shown in Fig. 18.10, reaction products were transported with the argon (Ar) gas-jet system to the chemistry laboratory. The transported products were dissolved in dilute HCl containing TiCl_3 , which reduced Np to the 3+ oxidation state. U, Th, and several fission products were extracted into di(2-ethyl-hexyl)orthophosphoric acid in CCl_4 (HDEHP/ CCl_4). Np was extracted in the second HDEHP/ CCl_4 step after oxidation to the 4+ state with HNO_3 , and was back-extracted with phosphoric acid. The neptunium fraction was continuously pumped from the SISAK system through a Teflon tube to the front face of a series of Ge γ -ray detectors. For the detailed description of SISAK see Chap. 52 in Vol. 5.

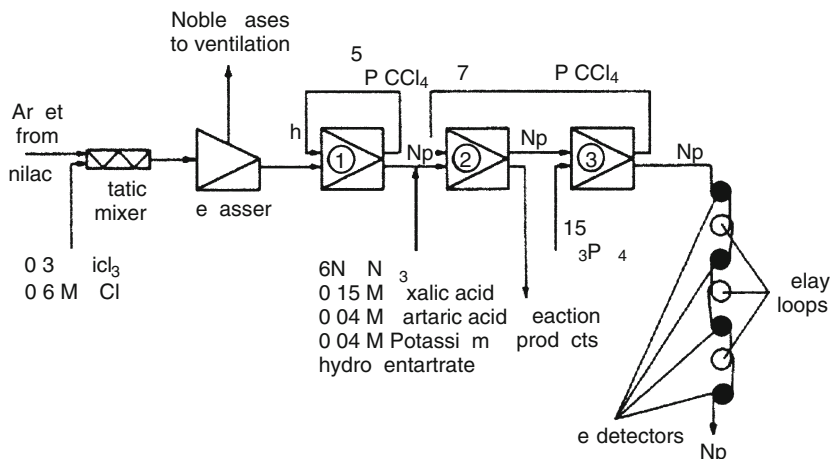

^{253}Md produced in the $^{243}\text{Am}(^{13}\text{C}, 3n)$ reaction was identified by using the Automated Chromatographic Chemical Element Separator System, ACCESS, in which ammonium α -hydroxy isobutyrate (α -HIB) was used for the separation of Md (Kadkhodayan et al. 1992). The other rapid chemical separation apparatus is described in the reviews (Herrmann and Trautmann 1982; Trautmann 1995) and also in Chap. 20 of this Volume.

As indicated in Table 18.5, for the detection and identification of isotopes with $T_{1/2} < 1$ ms, one has to employ in-flight separators based on electromagnetic separation of reaction products. Currently working in-flight separators for studies of transuranium nuclei are listed in Table 18.6. Detailed description of the in-flight separators is given by Münzenberg (1997).

In the region of heavy elements, spectroscopic studies were restricted because of the severe background arising from fission products. This problem was essentially solved by the employment of the new recoil decay tagging (RDT) technique (Paul et al. 1995) that consists of an in-beam γ -ray apparatus and the recoil mass separator.

The characteristic decay modes offer a signature that a particular nuclide has been produced, and can be efficiently detected by a focal plane detector behind the recoil mass separator. Prompt γ rays at the target are detected by large Ge detector arrays.

The gas-filled recoil separator RITU (Recoil Ion Transport Unit) and the recoil mass separator FMA (fragment mass analyzer) in conjunction with germanium (Ge) detector arrays

■ Fig. 18.11

Scheme of recoil separator RITU (Recoil Ion Transport Unit) (Münzenberg 1997)

have been used for the study of the nuclear structure in the region of No isotopes (Leino et al. 1999; Reiter et al. 1999; 2000; Herzberg et al. 2001).

The schematic of RITU is shown in Fig. 18.11. RITU has been designed to separate nuclides produced through compound nuclear reactions from beam particles and other reaction products, especially fission products. To collect reaction products efficiently in the focal plane of the separator, dilute gas was filled in a dipole magnet (Ghiorso et al. 1988). The nobelium nuclides, ^{254}No and ^{252}No , were produced in the fusion reactions of $^{208}\text{Pb}(^{48}\text{Ca}, 2n)$ and $^{206}\text{Pb}(^{48}\text{Ca}, 2n)$ with the cross sections of $2\ \mu\text{b}$ and $0.2\ \mu\text{b}$, respectively. Recently, Oganessian et al. (2001) measured the excitation functions for the reactions $^{204,206,207,208}\text{Pb}(^{48}\text{Ca}, xn)$.

18.1.4 Exotic Nuclear Decay Properties

Decay properties of transuranium nuclides lead to the understanding of proton excess heavy nuclei: verification of the proton drip line, nuclear structure of large deformed nuclei such as octupole and hexadecapole deformation, and fission barrier heights. There are several textbooks and review articles on nuclear decay properties of transuranium nuclei (e.g., Hyde et al. 1964; Seaborg and Loveland 1985; Poenaru 1996). Theoretical nuclear models of heavy nuclei are presented by Rasmussen (1975) and the nuclear structure with a deformed single-particle model is discussed by Chasman et al. (1977). Radioactive decay properties of transuranium nuclei are tabulated in the **Table of Isotopes** (Firestone and Shirley 1996). Recent nuclear and decay properties of nuclei in their ground and isomeric states are compiled and evaluated by Audi et al. (1997), while the calculated atomic mass excess and nuclear ground-state deformations are tabulated by Möller et al. (1995).

Fission barriers using the ETFSI (extended Thomas–Fermi plus Strutinsky integral) method have been calculated by Mamdouh et al. (1998, 2001) for a large number of nuclei. Möller et al. (2009) presented calculated fission barriers for heavy elements based on the macroscopic–microscopic finite-range liquid drop model.

As described in the previous ► Sect. 18.1.3, the spectroscopic studies of the No isotopes have been vigorously performed with large γ -ray detector arrays, Gammasphere (Lee 1990), Jurosphere and SARI (Segmented Array at RITU) arrays (Leino et al. 1999; Leino 2002), and the electron spectrometer SACRED (Solenoid and Array for Conversion Electron Detection) (Butler et al. 1996, 2002) coupled with the recoil separator. α - γ and α -electron (α -e) decay spectroscopy of the neutron-rich nuclide ^{257}No produced in the $^{248}\text{Cm}(^{13}\text{C},4n)$ reaction was carried out at JAEA using a rotating wheel detection system coupled with the gas-jet and the gas-jet transport coupled to ISOL, respectively. On the basis of the α - and γ -transition energies, α - γ , α -e, and e-e coincidence relations, the decay scheme of ^{257}No was established (Asai et al. 2005). As another interesting topic, enhanced stability of heavy nuclei due to high-spin isomers (*K*-isomers) is predicted (Walker and Dracoulis 1999; Xu et al. 2004). Multi-quasiparticle configurations (high-*K* isomer states) have been identified in ^{254}No (Herzberg et al. 2006). In-beam γ -ray spectroscopic studies of neutron-rich trans-U nuclei, $^{245,246}\text{Pu}$, and $^{249,250}\text{Cm}$, have been conducted through the unique nucleon transfer reactions using neutron-rich beams, such as ^{18}O . The ground-state bands of these nuclei were successfully established (Ishii et al. 2006, 2008; Makii et al. 2007). The recent experimental progress of nuclear structure study of the heaviest nuclei are summarized by Ahmad (2002), Leino and Hessberger (2004), and Herzberg (2008), while theoretical description is reviewed by Sobiczewski and Pomorski (2007).

A high-precision mass measurement system with Penning traps, SHIPTRAP (Block et al. 2007) at GSI has been developed to investigate nuclear structure of rare isotopes far from stability. The direct mass measurements of $^{252-254}\text{No}$ have been successfully performed (Block et al. 2010).

Spectroscopic studies of superdeformed fission isomers have been reviewed (Vandenbosch 1977; Metag et al. 1980; Bjornholm and Lynn 1980), while hyperdeformed nuclear shapes in the third minimum of the potential energy surface was discussed by Möller et al. (1972) and recently by Cwiok et al. (1994). Krasznahorkay et al. (1998) succeeded to observe hyperdeformed rotational bands in actinide nuclei.

In the following, exotic nuclear decay modes of heavy nuclei, cluster radioactivities, delayed fission, and spontaneous fission (SF) together with the recent progress on deformation paths toward fission are briefly introduced.

18.1.4.1 Cluster Radioactivities

A charged particle heavier than an α particle but lighter than a fission fragment, such as C, O, F, Ne, Mg, and Si isotopes, is spontaneously emitted in a cluster decay of a heavy nucleus. The cluster decay was first predicted by Sandulescu et al. (1980) and experimentally discovered by Rose and Jones (1984) in the decay: $^{223}\text{Ra} \rightarrow ^{14}\text{C} + ^{209}\text{Pb}$. Theoretical study of the cluster radioactivities is given by Greiner et al. (Sandulescu and Greiner 1992; Poenaru and Greiner 1996). The probability for the decay was $\sim 10^{-9}$ of the α -decay probability. The data obtained until now on half-lives and branching ratios relative to α decay are summarized in review articles (Price 1989; Bonetti and Guglielmetti 1996; Poenaru et al. 2002; Bonetti and Guglielmetti 2007). Some representative data are tabulated in ► Table 18.7.

18.1.4.2 Delayed Fission

Delayed fission is also an exotic nuclear decay process of heavy nuclei that is observed subsequent to β or EC decay. In the delayed fission process, β decays or electron captures (EC) of the parent nuclide populate excited states of the daughter nucleus, and if these states are of energies comparable to or greater than the fission barrier of the daughter nucleus, then fission may compete with other decay modes of the excited states. The process is schematically shown in ► Fig. 18.12. Reviews give a detailed description of delayed fission (Oganessian and Lazarev 1985; Hall and Hoffman 1992).

Delayed fission permits studies of fission properties of nuclei far from stability and γ de-excitation of nuclear levels in the second minimum of the potential energy surface (► Fig. 18.12). There has been also considerable theoretical interest in β -delayed fission process because it may significantly affect the final abundance of heavy elements produced in the astrophysical r-process and in other multiple neutron capture process taking place in very high neutron flux, such as thermonuclear explosions (Tielemann et al. 1983; Meyer et al. 1989; Cowan et al. 1991; Staut and Klapdor-Kleingrothaus 1992). The experimental data on the delayed fission are presented in ► Table 18.8.

18.1.4.3 Spontaneous Fission

Spontaneous fission (SF) is observed only in elements with $Z \geq 90$ where Coulomb forces make the nucleus unstable toward this mode of decay, although energetically SF is an exothermic process for nuclei with $A \geq 100$. Numerous reviews of SF properties, half-lives, and properties of fission fragments, have been summarized by several authors (von Gunten 1969; Hoffman and Hoffman 1974; Hoffman and Somerville 1989; Hulet 1990b, Wagemans 1991; Hoffman and Lane 1995; Hoffman et al. 1996) and basic properties of nuclear fission are described in ► Chap. 4 of Vol. 1. However, some current topics concerning SF are presented in this Subsection.

Schematic representations of all of the measured mass-yield distributions (normalized to 200% fragment yield) for SF of the trans-Bk isotopes are shown in ► Fig. 18.13 (Hoffman and Lane 1995). It is interesting to observe rather sudden changes from asymmetric to symmetric fission as reflected by the mass distributions changing from asymmetric to symmetric mass distributions as the neutron number increases toward $N \approx 160$ for the elements Fm ($Z = 100$), No ($Z = 102$), and Rf ($Z = 104$).

The other interesting feature in SF of very heavy actinides is bimodal fission. The existence of two distinctively different scission configurations for the same mass division was demonstrated in SF of the heavy actinides (Balagna et al. 1971; Hulet et al. 1986, 1989). The most

Fig. 18.12

Schematic illustration of the delayed-fission process. The potential energy of the daughter nucleus as a function of deformation is shown, displaying the double-humped fission barrier prevalent in the actinides. Region I is the inner, or ground-state, well (first minimum); region II is the outer, or shape isomer, well (second minimum). The horizontal arrows indicate the various kinds of deformation toward fission

striking and significant features are that the mass-yield distribution is essentially single peaked around the symmetric mass split, resulting in products with the mass number $A \approx 130$, whereas the total kinetic energy (TKE) distribution apparently exhibits the structure with a shoulder that strongly suggests the presence of at least two components in the TKE distribution.

■ Fig. 18.13

Schematic representation of all known mass-yield distributions for spontaneous fission (SF) of trans-Bk isotopes (Hoffman and Lane 1995) (see also ► Fig. 4.16 in Chap. 4, Vol. 1)

As typical data, the TKE and mass-yield distributions observed in SF of ^{260}Md (Hulet et al. 1989) are depicted in ► Fig. 18.14a, b, respectively; two components are clearly seen in the TKE distribution. The two-component analysis yielded the fact that the high-TKE events mostly constitute the sharp mass-yield curve around symmetry and the low-TKE ones a broad flat-topped distribution. Some theoretical calculations to understand bimodal fission of heavy actinides have been extensively performed (Warda et al. 2002; Asano et al. 2004; Bonneau 2006; Dubray et al. 2008; Ichikawa et al. 2009).

A sudden change of the mass distribution depending on the neutron number of the fissioning isotopes has been reported by Wagemans et al. for SF of plutonium, $^{236,238,240,242,244}\text{Pu}$ (Wagemans et al. 1989; Schillebeeckx et al. 1992; Dematte et al. 1997). The change of neutrons among the isotopes studied yields a drastic change in the mass and TKE

■ Fig. 18.14

(a) Total kinetic energy (TKE) distribution for SF of ^{260}Md . (b) Decomposed mass-yield distributions for the events with TKE ≥ 224 MeV (dashed histogram) and for those with TKE ≤ 210 MeV (solid histogram) (Wild et al. 1990)

distributions. An attempt was made to understand the phenomena in terms of the model of multimodal random neck rupture (Brosa et al. 1990).

Recent studies of SF of ^{252}Cf with large γ -ray detector arrays, Gammasphere (Lee 1990), revealed a new fission mode, cold fission with no neutron emission in the pair fragments of Zr–Ce and Mo–Ba (Ter-Akopian et al. 1994; Hamilton et al. 1995). Cold ternary SF, as $^{252}\text{Cf} \rightarrow ^{146}\text{Ba} + ^{96}\text{Sr} + ^{10}\text{Be}$, has also been identified by measuring the various γ -transitions of these nuclei in coincidence (Ramayya et al. 1998). The use of the high-resolution triple γ -coincidence technique can provide important information on very rare events in fission.

18.1.4.4 Progress in Two-Mode Fission

The presence of two kinds of deformation paths in low-energy fission of actinides has been verified by examining the correlation among saddle-point configurations, scission configurations, and mass-yield distributions (Nagame et al. 1996, 2001). The first path is initiated at

higher threshold energy and ends with an elongated scission configuration, giving a final mass-yield curve centered around symmetric mass division and lower TKE, the symmetric fission path. In the second path, the fissioning nucleus experiences lower threshold energy. This results in a more compact scission configuration, which gives a double-humped mass-yield distribution always centered around the heavy fragment mass number $A = 140$ with higher TKE, the asymmetric fission path. The above picture is well reproduced by the recent theoretical calculations of the potential energy surfaces by Möller et al. (2001); the saddle leading to the mass-symmetric division is found to be a few MeV higher than that of the mass-asymmetric division and the compact scission configuration is related to the asymmetric fission and the elongated one associated with the symmetric fission path. The clear ridge separating the two symmetric and asymmetric fission valleys is also pointed out (Möller et al. 2001).

Systematic features of the mass-yield and TKE distributions in both symmetric and asymmetric fission depending on A and Z of fissioning nuclei are discussed in detail by Ohtsuki et al. (1999) and Zhao et al. (2000). The effects of A and Z on the relative probability of taking either the deformation path or the characteristics of the final mass division phenomena and scission properties resulting from each deformation path have been extensively studied. Elemental yields of fission fragments in the Coulomb fission have been obtained for a number of neutron-deficient actinides and preactinides by using the unique method, relativistic radioactive beams (Schmidt et al. 1994, 2001). In [Fig. 18.15](#), the experimentally measured mass distributions are shown on the chart of nuclides, while the elemental yield distributions after Coulomb fission are depicted as functions of Z and N of the fissioning nuclei in [Fig. 18.16](#) (Schmidt et al. 2000). The transition from a single-humped mass-yield distribution at ^{221}Ac to a double-humped one at ^{234}U is clearly seen. In the transition region around ^{227}Th , triple-humped distributions appear, demonstrating comparable yields for the symmetric and asymmetric fission modes.

18.2 Chemical Properties of Transuranium Elements

18.2.1 Actinide Concept

The actinide elements are 5f transition elements having partly filled f and d orbitals in the valence states. Compared to the 4f transition elements, lanthanides, in the actinides 5f orbitals have an important role in chemical bonding because of their wider radial distribution and higher energy due to relativistic effects (Pepper and Bursten 1991; Balasubramanian 1997). Relativity becomes important when particles move with speeds comparable to the speed of light. Relativistic effects become significant for heavier elements, and influence energy level structure and radial distribution of wave functions. [Figure 18.17](#) shows the spatial orientations of the atomic orbitals of the general set of seven f orbitals. Because of the variety of the direction of f orbitals, interactions with different atoms of ligands are complicated.

For the lighter actinide elements, such as uranium, neptunium, plutonium, and americium, the promotion energy of $5f \rightarrow 6d$ is smaller than that of $4f \rightarrow 5d$ transition in the lanthanides. Due to this smaller promotion energy, the chemical bonding is complicated in the lighter actinides and these elements take from 3+ to 7+ oxidation states. However, the heavier actinides beyond curium more closely resemble the lanthanides and the trivalent state becomes stable. In order to understand the chemistry of transuranium elements, one has to consider the relative energy of the valence orbitals and the relativistic effects on

■ Fig. 18.15

5f electrons. The relative energy between 5f and 6d orbitals strongly affects the oxidation states and ionic radii of the ions.

The energy level structure is particularly important to understand the relativistic effects on the valence states of the actinide atoms. ➤ *Figure 18.18* shows relativistic effects on the energy level structure of Am calculated by the nonrelativistic Hartree–Fock–Slater and the relativistic

■ Fig. 18.17

The general set of seven f orbitals (Sakane 2009)

■ Fig. 18.18

Energy level structures of the valence electrons of Am as a result of nonrelativistic and relativistic calculations

Dirac–Fock–Slater programs. The relativistic effects are also significant in the orbital energy of valence electrons. The 6s orbital is strongly affected by the direct relativistic effect and energetically stabilized, while the 6p orbital splits into the $6p_{1/2}$ and $6p_{3/2}$ orbitals by the spin–orbit coupling. The 5f orbital also splits to the $5f_{5/2}$ and $5f_{7/2}$ orbitals and energetically destabilized by the indirect relativistic effect. The energies of the 5f orbitals become closer to those of the 6d orbitals, which cause the complex configuration of the valence states.

■ Fig. 18.19

Radial wave functions of valence orbitals for the Eu^{3+} and Am^{3+} ions. Solid perpendicular line indicates maximum density of Am 5f orbitals. The arrows indicate the ionic radii of Eu^{3+} and Am^{3+}

It is of interest to compare the radial wave functions between 4f and 5f elements. Figure 18.19 shows relativistic calculations of Eu^{3+} and Am^{3+} valence wave functions of the radial part. This figure indicates that the 4f subshell of Eu^{3+} is “core like” because of the lower density around the ionic radius of the ion. In the corresponding 5f ion, Am^{3+} , 5f subshell penetrates the 6s and 6p orbitals. The wider distribution of the 5f orbital allows much participation in bonding for the actinides than for the lanthanides. The 4f orbitals of lanthanide atoms are mainly localized in the core and do not contribute to the chemical bonding.

18.2.2 Ionic Radii and Oxidation States

Chemical properties of elements are determined by the valence electronic structure, oxidation states, ionic radii, and coordination number. As already described in Sect. 18.2.1, the oxidation states of the actinide elements are more variable than those of the lanthanides.

■ **Table 18.9**

Oxidation states of actinide elements: the most stable oxidation state is bold font, while unstable oxidation states are shown in parentheses (Katz et al. 1986)

Atomic Number	Element		Oxidation States
89	Actinium	Ac	3
90	Thorium	Th	(3) 4
91	Protactinium	Pa	(3) 4 5
92	Uranium	U	3 4 5 6
93	Neptunium	Np	3 4 5 6 7
94	Plutonium	Pu	3 4 5 6 (7)
95	Americium	Am	(2) 3 4 5 6 7 ²
96	Curium	Cm	(2) 3 4 5 ² 6 ²
97	Berkelium	Bk	3 4
98	Californium	Cf	(2) 3 4 5 ²
99	Einsteinium	Es	(2) 3 (4)
100	Fermium	Fm	2 3 4 ²
101	Mendelevium	Md	1 ² 2 3
102	Nobelium	No	2 3
103	Lawrencium	Lr	3

► **Table 18.9** gives oxidation states of actinide elements (Katz et al. 1986). Actinium and transplutonium elements (from Am to Lr) take 3+ as the most stable oxidation state and they behave similar to the lanthanide elements, except element 102, No, which seems to prefer the 2+ state. Because of the itinerancy of the 5f electrons, the lighter actinide elements take broad range of oxidation states. The light transuranium elements, Np, Pu, and Am can behave as 3+ to 7+ cations and the most stable oxidation states of these three elements are 5+, 4+, and 3+, respectively.

Pentavalent and hexavalent actinide elements take oxygenated actinyl ions AnO_2^+ and AnO_2^{2+} (An = actinide elements). Stable pentavalent neptunium takes the NpO_2^+ type structure in solution. The relationship between oxidation states and structural variation is fundamental information for solution and separation chemistry of actinide elements. As these actinyl ions, AnO_2^+ and AnO_2^{2+} , are less acidic than the An^{4+} ions, the tendency of hydrolysis decreases in the order, $\text{An}^{4+} > \text{AnO}_2^{2+} > \text{An}^{3+} > \text{AnO}_2^+$.

► **Table 18.10** shows ionic radii of actinide elements together with those of lanthanide elements (Seaborg and Loveland 1990). The useful data on the ionic radii and coordination number are given by Shannon and Prewitt (1969). They carried out comprehensive study of crystal, or ionic, radii by analyzing the crystal structures of many fluoride, oxide, chloride, and sulfide compounds. Marcus published a data book on the properties of ions (Marcus 1997). The book covers a wide range of information on ionic radii of the actinide elements and other ions. Ionic radii of actinide elements decrease with increasing atomic number. This behavior is called actinide contraction and is one of the important examples of the actinide concept.

Because of the limited production yields and shorter half-lives of heavy actinide elements, the determination of ionic radii and chemical properties for heavier actinides are quite difficult (Hulet 1983; Keller 1984). Brüchle et al. (1988) reported the hydration enthalpies and ionic radii of Md^{3+} and Lr^{3+} by the ion-exchange experiments. Recently, the most stable nobelium

ion, No²⁺, was successfully oxidized to the trivalent state, No³⁺, which was held in α -hydroxyisobutyric acid (α -HIB) solution by a newly developed flow electrolytic chromatography technique (Toyoshima et al. 2008, 2009). It was found that the oxidation state of No on an atom-at-a-time scale is absolutely controlled by the employed apparatus. The new approach is expected to lead to the determination of the ionic radius of No³⁺, which is a key to understanding the contraction of the ionic radii at the end of the actinide series.

18.2.3 Separation of Transuranium Elements

For the study of nuclear and chemical properties of transuranium elements, chemical separation of these elements is indispensable. Especially, in the field of nuclear fuel reprocessing and waste management, it is quite important to separate each transuranium element selectively from fission products of dissolved spent nuclear fuels.

The problems of practical separation of these elements are (1) the separation of actinide elements from the lanthanide group (trivalent actinide ions behave like lanthanide ions), and (2) the separation of the actinide elements from each other. Ion-exchange and solvent extraction methods have so far been extensively studied.

18.2.3.1 Ion-Exchange Properties

Ion exchange is a fundamental technique for selective separation of transuranium elements. Since ion-exchange behavior strongly depends on the oxidation states and ionic radii of

transuranium elements, this technique was applied for the discovery of the heavy actinides as described in ▶ Sect. 18.1.1. The order of elution of these actinide ions generally follows that of their ionic radii.

The pattern of this elution behavior made it possible to identify and predict a new actinide element. The adsorption strength of different oxidation states on cation-exchange resins is $An^{4+} > An^{3+} > AnO_2^{2+} > An^{2+} > AnO_2^+$.

Comprehensive data for ion-exchange separation are available in “Handbook of Ion Exchange Resins” (Korkisch 1989). The essential properties employed for the separation of transuranium elements are the behavior toward strongly basic anion-exchange resins in both hydrochloric acid (HCl) and nitric acid (HNO₃) systems.

Tetravalent uranium, neptunium, and plutonium forming anionic complexes with chloride ions are strongly adsorbed on the anion-exchange resin. The adsorption of these tetravalent actinides increases in the order of $U^{4+} < Np^{4+} < Pu^{4+}$. The $[AnCl_6]^{2-}$ type anion complex (Marcus 1967a, b) is formed in high HCl concentration that are stable and strongly retained by the anion-exchange resin from 8 to 12 M HCl solution. In lower concentration of HCl, the species $[AnCl_3]^+$ (6–9 M HCl), $[AnCl_2]^{2+}$ (4–6 M HCl), $[AnCl]^{3+}$ (2–4 M HCl), and An^{4+} (0.5– M HCl) are formed. Th^{4+} and Pa^{4+} do not form the $[AnCl_6]^{2-}$ type complexes and they are not adsorbed on the anion-exchange resin. Trivalent actinides are not at all or at most only slightly adsorbed on the resin. The trivalent transplutonium elements, however, form more stable anionic chloride complexes than do the trivalent lanthanide elements.

Tetravalent Np and Pu are adsorbed on strongly basic anion-exchange resins even from relatively dilute nitric acid solution by forming the $[An(NO_3)_6]^{2-}$ type anionic nitrate complexes. The adsorption of Np^{4+} and Pu^{4+} increases with the nitric acid concentration. Pu^{4+} is more strongly adsorbed than Np^{4+} and is best adsorbed on the resin from 7 to 9 M HNO₃ solutions. On the contrary to the HCl system, Th^{4+} form the $[Th(NO_3)_6]^{2-}$ type complex in the concentrated nitric acid solution of 4–5 M HNO₃ (Ryan and Wheelwright 1959; Ryan 1960). For the elution of these adsorbed tetravalent actinide ions from nitric acid solution, the oxidation state must be reduced to trivalent one by using hydroxylamine hydrochloride and Fe^{2+} ion (Reynolds and Scott 1975; Scott and Reynolds 1975). The trivalent actinides are very weakly adsorbed on the anion-exchange resin (Shabana and Ruf 1978) and the adsorption property decreases with an increase of the atomic number.

Recently, Arisaka et al. have applied time-resolved laser-induced fluorescence spectroscopy (TRLFS) (Kimura and Choppin 1994) to the study of cation- (Kimura et al. 1998; Arisaka et al. 2001a) and anion- (Arisaka et al. 2001b) exchange behavior of Eu^{3+} and Cm^{3+} . They measured the inner-sphere hydration number of Eu^{3+} and Cm^{3+} in the HCl–CH₃OH mixture/cation-exchange resin system and observed a decrease of hydration number with an increase of methanol molar fraction. The TRLFS is applicable to quantitative and direct observation of the inner-sphere hydration of minor actinides.

18.2.3.2 Solvent Extraction Separation

The solvent extraction separation is one of the major research fields of the chemistry of transuranium elements. Nash and Choppin published selected papers on the separation science of f-elements in 1995 (Nash and Choppin 1995) and Yoshida et al. published “Recent Progress in Actinide Separation Chemistry” in 1997 (Yoshida et al. 1997). Mathur et al. (2001) reviewed actinide partitioning, and more recently, Tachimori and Morita (2009) issued a review article

of solvent extraction chemistry for reprocessing. In a commercial nuclear fuel reprocessing plant, solvent extraction technique is applied for the recovery of uranium and plutonium. The process called PUREX (Plutonium and Uranium Refining by EXtraction) uses tributyl phosphate (TBP) as an extractant. The TBP ligand strongly coordinates to hexavalent uranium (UO_2^{2+}) and tetravalent plutonium (Pu^{4+}). In the PUREX process, these species are co-extracted from nitric acid solution of spent nuclear fuel. However, trivalent actinide and lanthanide elements are not extracted and selective stripping of Pu is accomplished by reduction with U^{4+} and Fe^{2+} (Benedict et al. 1981).

The redox reaction has been utilized in the separation of light actinide elements (U, Np, and Pu) with both ion-exchange process and solvent extraction process. For trivalent heavy actinides with $Z > 94$ (except No), separation of these actinide ions from lanthanide ions is required for safe storage of long-lived nuclear waste and transmutation of these nuclides. Fundamental researches have widely been carried out by several groups for the purpose of quantitative separation of transuranium elements. Recent topics on the development and application of solvent extraction for the separation of transuranium elements are briefly summarized below.

CMP, CMPO system. Horwitz and Kalina (1984), Horwitz et al. (1986) developed neutral bifunctional extractants CMP ($\text{R}_1\text{R}_2\text{-N,N-di(R') carbamoylmethyl phosphonate}$) and CMPO ($\text{R}_1\text{R}_2\text{-N,N,- di(R')-carbamoylmethyl phosphine oxide}$, see [Fig. 18.20](#)) for the separation of trivalent actinide ions. With thiocyanate as a counter ion in the CMPO system, americium is preferentially extracted and the separation factor S.F. ($\text{Am}^{3+}/\text{Eu}^{3+}$) is about seven (Muscatello et al. 1982).

TODGA system. Sasaki and coworkers developed tridentate oxygen donor extractant named TODGA ($\text{N,N,N',N'-tetraoctyl diglycolamide}$, see [Fig. 18.21](#)) for the selective separation of trivalent and tetravalent actinide and lanthanide ions (Sasaki et al. 2001; Sasaki and Tachimori 2002).

They reported the distribution ratios (D_M) of lanthanide and actinide ions and compared the D_M values with that of Am^{3+} in the extraction system of 1 M HNO_3 and 0.1 M TODGA/ n -dodecane as shown in [Table 18.11](#). The order of extractability of actinide ions from 1 M HNO_3 is An^{3+} , $\text{An}^{4+} > \text{AnO}_2^{2+} > \text{AnO}_2^{+}$. The TODGA has an ability of co-extraction of trivalent actinide ions and lanthanide ions from high-level liquid radioactive waste.

Lu^{3+}	631	21
Th^{4+}	147	4.9
UO_2^{2+}	0.8	0.027
NpO_2^{+}	0.0056	0.00020
Am^{3+}	30	1.0
Cm^{3+}	78	2.6
Cf^{3+}	156	5.2

■ **Fig. 18.22**

Structure of BTBP, 6,6'-bis-(5,6-diethyl-[1,2,4]triazin-3-yl)-2,2'-bipyridyl (*left*) and BTP, 2,6-bis-(5,6-dipropyl-[1,2,4]triazin-3-yl)pyridine (*right*) molecules (Drew et al. 2005)

These oxygen-donor type extractants have potential for co-extraction of trivalent lanthanide and actinide ions. For the mutual separation between trivalent actinides and lanthanides, so-called soft-donor (nitrogen-donor type and sulfur-donor type) extractants are promising and widely investigated for the application of nuclear waste treatment as follows.

BTP, BTBP system. Kolarik et al. (1999, 2008) and Madic et al. (2000) carried out comprehensive study of the separation of trivalent actinides from lanthanides by the nitrogen donor extractants. They developed several new nitrogen polydentate ligands, BTP [2,6-bis(5,6-dialkyl-1,2,4-triazin-3-yl)-4-alkyl-pyridines] and BTBP [6,6'-bis-(5,6-diethyl-[1,2,4]triazin-3-yl)-2,2'-bipyridyl] (see ● Fig. 18.22).

Cordier et al. (1999) reported S.F. ($\text{Am}^{3+}/\text{Eu}^{3+}$) > 100 in the extraction system of 1 M HNO_3 and 0.01 M *n*-propyl-BTP/tetrapropene + *n*-octanol. The *n*-propyl-BTP extracts Am^{3+} more than ten times higher than the other N-donor ligands like 2,2':6',2'-terpyridine. Although the BTP type extractants have potential for the selective separation of the An^{3+} group, they are not stable against oxidation, acidic hydrolysis, and radiolysis (Hill et al. 2002). Drew et al. (2005) and coworkers applied BTBP/1,1,2,2-tetrachloroethane to the $\text{Am}^{3+}/\text{Eu}^{3+}$ separation from 1 M HNO_3 . They reported exceptional S.F. ($\text{Am}^{3+}/\text{Eu}^{3+}$) > 160.

Cyanex-301 system. The sulfur type soft-donor extractant, thiophosphoric acid has potential for selective separation of trivalent actinides from lanthanides (Musikas 1985). Zhu et al. (Zhu 1995; Zhu et al. 1996) developed dithiophosphinic acid type extractant, Cyanex-301

■ Fig. 18.23

Structure of Cyanex-301 (Zhu 1995)

(bis(2,4,4-trimethylpentyl) dithiophosphinic acid) (see ► Fig. 18.23), for the separation of Am^{3+} . They reported the average separation factor of Am^{3+} against Ln^{3+} being greater than 2,300. Chen et al. (1996) reported that the equilibrium constant for the liquid–liquid extraction of Am^{3+} by Cyanex-301 is 5,900 times larger than that of Eu^{3+} , the homologous lanthanide.

18.2.4 Solid-State Properties of Transuranium Metals and Compounds

The lighter actinide metals, from Pa to Pu, are characterized by the presence of itinerant 5f electrons. The wider radial distribution of 5f orbitals contributes to the chemical bonding in metallic phase and alloys. On the other hand, properties of the heavier actinide metals, having localized 5f electrons, resemble those of the lanthanides, which have localized 4f electrons. The itinerant 5f electrons of lighter actinide metals hybridize with the conduction electrons and contribute to the metallic bonding.

The ionization potential of an element is one of its fundamental properties. It is known that the first ionization potential of heavy elements depends on relativistic effects. The Mainz group, in Germany, systematically determined the first ionization potential of the actinide elements from Ac through Es using laser spectroscopy as shown in ► Table 18.12 (Becke et al. 2002). ► Figure 18.24 shows the comparison of ionization potentials between lanthanide and actinide atoms (Moore 1971; Becke et al. 2002). The atomic level structure of ^{256}Fm (2.7×10^{10} atoms) with a half-life of 20.1 h was studied for the first time by the method of resonance ionization spectroscopy. Two atomic levels were identified at wave numbers $(25,099.8 \pm 0.2) \text{ cm}^{-1}$ and $(25,111.8 \pm 0.2) \text{ cm}^{-1}$ (Sewtz et al. 2003).

► Table 18.13 gives the crystal structures and phase transformations of the transuranium elements (Katz et al. 1986). The lighter actinide elements like Np and Pu have a bcc structure at the melting point and Pu has six distinct allotropic forms. The heavier actinides from Am to Es show face-centered cubic (fcc) structures at the melting point and double hexagonal close-packed (dhcp) structures below the melting point. These heavier actinides behave like lanthanide metals.

Because of the itinerancy of the 5f electrons, magnetic order is not observed in these lighter actinide metals. The localized 5f electrons of the elements heavier than Am do not contribute to the metallic bond, but they contribute to the magnetic order. Since the spin–orbit coupling is significant in the heavy elements, the effective magnetic moment for the actinide compounds depends on the J value ($J = L + S$, where J , L , and S denote total angular momentum, orbital

Table 18.12

First ionization potentials of actinide elements (Becke et al. 2002)

Atomic Number	Element	Ionization potentials/cm ⁻¹	Ionization potentials/eV

angular momentum, and resultant spin of the electrons). Therefore, theoretical treatment of a complicated spin state is quite important in the actinide series. These heavy actinide metals have lower cohesive energies and larger atomic volumes than those of the lighter actinide metals. Figure 18.25 shows atomic volumes of lanthanide and actinide metals. The lighter

actinide metals from Pa to Pu take smaller atomic volumes and higher densities compared with those of the heavier actinides. The metallic bonding becomes tighter by the contribution of 5f electrons in the lighter actinide metals.

Benedict et al. (Benedict 1987; Benedict and Holzapfel 1993) reviewed the study of pressure-induced structural transitions in the actinide metals. High pressure is the most efficient and cleanest way of changing the interatomic distances in a lattice.

Many physical properties of metals can be changed by pressure, and the pressure dependence supplies information on the electronic processes in the solid. For example, localized 5f electrons tend to be delocalized with increasing pressure. ➤ [Figure 18.26](#) shows high-pressure structural behavior of the actinide metals. The lighter actinide metals have wider pressure ranges without phase transitions, while the heavier actinide metals have several phase transitions with increasing the pressure. The low-symmetry orthorhombic phase appears at higher pressure, indicating that the localized 5f electrons become itinerant with an addition of higher pressure.

■ Fig. 18.25

Atomic volumes of lanthanide and actinide metals. Pa, U, Np, and Pu: density increased by 5f bonding. Low density of Eu, Es, and Yb is due to divalency (Benedict and Holzapfel 1993)

Variation of phase diagrams and behavior of transuranium alloys are attractive for both nuclear energy application and fundamental physics of 5f electrons in metallic phase. Comprehensive data of the phase diagrams of binary actinide alloys are available in the book of Kassner and Peterson (1995). Plutonium alloys with group IIIB metals (Al, Ga, In, or Tl) are well studied since the 1960s (Grison et al. 1961). Small addition of these metals stabilizes the δ phase of plutonium. Because of the six allotropic forms of the plutonium metal, the stabilization of the δ phase is required especially for storage of plutonium metal. Recently, Havela et al. (2002) carried out photoelectron spectroscopy of Pu metal and Espinosa et al. (2001) reported XAFS study of the local atomic structure of α -phase plutonium. Allen et al. (2002) examined local structures of Ga-stabilized δ -phase plutonium and Söderlind et al. (2002) investigated electronic structure of δ -phase plutonium by all-electron full potential linear muffin-tin orbitals (FPLMTO), Korringa–Kohn–Rostoker (KKR), and projector augmented wave (PAW) methods. Savrasov et al. (2001) correctly predicted the behavior of plutonium metal by the dynamical mean-field theory (DMFT) (Georges et al. 1996).

They compared the calculated density of states for δ -plutonium with the recent photoemission experiments and obtained a good agreement between them (Arko et al. 2000). They concluded that the fundamental features of physics and chemistry of actinide compounds are

■ Fig. 18.26

related to the behavior of 5f electrons in the system. The behavior of 5f electrons of the actinides is in between the more localized 4f electrons of the lanthanides and the itinerant d electrons of the transition metals. The combination of structural study and theoretical approaches become popular in the field of condensed-matter physics of actinide elements and their alloys and compounds.

In the following, some other current interesting topics on the metallic properties of actinides are introduced. Recently, Sarrao et al. (2002) discovered new plutonium-based superconductivity in PuCoGa_5 with a transition temperature $T_c = 18.5$ K. The temperature dependence of the magnetic susceptibility was indicative of the local moment behavior close to that expected for Pu^{3+} . Interestingly, the isostructural UCoGa_5 , having no sign of a local moment, is not a superconductor. Akiyama et al. (2001) studied high-performance liquid chromatography (HPLC) elution behavior of the fullerenes encapsulating actinide elements. The elution behavior of U, Np, and Am fullerenes was found extremely similar to that of Ce fullerenes. They concluded that the major products of the U-, Np- and Am- fullerenes are $\text{M}@\text{C}_{82}$ ($\text{M} = \text{U}, \text{Np}, \text{and Am}$) species with the oxidation state of +3.

A huge amount of research has been done on the solid compounds of transuranium elements. In this section, fundamental properties of oxide and some compounds of the transuranium elements are briefly overviewed. The oxygen to metal ratio (O/M ratio) is one of the important parameters to understand the solid-state behavior of these oxides. The fluorite-structure dioxide is well studied in the research of mixed oxide (MOX) nuclear fuels.

► Table 18.14 gives fundamental properties of transuranium oxides (Morss 1991). Neptunium

■ Table 18.14

Properties of the transuranium oxides

Compound	Color	Symmetry	Space group	Lattice parameters, $a_0, b_0, c_0/\text{\AA}$, β/deg
NpO ₂	Apple green	Cubic	<i>Fm</i> 3 <i>m</i>	$a_0 = 5.433$
Np ₂ O ₅	Dark brown	Monoclinic	<i>P</i> 2 ₁ / <i>c</i>	$a_0 = 4.183, b_0 = 6.584, c_0 = 4.086,$ $\beta = 90.32$

takes pentavalent oxide Np₂O₅, while the other transuranium elements take between trivalent and tetravalent states in the oxides. The chemical forms of these oxides give important information on properties of irradiated nuclear fuels and solidified high-level nuclear wastes.

Plutonium and neptunium nitrides were studied for the application to advanced fast breeder reactor (FBR) fuels. Details on the application of nuclear fuels is available in the reference (Matzke 1986). Fundamental properties of these plutonium and neptunium compounds are reviewed in the “Chemical Thermodynamics of Neptunium and Plutonium” (Lemire et al. 2001) issued by OECD/NEA (Organization for Economic Co-operation and

Development/Nuclear Energy Agency). Americium data are also available in the “Chemical Thermodynamics of Americium” (Silva et al. 1995).

18.2.5 XAFS: New Methodology for Chemical Studies of Transuranium Elements

One of the new fields of actinide chemistry since the 1990s is an application of X-ray absorption spectroscopy (Teo 1986) especially by use of the synchrotron radiation. XAFS (X-ray absorption fine structure) is a powerful technique for characterization of the local structure of specific elements, even radioactive elements such as actinides, and their electronic states. XAFS contains two fundamental information, EXAFS (extended X-ray absorption fine structure) and XANES (X-ray absorption near-edge structure). ➤ Figure 18.27 shows a fundamental pictorial view of the XAFS process (Koningsberger and Prins 1987).

■ Fig. 18.27

Pictorial view of the final-state wave functions in the core excitation in a diatomic molecule at high energies, extended X-ray absorption fine structure (EXAFS) region, and in the low-energy, X-ray absorption near-edge structure (XANES) region. The dotted curves are the wave functions of the emitted photoelectron (Koningsberger and Prins 1987)

EXAFS is based on an oscillatory structure observed in X-ray absorption spectra. Kronig (Kronig 1931, 1932) found this oscillation for the first time and Sayers and coworkers (Sayers et al. 1971) successfully explained it in 1971. EXAFS provides considerable information about coordination numbers and distances of each atomic species in complex, polyatomic solids, liquids, and gases.

XANES spectra contain information about the electronic states of a specific target (X-ray absorbing) atom and the local structure surrounding it. The near-edge structure is associated with the excitation process of a core electron to bound and quasi-bound states. Because of the multi-electron process of the excitation, the theoretical assignment of XANES spectra has several difficulties.

Rehr and Albers (2000) reported theoretical approaches to the assignment of XAFS spectroscopy. They described the advantages and the remaining problems of the multiple-scattering (MS) method for the analyses. Multiple-scattering (MS) formalism and first-principle molecular orbital (MO) calculation techniques so far have been proposed for the theoretical analysis of XANES. The *ab initio* XAFS codes FEFF series program is widely used for this purpose. The detailed information of the FEFF code is available in the Web site of the FEFF and in several references (e.g., Ankudinov et al. 1998; FEFF 2009).

Molecular orbital (MO) methods have been studied and reviewed by Kosugi (1996). Ellis and Goodman (1984) first applied local density functional method and Nakamatsu (1995) applied the discrete-variational (DV) $X\alpha$ method to the analyses of XANES.

XAFS studies for the actinide research are being carried out at the synchrotron facilities of the USA and EU. Advanced Photon Source (APS) of Argonne National Laboratory (APS 2009), Advanced Light Source (ALS) of UC Berkeley (ALS 2009), ESRF (European Synchrotron Radiation Facility) of Grenoble (ESRF 2009), and SOLEIL (SOLEIL 2009) in Saint-Aubin, France are the main synchrotron facilities for the actinide research. Useful information is available in the Web site of each facility.

D'Amico et al. (1996) published selected papers on the application of synchrotron radiation techniques in industrial, chemical, and material science. Although there are several papers on the structural research of actinide compounds and complexes, the results are mostly limited to uranium compounds. Allen et al. (1996a) briefly reviewed the application of XAFS to the environmental materials containing plutonium and neptunium. They introduced NpO_2^+ adsorption study of the α -FeOOH (goethite)/water interface reported by Combes et al. (1992). The application of XANES spectroscopy to the analysis of U, Np, and Pu solid compounds with different oxidation states is also reviewed (Petiau et al. 1986; Kalkowski et al. 1987a, b; Bertram et al. 1989).

Veirs et al. (1994) carried out structural study of Pu^{4+} in nitric acid solution. They observed coordination of nitrate ligands as bidentate and planar. Allen et al. (1996b) also reported the structural study of Pu^{4+} nitrate complexes by measuring EXAFS spectra as a function of nitric acid concentration and found highly coordinated plutonium complexes with coordination number of 11–12 for the first shell of oxygen nearest neighbors. The average Pu–O(nitrate) bond length was 2.49 Å, while the distance of Pu–O(water) was evaluated to be 2.38 Å. In the anion-exchange separation of Pu^{4+} from nitric acid solution, plutonium is adsorbed quantitatively on the resin. The Pu^{4+} species were considered to form anion complexes in highly concentrated nitrate solution. The 6 coordinated $[\text{Pu}(\text{NO}_3)_6]^{2-}$ species in the 13 M HNO_3 was observed and nitrates were all bidentate. The coordination number was determined to be 12 by the EXAFS technique.

In addition to the nitrate system, Allen et al. (1997) reported a structural study of UO_2^{2+} , NpO_2^+ , Np^{4+} , and Pu^{3+} species in HCl solution by the EXAFS method. They also conducted (Allen et al. 2000) EXAFS experiments on the trivalent lanthanide and actinide ions in HCl solutions. In the dilute HCl solution, on average, the Am^{3+} and Cm^{3+} aqua ions are coordinated by 10.3 oxygens at 2.48 Å and by 10.2 oxygens at 2.45 Å, respectively, while 9.2 water molecules are coordinated to the Pu^{3+} . The average distance between the Pu^{3+} ion and the oxygens of water molecules is 2.51 Å. They observed Cl^- coordination to the Cm^{3+} above the 10.5 M LiCl concentration. However, Pu^{3+} does not form inner sphere chloride complexation.

One of the most significant examples of the application of XANES in the chemistry of actinide elements was reported by Conradson et al. (1998). They measured L_{III} XANES spectra

■ Fig. 18.28

Plutonium XANES spectra for the aqua Pu^{3+} and Pu^{4+} , PuO_2^+ and PuO_2^{2+} species (Conradson et al. 1998)

of four oxidation states of Pu (3+, 4+, 5+, and 6+) at the Stanford Synchrotron Radiation Laboratory. As shown in ▶ Fig. 18.28, clear relation between the edge energies and the oxidation states are observed. The edge energies shifted progressively to higher energy with increasing valence, with an average energy of 1.68 eV per formal oxidation state (see inset of ▶ Fig. 18.28).

As already mentioned, XANES spectra are strongly affected by the geometry of the first coordination sphere. In ▶ Fig. 18.28, the general spectral shape of the Pu^{3+} and Pu^{4+} species is clearly different from that of the dioxo-containing PuO_2^+ and PuO_2^{2+} species. XANES spectra have potential for the determination of oxidation states and the nearest-neighbor structure in the complex and disordered system.

Ankudinov et al. (1998) conducted real-space multiple-scattering calculation and interpreted these plutonium hydrate spectra with the FEFF8 program package. The different behavior of the Pu^{3+} and Pu^{4+} relative to PuO_2^+ and PuO_2^{2+} can be understood in terms of their first coordination structure. Pu^{3+} and Pu^{4+} are surrounded by nine and eight nearly equidistant oxygen atoms of water molecules. For these species, the white-line intensity calculated by the FEFF8 code agrees well with the experiment.

Den Auwer et al. (1999) applied XAFS to the structural analysis of TBP (Tributyl phosphate) complexes of tetra- and hexavalent U, Np, and Pu. Similar to the results of hydrated Pu complexes, they observed significant difference in the XANES spectra between the Pu^{4+} and PuO_2^{2+} species as shown in ▶ Fig. 18.29. However, the XANES spectra of $\text{AnO}_2(\text{NO}_3)_2(\text{TBP})_2$ (An = U, Np, Pu) solution complexes show no significant difference among them.

■ Fig. 18.29

L_{III} edges of the $\text{AnO}_2(\text{NO}_3)_2(\text{TBP})_2$ solution complexes (An = U, Np, Pu) and $\text{Pu}(\text{NO}_3)_4(\text{TBP})_2$ (Den Auwer et al. 1999)

The separation of trivalent actinides, such as Am^{3+} and Cm^{3+} is of major concern in the field of nuclear technology. Den Auwer et al. (2000) studied the structure of N,N,N',N'-Tetraethylmalonamide (TEMA) complexes of lanthanides and americium by several methods including the X-ray absorption technique. They carried out first the X-ray diffraction study of the single crystals of $\text{Nd}(\text{NO}_3)_3(\text{TEMA})_2$ and $\text{Yb}(\text{NO}_3)_3(\text{TEMA})_2$ and compared the EXAFS spectra of these complexes in a solvent phase. The metal-centered polyhedron in the solvent phase was found to be similar to that of the solid-state complexes. They also measured an EXAFS spectrum of the $\text{Am}(\text{NO}_3)_3(\text{TEMA})_2$ complex in the solvent phase and confirmed the similar coordination spheres with the Nd^{3+} complex.

As briefly described in [Sect. 18.2.3.2](#), soft-donor extractants have potential for selective separation of trivalent actinide ions. To understand the difference in extraction between Am^{3+} and trivalent lanthanide elements, Yaita et al. (2001) studied Am^{3+} and Nd^{3+} complexes with N-donor ligand benzimidazole by EXAFS. Although they found slight difference in the coordination number of water molecules and in the distance, Yaita et al. concluded that the coordination structure of Am^{3+} – benzimidazole complexes is almost similar to that of Nd^{3+} complexes.

Tian et al. (2002) carried out an EXAFS study on the Am^{3+} complexes with di-*n*-octyldithiophosphinic acid and bis(2,4,4-trimethylpentyl) dithiophosphinic acid (S-donor type extractants) in kerosene. These complexes have the same coordination structure with an eight sulfur-coordinated tetrakis configuration. They observed larger steric hindrance in the Am^{3+} – bis(2,4,4-trimethylpentyl) dithiophosphinic acid complex than in the Am^{3+} – di-*n*-octyldithiophosphinic acid one. Jensen and Bond (2002) also studied Cm^{3+} , Nd^{3+} , and Sm^{3+} complexes with bis(2,4,4-trimethylpentyl) phosphinic acid ($\text{R}_2\text{PO}_2\text{H}$), bis(2,4,4-trimethylpentyl) mono-thiophosphinic acid (R_2PSOH), and bis(2,4,4-trimethylpentyl) dithiophosphinic acid ($\text{R}_2\text{PS}_2\text{H}$) in *n*-dodecane by EXAFS. They proposed neutral bidentate complexes, ML_3 , for dithiophosphinate ligand. Comparison of the EXAFS spectra of Cm^{3+} , Nd^{3+} , and Sm^{3+} shows that the structure and metal – donor atom bond distances are indistinguishable within experimental error.

Skanthakumar et al. (2007) and coworkers extensively studied the coordination structure of the hydrated Cm^{3+} ion by EXAFS and high-energy X-ray scattering (HEXS). They also carried out X-ray diffraction of $[\text{Cm}(\text{H}_2\text{O})_9](\text{CF}_3\text{SO}_3)_3$ single crystal to compare the coordination sphere of Cm^{3+} ions. The HEXS data show that the nine water molecules coordinated to the Cm^{3+} ions at 2.48 Å and hydrogen atoms are located at 3.05 Å.

Antonio et al. (2002) reported redox properties of berkelium by both XAFS and cyclic voltammetry. They obtained the formal potential of the $\text{Bk}^{4+}/\text{Bk}^{3+}$ redox couple, $E^{\circ'} = +1.388 \pm 0.005$ eV versus Ag/AgCl by in situ XANES spectroelectrochemistry and Nernst analysis. They also reported the information of coordination sphere for Bk^{3+} and Bk^{4+} . The Bk^{3+} is coordinated to 9 ± 0.5 O atoms at an average distance of 2.43(2) Å, while the Bk^{4+} is coordinated 8 ± 0.5 O atoms at an average distance of 2.32(1) Å.

18.2.6 Computational Chemistry of Transuranium Elements

The quantum chemical calculation and computational prediction of the behavior of transuranium elements has become very popular recently for being useful in the qualitative understanding of their complicated chemical properties. In order to calculate the electronic structure of actinide compounds, relativistic effects must be taken into account. One of the important

tools for the study of chemical properties of heavy elements is computation using first-principle relativistic molecular orbital calculation methods. Several groups have developed empirical, semiempirical, and nonempirical (so-called first-principle or *ab initio*) methods.

The relativistic calculations on the electronic structure of actinide compounds were reviewed by Pyykkö (1987). He also reviewed relativistic quantum chemistry in 1988, whereas the relativistic calculations were limited to small molecules containing one heavy atom only (Pyykkö 1988). Calculations on the uranyl and neptunyl ions were introduced in the review article. The general information on the computational chemistry of heavy elements and relativistic calculation techniques appear in the book written by Balasubramanian (1997). There are several first-principle approaches to the electronic structure of actinide compounds. The relativistic effective core potential (ECP) and relativistic density functional methods are widely used for complex systems containing actinide elements. Pepper and Bursten (1991) reviewed relativistic quantum chemistry, while Schreckenbach et al. (1999) reviewed density functional calculations on actinide compounds in which theoretical background and application to actinide compounds were described in detail. The “Encyclopedia of computational chemistry” also contains examples including lanthanide and actinide elements (Schleyer et al. 1998). The various methods for the computational approach to the chemistry of transuranium elements are briefly described and summarized below.

Semiempirical (INDO) approach. Zerner and coworkers developed the semiempirical, “Intermediate Neglect of Differential Overlap” (INDO) method for the calculation of electronic structures of actinide complexes (Cory et al. 1994). They presented ground-state resonance parameter sets for the actinide elements from Ac to Pu and applied the INDO parameters to the actinide halides, bis(cyclooctatetraenyl) actinide complexes $M(\text{COT})_2$ ($M = \text{Th, Pa, U, Np, Pu}$), the so-called actinocene and imide/amide complexes of uranium. The semiempirical approach is required for large systems, such as biological molecules containing actinide elements.

First-principle approach. Because of the difficulties of parameter generation for the calculation of actinide elements, the nonempirical or first-principle quantum chemical calculations become important. The Gaussian98 program doing *ab initio* calculation (Frische et al. 1998) is one of the most popular programs used for the calculation of actinide compounds. In order to reduce the computational time, core orbitals are not treated explicitly for the calculation of the actinide compounds. This technique is called the ECP (effective core potential) of the Gaussian98 program. Several ECPs have been proposed and these ECPs are available on the Web (Gaussian 2009). Craw et al. discussed the electronic structure of nitrate and sulfate complexes for uranyl and plutonyl by using ECP, and found that both structures of the nitrates were similar to each other (Craw et al. 1995). Tsushima and Suzuki (2000) reported a computational study on the hydration number of penta- and hexavalent uranyl, neptunyl, and plutonyl ions. The calculations showed that the hydration number $N = 5$ is the most stable for all penta- and hexavalent actinyl ions. The MP2 (Møller-Plesset 2) level calculations had good agreement with the experimental measurements.

Balasubramanian (2002) calculated potential energy surfaces of lawrencium and nobelium dihydrides (LrH_2 and NoH_2) by the relativistic effective core potentials with the ALCHEMY II code (Balasubramanian 2000). He predicts that Lr and No exhibit unusual non-actinide properties. 7s and 7p orbitals have major contribution to the bonding compared with 5f and 6d shells and they behave unlike other actinides.

The Dirac–Fock–CI formula is also available in the MOLFDIR program, which is developed by the Nieuwpoort group. Visscher, Nieuwpoort, and coworkers presented applications and

computational details of the MOLFDIR program in 1994 (Visscher et al. 1994). The Dirac program is also available for the calculation of actinide compounds by the fully relativistic all-electron Dirac–Hartree–Fock method. The detail of the program can be found at the Web site of Dirac (Dirac 2009).

Mochizuki and Okamoto applied the Dirac program for the estimation of stabilities of trivalent actinide elements and water or ammine complexes (Mochizuki and Okamoto 2002). Mochizuki and Tatewaki (2002) also carried out the electronic structure calculation on the hexa-hydrated ions of curium and gadolinium. They used the Dirac program and also predicted the fluorescence transition energy using the “Complete Open-Shell Configuration Interaction” (COSCI) method. Even the hexa-hydrate curium ion needs 2,108 basis functions for the fully relativistic four-component calculation.

Relativistic density functional approach. Ellis and his coworkers (Rosen and Ellis 1975; Nakamatsu et al. 1992) developed the relativistic density functional calculation using the discrete-variational (DV) $X\alpha$ formalism. They use numerical wave functions for the generation of molecular potential and molecular orbitals so that the integration becomes quite simple. Fricke and his group (Bastug et al. 1993, 1995) added a precise integration scheme to the relativistic DV- $X\alpha$ method and the program can calculate total energy of the system with several generalized gradient approximation (GGA) corrections (Vosko et al. 1980; Becke 1988). Hirata et al. (1998) studied the stability of actinyl nitrate – triethyl phosphate complexes using the relativistic DV-DFS (Dirac–Fock–Slater) method. They examined the contribution of 5f electrons to the chemical bonding between the actinide ions and donor atoms of the ligand. The bond-overlap population decreases in the order of $U > Np > Pu$. The application of nonrelativistic and relativistic DV- $X\alpha$ method and their development appeared in the special volume of *Advances in Quantum Chemistry* (Löwdin 1997, 2000). Te Velde and coworkers have published a review on the application of ADF (Amsterdam Density Functional) program including relativistic calculations (Te Velde et al. 2001). See also reference (ADF 2009) for its Web site. The ADF has been developed since 1973 (Baerends et al. 1973), which exploits Slater-type functions (STOs) as the basis set. Guillaumont et al. (2006) and coworkers extensively studied the simulation of liquid/liquid extraction systems for actinide/lanthanide separation. This review involves computer simulation techniques for quantum chemistry and molecular dynamics. Challenging application of the ADF program has been reported by Hancock et al. (2006). They estimated chemical properties of element 111, roentgenium (I) and predicted that Rg(I) is a very soft ion but also a stronger Lewis acid than the other monovalent cations.

For the solid-state actinide physics, VASP (Vienna Ab-initio Simulation Package) and Wien2k are widely used. VASP is a program package for ab initio quantum-mechanical molecular dynamics simulations using pseudopotentials or the projector-augmented wave method and a plane wave basis set (VASP 2009). Wolfer et al. (2007) and coworkers applied the VASP to simulate the effect of Ga addition to the stabilization of δ -plutonium and Minamoto et al. (2009) estimated thermodynamic properties of PuO_2 by using the VASP. The Wien2k (2009) program package is also useful for the actinide science. This program allows performing electronic structure calculations based on the DFT using all-electron scheme including relativistic effects. Robert et al. (2003) calculated thermodynamical properties of plutonium metals and Atta-Fynn and Ray (2009) predicted magnetic properties of δ -plutonium and adsorption properties of water molecules on the δ -plutonium (1,1,1) surface. Several applications on the properties of solid-state americium are reported by using the Wien2k program. Penicaud (2005) and Gao and Ray (2006) applied the Wien2k to the metallic americium to evaluate the effect of 5f electrons to the phase transition of americium.

Abstract: Microscopic nuclear theories predict a region of superheavy elements (SHEs) at the next doubly magic shell closure above ^{208}Pb . Early models locate the shell closure at $Z = 114$, more recent calculations place it at $Z = 120$. The closed neutron shell is located at $N = 184$. These predictions motivated the search for superheavy elements in nature and in the laboratory to explore the limits of the chart of nuclides toward its upper end. A new region of shell stabilization, centered at $Z = 108$ and $N = 162$ has been discovered. It interconnects the transuranium region and the superheavy elements. As of 2009, the heaviest element accepted by the Union of Pure and Applied Chemistry is $Z = 112$. The discovery of elements 113 to 116 and 118 has been reported. All of these elements have been created by the complete fusion of heavy ions. Production rates decrease to less than one atom per month for the heaviest species. Half-lives range down to below microseconds. The elements at the top of the nuclear chart have been discovered on the basis of single-atom decays after separation in-flight. The production and investigation of the transactinide elements with $Z = 104$ and beyond form the subject matter of this chapter. After a brief history of their discoveries and experimental methods, nuclear structure and the production of heavy elements will be discussed. The prospects for the synthesis and investigation of heavy elements using advanced technologies such as new high-current heavy-ion accelerators, radioactive beams, and ion traps will be outlined. The importance of closed nuclear shells for the existence and production of the heaviest elements will be addressed briefly.

19.1 Introduction

Two fundamental questions involve the number of chemical elements that can be found in nature and the limits of stability of matter in terms of nuclear mass and charge. The search for superheavy elements (SHEs) in nature is an attempt at answering the first question. The heaviest primordial element existing in large amounts is uranium (Herrmann 1979; Seaborg et al. 1979). The discovery of natural plutonium in trace amounts has been reported (Hoffmann et al. 1971). Large-scale searches for superheavy elements in nature, most of them aimed at element 114, have been unsuccessful (Kratz 1983).

The second question can only be answered by laboratory experiments and remains the subject matter of research. The first milestone on the way to the artificial transuranium elements is the work of Hahn and Strassmann, aiming at the synthesis of these elements by using Fermi's method of neutron irradiation and successive β^- decay to transmute a chemical element into its next heavy neighbor (Fermi 1934). In irradiations of ^{238}U with neutrons they found barium isotopes instead of the expected new heavy elements (Hahn and Strassmann 1939a, b). This resulted in the discovery of induced nuclear fission, a new type of nuclear reaction specific to the transuranium elements. (See [Chap. 4 in Vol. 1](#) for more details on fission). Meitner and Frisch interpreted this new phenomenon in terms of the charged nuclear droplet. As the large Coulomb force acting between the many protons cannot be balanced by the cohesive nuclear force, the heavy nucleus breaks into two large fragments (Meitner and Frisch 1939). Meitner and Frisch estimated the upper limit for the existence of chemical elements to be around $Z = 100$. The first experiments already contained two important characteristics of future heavy element research: the identification via a two-step process consisting of the separation and subsequent assignment based on nuclear spectroscopy, and the role of fission in their production and decay. Later McMillan and Abelson applied

Fermi's method successfully to create the first transuranium element $Z = 93$, later named neptunium (McMillan and Abelson 1940). This method worked successfully up to fermium, $Z = 100$.

With the addition of microscopic effects to the nuclear droplet, which add stabilization (Strutinsky 1967), the question arose as to whether superheavy nuclei can exist *only* due to shell stabilization beyond the macroscopic limit estimated by Meitner and Frisch. In a first semi-empirical approach the possible evidence for an island of superheavy nuclei was predicted for 126 protons and 184 neutrons (Myers and Swiatecki 1966). A series of more basic calculations followed to confirm the hypothesis of shell stabilization playing a predominant role in the existence of superheavy elements (Mosel and Greiner 1969; Nilsson et al. 1969; Fizet and Nix 1972). Most of these calculations predicted $Z = 114$ and $N = 184$ as the center of the island of superheavy nuclei located in the sea of macroscopic instability, well separated from the transuranium elements. The situation remained practically unaltered until 1984. With the discovery of element 108 (Münzenberg et al. 1984b) it became clear that the island of superheavy elements is connected to the transuranium elements by a bridge of shell-stabilized nuclei.

The unexpected discovery of this new subshell challenged theoreticians to reinvestigate their predictions. Calculations were performed with improved macroscopic–microscopic models (Möller et al. 1986; Sobiczewski et al. 1987) predicting a region of deformed shell-stabilized nuclei, centered at $Z = 108$ and $N = 162$. The discovery of the shell-stabilized island around $Z = 108$ and $N = 162$ is the basis of contemporary heavy element research. Without shell stabilization, nuclei could not exist in the region around hassium ($Z = 108$).  Figure 19.1 shows the presently known isotopes of the heaviest elements in the landscape of shell correction energies. At the boundaries of the shell-stabilized region, fission begins to play a role. Element 112, copernicium (Cn), is the heaviest element accepted by the International Union of Pure and Applied Chemistry, IUPAC (Barber et al. 2009,  Fig. 19.2). Element 118 is the heaviest element reported to date. Element 117 has not been observed yet (Oganessian et al. 2007; Oganessian 2007). Attempts to synthesize element 120 have been without success (Hofmann et al. 2008; Oganessian et al. 2009). All known isotopes of the heaviest elements are neutron deficient and still about eight neutrons away from the magic neutron number 184. New systematic calculations with self-consistent mean field models and realistic nucleon–nucleon interactions were carried out to predict nuclear properties of the heavy and superheavy elements (Cwiok et al. 1996; Rutz et al. 1997; Bender et al. 1999; Heenen and Nazarewicz 2002). Besides $Z = 114$, new magic proton numbers at $Z = 120$ and $Z = 126$ were suggested while the magic neutron number remained at $N = 184$ for all predictions. A recent theoretical analysis of the experimental data concludes that the position of the proton shell closure lies beyond $Z = 120$ (Adamian et al. 2009).

Transuranium elements are artificially created. The (n, γ) reaction, first used successfully for the production of neptunium ($Z = 93$), works only up to fermium ($Z = 100$). It ends at ^{257}Fm due to the short half-life of this isotope (e.g., Seaborg and Loveland 1990). With neutron irradiation, transuranium elements can be produced in weighable amounts by breeding in high flux reactors because the cross sections are of the order of barns, neutron fluxes are high, and the usable target thickness is large.

Transfermium elements are created by the complete fusion of heavy nuclei. Energetic heavy ions from accelerators are shot at heavy targets to create a combined nuclear system through complete fusion. The production cross sections are small. For nobelium ($Z = 102$), it is of the order of microbarns, six orders of magnitude below the cross section for neutron capture.

Fig. 19.1

Upper end of the chart of nuclides showing nuclear half-lives. Theoretical shell correction energies (Smolanczuk 1997) are underlain in blue color. The shading indicates the height of the shell correction energy in steps of 1 MeV. The decay modes are as follows: α decay (yellow), β^+ decay (red), spontaneous fission (green) (Courtesy M. Schädel)

■ Fig. 19.2

Known (filled squares) and proposed (hollow squares) transfermium isotopes (Barber et al. 2009). Nuclides marked in blue have been synthesized with cold fusion, while the ones in red have been synthesized with hot fusion. The subshell at $Z = 108$ and $N = 162$ (dashed-dotted lines) and the spherical shell closure $Z = 114$ and $N = 184$ (solid lines) are indicated

For the heaviest elements, cross sections drop to values below 1 pb. Due to the energy loss of the energetic projectile ions in the target and the narrow width of the excitation function, usable target thicknesses are of the order of a milligram. As a consequence, production rates count in quantities of single atoms. For the heaviest elements only one atom per week or even month are available.

The transfermium elements up to seaborgium were created by irradiations of reactor bred actinide targets with light projectiles, typically oxygen or nitrogen (Seaborg and Loveland 1985). Cold fusion with lead or bismuth targets and appropriate beams such as nickel led to the synthesis of element 113 (Hofmann and Münzenberg 2000; Morita 2008). The elements beyond were created by hot fusion with calcium beams together with suitable actinide targets (e.g., Oganessian et al. 2007; Oganessian 2007). It is interesting to note that for both types of fusion reactions doubly magic nuclei, ^{208}Pb and ^{48}Ca , play a key role. Also as with production cross sections, the half-lives decrease steeply toward the heaviest elements dropping more than ten orders of magnitude from 100 days for the longest-lived fermium isotope to about 1 ms for element 118 presently defining the top end of the nuclear chart.

Since transfermium work involves research with one single, short-lived, atom at a time it requires sensitive and fast detection techniques. As chemical techniques are limited to half-lives of seconds, all of the transactinide elements beyond seaborgium have been discovered using separation in-flight with ion optical separators (Münzenberg 1997). The identification is based on the parent–daughter α – α correlation method (Ghiorso et al. 1969), which has been refined by the implantation technique (Hofmann et al. 1984), permitting the identification of new isotopes or even new elements by single-atom decay sequences (Münzenberg et al. 1984a).

Presently superheavy element (SHE) research concentrates on the production and unambiguous identification of elements 114 and above using both physical and chemical methods. Developments include dedicated facilities for SHE production with accelerators delivering high beam intensities, detailed structure investigations with new generation gamma arrays of the highest efficiency, and trapping in ion traps for direct mass measurements and atomic physics (Sewtz and Habs 2007).

19.2 A Brief History of Discoveries

The transactinides are the doorway to the superheavy elements. The region of shell stabilization starts here (► Fig. 19.1) without which the chart of the nuclides would end around seaborgium. For this reason, these elements are sometimes also referred to as “superheavy” nuclei. In this chapter the conventional definition will be adopted when referring to the superheavy elements: spherical nuclei that lie around the next double shell closure above ^{208}Pb .

The first of the transactinide elements rutherfordium ($Z = 104$, Rf), dubnium ($Z = 105$, Db), and seaborgium ($Z = 106$, Sg) were discovered in hot fusion reactions by irradiating actinide targets, bred in high flux reactors, with light projectile beams such as oxygen or carbon (Flerov and Ter Akopian 1983; Seaborg and Loveland 1990). Rutherfordium was discovered in the irradiation of ^{249}Cf with ^{12}C (Ghiorso et al. 1969). After the evaporation of four neutrons from the resulting compound nucleus (CN) the isotope ^{257}Rf was formed. This reaction may be written as $^{249}\text{Cf}(^{12}\text{C}, 4n)^{257}\text{Rf}$. The first experiment to produce dubnium (Flerov et al. 1971) used the reaction $^{243}\text{Am}(^{22}\text{Ne}, 4n)^{261}\text{Db}$. Seaborgium was discovered with $^{249}\text{Cf}(^{18}\text{O}, 4n)^{263}\text{Sg}$ (Ghiorso et al. 1974). Production cross sections are given in ► Table 19.1. The “Criteria that must be satisfied for the Discovery of a New Chemical Element to be recognized” are provided in the report of the Transfermium Working Group (Barber et al. 1992) together with the detailed discovery profiles of the transfermium elements including meitnerium ($Z = 109$).

In the discoveries of the light transactinides, the reaction products recoiling from the thin production target due to the momentum transfer from the projectile, were stopped in a gas cell and transported with a helium gas jet to a detector system where their α decays were observed over several daughter generations. As the α spectra of the daughter nuclides were known, the mother element could be unambiguously identified with the method of α - α parent-daughter correlation (Ghiorso et al. 1974).

At seaborgium, the production cross sections drop below 1 nb and half-lives are shorter than 1 s. To access the region beyond seaborgium innovative methods were devised (Münzenberg 1988; Hofmann and Münzenberg 2000). A new type of synthesis reaction, cold heavy-ion fusion, using lead and bismuth targets (Oganessian 1974) was employed together with fast and sensitive detection methods allowing the identification of new nuclides or even new elements by the observation of single-atom decay chains (Münzenberg et al. 1981b). In irradiations of ^{208}Pb targets with ^{48}Ca , ^{50}Ti , and ^{54}Cr projectiles the cold production of transfermium elements in two-neutron evaporation channels had been observed (Oganessian et al. 1975). The final and most convincing proof of the validity of this new concept was given by the observation of ^{257}Rf in irradiations of ^{208}Pb with ^{50}Ti produced by the evaporation of one neutron from the compound nucleus ^{258}Rf (Münzenberg et al. 1982a). Single-atom detection comprises separation in-flight (Münzenberg 1974; Münzenberg et al. 1979, 1981b) using ion optical methods in combination with the α - α parent-daughter correlation technique. The implantation of the heavy atom, separated in-flight, into a position sensitive silicon

^bRevised cross section.

^cCross section provided by V. Utyonkov (2009, private communication).

It should be noted that discrepancies in production cross sections measured with vacuum separators such as SHIP and gas-filled separators may be caused by short-lived states decaying by converted transitions followed by Auger cascades. These lead to charge states considerably higher than the equilibrium charge state. Therefore, at SHIP a thin carbon foil located about 10 cm downstream the target equilibrates the ionic charge state of the passing ions. Species which decay during their flight through SHIP after passing the equilibration foil may be lost (Münzenberg et al. 1984a). The time window is 10^{-8} to 10^{-6} s. Such cases have been observed in systematic cross-section investigations. This problem is less relevant for gas-filled separators where ionic charge states are continuously equilibrated while passing the filling gas. A typical example is ^{257}Rf . Experiments to investigate this problem in more detail are planned.

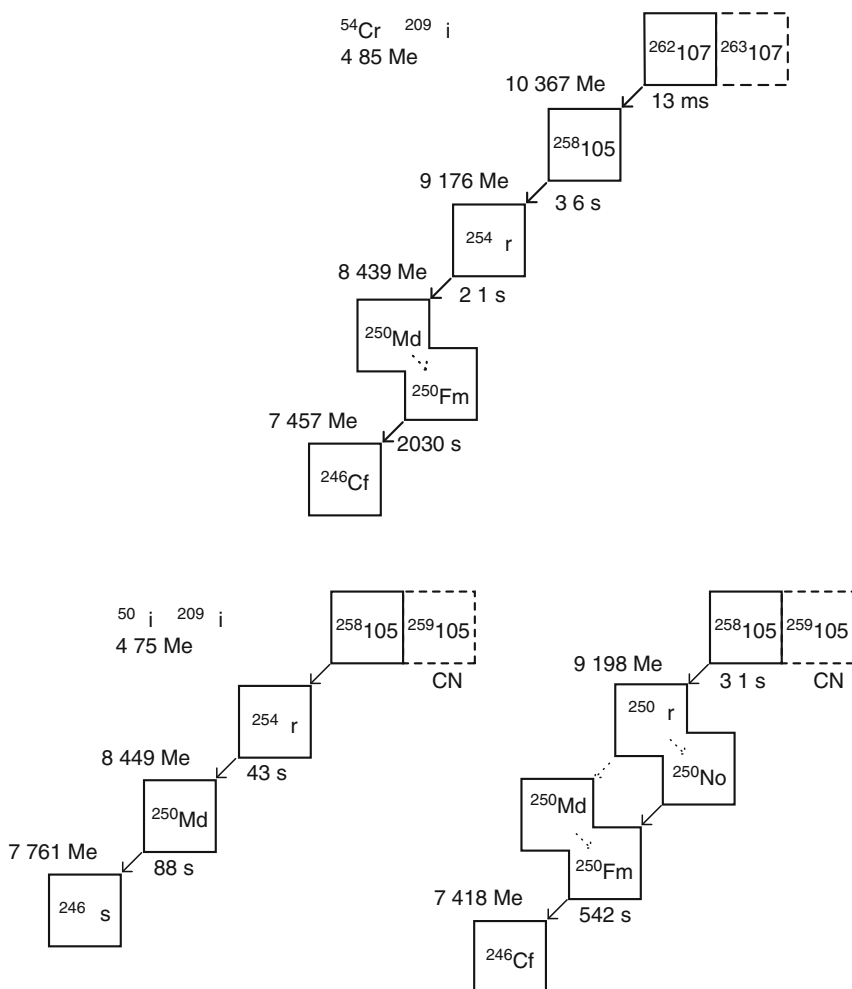

surface-barrier detector allows the observation of its individual decay history over several generations *in situ* (Hofmann et al. 1984). If at least one member of the sequence is known, the whole chain can be identified. At present, 12 isotopes of rutherfordium, 11 of dubnium, and 11 of seaborgium are known.

Bohrium (Bh), $Z = 107$, was the first of a series of elements discovered with this new method (Münzenberg et al. 1981a, 1989). In irradiations of ^{209}Bi with ^{54}Cr six atoms of ^{262}Bh were identified. An example of the observed decay sequence of one atom of ^{262}Bh together with decay chains of two atoms of the daughter nuclide ^{258}Db , observed in a companion experiment, is displayed in (► Fig. 19.3) for comparison. Since then, ten isotopes of bohrium have become known. The proton-rich ones with masses 260, 261, and 262 were directly produced by cold fusion. The isotopes with mass 262 and 264 appear in the discovery chains of the elements 109 and 111 (Hofmann et al. 2002). The neutron-rich isotopes with masses 266, 267 were created in irradiations of actinide targets. The three most neutron-rich ones with masses 270, 271, and 272 appear in decay chains from $^{282}\text{113}$ (Oganessian et al. 2007; Oganessian 2007), $^{287}\text{115}$ (Oganessian et al. 2004d, 2005), and $^{288}\text{115}$ respectively (Dmitriev et al. 2005, Oganessian et al. 2005), which were produced with ^{48}Ca projectiles in a series of experiments done at Dubna. These ten isotopes have half-lives ranging from 8 ms to 61 s. All of them undergo α decay.

Hassium (Hs), $Z = 108$ was discovered in the reaction $^{208}\text{Pb}(^{58}\text{Fe}, n)^{265}\text{Hs}$ (Münzenberg et al. 1984b, 1987) and unambiguously confirmed in a later experiment (Hofmann et al. 1995a). This element was synthesized after meitnerium as theoretical predictions available at that time suggested the predominance of spontaneous fission with half-lives below microseconds for the doubly even hassium isotopes (Randrup et al. 1976). Hence, to proceed with the synthesis of meitnerium was considered to be safer since it was possible to profit twice from the fission hindrance provided by the odd proton and the odd neutron, if an odd-odd nuclide was to be produced. The resulting observation of α decay is necessary for the identification of the new element with the correlation method. The synthesis of hassium with the unexpected

■ Fig. 19.3

A typical decay chain of ^{262}Bh with daughter decays illustrating the method of identification of a new species by single-atom decay sequences (Münzenberg et al. 1981a). Note that lifetimes of the individual nuclei fluctuate according to the “rules” of exponential distribution (see Sect. 9.4.4 in Chap. 9, Vol. 1)

observation of α decay provided the first hint of the existence of a new region of shell stabilization (Münzenberg et al. 1989). It became the cornerstone for paving the way to the creation of the heavier transactinides. The production cross section for ^{265}Hs , measured in a later experiment (Hofmann et al. 1995a) was found to be one order of magnitude larger than that measured in the first experiment. Both unexpected results opened the door to the synthesis of elements $Z = 110$, 111, and 112. The hassium isotopes with masses 264 and 265 were produced in cold fusion reactions. The isotope with mass 263 has been observed recently (Kaji et al. 2009; Dragojevic et al. 2009). The isotopes 265, 266, and 267 appear in the decay chains of

darmstadtium isotopes. The isotopes with mass 269 (Türler et al. 2003), 270, and 271 (Dvorak et al. 2006, 2008) were produced in hot fusion reactions. The most neutron-rich isotope with mass 275 has been observed in the decay chain of $^{283}_{112}$ produced with ^{48}Ca (Oganessian et al. 2004a, b). All eight hassium isotopes known today are α emitters including the doubly even ^{264}Hs for which a fission branch is reported. The half-lives of the hassium isotopes span more than four orders of magnitude from 0.26 ms for ^{264}Hs to 9.3 s for ^{269}Hs .

Meitnerium (Mt), $Z = 109$, was discovered in the reaction $^{209}\text{Bi}(^{58}\text{Fe}, n)^{266}\text{Mt}$ by the observation of the decay chain (► Fig. 19.9) of one single atom (Münzenberg et al. 1982a). The assignment, based on statistical arguments (Münzenberg et al. 1984a), was confirmed in two independent experiments (Münzenberg et al. 1988; Hofmann et al. 1997). At present, six meitnerium isotopes are known. The isotope with mass 266 and a half-life of 1.7 ms was produced directly, the isotope with mass 268 and a half-life of 70 ms was found in the decay chain of ^{272}Rg (Hofmann et al. 1995a), and the isotope with mass 270 was observed in the decay chain of $^{278}_{113}$ (Morita et al. 2004d, 2007b). The three most neutron-rich isotopes with masses 274, 275, and 276 were observed as daughter nuclei in the decay chains of $^{282}_{113}$ (Oganessian et al. 2007), $^{287}_{115}$ (Oganessian et al. 2004d, 2005), and $^{288}_{115}$ (Dmitriev et al. 2005; Oganessian et al. 2005). All known isotopes are α -emitters. Their half-lives range from 1.7 ms to 0.7 s.

Darmstadtium (Ds), $Z = 110$, was discovered in 1994 (Hofmann et al. 1995a). The isotope with mass 269 was observed in irradiations of ^{208}Pb with ^{62}Ni . Four α chains were measured. One of these was retracted later (Hofmann et al. 2002). For the elements up to $Z = 110$ the most neutron-rich beams available in nature were used: ^{50}Ti , ^{54}Cr , ^{58}Fe , and ^{62}Ni each separated by one α . Consequently it was possible to build up the “reversed” decay chains toward the heavier elements step by step. For nickel and heavier projectiles more neutron-rich isotopes of these elements exist. By replacing the projectile ^{62}Ni by ^{64}Ni the production cross section is enhanced by a factor of five (Hofmann et al. 1995b). This led to the synthesis of ^{271}Ds paving the way for the discovery of roentgenium. The production of element 110 was confirmed by the RIKEN (Japan) group (Morita et al. 2004a, b). The isotope with mass 270, the heaviest even–even nucleus identified with the correlation method, was produced by the irradiation of ^{207}Pb with ^{64}Ni (Hofmann et al. 2001). Alpha decay sequences assigned to the isotope with mass 273 have been observed in the bombardment of ^{244}Pu with ^{34}S (Lazarev et al. 1996). The isotopes with masses 279 and 281 undergo fission. They are the endpoints of the α decay chains from $^{291}_{116}$ (Oganessian et al. 2004c; Oganessian 2007) and $^{293}_{116}$ (Oganessian et al. 2004a, b) respectively. Altogether six isotopes of darmstadtium have been reported with half-lives ranging from 0.1 ms to 17 s. They are mostly α emitters except for the two most neutron-rich ones, which fission just at the boundary of the shell-stabilized region around $N = 169$ and $N = 171$ (► Fig. 19.1). For more detailed discovery profiles and priorities of discovery, see the corresponding IUPAC report (Karol et al. 2001).

Because of the strong enhancement of the production cross section for element 110 with the ^{64}Ni beam, roentgenium (Rg), $Z = 111$, was produced in the same series of experiments by proceeding from the ^{208}Pb target to ^{209}Bi (Hofmann et al. 1995b). Three decay chains of ^{272}Rg were measured. The Q_{α} value of this isotope is 10.99 MeV, the half-life is 3.8 ms, and the production cross section is 2.9 pb. This result was confirmed in later experiments (Hofmann et al. 2002; Morita et al. 2004c). The isotope ^{274}Rg has been observed in the decay chain of $^{278}_{113}$ (Morita et al. 2004d, 2007b). The three most neutron-rich isotopes with masses 278, 288, and 289 appear in the decay chains from elements 113 (Oganessian et al. 2007) and 115 (Oganessian et al. 2004d, 2005; Dmitriev et al. 2005). The half-lives of the five observed

isotopes span from 3.8 ms to 3.6 s. For more details of the history of discovery see the corresponding IUPAC report (Karol et al. 2003).

The heaviest element accepted by IUPAC is copernicium (Cn), $Z = 112$ (Barber et al. 2009). It has been discovered in the reaction $^{208}\text{Pb}(^{70}\text{Zn}, n)^{277}112$ (Hofmann et al. 1996). The first atom of $^{277}112$ that was observed, decays over six generations of alphas to ^{253}Fm . The last two generations were known and provided the anchor for its identification. The second chain reported in this paper was retracted after a reanalysis of the original data (Hofmann et al. 2002). The Q_α value is 11.43 MeV, the half-life 0.69 ms, and the production cross section is 0.5 pb corresponding to the production rate of one single atom per 6 weeks. Later experiments (Hofmann et al. 2002; Morita 2005; Morita et al. 2007a) confirmed the discovery chain. The isotopes $^{282}112$ and $^{283}112$ have been observed in irradiations of ^{238}U with ^{48}Ca in 3n and 4n reactions in a series of experiments done at Dubna using ^{48}Ca beams (Oganessian et al. 2007; Oganessian 2007). This new concept will be discussed in more detail with element 114, the first element discovered with this method. The isotope $^{283}112$ was produced in the reaction $^{238}\text{U}(^{48}\text{Ca}, 3n)$ as the first of this new series (Oganessian et al. 1999a). This was followed by more experiments using the same reaction (Oganessian et al. 2004a, b). The properties measured in the second set of experiments were confirmed at Gesellschaft für Schwerionenforschung (GSI) using the Separator for Heavy Ion reaction Products (SHIP) (Hofmann et al. 2007). The heavier isotopes with masses 284 and 285 appear in decay chains from heavier elements and are reviewed in (Oganessian et al. 2007; Oganessian 2007). The five isotopes cover a half-life ranging from 0.7 ms to 29 s. The two even-even isotopes with masses 282 and 284 undergo spontaneous fission, while for the isotope with mass 283 a fission branch is reported. A detailed discovery profile and the priorities for assignment are given in a recent IUPAC report (Barber et al. 2009).

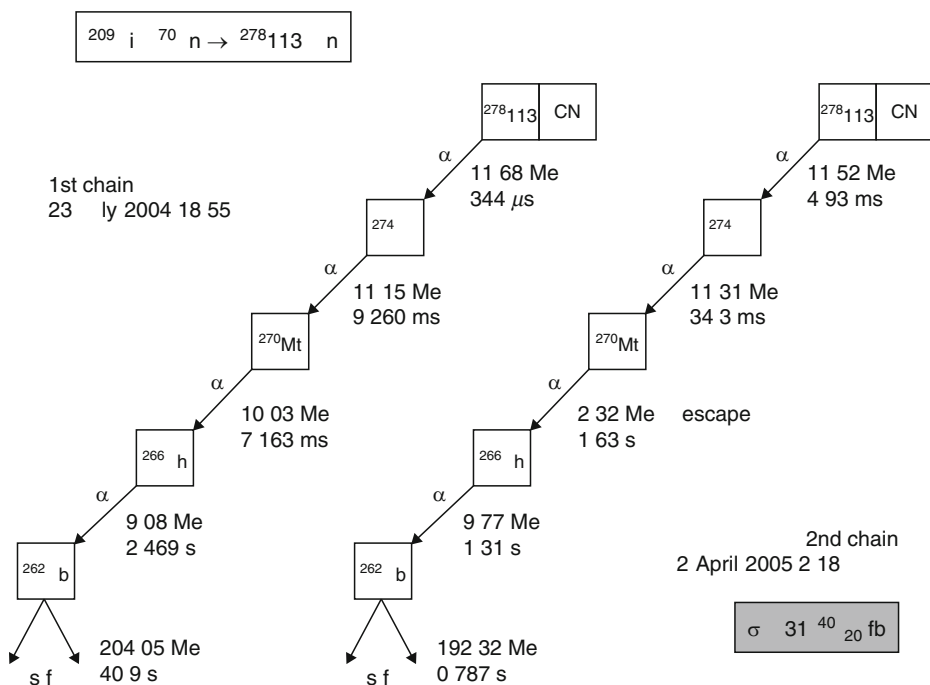

Element 113 has been discovered at RIKEN in the reaction $^{209}\text{Bi}(^{70}\text{Zn}, n)^{278}113$ (Morita et al. 2004d). In an irradiation time of 79 days with a projectile dose of 1.7×10^{19} the α -decay sequence of one atom had been observed. In a second experiment (Morita et al. 2007b) one more chain was found (► Fig. 19.4). The production cross section is 30 fb, the smallest cross section ever measured for the production of a heavy element. The Q_α value is 11.68 MeV and the half-life, 0.24 ms (Morita 2008). The isotope $^{282}113$ has been produced in the reaction $^{237}\text{Np}(^{48}\text{Ca}, 3n)$ (Oganessian et al. 2007), while the isotopes with masses 283 and 284 appear in the decay chains of element 115. The half-lives of the four isotopes range from 0.24 ms to 0.48 s. Element 113 is presently at the experimental limit for heavy-element production by cold fusion, because of the required beam time. A simple extrapolation would require a beam time of the order of 1 year for one atom of element 114. To go beyond, new concepts are needed.

While noting the success of cold fusion to create elements 107 to 113 with the doubly magic ^{208}Pb and its neighbor ^{209}Bi as targets, it is tempting to use hot fusion and another strongly bound doubly magic nucleus ^{48}Ca with actinide targets for the production of the heavier new elements in a more asymmetric target-projectile combination. A first attempt at the production of element 116 by the irradiation of ^{248}Cm with ^{48}Ca was without success (Armbruster et al. 1985). The cross section limit for this experiment was 0.3 nb. From the experimental data available as of 2009, it is evident that beyond element 110 cross sections drop down to the picobarn (pb) region.

In 1999, the Dubna group started a series of experiments with the new concept of using ^{48}Ca beams for the synthesis of unknown elements beyond $Z = 113$ (Oganessian 1996). They upgraded their equipment to enhance the sensitivity by a factor 1,000 over the 1985 experiment and started their series with an attempt to produce the new element 114 with the irradiation of

Fig. 19.4

Two decay chains of $^{278}_{113}$ (Morita 2008). Note that the length of the α decay chains increases for the heavier elements in the region of α emitters generated by the subshell closure at $Z = 108$

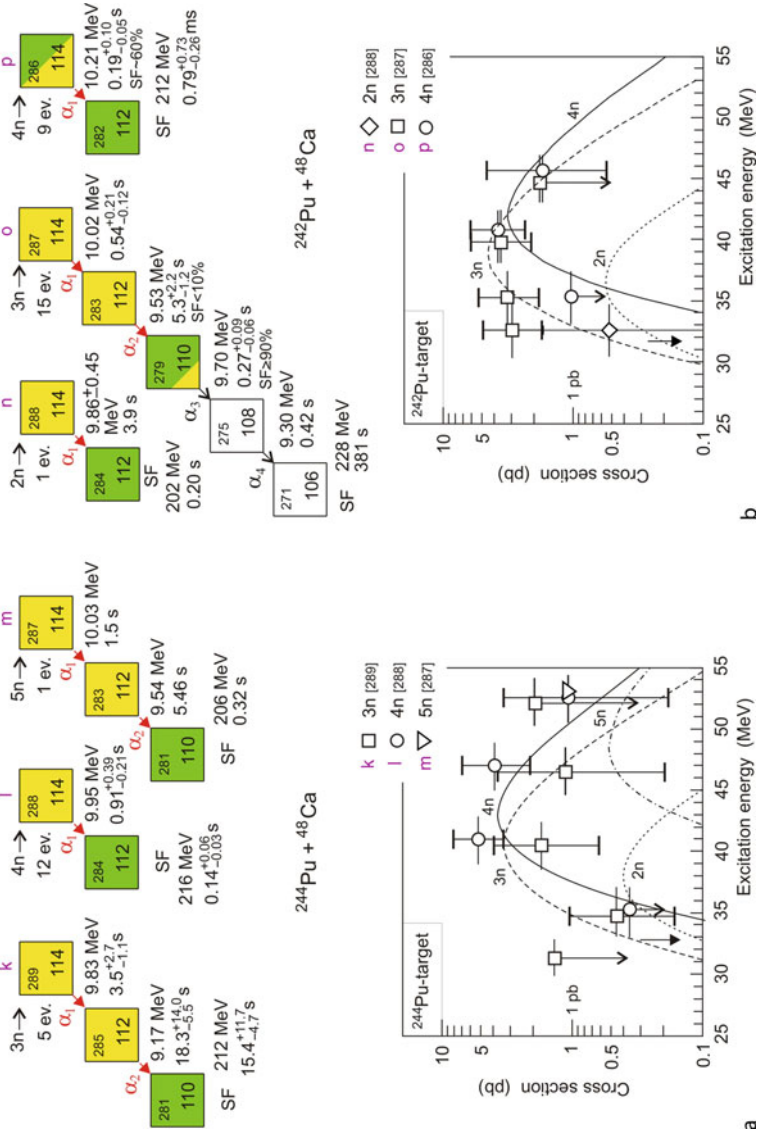

^{244}Pu with ^{48}Ca (Oganessian et al. 1999b) as the first in a series of Superheavy Element synthesis. The isotopes created in irradiations of actinide target with ^{48}Ca beams are on an average richer by three to four neutrons over those produced in cold fusion reactions. Their decay chains traverse the shell-stabilized region of deformed nuclei centered at $Z = 108$ and $N = 162$, and terminate by fission before they enter the region of known transuranium elements (Fig. 19.1). Since the chains end in an unknown region, the parent–daughter correlation method cannot be applied. Therefore, the assignment of new elements and isotopes is based on the assumption that the charge Z of the new element is the sum of the charges Z_t of the target and Z_p of the projectile. This assumption is justified by the observation that charged-particle emission is suppressed in heavy-element synthesis because of the high Coulomb barrier of the heavy compound nuclei. The mass assignment is based on the measurement of excitation functions and comparison to theoretical predictions (Zagrebaev, 2001). Generally, the assignments are supported by Q_α systematics. In the early experiments with ^{48}Ca where the number of evaporated neutrons was simply estimated from the excitation energy of the compound nucleus, the mass number had not been correctly assigned in some cases (Gupta and Burrows 2005).

The strategy of the Dubna group is to build up a region of nuclides in an internally consistent manner where descendants appearing in decay chains are, in addition, directly synthesized by the complete fusion of heavy ions including using the technique of cross bombardments (Fig. 19.5). Thus, if one nuclide in this region is safely identified, the whole island is fixed. This process explains the importance of the recent experiment (Hofmann

Fig. 19.5

Upper panel: Decay chains from the irradiations of (a) ^{244}Pu (labeled k, l, m) (b) ^{242}Pu (n, o, p). The lifetimes and fission energies are averaged from all observed events. The numbers of events are indicated (e.g., “5 ev” for $^{289}\text{114}$). Note that the chains l and n as well as m and o belong to the same isotopes. Lower panel: The corresponding excitation functions (Oganessian 2007)

et al. 2007) using SHIP at GSI to confirm the properties and the production cross section of ^{283}Cn . SHIP is a kinematic separator and only sensitive to nuclei produced in complete fusion. Thus, if ^{283}Cn had been produced in another type of reaction, it would not have been observed.

In the first experiment to create element 114 in an irradiation of ^{244}Pu with ^{48}Ca one single decay chain terminated by spontaneous fission, after a sequence of three α decays with lifetimes up to 16.5 min, was observed and proposed as a candidate for $^{289}114$. This nuclide was formed after the evaporation of three neutrons from the compound nucleus $^{292}114$ (Oganessian et al. 1999b). This decay mode has not been confirmed yet. New results (Oganessian et al. 2004c) indicate much shorter lifetimes of the order of seconds with the chains terminating by fission at ^{281}Ds (Oganessian et al. 2007; Oganessian 2007) as indicated in  Fig. 19.1. Four isotopes with masses 286 to 289 and half-lives from 0.13 to 2.6 s have been reported. They were produced in irradiations of ^{244}Pu and ^{242}Pu with ^{48}Ca . All their decay chains end by fission. The even–even chains end at copernicium, the even–odd ones at darmstadtium. The isotopes with masses 288 and 287 (Oganessian et al. 2004a, c) were observed with both targets ( Fig. 19.5). They were also observed in the decay chains from isotopes of element 116, which gives a consistent picture. Nevertheless, the early assignments (e.g., Oganessian et al. 1999a, b) were disputed and many attempts were made to confirm results.

Chemical investigations are being pursued actively. An experiment to investigate the chemical properties of copernicium began with an attempt at producing element 114. Recently, in an irradiation of ^{242}Pu with ^{48}Ca , two decay chains were observed after chemical separation where the daughters were attributed to ^{283}Cn following the (unobserved) decay of $^{287}114$ (Eichler et al. 2007). Although the measured decay properties support the later Dubna assignments (Oganessian et al. 2004a), this experiment in itself cannot be considered as a proof of a Z assignment as the chemical properties of copernicium remain the subject matter of discussion.

Two isotopes of element 115 with masses 287 and 288 have been reported (Oganessian et al. 2004d, 2005; Dmitriev et al. 2005). Both have been produced in irradiations of ^{243}Am . They are α emitters with half-lives of 32 and 87 ms respectively.

In the first successful experiment on the synthesis of element 116 one single α chain was observed (Oganessian et al. 2001) and initially attributed to the isotope with mass 292, produced in the reaction $^{284}\text{Cm}(^{48}\text{Ca}, 4n)$. Subsequently, the parent was reassigned to $^{293}116$ and four new events attributed to the isotope with mass 292 were reported using the same reaction at a higher energy (Oganessian et al. 2004a, b). Three more isotopes have been measured for element 116. The isotope $^{293}116$ was produced in the $3n$ channel (Oganessian et al. 2004a, b) while the isotopes with masses 290 (Oganessian et al. 2004c, 2006) and 291 (Oganessian et al. 2004c) have been observed in irradiations of ^{245}Cm and $^{290}116$ also appears in the decay chain of $^{294}118$. All four of them are α emitters with half-lives ranging from 7 to 61 ms. The production cross section for $^{292}116$ is 3.3 pb, a factor of 100 below the cross section limit of the experiment from 1985 (Armbruster et al. 1985).

Element 117 has not been created yet. Experiments to synthesize this element are still under preparation. It will be produced in irradiations of ^{249}Bk , which is a difficult target because of its short half-life of 320 days. (In December 2009, the experiment on the synthesis of element 117 was in progress at Dubna.)

Element 118 is the heaviest one reported at present. The isotope $^{294}118$ was observed in the reaction $^{249}\text{Cf}(^{48}\text{Ca}, 3n)$. Three chains were measured in total (Oganessian et al. 2004a, 2006). The half-life is 0.9 ms and the α decay energy, 11.65 MeV. The α sequences are quite short,

ending after three generations by the spontaneous fission of ^{282}Cn . With the synthesis of element 118, the reactions using the ^{48}Ca beam are exhausted. There are no targets available with $Z > 98$.

To go beyond element 118, new production techniques are being explored. The first but unsuccessful attempts to synthesize element 120 have been reported recently (Hofmann et al. 2008; Oganessian et al. 2009). New concepts to go beyond element 118 are being discussed (e.g., Zagrebaev and Greiner 2008).

19.2.1 Priorities and Naming

The decision on the priority of the discovery of a new chemical element is the responsibility of the IUPAC. The detailed definition of the criteria for the discovery of a new element was prepared by the Transfermium Working Group (Barber et al. 1992). [Table 19.2](#) displays the elements for which the priority of discovery has been assigned. The IUPAC accepted the following names and symbols for the transactinides (Sargeson 1997). The laboratories associated with their discovery as accepted by IUPAC are given in parentheses (Barber et al. 1992, 2009; Karol et al. 2001, 2003).

19.3 Experimental Methods

19.3.1 Accelerators and Ion Sources

The development of heavy-ion accelerators providing intense beams, even for isotopes appearing with small abundances in nature, and the availability of fast and sensitive detection systems paved the way to the synthesis of the transactinides. The projectile energy for the production of heavy elements is close to the Coulomb barrier, i.e., around 5 A MeV (A is

Table 19.2

Priorities of discovery and associated laboratories as accepted by International Union of Pure and Applied Chemistry (IUPAC)

Element 104	Rutherfordium (Rf) honoring Sir Ernest Rutherford (LBL Berkeley, JINR Dubna, shared).
Element 105	Dubnium (Db) named after Dubna, its place of discovery (LBL Berkeley, JINR Dubna, shared).
Element 106	Seaborgium (Sg) honoring Glenn T. Seaborg (LBL Berkeley).
Element 107	Bohrium (Bh) honoring Niels Bohr (GSI Darmstadt).
Element 108	Hassium (Hs) named after Hessen, Latin: Hassia, its state of discovery (GSI Darmstadt with contribution from Dubna).
Element 109	Meitnerium (Mt) honoring Lise Meitner (GSI Darmstadt).
Element 110	Darmstadtium (Ds) named after Darmstadt, its town of discovery (GSI Darmstadt).
Element 111	Roentgenium (Rg) honoring Wilhelm Conrad Röntgen (GSI Darmstadt).
Element 112	Copernicium (Cn) honoring Nicolaus Copernicus (GSI Darmstadt).

the mass number of the projectile). Accelerators used for heavy-element production are large cyclotrons such as the U400 at Dubna or linear accelerators such as the UNILAC at GSI or the RILAC facility at RIKEN.

The largest production yields for heavy elements are obtained with the most neutron-rich projectiles available in nature. As most of the neutron-rich isotopes used for SHE production occur with low abundances, the ion sources have to be operated with enriched material to provide intense beams. (See ► Chap. 51 in Vol. 5 on isotope separation techniques.) For the production of the elements hassium to copernicium with lead or bismuth targets, beams of the isotopes ^{58}Fe (0.3% natural abundance), ^{64}Ni (0.9% natural abundance), or ^{70}Zn (0.6% natural abundance) were used. For the Dubna series of experiments ^{48}Ca is used, which has a natural abundance of 0.2%. At present, all heavy-element laboratories use electron cyclotron resonance (ECR) ion sources, which have a material consumption of about 0.5 mg/h for ion currents as high as one particle- μA (corresponding to 1 μA of single-charged ions). Because of the excellent long-term stability of this ion source, experiments of several weeks and even months of duration are possible. To further explore the region of superheavy nuclei around $Z = 114$ and beyond, ion sources and accelerators for intense beams of stable isotopes with intensities up to 20 particle- μA , equivalent to 10^{14} ions/s, are under development (U. Ratzinger 2009, private communication; Yu. Ts. Oganessian 2009, private communication).

The small production yields for the heaviest elements need isotopically pure targets to avoid background from contaminants with large cross sections, which is a problem specific to actinide targets that sometimes have lead contaminations. High beam intensities need specialized targets, especially when using lead or bismuth, which melt easily. The optimum target thickness for recoil separators is of the order of 0.5 mg/cm^2 to preserve the reaction kinematics. Thin targets have practically no thermal conduction. Therefore, the target temperature is determined by radiative cooling. Target problems increase for heavy beams, as the energy loss of the beam (i.e., the heat deposition) increases with Z_p^2 (see ► Eq. (8.1) in Chap. 8, Vol. 1). For beam currents in excess of 10^{12} projectiles/s, rotating wheels have been developed to obtain a large effective irradiated surface and to aid radiative cooling. Targets in gas-filled separators profit from cooling of the gas. The technology for the development of new targets intended for high-intensity beams include chemical compounds with high melting points such as sulfides, oxides, or fluorides and efficient gas cooling.

19.3.2 Separation In-Flight

The key to the discovery of the short-lived nuclides at the very limits of nuclear stability is separation in-flight. It is fast, sensitive, and independent of the chemical properties of the species to be separated. The separation time is determined by the flight time through the separator, which is of the order of microseconds. Presently kinematic separators such as velocity- or energy filters and gas-filled separators are used successfully (see Münzenberg 1997; Oganessian 2007; Düllmann 2008, and conference volume Emis-14 (2002) for a review of recent separator developments). Separation, sensitive to the specific kinematic properties of the desired reaction products is most efficient for a clean SHE selection as products from other types of reactions are suppressed. The key to kinematic separation of products from complete fusion is based on the principle that since only nuclei formed by complete fusion, recoil from the target with the full momentum transferred from the projectile, they are the only recoils moving with center-of-mass velocity. Their speed as determined from momentum conservation is

$$v_c = \frac{v_p M_p}{M_c} \quad (19.1)$$

with v_p denoting the speed of the projectile. M_p and M_c are the masses of the projectile and the compound nucleus, respectively. Therefore, velocity filters are the ideal separators for fusion products (Münzenberg 1997).

The velocity filter SHIP (Separator for Heavy Ion reaction Products, [Fig. 19.6](#)) at GSI Darmstadt (Münzenberg 1974; Münzenberg et al. 1979) has been developed for sensitivities down to picobarns. The intense projectile beam is focused onto lead or bismuth targets (which have low melting points) mounted on a rotating wheel. The reaction products recoil almost unretarded from the thin target into SHIP with its combination of two velocity filters with separated electrostatic and magnetic deflection fields. Here, magnetic quadrupole lenses arranged in a triplet at the entrance collect the recoils from nearly the full solid angle. At the symmetry plane, the projectile beam is separated from the recoils. A second quadrupole triplet focuses the separated recoils onto the detector system (see the [Sect. 19.3.3](#) for more detail). Recently a small dipole magnet has been added to further improve the suppression of scattered projectiles and to move the detector out of the zero degree direction (Hofmann et al. 1995a).

The separation characteristic of SHIP is shown in [Fig. 19.7](#). The upper panel displays the reaction $^{175}\text{Lu}(^{40}\text{Ar}, 5n)$, which has its maximum within the velocity window of SHIP while the lower panel shows the reaction $^{175}\text{Lu}(^{40}\text{Ar}, \alpha 4n)$, which has a minimum in this velocity window. The recoil from the α particles emitted from the compound nucleus is large enough to drive the remaining residue out of the velocity window. This results in a strong suppression of α -channels and all channels, which involve the emission of a fragment like an α particle or a heavier product in the exit channel (Faust et al. 1979).

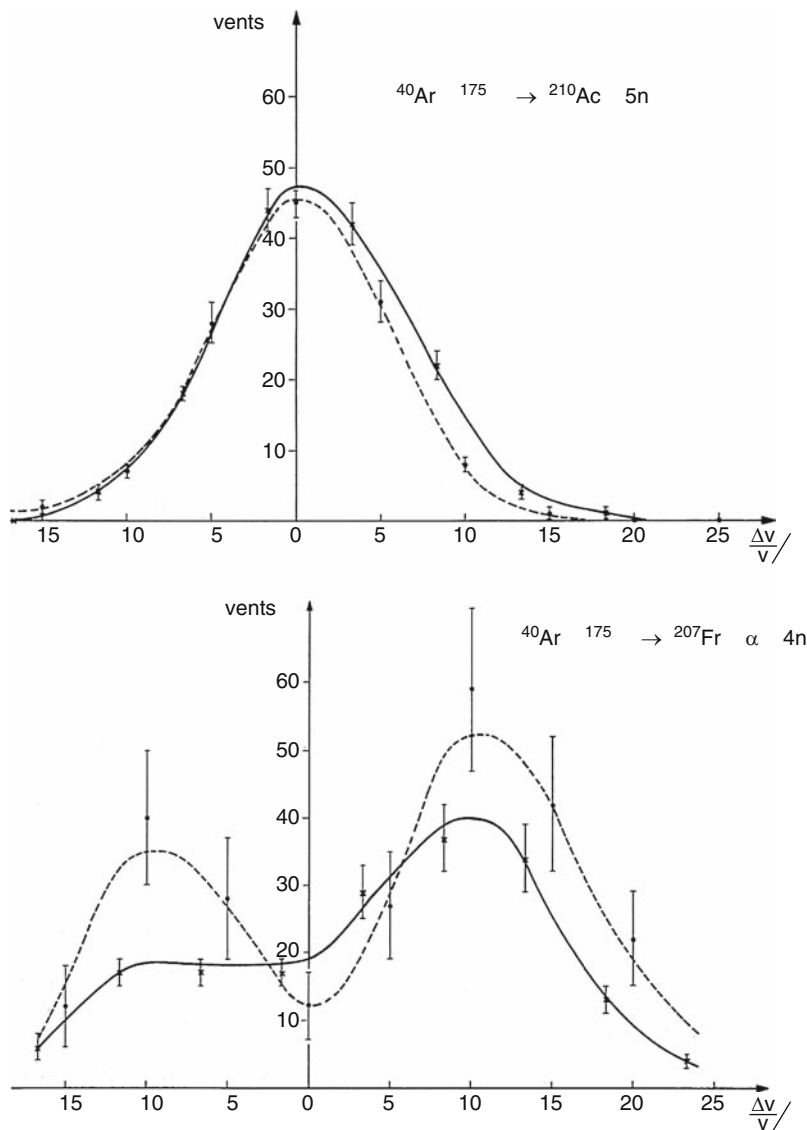

■ **Fig. 19.6**

■ Fig. 19.7

Separation characteristic of SHIP. *Upper panel: 5n channel; lower panel: α , 4n channel. Line and crosses: data; dashed line and dots: Monte-Carlo calculation (Faust et al. 1979). The velocity window of SHIP is indicated in gray*

The experiments at Dubna (Russia) and RIKEN (Japan), and LBNL Berkeley (USA) have been carried out with gas-filled separators. Gas-filled separators (Münzenberg 1997; Oganessian 2007) are filled with helium (GSI, RIKEN, LBNL) or hydrogen (Dubna) and maintained at a pressure of typically 0.5 mbar. A schematic view is given in ► Fig. 19.8. Heavy nuclei recoil from the rotating target into the dipole magnet where they are separated

■ Fig. 19.8

Layout of the Dubna gas-filled recoil separator (DGFRS) with target wheel, dipole magnet, and detector station (Oganessian 2007). A schematic view of the detector system is displayed in the upper part of the figure

from the projectile beam. The separated nuclei are focused by a magnetic quadrupole doublet onto the detector system, displayed in the upper part of the figure. In a gaseous medium, fast-moving ions approach an equilibrium charge expressed usually by the Bohr formula

$$q = \frac{v}{v_0} Z^{1/3} \quad (19.2)$$

where v_0 is the Bohr velocity.

Since the deflection in a magnetic field, $B\rho$, is determined by the momentum to ionic charge ratio $B\rho = mv/q$, the magnetic rigidity of a ion traveling in the filling gas (Oganessian et al. 2007) is

$$B\rho = \frac{0.027A}{Z^{1/3}} \quad (19.3)$$

As A/Z is roughly constant, the separation is proportional to $A^{2/3}$. The deflection of the ions passing the gas-filled separator is independent of velocity and the ionic charge state. Therefore, transmission is high and provides a great advantage for reactions with light projectiles where the relative velocity spread and charge distribution of the ions emerging from the solid target are broad. However, due to scattering in the gas the beam spot is large and the separation poor. Hence, although the resolution is sufficient to achieve an efficient suppression of the projectile

beam, it is not sufficient to discriminate between the SHE created by complete fusion and the products of incomplete fusion or transfer products. The separation can only be achieved with a kinematic separator such as SHIP. Using the combination of both separation methods for the same reaction, a cross section measured with a gas-filled separator when compared to the cross section measured at SHIP for instance, provides a clear proof of complete fusion with the emission of only neutrons or protons. Proton emission cannot be excluded, though the recoil from an emitted proton is too small to drive the recoil out of the velocity window.

19.3.3 Working with Single Atoms

All transactinide elements are identified by their decay properties. An unambiguous method is the parent–daughter α – α correlation. It relies on the identification of an unknown species by its known daughter decays. This method, which has been originally developed in connection with the helium jet gas transport system (Ghiorso et al. 1974), allows extending the nuclear table safely in a stepwise manner. At SHIP the parent–daughter correlation technique has been developed to the highest possible sensitivity: the identification of new isotopes or even elements by single-atom decay chains. The implantation of the energetic recoils into a position-sensitive silicon detector allows the observation of a detailed decay history for each single nucleus over hours or even days, *in situ*. This is possible as all the decay events are localized once the parent atom is stuck to a well-defined position in the detector (Hofmann et al. 1984). The decays originating from an individual mother nucleus are observed at that very position of implantation and can be traced over all generations until the chain is terminated by long-lived daughters, spontaneous fission, or β decay the last of which is not visible in the silicon stop detectors.

The detector arrangement as developed at SHIP (Hofmann and Münzenberg 2000) is similar to all recoil separators used at present for SHE research. As an example see the upper part of  Fig. 19.8. The silicon box with the position-sensitive implantation detector at the back allows for the efficient detection of α decay and fission. The side detectors detect α particles and fission fragments escaping from the implantation detector into the backward hemisphere. This is possible as the heavy nuclei are stopped close to the surface of the silicon chip. With this Si-detector box open in front, it is possible to achieve near 4π geometry (Hofmann et al. 1995a). Thin carbon foil secondary-electron detectors allow for time-of-flight (TOF) measurements, which give approximate information on the recoil mass in combination with the energy signal from the implantation of the SHE into the silicon detector. The TOF detectors simultaneously work in anticoincidence to the implantation array to discriminate between beam particles and decays. In recent experiments the projectile beam is switched off after the implantation of a possible SHE has been detected. This makes it possible to obtain clean decay sequences not contaminated by scattered particles of low energy. Optionally, the system may be complemented by X- and γ -ray detectors.

Meitnerium is an example of the identification of a new element by the decay of only one single atom (Münzenberg et al. 1982, 1984a).  Figure 19.9 displays the discovery chain together with the mass spectrum from the measurement of TOF and implantation energy, the resolution of which is limited by the large pulse-height defect of the slow, large Z -ions implanted into the Si detector. To check the reliability of the experimental results, careful investigations of background, Poisson statistics of the decay sequences, and background and consistency tests of the observed decay properties with theoretical predictions are necessary.

■ Fig. 19.9

The discovery chain of meitnerium (left panel) with the mass spectrum (right panel, Münzenberg et al. 1982)

The general problem is however, that superheavy nuclei are the very definition of “terra incognita” being as they are at the frontiers of the chart of nuclides with unknown properties. Therefore, all such evidence is of limited value for the identification of a new element and while necessary, it is not sufficient to make a conclusive determination according to the rules of IUPAC as elaborated by the transfermium working group (Barber et al. 1992).

19.3.4 Statistics of Single-Atom Chains

The identification of a new element from a correlated single-atom chain requires statistical analysis done in two steps (Münzenberg et al. 1984a). In the first step, the *statistical significance* of the correlation in each decay step must be established. It is determined by the observed time interval t , the background rate r , and the number of leading signals n , observed during the entire experiment. The leading signal is the most relevant event in the sequence, e.g., the decay of the mother nucleus. The error probability

$$p = nrt \quad (19.4)$$

should be below 10^{-3} or 3σ .

The second step is the *assignment* of each decay step to the known daughter nuclides. For full-energy α decays, the observed decay energy including calibration precision and detector resolution is compared to the known decay energy of the corresponding daughter nuclides. The measured time interval t permits a comparison with the known mean life (see remark (#31) in ► Chap. 9, Vol. 1) (as obtained from the half-life $\tau = 1/\lambda = T_{1/2}/\ln 2$) using the exponential probability density function

$$f(t) = \lambda e^{-\lambda t} = \frac{e^{-t/\tau}}{\tau} \quad (19.5)$$

With this method, all possible assignments can be checked to select the most probable one. It also allows for a compatibility test of measured time intervals assigned to the same transition

■ Fig. 19.10

Decay curve for $^{261}\text{106}$ in logarithmic bins. The histograms show the daughter decays from $^{265}\text{108}$ (hatched) in comparison to the decays from the directly produced $^{261}\text{106}$ (Münzenberg 1988)

to check, for instance, data from different experiments. The half-life estimate is made by the maximum likelihood method. The error is given by Poisson Statistics (see ▶ Sect. 9.4.3 in Chap. 9, Vol. 1) (Schmidt et al. 1984). To test the random distribution of the measured time interval distributions it is convenient to transform the decay curve into a function peaked at the average lifetime (mean life, τ) by a logarithmic binning of the measured time intervals (Schmidt et al. 1984). ▶ Figure 19.10 shows this transformation for the daughter decays of $^{261}\text{106}$ observed in the $^{265}\text{108}$ decay chains in comparison to the directly produced $^{261}\text{106}$. The curve is asymmetric and peaks at the average lifetime. (See also ▶ remark (#33) in Chap. 9, Vol. 1.) This probability distribution also holds for one single decay for which the error amounts to about one order of magnitude for a two σ confidence level (Münzenberg 1988).

19.4 Nuclear Structure of the Transactinide Nuclides

19.4.1 Superheavy Elements: The Limits of Stability

The existence of heavy and superheavy elements is limited by their stability against fission, which finally terminates the chart of nuclides and limits the number of the chemical elements. In the macroscopic description, the limit of stability for heavy nuclei beyond uranium is determined by the balance between the cohesive nuclear force and the disruptive Coulomb force. The stability against fission is described by the fissility parameter x , which is the ratio between Coulomb energy and surface energy of the charged nuclear droplet, normalized to the critical fissility beyond which nuclei promptly disintegrate (Myers and Swiatecki 1966)

(See also ► Sect. 4.3.3 in Chap. 4, Vol. 1, discussing in detail the (un-normalized) fissility parameter Z^2/A):

$$x = \frac{Z^2/A}{(Z^2/A)_{\text{crit}}} \quad (19.6)$$

with

$$(Z^2/A)_{\text{crit}} = 50.883 \left[1 - 1.7826 \left(\frac{N-Z}{A} \right)^2 \right]. \quad (19.7)$$

In ► Fig. 19.11 the partial fission half-lives of the doubly even isotopes of uranium and beyond are plotted on a logarithmic time scale versus the fissility parameter. In accordance with the expectation from the liquid drop model the dashed line labeled B_{LD} , describing the fission half-life calculated with only the liquid drop barrier B_{LD} , crosses the T_e line at nobelium. The time T_e is needed for the formation of the electron shell of the atom, the lower time limit considered beyond which a chemical element cannot be formed (Barber et al. 1992). The experimental half-lives follow this general trend. They decrease from uranium to nobelium over more than 20 orders of magnitude, from the age of the solar system down to fractions of seconds. The structure of the isotopic chains of elements from curium to nobelium is caused by a subshell closure at $N = 152$.

A change in the half-life systematics occurs at rutherfordium. Fission half-lives become independent of the fissility parameter and stay almost constant. A comparison of the data to the calculated liquid-drop half-lives shows an enhancement of the fission half-lives by about 15 orders of magnitude. This stabilization is caused by a new shell at hassium.

■ Fig. 19.11

Partial fission half-lives of the even-even isotopes of the transuranium elements (dots) compared to the fission half-lives as calculated from a macroscopic model. The dashed lines and the labels are explained in the text after ► Eq. (19.7)

19.4.2 Alpha-Decay Properties and the New Shell Region Around Hassium

The stabilization against fission in the transactinide region makes α decay the dominating decay mode and enables us to extract basic information on the structure of the elements at the top of the chart of nuclei. Dealing with only a few atoms this information is rather scarce and needs support from theory to get some more detailed understanding of the underlying physics. Obviously the decay mode, half-life, and Q_α are the most important pieces of information about the stability and the physical nature of these nuclides. Naturally, structure information is available in greater detail for the lighter transactinide nuclei where fine structure in the α -decay spectra (Hessberger et al. 1997, 2009) and γ transitions have been measured. This information then can be used to help predict the structure of heavier nuclei by investigating their isotones or using appropriate theoretical calculations. Shells in the heaviest nuclei are large and they carry high angular momenta. The level densities are high. As a consequence, high-spin and low-spin states are close together and isomers are observed. Internal conversion has been observed in the light transactinides where statistics for the decay spectra are sufficiently high. As the mother nuclei are implanted in the Si-detector, summing with conversion electrons shifts the measured α -decay energy. An example is the first 2^+ state in ^{256}Rf . An α transition into the 2^+ level is strongly influenced by energy summing with conversion electrons (Hessberger et al. 2009) where the α lines are shifted or show tails.

The Q_α systematics for even- Z transuranium elements (including both even- N and odd- N isotopes) is displayed in [Fig. 19.12](#). The experimental data are compared to

Fig. 19.12

Q_α systematics for the even Z transuranium elements. *Dotted line: theory (Muntian et al. 2003a, b).* Note that very few observations exist for even-even superheavy element (SHE)

predictions with the macroscopic–microscopic model (Muntian et al. 2003a, b). In general, the observations agree well with predictions, including the data from Dubna. Data and calculations show a small shell effect for $N = 152$. Beyond $N = 156$ the Q_α values decrease toward the neutron-rich isotopes, a characteristic associated with the enhancement of stability. The calculations (solid lines) predict a shell closure at $N = 162$, which is reflected in the experimental Q values. The effect of shell closure is also reflected in the half-lives. The nuclide ^{270}Hs , located at the double shell closure has a half-life as long as 23 s (Dvorak et al. 2006).

Detailed spectroscopic data are still scarce. As an example, the ground-state deformation has been derived from spectroscopy for the nucleus ^{256}Rf . It has been obtained from the α decay of ^{260}Sg to a 2^+ rotational level of this nucleus. The quadrupole deformation is $\varepsilon = 0.28$ close to $\varepsilon = 0.25$ following the trend of the actinides and as predicted by theory (Münzenberg 1989a). The investigation of K -Isomers in ^{254}No probes single-particle energies and pairing strengths including the energies of the proton levels that govern the stability of SHE (Tandel et al. 2006). Experimental data favor $Z = 114$ as a SHE-magic proton number. More detailed experimental investigations on the structure of transactinide elements have been undertaken (Hofmann and Münzenberg 2000; Hofmann et al. 2001, 2002; Hessberger et al. 1997, 2009).

19.4.3 Shells and Fission Barriers

A universal definition of nuclear shells including deformed nuclei was given by Strutinsky (1967). He defined a shell as a large-scale nonuniformity in the distribution of the single-particle states. From this definition, shells may be expected for any nuclear shape. The nonuniformity in the level spacing creates the required shell correction to an appropriately chosen average, the liquid drop. The shell correction energy is closely connected to the density fluctuations of the single-particle states near the Fermi surface as calculated with a realistic model. This new concept allowed calculating the deformation energy of a nucleus on its way to fission and fission barriers while including shell effects. In this macroscopic–microscopic picture, the mass of a nucleus is represented as

$$M = M_{\text{LD}} + \delta M + P \quad (19.8)$$

where M_{LD} is the liquid drop mass, δM the shell correction, and P the pairing correction.

By using the macroscopic–microscopic model, shell correction energies can be extracted from the experimental mass M and a macroscopic (spherical) mass M_{LD} taken from a theoretical model. The shell correction is negative and it stabilizes the nucleus:

$$E_{\text{SH}} = (\delta M + P)c^2. \quad (19.9)$$

The ground state masses are taken from the Q_α values. For doubly even isotopes, α decays are expected to be ground state transitions.  Figure 19.13 shows the experimental shell effects for the $N - Z = 48$ nuclides from uranium to element 108 obtained with the macroscopic mass taken from the finite-range droplet model (Möller and Nix 1988, 1994). The experimental shell correction energies increase from 2 MeV for ^{232}U to more than 6 MeV for $^{264}108$. This is about half the shell strength of the most strongly bound doubly magic nucleus ^{208}Pb . Microscopic calculations (Cwiok et al. 1983; Patyk and Sobizcewski 1991; Möller and Nix 1988, 1994) reproduce the experimental data sufficiently well.

■ Fig. 19.13

Upper panel: Experimental shell correction energies (E_{SH}) for even–even nuclides characterized by the difference $N-Z = 48$ compared to current theoretical predictions. **Lower panel:** Experimental and calculated fission barriers for the same nuclides. The dashed line displays the macroscopic fission barrier as explained after ► Eq. (19.10)

In close analogy, an estimate of an experimental fission barrier can be obtained by superimposing the shell correction energy and the liquid drop barrier B_{LD} :

$$B_{\text{F}} = B_{\text{LD}} + E_{\text{SH}}. \quad (19.10)$$

B_{LD} , shown in the lower panel of ► Fig. 19.13 displays the experimental barriers obtained with a liquid drop barrier taken from systematics (Dahlinger et al. 1982). They remain practically constant between 6 and 7 MeV from uranium to hassium and are in reasonable agreement with theory (dashed line, Sobiczewski et al. 1987). Near rutherfordium, the macroscopic contribution to the barrier falls below 0.5 MeV, the calculated zero-point energy, and becomes practically ineffective. The dramatic decrease of the partial fission half-lives from 10^{25} s for uranium to 10^{-3} s for the transactinides despite a constant height of the barrier can be attributed to the small width characteristic of shell-stabilized barriers (Münzenberg et al. 1988). The barrier width can be estimated from the partial fission half-life and the barrier height with a parabolic approximation for the barrier:

$$T_{1/2} = \left[1 + e^{\frac{2\pi B_{\text{F}}}{\hbar\omega_{\text{f}}}} \right] \frac{\ln 2}{n}. \quad (19.11)$$

■ Fig. 19.14

Barrier curvature parameter. *Dots:* experimental data; *crosses:* curvature of the inner barrier; *line:* calculated curvature of the liquid drop barrier; *inserts:* representative barrier shapes for an actinide and a transactinide nucleus

Here $\hbar\omega_f$ is the barrier curvature parameter and n the number of barrier assaults, $n = 2.5 \times 10^{20} \text{ s}^{-1}$. Figure 19.14 shows the experimental barrier curvatures plotted against the fissility parameter. The liquid drop barrier (Nix 1967) is indicated as a line. The actinides show weakly curved thick liquid-drop dominated barriers with a curvature of 0.5 MeV. The transactinide barriers have curvatures close to 1 MeV, compatible with the curvature of the inner barrier measured for the light actinides (Bjornholm and Lynn 1980).

For illustration, the two insets show examples of a typical actinide and transactinide barriers. The actinides exhibit broad and double-humped barriers, dominated by the thick liquid drop barrier. For the transactinides, because of the vanishing liquid drop barrier, the outer hump sitting on top of the liquid drop barrier falls below the ground state. The remaining inner hump of the barrier creates the typical single-humped, thin barrier of shell-stabilized nuclei.

19.4.4 Theoretical Predictions

Superheavy elements mark the limit of nuclear mass and charge. Specific features are the large nuclear shells that carry large angular momenta and the large Coulomb force. The high number of protons creates a large electrostatic repulsion. SHEs are the biggest nuclear objects available and are therefore expected to have a complicated structure. Some developments are reviewed by Heenen and Nazarewicz (2002). Present theoretical models concentrate on mean-field

concepts. Theory suggests that the enhanced stability of the deformed nuclei near hassium and $N = 162$ may be due to a hexadecapole deformation in the ground state (Cwiok et al. 1983; Möller et al. 1986; Sobiczewski et al. 1987). Such nuclei are shaped like a barrel.

This discovery of a new region of enhanced stability interconnecting the transuranium elements and the spherical superheavies has dramatic consequences for the production of heavy and superheavy elements. It opened the door to the nuclei around the spherical shell closure at or beyond $Z = 114$ and $N = 184$, which can be approached stepwise starting with the transuranium elements. It is not necessary to jump across the “sea of instability” as was expected from the earlier predictions. The long half-lives of the neutron-rich isotopes allow for chemical studies and open up a new field of investigation with ion and atom traps. The macroscopic–microscopic method includes nuclear deformation and nicely reproduces the deformed region whereas most of the early self-consistent models only calculate spherical nuclei and are best suited to predicting the location of the spherical superheavy shell closure (Cwiok et al. 1996; Smolanczuk 1997; Bender et al. 1999; Kruppa et al. 2000).

➤ **Figure 19.15** displays the contour map of fission barriers from a macroscopic–microscopic calculation (Möller et al. 2009) for the region from the last stable spherical double shell closure at ^{208}Pb to the predicted superheavy elements. The colors give the height of the fission barrier. Orange corresponds to a barrier height of 7 MeV, red to 8 MeV or higher. The spherical superheavy nuclei at $Z = 114$ and $N = 184$ have fission barriers of 8 MeV or higher. It is interesting to note that the spherical shell region around $Z = 114$ is quite extended. High fission barriers cover the region up to $Z = 120$ and the region from $N = 170$ to $N = 184$. The deformed-shell nuclei around $Z = 108$ and $N = 162$ have fission barriers of 7 MeV in good agreement with experiment (➤ **Fig. 19.13**) and interconnect the transfermium region and the region of spherical SHEs (Möller and Nix 1988; Smolanczuk 1997; Muntian et al. 2003a, b).

A study of the superheavy region with self-consistent mean field models (employing mean field and Skyrme–Hartree–Fock approaches) yields different results for predicted regions of stability. ➤ **Figure 19.16** displays the single-particle spectra for neutrons and protons (Bender et al. 2001) for ^{132}Sn , the superheavy nucleus $^{310}126$, and the hyperheavy nucleus $^{472}164$. They exhibit a significant difference in the nature of the shells of doubly magic tin (where proton and

■ Fig. 19.16

Single-particle spectra for protons (left panels) and neutrons (right panels) at spherical shape for different mean-field forces. The small diagrams at the bottom of the right panel show the predicted radial neutron distributions. (Bender et al. 2001)

neutron shells are well pronounced) and of the superheavy element $Z = 126$ (where a region of low-level density between $Z = 114$ and $Z = 126$ creates the enhanced stability). Depending on the parameterization of the interaction and the method – Skyrme–Hartree–Fock (SKP, Sly6, SKI4, SKI3) or relativistic mean field (NL-Z2 and NL3) – the shell gap appears at $Z = 114$, $Z = 120$ or $Z = 126$. Nonrelativistic microscopic models such as the Skyrme–Hartree–Fock–Bogoliubov method (Cwiok et al. 1999), where the spin–orbit term so crucial to the prediction of shell closures has to be manually introduced into the calculation, predict that both $Z = 120$

and $Z = 114$ are equally probable. This indicates that magic shells in the SHE region are strongly isotope dependent (Greiner 1995; Rutz et al. 1997).

The neutron shell is located at $N = 184$ for all predictions. The situation for the hyperheavy nucleus $Z = 164$ is similar. Comprehensive microscopic calculations based on relativistic mean field (RMF) theory (NL3) using the double folding and WKB approximations in an internally consistent manner over the observed SHE region (Gambhir et al. 2005) have suggested an additional but weaker shell closure around $N \approx 164$ corresponding to $Z = 108$ – 110 and also around $N \approx 172$. This effect is clearly seen where neutron pairing energies go to zero (► Fig. 19.17, Gambhir et al. 2005). There is some support for these calculations in the observed decay chains from $^{277}_{112}\text{GSI}$ and $^{287,288}_{115}\text{Dubna}$ that traverse this region. The spread in theoretical estimates of closure underscore the fact that predictions remain strongly isotope dependent, i.e., a function of both N and Z . A recent theoretical extrapolation of the experimental data concludes that the position of the proton shell closure lies beyond $Z = 120$ (Adamian et al. 2009). One explanation for the less-pronounced SHE shell gap when compared to the magnitude of closure at $N = 126$ for instance, is the higher-level density prevalent in the large proton and neutron shells. Moreover, according to the calculations, superheavy nuclei have enhanced proton and neutron densities near the nuclear surface, created by the high-spin orbits (as indicated in the lower right panel of ► Fig. 19.16, bottom line). This affects the spin–orbit splitting and hence the location and strength of the shells. Macroscopic–microscopic models tend to overestimate the splitting of levels since the spin–orbit interaction has to be put in by hand. This may affect the location and extent of predicted closures. While RMF theories may do better in this regard, given the high-level densities, SHEs serve as a sensitive probe to distinguish between the various predictions, especially when all models describe stable nuclei with comparable accuracy (Gambhir et al. 2005).

► Fig. 19.17

Neutron pairing energies using relativistic mean field (RMF) calculations (NL3) for even–even nuclei in the region $108 \leq Z \leq 118$ (Gambhir et al. 2005)

■ Fig. 19.18

Maps of shell correction energies obtained from self-consistent calculations plotted versus proton and neutron number. The darker the shading, the larger is the shell correction. The scale of E_{SH} (upper right figure) is in MeV (Bender et al. 2001)

Some results from self-consistent RMF calculations are compiled in Fig. 19.18. The region of superheavy nuclei is centered around $Z = 120$ and $N = 184$ and rather extended in Z . Only for NL3 and NL3+2 is the proton number $Z = 114$ well pronounced. The calculations suggest a diffused region of superheavy nuclei, which is caused by a low-level density in the proton levels around $Z = 112$ rather than a sharp level gap as known for ^{208}Pb . This may be due to the fact that it is difficult to create a pronounced gap in the proton shell with its relatively large spread of levels as shown in Fig. 19.16. Half-life estimates range from 1 year for ^{270}Hs at the center of the deformed region and 10^6 year for ^{292}Hs , at the closed neutron shell $N = 184$ (Smolanczuk 1997) down to 1 h for ^{270}Hs and 100 year for ^{292}Hs (Hofmann and Münzenberg 2000).

19.5 Production of the Transactinide Elements

19.5.1 Fusion of Massive Nuclear Systems

The only successful method to synthesize transactinide elements is through the complete fusion of heavy ions (Schmidt and Morawek 1991; Vandenbosch 1992; Reisdorf 1994). Two types of reactions have been employed to create new chemical elements: cold fusion with ^{208}Pb or ^{209}Bi targets and hot fusion with ^{48}Ca projectiles (Fig. 19.19). The success of reactions involving doubly magic nuclei has been explained in the framework of the fragmentation model (Sandulescu et al. 1976).

To start the fusion process, the projectile needs sufficient kinetic energy to overcome the Coulomb repulsion between target and projectile. In a simple model fusion starts at the touching point of the spherical target–projectile configuration, the conventional Coulomb barrier, when the nuclear forces become effective and drive the dinuclear system (DNS) toward a mononucleus. For the creation of superheavy nuclear systems, the minimum kinetic energy of the projectile exceeds the Q -value needed for the formation of the compound system. The compound nucleus is created above its ground state. To reach the ground state, the excitation

■ Fig. 19.19

Experimental production cross sections of heavy and superheavy nuclei for 1n emission (*filled squares*) and ^{48}Ca (*open squares*) induced reactions; the solid lines indicate fits to the data

energy is dissipated by particle-evaporation, generally neutrons, and γ emission. Charged-particle emission is strongly suppressed because of the high Coulomb barrier and the relatively small excitation energy. For these heavy, fissile nuclei the de-excitation process is dominated by fission, which becomes of increasing importance toward the upper end of the periodic table. As the collision is not central in general, the compound nucleus has an angular momentum. Nuclei with an angular momentum above a critical value will not survive but fission.

The fusion–evaporation reaction is a two-step process. The production cross section is determined by the fusion and the de-excitation of the intermediate (compound) nucleus:

$$\sigma = \sigma_{\text{fus}}(E_p - E_B, l) w_x(E^*, l). \quad (19.12)$$

The fusion cross section σ_{fus} depends on the projectile energy E_p , the height of the fusion barrier E_B , and the angular momentum l of the system. The survival probability w_x of the compound nucleus is determined by the excitation energy E^* , which yields the number of evaporated neutrons x . For each step of neutron evaporation there is a strong competition between neutron evaporation and fission given by the ratio of neutron to fission width Γ_n/Γ_f . It is of the order of 10^{-2} to 10^{-3} . The geometric fusion cross section is

$$\sigma_{\text{fus}} = \pi \lambda^2 - \sum_{l=0}^{l_{\text{lim}}} (2l+1) T_l(E_p - E_B), \quad (19.13)$$

where $\lambda = 2\pi\lambda$ is the de Broglie wavelength of the dinuclear system and T_l is the transmission of the l th partial wave through the fusion barrier. The limiting angular momentum l_{lim} of the compound system up to which the partial waves contribute to the fusion cross section can

■ Fig. 19.20

Rotational levels populated in the production of nobelium, measured with in-beam γ spectroscopy, converted transitions: *dashed lines* (Courtesy P. Reiter)

be obtained from the rotating liquid drop model (Cohen et al. 1974). (See Sect. 2.2.1, Chap. 2, Vol. 1 as well as Sect. 4.3, Chap. 4, Vol. 1 for a detailed explanation of the liquid drop model in general.) The limiting angular momentum for elements near fermium (Münzenberg et al. 1981c) is below $15\hbar$ according to this model. Recent in-beam γ measurements with the new recoil–decay–tagging technique for ^{48}Ca on ^{208}Pb to produce ^{254}No show however that the rotational band is populated up to $20\hbar$ (Fig. 19.20, Reiter et al. 2000).

19.5.2 Experiment

The first transuranium elements were produced from actinide targets such as ^{248}Cm , ^{249}Bk , and ^{249}Cf (bred in high flux nuclear reactors) by irradiating them with beams of neutron-rich light ions of ^{15}N or ^{18}O . The idea was to start with a target close in mass to the final nucleus and use

a light projectile. There was a strong physics argument for this procedure. To create a compound nucleus, the dinuclear system must pass the fission barrier. The distance from the point of nuclear contact to the mononuclear system inside the barrier is much closer for asymmetric systems (when a small-sized projectile is added to the heavy target) than for symmetric systems combining two nuclei of similar radii.

The disadvantage is that the compound nuclei are produced at high excitation energy and have to evaporate four to five neutrons, which dramatically reduces their survival probability. The use of ^{208}Pb or its neighbor ^{209}Bi in combination with neutron-rich beams of ^{54}Cr , ^{58}Fe , $^{62,64}\text{Ni}$, and ^{70}Zn profits from the strongly bound doubly magic nucleus and the higher symmetry of target and projectile allowing the formation of “cold” compound systems with excitation energies of 10 to 20 MeV at the Coulomb barrier. Only one or two steps of fission–evaporation competition are necessary to dissipate the excitation energy. In this way, a high survival probability is expected even for the most heavy and fissile nuclei at the upper end of the periodic table (Oganessian 1974). In contrast, compound systems created using the actinides are formed with excitation energies of typically 40 to 50 MeV.

The production cross sections of cold heavy-ion fusion by 1n evaporation, and ^{48}Ca -induced reactions in 3n evaporation channels are displayed in [Fig. 19.19](#) and [Table 19.1](#). The cross sections for cold fusion drop steeply from the order of 1 μb for nobelium to 0.03 pb for element 113, which is more than six orders of magnitude. The ^{48}Ca data do not follow this trend. They stay constant around 1 pb from copernicium to element 118.

To explain the small cross sections for SHE synthesis and in particular the fast decrease of the cold fusion cross sections, the concept of “extra push” has been developed. In this model, the barrier for complete fusion is shifted dynamically above the Coulomb barrier until the experimental cross section is reproduced (Hessberger et al. 1985). The barrier shift is explained (in terms of a macroscopic approach) as a result of dynamical hindrance of the nuclei on their way to fusion (Swiatecki 1982; Armbruster 1989). However, for the transactinide elements known to exist only due to shell effects, the application of a macroscopic model to explain all structure effects related to their production is questionable if not wrong (Münzenberg 1988). In contrast to the extra push concept, experiment shows that the maximum of the excitation function shifts toward a smaller excitation energy for heavier systems, with ^{278}Cn being the coldest compound nucleus ever produced at an excitation energy of only 10 MeV (Hofmann et al. 1996).

Up to now, there is no fundamental theoretical approach to *quantitatively* explain the fusion of heavy systems in terms of a microscopic theory. The first attempt in that direction is the fragmentation model, a two-center microscopic calculation predicting the most favorable target–projectile combinations employing magic nuclei (Sandulescu et al. 1976). Recently calculations that are more refined have been carried out taking into account microscopic effects. The diffusion model uses a microscopic–macroscopic approach with temperature dependent shell corrections to create a fusion pocket the depth of which is determined by the excitation energy of the system on its way to fusion (Arimoto et al. 1999). The dinuclear system (DNS) concept assumes that complete fusion is achieved by transferring the nucleons shell by shell to the other one. Due to their shell structure, the nuclei keep their individuality all the way toward the formation of the compound nucleus (Cherepanov 1999).

[Figure 19.21](#) illustrates the possible trajectories of collective motion on the potential-energy surface for the fusion of ^{70}Zn with ^{208}Pb to create element 112, and for ^{48}Ca on ^{248}Cm to produce element 116 (Zagrebaev et al. 2003). For the cold fusion example, ^{70}Zn on ^{208}Pb , the system has to move a long distance from the contact point to the compact shape of the

■ Fig. 19.21

Trajectories of collective motion in the potential energy surface for the reactions $^{70}\text{Zn} + ^{208}\text{Pb}$ (left panel) and $^{48}\text{Ca} + ^{248}\text{Cm}$ (right panel) in dependence on the symmetry coordinate of target and projectile and the elongation (Courtesy V. Zagrebaev)

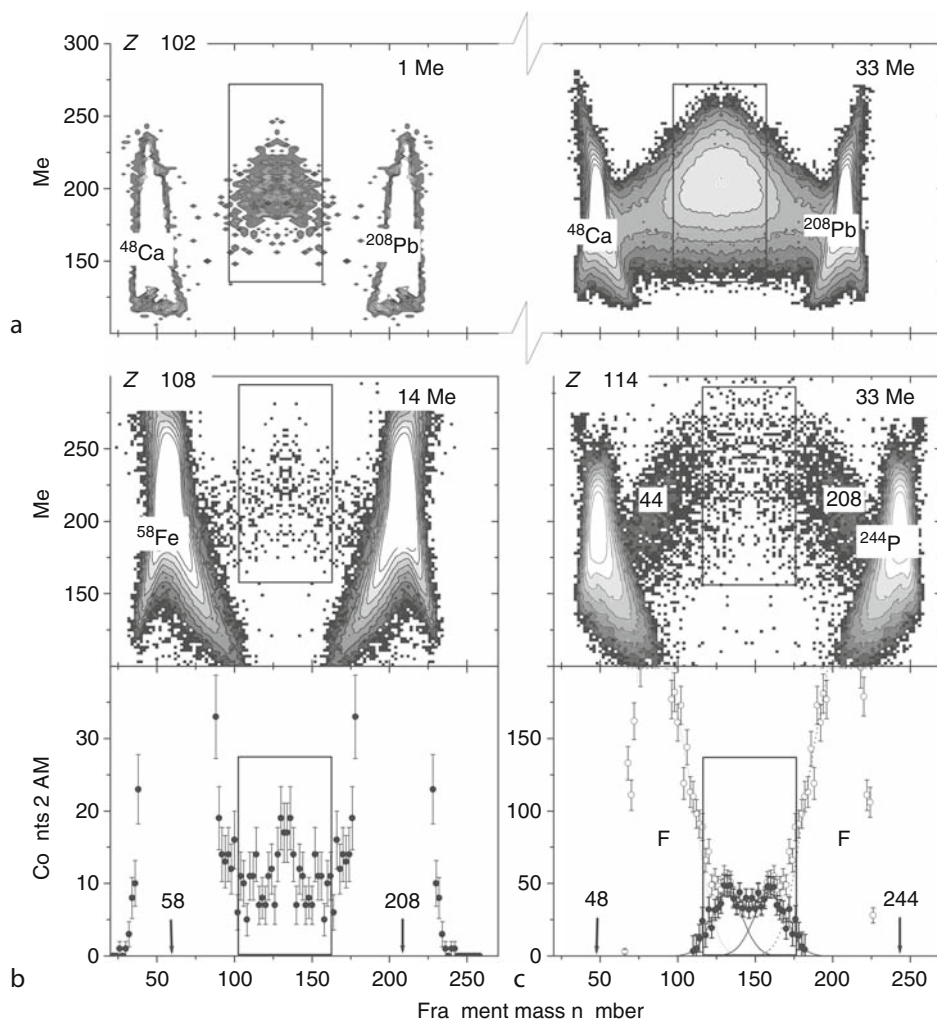

compound nucleus (CN) passing two barriers. Since deep inelastic collisions (DIC) and fast fission (FF) are much more likely, the resulting fusion cross section is small. For the fusion of ^{48}Ca with ^{248}Cm the contact point is much closer to the compound shape. Though only one small barrier has to be passed, quasi fission (QF) and fast fission are competing and the fusion cross section will be higher as with the more symmetric case of cold fusion. The calculations suggest that the fusion of an asymmetric system is favored (Oganessian 2007).

Experimental studies to investigate the fusion of massive systems (Oganessian et al. 2000) support these findings. ▶ Figure 19.22 shows the measured fragment distribution in mass

■ Fig. 19.22

Experimental fission fragment distributions for the production of $Z = 102$ and $Z = 108$ in cold fusion, and $Z = 114$ in hot fusion with a ^{48}Ca beam. In the upper panels the total kinetic energy (TKE) is plotted vs. the mass number of the fission fragment. In the lower panels the counts of the mass distributions of fission fragments are displayed (Oganessian 2001)

versus energy coordinates as a scatter plot for three reactions: $^{48}\text{Ca} + ^{208}\text{Pb}$, $^{58}\text{Fe} + ^{208}\text{Pb}$, and $^{48}\text{Ca} + ^{244}\text{Pu}$. Between the large asymmetric peaks, there is a symmetric component. From its energy and angular distribution, it has been concluded that it stems from compound fission (e.g., from the equilibrated mononucleus), and hence can be taken as a measure of the fusion cross section. For the light system $Z = 102$, formed in the reaction $^{48}\text{Ca} + ^{208}\text{Pb}$, a strong symmetric component is observed. It is well developed close to the fusion barrier (corresponding to an excitation energy of the compound system $E_x = 17.6$ MeV) and increases strongly with increasing energy. For $Z = 108$ fusion is also well pronounced. For $Z = 114$, some events can still be attributed to the fusion component though the fast-fission components have grown strongly. Experiment shows that in accordance with the fragmentation model there is some influence of shells in the entrance channel, either in the projectile or in the target, which serves to enhance the fusion probability (Münzenberg 1988; Schmidt and Morawek 1991).

The different behavior of the cross section systematics for cold fusion and ^{48}Ca reactions (► Fig. 19.19) is not understood in detail. The steep decrease of the cold fusion cross section is caused by the strong increase of the Coulomb forces in the entrance channel, with the entrance channel fissility scaling with the factor $(Z_p Z_t)$. It increases from 1,640 for calcium on lead to 2,460 for zinc on lead, by a factor of 1.5, whereas the entrance channel fissility for calcium-induced reactions varies from 1,840 for calcium on uranium to 1,960. For calcium on californium, it changes only by a factor of 1.06. Here the exit channel dominates. The shell structure of the compound system becomes important (Oganessian 2007).

The fissility of the compound system increases with Z^2/A very fast toward the upper end of the periodic table. The consequence is a strong competition between penetration probability through the fusion barrier and survival of the compound nucleus as shown by the calculation presented in ► Fig. 19.23 for the example of cold fusion to produce element 110. It leads to an

■ Fig. 19.23

Calculated quasi fission (dotted curve), fusion (dashed curve), and survival cross section of the compound nucleus (CN) (line) for $^{64}\text{Ni} + ^{208}\text{Pb}$. The resulting cross section for the 1n channel is given by the dash-dot line together with the data points from experiment (Giardina et al. 2000)

extremely narrow excitation function for the one-neutron evaporation channel of a width of about 5 MeV, which has also been observed in experiment (Hofmann and Münzenberg 2000; Giardina et al. 2000).  [Figure 19.23](#) also shows the large quasifission cross section of about 1 μb to be compared to a fusion cross section of 10^{-2} μb at the maximum of the 1n excitation function.

The survival probability P_{sur} of the compound nucleus after evaporation of x neutrons is

$$P_{\text{sur}} \approx \prod_{i=1}^n \frac{e^{B_f - B_n}}{T}, \quad (19.14)$$

It is dominated by the difference between the fission B_f and the neutron binding energy B_n of the compound nucleus. For heavy systems beyond $Z = 114$ the fission barrier increases while for very neutron-rich species the neutron binding energy decreases. Consequently, $(B_f - B_n)$ increases for compound systems $Z = 114$ to $Z = 118$ and the net effect results in the cross section remaining almost constant (Oganessian 2007). Recent calculations reproduce the SHE production cross sections in cold fusion as well as from the ^{48}Ca data fairly well (Zagrebayev et al. 2001; Zagrebayev 2001; Oganessian 2007).

19.5.3 Future Perspectives

 [Figure 19.19](#) shows that with the existing experimental capabilities the limit for cold fusion is reached at element 113. A promising way to proceed to the region beyond is through ^{48}Ca -induced reactions using hot fusion. The limit for hot fusion is reached with element 118 due to the unavailability of suitable targets. Since the heaviest target available for hot fusion is californium, to go beyond element 118 projectiles heavier than ^{48}Ca are needed. First attempts to produce element 120 with ^{64}Ni on ^{238}U (Hofmann et al. 2008) and ^{244}Pu on ^{58}Fe (Oganessian et al. 2009) were unsuccessful.

The fragmentation model predicts three paths to the production of superheavy elements (Sandulescu et al. 1976): cold heavy-ion fusion with lead and bismuth targets, fusion with actinides, and symmetric fusion or reversed fission. Presently only cold fusion has been explored systematically while hot actinide-based fusion has recently generated a wealth of data. The exploration of symmetric fusion with a high level of sensitivity is still missing given the argument that the fusion of such massive target–projectile combinations is unlikely because of the large Coulomb force expected in the entrance channel.

The magic proton number at $Z = 114$ has been arrived at and the synthesis of $Z = 118$ places within reach the other possible magic proton number at $Z = 120$. However, the question as to how the magic neutron number $N = 184$ can be reached remains unanswered. The reaction $^{82}\text{Se}(^{208}\text{Pb}, n)$ leads to the nuclide $^{289}116$ (not observed yet) with 173 neutrons, which is still more than 10 neutrons away from $N = 184$. The reaction $^{48}\text{Ca}(^{248}\text{Cm}, 4n)$ leads to the nuclide $^{292}116$ with only three more neutrons. Even $^{294}118$ with 176 neutrons is still far away from the magic $N = 184$. The most neutron-rich isotope reported to date is $^{293}116_{177}$, which is still 7 neutrons away. There are two possibilities for complete-fusion reactions to come closer to the $N = 184$ shell. In the first case, *overshooting the proton number* may be possible as this would automatically lead to more neutrons due to the increasing neutron excess for heavier projectile–target combinations. The magic region would then be crossed by a later generation of the α -decay chain. A nice example demonstrating this is the chain starting from ^{277}Cn passing by the center of the hexadecapole-stabilized region at hassium. The second possibility is presently

discussed in the context of new radioactive ion beam facilities, which provide energetic exotic nuclear beams (Münzenberg 1998; Hofmann 2001). New ways of SHE synthesis need to be explored including other reactions for fusion such as transfer or deep inelastic collisions (Zagrebaev and Greiner 2008).

19.6 New Experimental Developments and Prospects for SHE Research

In-flight separation is the most important tool for heavy-element research and has been successful in the discovery of new elements together with recently developed detection techniques. These methods have enabled the identification of new elements through a measurement of their gross nuclear properties from the decay of single atoms. Recent heavy-element research led to the discovery of deformed, shell-stabilized nuclei, creating a region of enhanced stability, which extends the nuclear chart to the magic proton number 114 and beyond up to element 118. Though great progress has been made, there is still no convincing evidence for the discovery of superheavy elements. The knowledge of the atomic and nuclear structure of the transactinide elements is still scarce. In-beam spectroscopy and decay spectroscopy with the new generation of X-ray and γ -detection systems of high efficiency will be certainly an important field of future research. The combination of recoil separators and ion traps will address interesting new physics with single atoms such as offering the possibility to make direct mass measurements with high precision and using laser spectroscopy to determine deformations or ionization potentials.

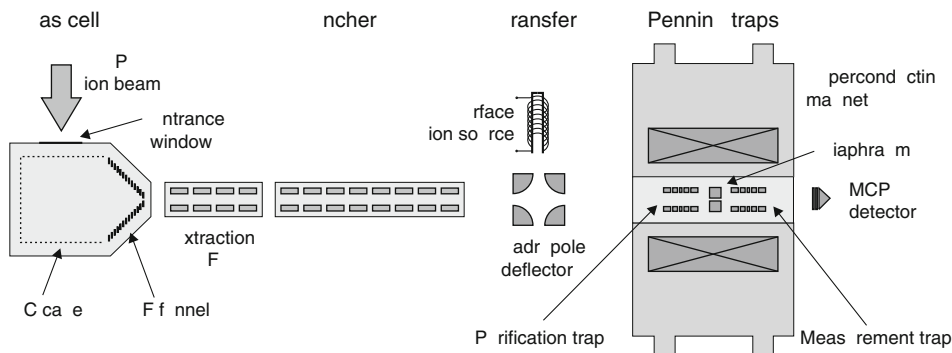

SHE chemistry at the picobarn level gives access to the elements 114 and heavier and is another important issue for future research. This would include addressing the important question of where the Mendeleev systematics will break down due to relativistic effects of the inner electrons of increasingly heavy, proton-rich nuclei. Pre-separation with gas-filled separators such as BGS at LBNL Berkeley, GARIS at RIKEN, or TASCA at GSI have been successfully applied in SHE chemistry experiments (Düllmann 2008).

Presently the only method applicable to identify a new chemical element according to the guidelines set down by IUPAC (Barber et al. 1992) is the α - α parent-daughter correlation method, which is not applicable for nuclides remotely removed from the known region where decay chains may terminate by fission in an unexplored mass region. Even chemical identification is not a safe method as the chemical properties of the new elements are difficult to predict (Schädel 2006). Plans to measure the mass of SHE directly with conventional methods such as online separation with a high resolving spectrometer are under way (Oganessian 2007). New facilities include time-of-flight mass spectrometers (TOF-MS, Plass et al. 2008) and ion traps such as SHIPTRAP (Block et al. 2007).  Figure 19.24 shows SHIPTRAP, an ion trap coupled to SHIP. The in-flight separated ions are injected into a buffer gas cell, stopped and thermalized in high purity helium gas at a pressure of about 50 mbar, and swept out by a supersonic gas jet. Then the ions are transported by a radio-frequency quadrupole (RFQ) ion guide to a cooler for accumulation, cooling, and bunching. Cooled beams have low emittance and are ideally used for high-resolution experiments such as Penning traps. SHIPTRAP has two traps. The first one is used for isobar separation, the second one for high-precision mass measurements. Recently the masses of the isotopes $^{252-254}\text{No}$ have been measured.

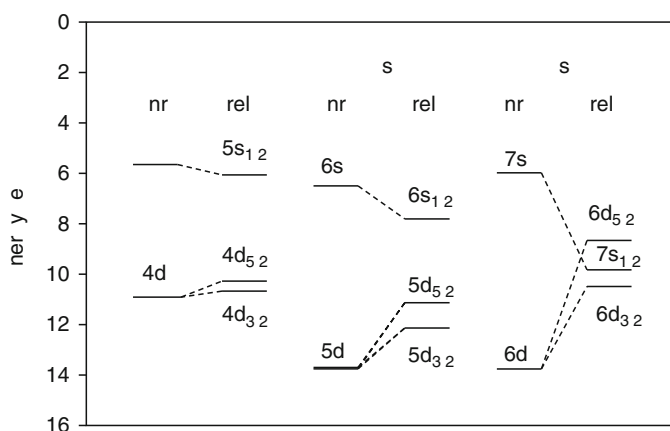

Optical spectroscopy is being considered for various nobelium isotopes (Backe et al. 2007). Here, investigations of the relativistic effects of the inner electrons of nuclei with large Z , which shift the optical levels and ionization potentials are of interest. Relativistic effects are already observed in gold as “nonrelativistic” gold would be white in color. For heavy elements with large

■ Fig. 19.24

SHIPTRAP: a schematic overview (Block et al. 2007)

■ Fig. 19.25

Relativistic and nonrelativistic energy levels of the valence ns and $(n - 1)d$ electrons for the group-8 elements (Pershina 2003)

proton numbers, the inner electrons move with relativistic velocity. The relativistic mass increase causes a shrinkage of the inner electron orbitals, the shielding of the nuclear charge increases and the outer electron orbitals are energetically destabilized and expand. ➤ Figure 19.25 shows the relativistic and nonrelativistic levels of the valence ns and $(n - 1)d$ electrons. It demonstrates the relativistic stabilization of the ns orbitals as well as the relativistic destabilization $(n - 1)d$ orbitals for group-8 elements. The trends of the relativistic and nonrelativistic energies of the valence electrons are opposite from the 5d to the 6d elements. The depression of the levels by relativistic effects increases from 5s to 6s and continues, so that the 7s for hassium falls below the 6d level. A fundamental query of chemical research question is to locate the point at which the dramatic influence of the relativistic effect on atomic levels will cause the breakdown of the Mendeleviev systematic (Pershina 2003).

Decay spectroscopy of the heavy elements with the new generation of highly efficient 4π γ -arrays will give detailed structure information to test and improve the nuclear models in that

region and may help to clarify the question for the location of the spherical proton and neutron shells. Highly sensitive in-beam spectroscopy, combined with recoil-decay tagging (Reiter et al. 1999) is extremely sensitive. It will allow in-beam spectroscopy below the microbarn level to extract ground state deformation and level structure information including for the excited levels of the compound nucleus. Nuclear spectroscopy of the transactinide elements will be an important component of future research (Hessberger et al. 2009).

The prerequisite for this new generation of experiments to investigate nuclear, atomic, and chemical properties of the heavy and superheavy elements as well as to proceed beyond $Z = 118$ are high-current accelerators that provide beam intensities of $5 \times 10^{14} \text{ s}^{-1}$. The use of radioactive beams is being explored. First-generation experiments of fusion–fission studies to estimate cross sections for SHE production and to explore new types of reactions should be started. New and upgraded rare-isotope facilities, FAIR-NUSTAR at GSI (Germany), SPIRAL II at GANIL (France), RIKEN (Japan) and its upgrade, MSU and its upgrade (Michigan, USA), as well as HIRFL (Lanzhou, China) are expected to provide beams of unstable neutron-rich nuclei with intensities up to 10^7 s^{-1} for existing laboratories and in excess of 10^{10} s^{-1} for projected facilities. Currently, the most promising way to produce new superheavy elements is through an intensity upgrade of stable beams (U. Ratzinger 2009, private communication; Yu. Ts. Oganessian 2009, private communication).

■ Fig. 19.26

Calculated partial fission and α half-lives for elements 108 and 114. Circles and squares mark experimental partial α half-lives. The limiting half-life for ^{286}Hs according to data from Dubna is indicated (Oganessian 2007)

Finally, the existence of SHEs in nature remains an open question. Experimental results and new calculations do not exclude the possibility that the very heavy elements can be found in nature (► Fig. 19.26). In contrast to numerous earlier searches that concentrated on long-lived nuclides expected to be seen around the magic proton number $Z = 114$, new calculations suggest a search for hassium or a lighter chemical element may be more productive. For these elements, the most stable species are expected with fission half-lives of the order of 10^5 to 10^6 years (Smolanczuk 1997) comparable to the half-life of ^{234}U . New investigations have already begun at Dubna (Oganessian 2007) with renewed interest.

Note added in proof

The experiment on the synthesis of element 117 has been finished successfully at Dubna. The discoveries of isotopes with masses 293 and 294 are reported.
Oganessian YuTs et al. (2010) Phys Rev Lett 104:142502

Abstract: In this chapter, the chemical properties of the man-made transactinide elements rutherfordium, Rf (element 104), dubnium, Db (element 105), seaborgium, Sg (element 106), bohrium, Bh (element 107), hassium, Hs (element 108), and copernicium, Cn (element 112) are reviewed, and prospects for chemical characterizations of even heavier elements are discussed. The experimental methods to perform rapid chemical separations on the time scale of seconds are presented and comments are given on the special situation with the transactinides where chemistry has to be studied with single atoms. It follows a description of theoretical predictions and selected experimental results on the chemistry of elements 104 through 108, and element 112.

20.1 Introduction

At present, 25 man-made transuranium elements are known. The first 11 artificial elements beyond uranium belong to the actinide series. Their chemistry is documented in a number of review articles and books (see, e.g., Seaborg and Loveland 1990; Seaborg 1993, 1995; Morss et al. 2006). According to the actinide concept (Seaborg 1945), the 5f series ends with lawrencium, Lr (element 103), and a new 6d transition series is predicted to begin with rutherfordium, Rf (element 104) (see, e.g., Fricke and Greiner 1969). Hence, the currently known transactinide elements 104 through 112 have been placed in the periodic table under their lighter homologs in the 5d series Hf, Ta, W, Re, Os, Ir, Pt, Au, and Hg. The first 7p element, element 113, eka-thallium, has been synthesized at RIKEN, Japan (Morita et al. 2004). Evidence for the syntheses of elements 112, 114, 115, 116, and 118 in ^{48}Ca -induced fusion reactions with actinide targets with partly mutually inconsistent results reported by the Dubna laboratory (Oganessian et al. 1999a, b, c, 2000, 2001, 2002, 2004a, b, c, d; Oganessian 2007) would mean that further 7p elements, eka-lead, eka-bismuth, eka-polonium, and eka-radon, have been synthesized. In one case, concerning the isotope $^{283}112$, the data obtained (Oganessian et al. 2004c, d) with the dubna gas-filled recoil separator (DGFRS) were reproduced at GSI, Darmstadt, with the velocity filter separator for heavy-ion products (SHIP) (Hofmann et al. 2007). The same decay pattern was measured in a chemistry experiment, where $^{283}112$ (i.e., ^{283}Cn) was produced through α decay of $^{287}114$ in the $^{48}\text{Ca} + ^{242}\text{Pu}$ reaction (Eichler et al. 2007a, b, 2008). Independent verification of $^{286}114$ and $^{287}114$ in the $^{242}\text{Pu}(^{48}\text{Ca}, 3\text{-}4\text{n})$ reaction was reported from Berkeley (Stavsetra et al. 2009).

The peculiar arrangement of the first five actinides in some representations (see, e.g., the cover of the textbook by Adloff and Guillaumont (1993)) of the periodic table in [Fig. 20.1](#) with a shifted position with respect to the other actinides reflects the fact that, due to a large delocalization of their 5f electron orbitals, the 5f electrons take part in their chemistry, a feature that is much less pronounced in the 4f series of the lanthanides. This makes Th a pseudo-homolog of the group-4 elements Zr and Hf, Pa a pseudo-homolog of Nb and Ta, and, to a decreasing extent, U, Np, and Pu, pseudo-homologs of the group-6, group-7, and group-8 elements, respectively. The more uniform actinide behavior is found only in the second half of the actinide series starting with Am.

Investigating the chemical properties of the transactinides is challenging both experimentally and theoretically. Due to increasingly strong relativistic effects, increasing deviations from the periodicity of the chemical properties based on linear extrapolations from the lighter homologs in the periodic table have been predicted for some time (Fricke and Greiner 1969). They result from the increasingly strong Coulomb field of the highly charged nucleus,

If rutherfordium (in this chapter, the element names endorsed in 1997 by the International Union of Pure and Applied Chemistry are used. Note that the names Kurchatovium (Ku) and

nielsbohrium (Ns) were used in some original publications of the Dubna group for elements 104 and 105. In publications by the Berkeley group and in earlier publications by the author, the name hahnium has been used for element 105.) exhibits chemical properties similar to those of zirconium and hafnium it should form volatile tetrachlorides. Thus, early experiments exploited the volatility of RfCl_4 in the gas-phase (Zvara et al. 1966, 1969; Chuburkov et al. 1969; Zvara et al. 1971a). In aqueous solutions, the complexing with α -hydroxyisobutyrate (α -HIB) (Silva et al. 1970) and the formation of chloride anions (Hulet et al. 1980) confirmed a behavior radically different from that of the heavy actinides. Although these were key experiments demonstrating that a new transition element series, the 6d series, begins with element 104, none of these experiments provided a detailed study of rutherfordium chemistry. First generation gas-phase experiments with chlorides (Zvara et al. 1974) and bromides (Zvara 1976; Zvara et al. 1976) of dubnium, element 105, indicated also for Db halides a much greater volatility than that of the respective actinide compounds. As the deposition temperature in such thermochromatography experiments depends on the migration time and the latter, in turn, strongly depends on the nuclear half-life, these experiments (Zvara et al. 1966, 1969; Chuburkov et al. 1969; Zvara et al. 1971a, b, 1974; Zvara 1976; Zvara et al. 1976) did not allow detailed comparisons of the volatility of rutherfordium and dubnium with the volatilities of their homologs. The respective correction technique based on a microscopic model of gas–solid interactions (Zvara 1985, 1990) in open columns was outlined later. It was systematically applied by Türlér (1996, 1999). The results from the first generation experiments on the chemistry of the transactinides were summarized by Keller and Seaborg (1977), Hulet (1981), Keller (1984) and Silva (1986).

A renewed interest in studying the chemical properties of the transactinide elements in more detail both experimentally and theoretically arose in the late 1980s, (see, e.g., Hoffman 1990, 1993, 1994; Kratz 1994, 1995; Schädel 1995; Kratz 1999; Schädel 2003; Kratz 2003a, b, c; Schädel 2006) for recent reviews. This extensive series of detailed investigations was made possible by the development of new experimental techniques such as computer-controlled automated systems that have greatly improved one's ability to perform rapidly and reproducibly large numbers of chromatographic separations on miniaturized columns in the liquid phase and to detect the transactinides through their characteristic α decay and preferably by $\alpha\alpha$ -mother-daughter correlations. Also, vastly improved techniques for gas-phase experiments coupled online to versatile detection systems for α -decay chains have been developed. Both techniques have produced detailed and sometimes surprising results that called for a detailed theoretical modeling of the chemical species with improved quantum-chemical codes.

In this chapter, the special conditions of the synthesis and decay of the transactinides are considered followed by some remarks about performing chemistry with only one atom at a time (referred to therefore as one-atom-at-a-time chemistry or single-atom chemistry). The experimental techniques are outlined, and a description of theoretical predictions and experimental results on the chemistry of Rf, Db, Sg, Bh, Hs, and Cn is given and mutually compared. Perspectives to go beyond 112 are also briefly discussed.

It should be noted that chemical studies of the transactinides have added a new dimension to heavy element research. While in the physics experiments, for example, in recent experiments using electromagnetic separators, the transactinides are implanted into a Si detector (see ► Fig. 19.6 in Chap. 19) and thereafter, their radioactive decay and decay properties are registered. In chemistry experiments, the transactinides are transferred into a chemistry apparatus, subsequently chemically manipulated and chemically characterized, before their radioactive decay is registered.

20.2 Synthesis and Decay of Transactinides

Transactinides are being synthesized in nuclear fusion reactions with heavy-ion projectiles. Details of the production and decay of the heaviest elements are discussed in a number of reviews (Armbruster 1985; Münzenberg 1995; Münzenberg and Hofmann 1999), see also ► Chap. 19 on “Production and Identification of Transactinide Elements.” The production rates rapidly decrease from about one atom per minute for element 104 to one atom per several days for the heaviest man-made elements. Half-lives decreasing from about 1 min to the order of magnitude of 1 ms for the longest lived isotope of these elements present an additional challenge, especially for chemical investigations. Low production rates and short half-lives lead to the situation in which, on the average, each synthesized atom has decayed before a new one is made. The consequences for chemical studies performed with one atom at a time are discussed in the next section.

Cold fusion reactions¹ in which ^{50}Ti , ^{54}Cr , ^{58}Fe , $^{62,64}\text{Ni}$, and ^{70}Zn projectiles are fused with ^{208}Pb and ^{209}Bi targets tend to give the highest cross sections, however, the neutron deficient product nuclei in these reactions have half-lives of mostly less than 1 s. This is too short for most existing chemical techniques, in particular for those which allow the study of detailed chemical properties. More neutron rich and, hence, longer-lived products are obtained in hot fusion reactions of ^{18}O , ^{22}Ne , ^{26}Mg , ^{34}S , and ^{48}Ca projectiles with actinide targets such as ^{238}U , $^{242,244}\text{Pu}$, ^{243}Am , ^{248}Cm , ^{249}Bk , and ^{249}Cf . Typical experimental conditions have been heavy-ion beam currents of 3×10^{12} particles per second, and target thicknesses on the order of $800 \mu\text{g}/\text{cm}^2$. Recent chemical studies of rutherfordium have used $78 \text{ s } ^{261\text{a}}\text{Rf}$ produced in the $^{248}\text{Cm}(^{18}\text{O},5\text{n})$ reaction with a cross section on the order of 10 nb. Recent studies of dubnium used $34 \text{ s } ^{262}\text{Db}$ and $27 \text{ s } ^{263}\text{Db}$ produced in 5n- and 4n- reactions of ^{18}O with ^{249}Bk targets with cross sections of about 6 nb at 99 MeV and 10 nb at 93 MeV, respectively. The seaborgium isomers $9 \text{ s } ^{265\text{a}}\text{Sg}$ and $16 \text{ s } ^{265\text{b}}\text{Sg}$ are produced in the 5n- reaction of ^{22}Ne with ^{248}Cm with a cross section of 240 pb around 124 MeV. An isotope of bohrium suitable for chemical studies is $17 \text{ s } ^{267}\text{Bh}$ produced in the $^{249}\text{Bk}(^{22}\text{Ne},4\text{n})$ reaction at 117 MeV with a cross section of about 60 pb. Recently, in 5n-, 4n-, and 3n- reactions of 130, 136, 140, 145, and 150 MeV ^{26}Mg ions with ^{248}Cm , $9 \text{ s } ^{269}\text{Hs}$, $23 \text{ s } ^{270}\text{Hs}$, and $4 \text{ s } ^{271}\text{Hs}$ were produced with cross sections on the order of 6 pb, 3 pb, and 3 pb, respectively, and used for chemical and nuclear studies of element 108, hassium. An isotope suitable for chemical studies of element 112, copernicium is $3.8 \text{ s } ^{283}\text{Cn}$. For element 114, $\sim 0.8 \text{ s } ^{288}\text{114}$ and $\sim 2.6 \text{ s } ^{289}\text{114}$ are candidates for chemical investigations; they are produced in the bombardment of $^{242,244}\text{Pu}$ targets with ^{48}Ca beams. The reactions used for chemical studies are summarized in ► Table 20.1. For completeness, it should be mentioned that in the decay chain of $288(115)$ a long-lived ($\sim 30 \text{ h}$) spontaneously fissioning isotope of dubnium (Stoyer et al. (2007)), presumably ^{268}Db , was chemically identified, that might be a candidate for further chemical studies of dubnium.

20.3 Single-Atom Chemistry

For a chemical reaction

the change of the Gibbs free energy is

^a Assuming typical values of 0.8 mg/cm² target thickness and 3×10^{12} s⁻¹ beam particles.^b Nuclide observed as a “by-product” or discovered in a radiochemical experiment.^c Estimated from measured E_{α} .

$$\Delta G = \Delta G_0 + RT \frac{[X]^x [Z]^z}{[A]^a [E]^e}, \quad (20.2)$$

where the brackets indicate activities (concentrations, partial pressures) of the substances involved. According to the law of “mass action,”

$$\frac{[X]^x [Z]^z}{[A]^a [E]^e} = K, \quad (20.3)$$

where K is the equilibrium constant. In equilibrium, $\Delta G = 0$, and

$$\Delta G_0 = -RT \ln K. \quad (20.4)$$

This is well established for macroscopic quantities where, for example, ions of the metal M are constituents of A and X at the same time, and ➤ Eq. (20.1) characterizes a dynamical, reversible process in which reactants and products are continuously transformed into each other back and forth even at equilibrium. If only one atom of M is present, it cannot be constituent of A and X at the same time, and at least one of the activities on the left or right hand side of ➤ Eq. (20.1) is zero. Consequently, an equilibrium constant can no longer be defined, and the same holds for the thermodynamic function ΔG_0 . Does it make sense, then, to study chemical equilibria with a single atom?

Guillaumont et al. (1989, 1991), in view of this dilemma, have pointed out that chemical speciation of nuclides at the tracer scale is usually feasible with partition methods in which the

species to be characterized is distributed between two phases. This can be an aqueous and an organic phase or a solid phase and the gas phase. According to Guillaumont et al. (1989), single-atom chemistry requires the introduction of a specific thermodynamic function, the single-particle Gibbs free energy. An expression equivalent to the law of mass action is derived by Guillaumont et al. (1989) in which activities (concentrations or partial pressures) are replaced by the probability of finding the species in the appropriate phase. According to this law, an equilibrium constant, that is, the distribution coefficient K_d of M between two phases, is correctly defined in terms of the probabilities of finding M in one phase or the other. If a static partition method is used, this coefficient must be measured many times in repetitive experiments. Since dynamical partition methods (chromatographic separations) can be considered as spatially repetitive static partitions, the displacement of M along the chromatographic column, in itself, is a statistical result and only one experiment is necessary, in principle. This underlines the validity of partition experiments with single atoms and the particular attractivity of chromatographic methods in single-atom chemistry.

For short-lived atoms, additional considerations with regard to the kinetics are in order. The partition equilibrium must be reached during the lifetime of the atom, which requires high reaction rates. Consider a single-step exchange reaction

Here, M is the single atom that can bind with either X or Y, and k_1 and k_2 are the rate constants for the reactions forth and back. The rate of a chemical reaction depends on the

■ Fig. 20.2

The reaction barrier between two chemical states $MX + Y$ and $MY + X$. The metastable transition state $[Y \cdots M \cdots X]$ has a higher potential energy than the reactants and the products. The energy differences ΔG_1^\ddagger and ΔG_2^\ddagger are the activation energies for the reactions from left to right and from right to left, respectively (Adapted from (Borg and Dienes 1981))

height of the reaction barrier between the states $\text{MX} + \text{Y}$ and $\text{MY} + \text{X}$, because in-between, there is a state of high potential energy (the transition state $[\text{Y} \cdots \text{M} \cdots \text{X}]$), see ► Fig. 20.2.

This state is unstable because the old chemical bond is not completely disrupted and the new one not yet completely formed. If the (Gibbs free) energies of activation ΔG_1^\ddagger and ΔG_2^\ddagger are high, the reaction proceeds very slowly. The transitions from left to right and from right to left do not occur with sufficient frequency and the system is far from its thermodynamical equilibrium. Borg and Dienes (1981) found that if ΔG^\ddagger is less than 15 kcal (60 kJ), then the residence time of M in either state (MX or MY) is rather short (<1 s) and an equilibrium is rapidly reached (in comparison with the nuclear half-lives of the transactinides). Borg and Dienes point out that the average time that M spends as MX or MY is proportional to the equilibrium constant. Thus, a measurement of the partition of M between the states MX and MY with very few atoms of M will already yield an equilibrium constant close to the “true” value provided that both states are rapidly sampled. This shows again that chromatographic systems with fast kinetics are ideally suited for single-atom separations as there is rapid, multiple sampling of the absorbed or mobile species. The fractional average time that M spends as the absorbed species (which is proportional to the equilibrium constant, see above) is closely related to the chromatographic observable, the retention time.

20.4 Experimental Techniques

Recent reviews of fast chemical separation procedures developed for transactinide studies can be found in (Schädel 1995; Trautmann 1995). Nevertheless, the most pertinent techniques are also presented here.

20.4.1 Target and Transport Systems

A scheme of a target- and recoil chamber arrangement is shown in ► Fig. 20.3. Heavy-ion beams pass through a vacuum isolation window, a volume of nitrogen cooling gas, and a target backing before interacting with the target material. Reaction products recoiling out of the target are thermalized in a volume of He gas loaded with aerosol particles of 10–200 nm size to which the reaction products attach. At a flow rate of about 2 l/min the transport gas with the aerosols is transported through capillary tubes (~ 1.5 mm inner diameter) to the chemistry apparatus where it deposits the reaction products. He/aerosol-jets allow transportation over distances of several tens of meters with yields of about 50% (Gregorich et al. 1988; Schädel et al. 1988; Gäggeler et al. 1991; Günther et al. 1995a, b). Transport times are on the order of 2–5 s. Aerosol materials are selected such as to minimize their influence on the chemical procedures. Separations in the aqueous phase often use KCl (Gregorich et al. 1988; Schädel et al. 1988; Günther et al. 1995a, b) as aerosol while MoO_3 and carbon clusters are preferred in gas-phase separations (Gäggeler et al. 1991).

In the early frontal gas-chromatographic experiments with element 104 (Zvara et al. 1966, 1969; Chuburkov et al. 1969), the target- and recoil chamber was bombarded by the internal beam inside the cyclotron. The recoils were stopped in nitrogen heated to 300°C (flow rate 18–20 l/min) and transported into an outlet tube (i.d. 3.5 mm) where, at a distance of 3 cm from the target, a stream of nitrogen (0.5–1.0 l/min), containing the chlorinating reactive gases NbCl_5 and ZrCl_4 , was introduced. The volatile RfCl_4 was transported through the 4 m long outlet tube to mica fission-track detectors outside of the cyclotron.

■ Fig. 20.3

Schematic representation of a target and recoil chamber arrangement with He/aerosol-jet
(Reprinted with the permission of Oldenbourg Wissenschaftsverlag, München, (Trautmann 1995))

Later, the external beam of the cyclotron was used with the chromatography columns coupled directly to the target and recoil chamber (Zvara et al. 1970, 1971a, b, 1974, 1976; Timokhin et al. 1996; Yakushev et al. 1996a, b; Zvara et al. 1998). In this configuration, typically 60% of the recoils reach the column without the use of aerosols. Transport times of <1 s were measured (Zvara et al. 1971b). The disadvantage of this thermochromatography technique is that the detection of the transactinides has to be performed in a hostile chemical environment so that detection of α particles with semiconductor detectors is not possible and the detection is limited to the unspecific spontaneous fission (SF) by solid-state track detectors.

Recent important developments in the field of target and transport systems are the use of (1) rotating target wheels (Eberhardt et al. 2008) that allow for higher beam intensities, and (2) pre-separation of the fusion- evaporation residues in an electro-magnetic separator such as the **Berkeley Gas-Filled Separator BGS** (Omtvedt et al. 2002; Düllmann et al. 2009) or the newly commissioned **TransActinide Separator and Chemistry Apparatus TASCA** at the GSI Helmholtz center for heavy ion research, Darmstadt, (Schädel et al. 2008), both coupling the chemistry apparatus to the separator via a He/KCl gas jet leaving a **Recoil Transfer Chamber RTC** in the focal plane, and (3) avoiding vacuum windows by differential pumping in the target area.

20.4.2 Gas-Phase Chemistry

Vapor pressure curves (Gäggeler 1994; Türler 1996; Gärtner et al. 1997) give a measure of the volatility of compounds. In ► Fig. 20.4, the vapor pressure curves of the monomeric gas over the respective solids for Zr and Hf tetrachlorides and -bromides and for Nb and Ta pentachlorides and -bromides are shown, respectively. Also shown are vapor pressure curves for Nb and Ta oxytrichlorides. These curves are calculated using tabulated standard

■ Fig. 20.4

Vapor pressure curves of the monomeric gas over the respective solids for (a) ZrCl_4 , ZrBr_4 , HfCl_4 , HfBr_4 , and (b) NbCl_5 , NbBr_5 , TaCl_5 , TaBr_5 , NbOCl_3 and TaOCl_3 (Reprinted with permission of Oldenbourg Wissenschaftsverlag, München, (Türler 1996)⁸)

sublimation enthalpies, $\Delta H_s^{\circ(298\text{ K})}$, and standard sublimation entropies, $\Delta S_s^{\circ(298\text{ K})}$ (Knacke et al. 1991). HfCl_4 and HfBr_4 are slightly more volatile than the Zr homologs, but less volatile than TaCl_5 and NbCl_5 .

It is interesting to note that the chlorides and bromides of Zr and Hf show similar volatilities, whereas NbBr_5 and TaBr_5 are considerably less volatile than the respective pentachlorides. In Fig. 20.4, no vapor pressure curves for ZrOCl_2 and HfOCl_2 are shown because their existence in the gas phase is uncertain. Morozov and Karlova (1971) found that ZrOCl_2 and HfOCl_2 decompose to tetrachloride and oxide when heated. They also determined the vapor pressure curves of the tetrachlorides over their oxychlorides. Domanov and Jin (1989) observed that the deposition temperature for Zr and Hf depends on the O_2 concentration in the reactive gas. Eichler (1996) suggested a transport reaction mechanism (“reaction gas chromatography”) with the tetrachloride in the gas phase and the oxychloride in the adsorbed state, that is,

Jost et al. (1996) presented experimental evidence for this transport reaction mechanism. Since in experiments with transactinide elements only single molecules can be studied, $\Delta H_s^{\circ(298\text{ K})}$ of, for example, RfCl_4 cannot be determined directly. The quantity deduced from gas chromatography experiments is $\Delta H_a^{\circ(T)}$, the adsorption enthalpy on the chromatographic surface (usually quartz) at zero coverage. As was demonstrated by Zvara et al. (1970), there exists a linear relationship between $\Delta H_a^{\circ(T)}$ and $\Delta H_s^{\circ(298\text{ K})}$ for chlorides. By measuring $\Delta H_a^{\circ(T)}$ of chlorides of 24 elements on quartz surfaces, Eichler et al. (1976) established the empirical relation

$$-\Delta H_a^{\circ(T)} = (0.655 \pm 0.042) \times \Delta H_s^{\circ(298K)} + (18.0 \pm 8.8) \text{ kJ mol}^{-1}, \quad (20.7)$$

Thus, $\Delta H_a^{\circ(T)}$ is the quantity used to judge the volatility of the transactinide compounds relative to the volatility of their lighter homologs.

There are two experimental approaches to determine $\Delta H_a^{\circ(T)}$, thermochromatography and isothermal gas chromatography. In thermochromatography (Zvara et al. 1970, 1971a, b, 1974, 1976; Zvara 1976, 1985, 1990; Timokhin et al. 1996; Yakushev et al. 1996; Zvara et al. 1998), a longitudinal, negative temperature gradient is established along the chromatography column in the flow direction of the carrier gas.² Volatile species are deposited in the column according to their volatility and form distinct deposition zones. Mica sheets inserted into the chromatography column serve as fission track detectors. The method has the advantage of a very high speed at which the production of volatile species and their separation occurs. The recoiling reaction products are rapidly swept from the target chamber to the entrance of the chromatography column where gaseous halogenating agents are added. Transactinides decaying by SF are registered in the column at a characteristic deposition temperature thus providing information about their volatility. These experiments are simple and relatively easy to perform. However, thermochromatography, as applied in the above references, shows also serious disadvantages. The fact that the position of the deposition zones of homologs can be measured only after completion of the experiment makes the interpretation of the relative volatility of the short-lived transactinides difficult compared to the detected, much longer-lived homologs. In addition, real-time detection of the nuclear decay of transactinides and the determination of their half-lives is not possible. Moreover, SF is an unspecific decay mode of many actinides and transactinides which allows no identification of the decaying nuclide.

In order to overcome these serious disadvantages, the online isothermal gas chromatography was developed and was successfully applied to study the volatility of Rf, Db, Sg, and Bh halides and oxyhalides (Gäggeler et al. 1991, 1992a, b, Türlér et al. 1992; Gäggeler 1994; Jost et al. 1996; Türlér 1996; Türlér et al. 1996; Kadkhodayan et al. 1996; Yakushev et al. 1996; Gärtner et al. 1997; Gäggeler 1998). The most advanced version of the Online Gas Chemistry Apparatus, OLGA III, is shown in  Fig. 20.5. The reaction products, attached to graphite aerosols, are continuously transported through a capillary to the OLGA setup. In the first section of the chromatography column, the aerosols are stopped on a quartz wool plug. This section is heated to 900–1,000°C. At the position of the quartz wool plug, reactive gases such as HBr, BBr₃, HCl, Cl₂, SOCl₂, and O₂ are added.

The second part of the quartz column serves as isothermal chromatography section. Volatile species pass this section whereby they undergo numerous sorption/desorption steps with retention times indicative of the volatility at the given temperature of the isothermal part of the column. The chemical yield of the volatile species is studied as a function of the temperature of the isothermal part of the column. The chemical yield rises steeply above a certain temperature and reaches a plateau at higher temperatures (see  Fig. 20.11). The retention time of the volatile species is determined by using the nuclear half-life of the radionuclides as a “clock”: at the temperature at which 50% of the plateau yield is observed, $T_{50\%}$, the retention time is equal to one half-life.

To measure the decay of the separated species, they are – after leaving the chromatographic column and entering a water-cooled “recluster chamber” – attached to new aerosols and transported through a capillary to a detection system, a rotating wheel or a moving tape system (Türlér 1996) that positions the deposited activity in front of successive PIPS detectors (Passivated Ion-implanted Planar Silicon), which register α particles and SF events.³ The

■ Fig. 20.5

The OLGA III system used for the study of seaborgium (Gäggeler 1998). The gas jet transports the seaborgium atoms attached to graphite particles in He gas to the reaction oven where the reactive gas $\text{Cl}_2/\text{SOCl}_2/\text{O}_2$ is added to form volatile oxychlorides and to convert the graphite particles into CO_2 . Behind the isothermal chromatography section, the gaseous molecules are attached to new aerosol particles and transported to the rotating-wheel counting device ROMA (Reprinted from Gäggeler 1998), copyright (2009), with the permission from Elsevier)

energies of the events are stored in list mode with the time and detector designation for off-line processing of the data. This allows searching for time-correlated parent-daughter pairs of α events allowing for an unambiguous identification of single events.

Based on a microscopic model of gas-solid thermochromatography in open columns by Zvara (1985), a Monte Carlo code has been made available (Türler 1996), which allows to generate thermochromatographic deposition zones as well as yield versus temperature curves as observed in isothermal chromatography. This model accommodates the influence of the carrier gas flow, the actual temperature profiles, and the different half-lives of the investigated species. For each isothermal temperature, the transport through the column is modeled for a large number of sample molecules. These calculations result in a curve of yield versus temperature for each value of the adsorption enthalpy $\Delta H_a^{\circ(T)}$. The curve for the particular $\Delta H_a^{\circ(T)}$, which best fits the measured data, is chosen by a least-squares method. In the correlation of the retention time with $\Delta H_a^{\circ(T)}$, the adsorption entropy $\Delta S_a^{\circ(T)}$ calculated according to the formalism of Eichler and Zvara (1985) is used.

The most obvious chemical compound of hassium suitable for its chemical separation is the tetroxide, HsO_4 , which is likely to be highly volatile. Zhuikov et al. (1986) have set up an online system in which radioactive Os recoils were thermalized in a gas mixture of 1.2 bar Ar + 2% O_2 whereby volatile OsO_4 was formed in situ and was transported without aerosols through a Teflon capillary to the detection device. This technique has been adapted (Düllmann et al. 2002a; Kirbach et al. 2002; von Zweidorf et al. 2002) in the preparation of the first chemical identification of Hs. The IVO technique developed by Kirbach et al. and Düllmann et al. combines the in situ volatilization of compounds with their online detection in a narrow, ~ 40 cm

long channel consisting of pairs of PIN-diode detectors to which a negative temperature gradient from typically room temperature down to $\sim -180^{\circ}\text{C}$ is applied. This powerful cryo-detection technique has also been instrumental in the studies of the volatility of element 112 (Eichler et al. 2008).

At the velocity filter SHIP (Münzenberg et al. 1979) at GSI in Darmstadt, a Penning trap, SHIPTRAP, has been installed (Marx et al. 2002) in which heavy-ion fusion evaporation residues can be stored for precision mass measurements and manipulated, for example, by laser spectroscopy or by chemical interactions with reactive gases. In order to explore the merits of ion-chemical investigations of heavy elements in a Penning trap, Rieth et al. (2002) have studied the reactions of Ru^+ and Os^+ ions with O_2 , thus demonstrating that ion-molecule reactions may be considered a new way to study the chemical properties of heavy elements.

20.4.3 Aqueous Chemistry

While gas-phase chemistry is generally carried out continuously as an online process, aqueous chemistry has been performed mostly in a discontinuous, batch-wise manner. It is then necessary, in order to get statistically significant result, to repeat the same experiment several hundred or even several thousand times with a cycle time of typically 1 min. These discontinuous studies were either performed manually (Gregorich et al. 1988; Czerwinski et al. 1994a, b; Bilewicz et al. 1996; Kacher et al. 1996a, b) or with the Automated Rapid Chemistry Apparatus ARCA II (Kratz et al. 1989, 1992; Schädel et al. 1992; Gober et al. 1992; Zimmermann et al. 1993; Schädel et al. 1997a, b, Günther et al. 1998; Schädel et al. 1998; Paulus et al. 1999a, b; Strub et al. 2000) or with the Automated Ion-exchange separation apparatus coupled with the Detection system for Alpha spectroscopy AIDA (Nagame et al. 2005).

One of the manual separations made use of the characteristic adsorption of the group-5 elements Nb, Ta, and element 105 from nitric acid on glass surfaces (Gregorich et al. 1988). Another used thin film ferrocyanide surfaces for the study of the hydrolysis of rutherfordium (Bilewicz et al. 1996). All other manual separations were liquid-liquid extractions typically comprising the following steps: the KCl aerosol with the reaction products was collected on a platinum or TeflonTM slip for 60 to 90 s, picked up with 10 μl of the aqueous phase and transferred to a 1 ml centrifuge cone containing 20 μl of the organic phase. The phases were mixed ultrasonically for 5 s and centrifuged for 10 s for phase separation. The organic phase was transferred to a glass cover slip, evaporated to dryness on a hot plate, and placed over a PIPS detector. This procedure took about 1 min and was mainly applied to study the aqueous chemistry of element 104 with the isomer $78\text{ s }^{261\text{a}}\text{Rf}$ (Czerwinski et al. 1994a, b; Kacher et al. 1996a, b). A serious drawback of these latter investigations is that only the organic phase was assayed for $^{261\text{a}}\text{Rf}$; the aqueous phase was not counted.

Automated separations with ARCA II were performed with element 104 (Günther et al. 1998; Strub et al. 2000), element 105 (Kratz et al. 1989; Gober et al. 1992; Kratz et al. 1992; Schädel et al. 1992; Zimmermann et al. 1993; Paulus et al. 1999a, b), and element 106 (Schädel et al. 1997a, b, 1998). ARCA II is a computer-controlled apparatus for fast, repetitive High Performance Liquid Chromatography (HPLC) separations (Schädel et al. 1989). A schematic representation of ARCA II is shown in  Fig. 20.6.

ARCA II consists of a central catcher-chemistry part incorporating the sliders SL1-SL3, and two movable magazines containing 20 of the chromatographic columns C_1 , C_2 (1.6 mm i.d. \times 8 mm) each, and peripheral components, that is, three chemically inert HPLC pumps,

■ Fig. 20.6

Schematic representation of the computer-controlled HPLC-system ARCA II; for details see text (Reprinted with the permission of Oldenbourg Wissenschaftsverlag, München, (Schädel et al. 1989))

P_1 - P_3 , and a number of pneumatically driven four-way slider valves, S1-S4. Each pump pumps one eluent, in case of the separations of element 105 in mixed HCl/HF solutions (Kratz et al. 1989), one 12 M HCl/0.02 M HF, another 4 M HCl/0.02 M HF, and the third 6 M HNO₃/0.015 M HF, through Teflon tubing of 0.3 mm inner diameter to the central catcher-chemistry unit. The He(KCl) gas jet deposits the transported reaction products continuously onto one of two polyethylene frits F. After 1 min collection, the frit is moved on top of one of the microcolumns C1, washed with 12 M HCl/0.02 M HF, whereby the reaction products are dissolved, complexed, and extracted into the organic phase (the columns are filled with TeflonTM grains coated with tri-isooctyl amine, TiOA), while the non-extractable species (notably the actinides) run through into the waste, W3. The column is then washed with 4 M HCl/0.02 M HF, and the effluent (containing Nb, Pa, and element 105) is directed through SL 2 to the fraction collector FC where it is collected on a Ta disk and quickly evaporated to dryness by intense IR light and hot He gas. Next, the Ta fraction is eluted with 6 M HNO₃/0.015 M HF, collected on a Ta disk, and evaporated to dryness. The Ta disks are inserted into the counting chambers about 55 s after the end of collection. Five seconds later, the next 1 min collection on the twin frit is complete. That frit is moved on top of the column

C2 contained in the opposite magazine, and the next separation cycle is carried out. After each separation, the magazine is moved by one step, thus introducing a new column into the elution position. In this way, the time-consuming reconditioning of used columns and cross contaminations from previous separations are avoided. After 40 min of continuous collection and separation cycles, the program is stopped, the used magazines are removed, two new magazines are introduced, and another 40 cycles are started. More than 7,800 of such and similar ARCA II experiments have been conducted in the study of element 105 so far.

► **Figure 20.7** shows an example for such a separation (Schädel et al. 1989). The upper part is the result of a manually operated HPLC separation on a TiOA/TeflonTM column (1.7 mm i.d. \times 11 mm). Radioactive tracers of lanthanides (Ln), actinides (An), Zr, Hf, Pa, Nb, and Ta are introduced into the system through a sample loop in 12 M HCl/0.02 M HF. Under these conditions, halide complexes of Pa, Nb, and Ta are extracted into the amine, while Ln, An, Zr, and Hf pass the column (fraction A). Pa and Nb are then eluted together with 4 M HCl/0.02 M HF (fraction B), and finally, Ta is stripped from the column in 6 M HNO₃/0.015 M HF (fraction C). The manually performed separation takes about 75 s. This time does not include the times required for rinsing the tubings when the eluent is changed.

The lower part of ► **Fig. 20.7** shows the same separation performed automatically with ARCA II. A volume of 50 μ l of 12 M HCl/0.02 M HF is used to precondition each column before the tracer activities are loaded onto the column in 25 μ l 12 M HCl/0.02 M HF. The complete extraction and elution cycle is complete in ≤ 35 s. This is achieved by the reduction of the void volumes to a minimum.

Recently, an apparatus similar to ARCA II was constructed at JAERI, now JAEA, Tokai, Japan, called AIDA (Automated Ion-exchange separation apparatus coupled with the Detection system for Alpha spectroscopy) (Haba et al. 2001; Nagame et al. 2002b, 2005), and was used for a start-up of transactinide chemistry in Japan. A schematic diagram of the experimental set-ups at JAEA is shown in ► **Fig. 20.8**. In the modified ARCA, there are two different paths to supply solutions; the first eluent goes through the collection port to the microcolumn, while the other one is directed to the column without going through the collection port. This minimizes contamination of the strip fraction. A schematic drawing of AIDA is given in ► **Fig. 20.9**. The Ta disks with the evaporated samples are automatically inserted into the eight vacuum chambers for α spectroscopy.

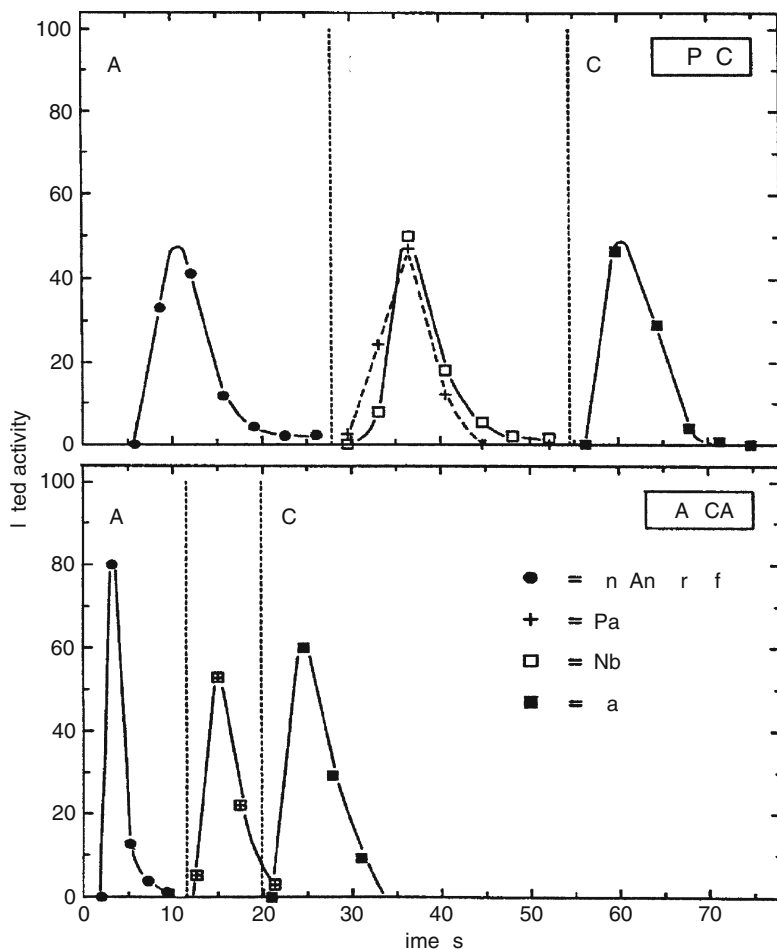

Continuous isolation procedures have also been developed, the first one for nuclear decay studies of Hf, Ta, and W isotopes (Bruchertseifer et al. 1989), which was subsequently applied to element 104 (Szegłowski et al. 1990) in combination with a discontinuous sample preparation step.

Reaction products transported by an aerosol jet were continuously dissolved in the aqueous phase which was pumped through three consecutive ion-exchange columns (multicolumn technique, MCT). Trivalent actinides were retained on the first cation exchange column followed by an anion exchange column to adsorb anionic fluoride complexes of element 104, and a third column filled with a cation exchange resin to collect the trivalent daughter products from the α decay of ^{261a}Rf. At the end of an experiment, the ²⁶¹Rf daughter products, 3.0 d ²⁵³Fm and 20 d ²⁵³Es, were stripped from this third column to prepare a sample for off-line α spectroscopy. The detection of ²⁵³Es in that sample was proof that ^{261a}Rf had formed anionic fluoride complexes that had been retained on the anion exchange column.

Pfreppep et al. (1997, 1998) have developed this technique further, thereby making it a quantitative technique capable of measuring distribution coefficients K_d . In the conventional

■ Fig. 20.7

Separation of trivalent lanthanides (Ln) and actinides (An), Zr, Hf, Nb, Ta, and Pa in an extraction chromatographic system with TiOA (tri-isooctyl amine) on an inert support as stationary phase and 12 M HCl/0.02 M HF (A), 4 M HCl/0.02 M HF (B), and 6 M HNO₃/0.015 M HF (C) as eluents. In the upper part of the figure (HPLC) the chromatogram of a manually performed separation with standard HPLC techniques on a 1.7 × 11 mm column is shown. The lower part of the figure (ARCA) shows a fully automated separation in ARCA II on a 1.6 × 8 mm column at a flow rate of 1.0 ml/min (Reproduced with the permission of Oldenbourg Wissenschaftsverlag, München, (Schädel et al. 1989))

off-line chromatography as performed by ARCA II, the distribution coefficient is determined via the retention time (elution position) as

$$K_d = (t_r - t_0) \frac{V}{M} \quad (20.8)$$

where t_r denotes the retention time, t_0 is the column hold-up time due to the free column volume, V is the flow rate of the mobile phase (ml/min), and M is the mass of the ion exchanger (g).

As in (Szegełowski et al. 1990), the detection of the transactinide isotope itself, $^{261\text{a}}\text{Rf}$, is abandoned and replaced by the detection of its long-lived descendant, 20 d ^{253}Es . This way, one gains the possibility of a continuous online mode over many hours. The feeding of $^{261\text{a}}\text{Rf}$ onto the anion exchange column is performed under conditions in which the retention time t_r is on the order of the nuclear half-life $T_{1/2}$, that is, K_d values on the order of 10–50 are selected (Pfrepper et al. 1997). Similarly to the principle used in the online isothermal gas chromatography, one is using the nuclear half-life as an internal clock. As in (Szegełowski et al. 1990), three ion exchange columns are used in series; first a cation exchange column that retains the ^{253}Es from the continuously flowing feed solution. This is necessary as ^{253}Es could be produced directly by transfer reactions. It follows the true chromatographic column filled with an anion exchange resin. The long-lived decay products (whose number is denoted by D_1) that are formed by radioactive decay of $^{261\text{a}}\text{Rf}$ during its retention time on the anion exchange column are eluted from this column as cations and are fixed on the following cation exchange column. The part of the $^{261\text{a}}\text{Rf}$ that survives the retention time on the anion exchange column is eluted from it and passes the following cation exchange column to be subsequently collected in a reservoir in which it decays into the long-lived decay products (D_2). Thus D_1 and D_2 decay products are isolated separately after the end of the online experiment and assayed off-line for α activity of ^{253}Es . From the ratio of D_1 and D_2 and the nuclear half-life of $^{261\text{a}}\text{Rf}$, one obtains the distribution coefficient

$$K_d = \left[\frac{T_{1/2}}{\ln 2} \ln \frac{D_1 + D_2}{D_2} - t_0 \right] \frac{V}{M}. \quad (20.9)$$

This principle has been applied to rutherfordium in fluoride solutions (Pfrepper et al. 1998; Kronenberg et al. 2004a) and in preliminary studies of rutherfordium and dubnium by Le Naour et al. (1999).

The centrifuge system SISAK III (Persson et al. 1989) allows for a continuous separation of nuclides with half-lives down to 1 s⁴. The separation is based on multistage liquid-liquid extractions using static mixers and specially designed mini-centrifuges for subsequent phase separation. SISAK was successfully applied to a large number of γ -spectroscopic studies of lighter elements. Recently, a new detection system based on liquid scintillation counting (LSC) was developed for online α spectroscopy and SF-detection in the flowing organic phase behind SISAK (Wierczinski et al. 1996). Between α energies of 4.8 and 7.4 MeV, energy resolutions of 210 through 330 keV are achieved. Suppression of interfering β and γ radiation is done by pulse-shape discrimination and pile-up rejection. An online model experiment for element 104 was carried out (Wierczinski et al. 1996) using the α emitter 17 s ^{161}Hf . However, in experiments with $^{261\text{a}}\text{Rf}$, due to a high level of interfering β and γ radiation, the number of random $\alpha\alpha$ -mother-daughter correlations due to pile-up was too large to allow an unambiguous identification of $^{261\text{a}}\text{Rf}$ decay chains. Two solutions of this problem have been pursued recently: (1) The Berkeley Gas-Filled Separator (BGS) was used as a preseparator for ^{257}Rf produced in the $^{208}\text{Pb}(^{50}\text{Ti}, \text{In})$ reaction followed by the transfer of ^{257}Rf to a gas jet delivering the activity to the SISAK system (Omtvedt et al. 2002). This reduced the interfering β and γ radiation by more than three orders of magnitude thus enabling the unambiguous detection of ^{257}Rf by LSC. (2) A fast transient recorder was introduced into the data acquisition in order to digitally record the pulse shapes, and a neural network was trained to recognize true α events and to distinguish these from $\beta\beta$ -pileup and $\beta\gamma$ -pileup events (Langrock et al. 2002; Eberhardt et al. 2002).

20.5 Element 104 (Rutherfordium)

20.5.1 Theoretical Predictions

Extrapolating the ground state electron configuration of Ti, Zr, and Hf to Rf gives the configuration $[\text{Rn}]5f^{14}6d^27s^2$ for the latter. This configuration was also indicated by early relativistic calculations (Fricke 1975; Desclaux 1973) in a Dirac-Fock computer code with a single configuration approximation.

After multiconfiguration Dirac-Fock (MCDF) calculations had indicated that, because of the relativistic stabilization of the $p_{1/2}$ orbital, the electronic structure of lawrencium (element 103) is $[\text{Rn}]5f^{14}7s^27p_{1/2}$ rather than $[\text{Rn}]5f^{14}6d7s^2$ (Desclaux and Fricke 1980; Brewer 1984) it was extrapolated that element 104 should have a $7s^2p^2$ rather than a $6d^27s^2$ configuration (Keller 1984). This raised the question whether element 104 might be a “p-element” with properties similar to Pb, which has a ground state configuration $[\text{Xe}]4f^{14}5d^{10}6s^2p^2$. However, it should be noted that, contrary to Rf, Pb has a closed 5d shell and a large energy gap of more than 4 eV between its ground state and the next higher state.

A more recent MCDF calculation using 468 *jj*-configurations gave a (80%) $6d7s^27p$ ground state configuration for Rf (Glebov et al. 1989) with the $6d^27s^2$ level (95%) only 0.5 eV higher. This calculation predicted the $7s^27p^2$ state 2.9 eV above the ground state. The $6d7s^27p$ ground state configuration was confirmed in a similar MCDF calculation (Johnson et al. 1990) with an energy gap of only 0.24 eV to the next higher state.

Relativistic coupled-cluster calculations based on the Dirac-Coulomb-Breit Hamiltonian (CCSD) including dynamical correlations (Eliav et al. 1995) reverted to the $6d^27s^2$ configuration as the ground state of Rf. Here, the $6d7s^27p$ state is 0.274 eV above the ground state.

From MCDF calculations, ionization potentials, atomic radii, and ionic radii were deduced (Johnson et al. 1990; Zhuikov et al. 1990). It was found that radii, orbital energies, and ground levels of ionized states of Rf are similar to Hf and much different from Pb (Zhuikov et al. 1990) so that it was concluded that there is no solid ground for expecting a “p-character” for Rf and that its chemical properties will resemble those of Zr and Hf. From a relativistic SCF- $X\alpha$ scattering wave Dirac-Fock computation for RfCl_4 , a lower effective charge of the central metal ion and a higher covalency in the metal-chloride bonds was obtained (Zhuikov et al. 1990). This could give rise to a higher volatility of RfCl_4 as compared to that of ZrCl_4 and HfCl_4 .

Quantum chemical calculations using the Dirac-Slater Discrete Variational Method (DS DVM) were performed to study the electronic structure of the group-4 tetrachlorides and of PbCl_4 (Ryshkov et al. 1992) and of the highest chlorides of the group-4, group-5, and group-6 elements (Pershina and Fricke 1994a). These calculations agree that the electronic structures of RfCl_4 and HfCl_4 are similar and that the bonding is typical of a d-element compound. Both calculations also show that RfCl_4 is a rather covalent compound, more covalent than HfCl_4 . A stronger metal-ligand bond in RfCl_4 should make RfCl_4 thermally more stable than ZrCl_4 and HfCl_4 (Pershina and Fricke 1994a).

More recently, calculations of the total binding energies of the group-4 tetrachlorides were performed in order to test the predictive power of an improved DVM scheme using the four-component fully relativistic density functional method (Varga et al. 2000). The calculations show the binding energies to be in very good agreement with thermochemical dissociation energies obtained via the Born-Haber cycle, thus demonstrating a new quality in theoretical predictions.

20.5.2 Experimental Results

The pioneering experiments with rutherfordium in the gas phase (Zvara et al. 1966; Chuburkov et al. 1969; Zvara et al. 1969, 1971a) demonstrated that element 104 forms volatile chlorides and that RfCl_4 is much more volatile than the actinide chlorides and similar to HfCl_4 . Originally, the authors claimed (Zvara et al. 1969) that the spatial distribution of fission tracks was compatible with the half-life of 0.3 s that they believed to be associated with the isotope ^{260}Rf . It was also claimed that the volatility of RfCl_4 was somewhat less than that of HfCl_4 (Zvara et al. 1969). These claims are evidently incorrect. Firstly, an isotope of element 104 with a half-life of 0.3 s has never existed (Ter-Akopyan et al. 1985), and secondly, it is impossible to determine both the half-life and the heat of adsorption from a fission track distribution. Later, Zvara et al. (1971b) reinterpreted their original experiments by considering “the possible chromatographic effect of retention” and suggested that they were evidently dealing with 3 s ^{259}Rf , an α emitter discovered earlier at Berkeley (Ghiorso et al. 1969). There has been on-going discussion about the existence of a fission branch in this isotope. New studies (Gates et al. 2008) have found an electron capture branch in the decay of ^{259}Rf leading to ^{259}Lr that partially decays by spontaneous fission. The thermochromatographically determined deposition zones for spontaneously fissioning isotopes in (Zvara et al. 1971b) are shown as full circles in  Fig. 20.10 where they are compared to the distribution of $^{44\text{m}}\text{Sc}$ modeling trivalent actinides and to the distribution of $^{170,171}\text{Hf}$.

The fission tracks designated by open circles were thus assigned to heavy actinides, those designated by the full circles to rutherfordium. Zvara et al. (1971b) also reported a strongly enhanced retention of the RfCl_4 when KCl is provided as the solid phase instead of glass, most likely due to the formation of nonvolatile K_2RfCl_6 .

A careful discussion of the results of online isothermal gas chromatography experiments with the group-4 elements Zr, Hf, and Rf, is given by Türlér (1996). The most recent results are given by Kadkhodayan et al. (1996). In these experiments, a MoO_3 aerosol gas jet was used to transport the activities from the recoil chamber to the chromatography apparatus.

The MoO_3 after reaction with chlorinating reagents forms volatile oxychlorides that do not deposit inside the chromatography column. A total of 837 α particles attributed to the decay of $^{261\text{a}}\text{Rf}$ and its daughter ^{257}No were detected after the gas-phase separation including 170 $\alpha\alpha$ -correlations. A half-life of 78_{-6}^{+11} s resulted from the decay of $^{261\text{a}}\text{Rf}$, in good agreement with the 65 ± 10 s literature value (Ghiorso et al. 1970).⁵ The relative yields measured as a function of the isothermal temperature for chlorides of ^{98}Zr , ^{162}Hf , and ^{261}Rf under similar experimental conditions are shown in  Fig. 20.11.

Chlorinating agent was 100 ml/min HCl in experiments with Zr and Hf. The experimental data were analyzed with the Monte Carlo model mentioned above to yield adsorption enthalpies $\Delta H_{\text{a}}^{\circ(T)}$ for group-4 chlorides on SiO_2 surfaces which are -74 ± 5 kJ/mol for Zr, -96 ± 5 kJ/mol for Hf, and -77 ± 6 kJ/mol for Rf. The lower volatility of Hf chloride is surprising in view of the known vapor pressure curves ( Fig. 20.4) as the experimental conditions were kept as similar as possible to the ZrCl_4 and RfCl_4 experiments (Kadkhodayan et al. 1996). It is not clear whether Hf is more susceptible to trace impurities in the system (O_2 , H_2O) thus forming HfOCl_2 in the adsorbed state, in a similar way as shown by  Eq. (20.6). This would shift the yield versus temperature curve to higher temperatures.

Within the error limits, RfCl_4 exhibits about the same volatility as ZrCl_4 and thus shows the volatility expected from relativistic calculations (Pershina and Fricke 1994a). From “nonrelativistic” extrapolations one would expect a less volatile RfCl_4 . Further experiments under

■ Fig. 20.10

(a) Thermochromatogram of Sc (dashed line) and Hf (solid line) and circles indicating the number and position of SF tracks produced in the $^{242}\text{Pu} + ^{22}\text{Ne}$ reaction at 119 MeV (Adapted from (Zvara et al. 1971b)). The full circles near the Hf deposition zone are interpreted as being due to element 104, the open circles as being due to heavy actinides. (b) Temperature profile along the chromatographic tube

absolutely oxygen-free conditions with also a higher resolution with respect to the determination of the observable $T_{50\%}$ are desirable before quantitative conclusions on the influence of relativistic effects on the volatility of RfCl_4 can be drawn.

The volatility of short-lived Hf and Rf in chlorinating, oxygen-containing gases was investigated recently by Jost et al. (1996). 150 ml/min Cl_2 , saturated with thionylchloride (SOCl_2) and 20 ml/min O_2 were used as reactive gases. The 50% temperature for Hf was found to be shifted to 390°C whereas for a simple adsorption/desorption process of HfCl_4 $T_{50\%}$ would be expected at $\sim 200^\circ\text{C}$. Preliminary data for Rf are shown in ▶ Fig. 20.12 where the yield versus temperature curves are compared for the reactive gases 300 ml/min HCl and 150 ml/min Cl_2 saturated with SOCl_2 , 20 ml/min O_2 .

A shift of the $T_{50\%}$ value from about 125°C to about 330°C is observed with a much slower increase of the yield in the presence of oxygen. This is strong evidence for the proposed transport reaction, ▶ Eq. (20.6). A modification of the Monte Carlo model to take care of the different transport reaction mechanism (“reaction gas chromatography”) will be discussed in ▶ Sect. 20.7. The data for HCl as chlorinating agent (Jost et al. 1996) are in agreement with those reported by Kadkhodayan et al. (1996).

Preliminary data (Yakushev et al. 1996a) allow comparing the volatility of RfCl_4 with that of the bromide compound, RfBr_4 , which turns out to be less volatile with the yield versus temperature curve of the latter being shifted by about 150°C to higher temperatures. It is

■ Fig. 20.11

Relative chemical yields for Zr (*open circles*), Hf (*triangles*), and Rf (*solid squares*) chlorides as a function of the temperature of the isothermal part of the gas-chromatographic column with Monte Carlo simulations (*solid lines*). Inserted into the figure is information about the chlorinating reagents and the deduced adsorption enthalpies (Türler 1996) (Reproduced with the permission of Oldenbourg Wissenschaftsverlag, München)

■ Fig. 20.12

Chromatographic yield of ²⁶¹Rf as a function of the temperature of the isothermal part of the column in 1 l/min He, 150 ml/min Cl₂, saturated with SOCl₂, 20 ml/min O₂ (*full circles*), and with 1 l/min He, 300 ml/min HCl (pure HCl) (*full squares*). Preliminary data from Jost et al. (1996)

interesting to note that, in these experiments, the simultaneously measured behavior of Hf indicated a lower volatility of both the chloride and the bromide if compared with the corresponding Rf chloride and bromide, respectively.

One experiment in the gas phase was carried out to probe possible p-element behavior of Rf in its atomic state (Zhuikov et al. 1989); p-elements such as Tl, Pb, and Bi in the elemental state show a much higher volatility than the group-4 elements Ti, Zr, and Hf. In analogy to a similar experiment on element 103 (Jost et al. 1988; Eichler et al. 1988), the retention of element 104 in a quartz column at 1,170°C was measured in Ar carrier gas containing some hydrogen. All fission tracks from 2.6 h ^{256}Fm (an unwanted by-product) and from 3 s ^{259}Rf were observed in the region of the column where d-elements deposit. A lower limit for the sublimation enthalpy of $\Delta H_s^\circ(\text{Rf}) \geq 370$ kJ/mol was determined. This result is in agreement with predictions (Zhuikov et al. 1990; Ryshkov et al. 1992) saying that, despite possible $6d7s^27p$ ground state configuration, in the interaction with any chemical environment, Rf will behave similar to Hf.

The first aqueous-phase separations of Rf (Silva et al. 1970) were performed with a cation-exchange chromatography column and the chelating reagent α -hydroxyisobutyric acid (α -HIB). Rf was eluted together with Zr and Hf from the column while the trivalent actinides were strongly retained on the column. The chloride complexation of Rf was investigated in an automated solvent extraction chromatography experiment with the quaternary ammonium chloride Aliquat 336 on an inert support as stationary phase and 12 M HCl as the mobile phase (Hulet et al. 1980). Under these conditions, Zr, Hf, and Rf were extracted into the amine while the trivalent actinides were not retained on the column. The Rf, together with the Hf tracer, was then eluted in 6 M HCl. Although only six α decays of ^{261a}Rf were detected, this experiment demonstrated that the chloride complexation of Rf is similar to that of Hf and much stronger than that of the actinides (Hulet et al. 1980).

A series of manually performed separations of ^{261a}Rf from aqueous solutions was performed by the Berkeley group (Czerwinski et al. 1994a, b; Bilewicz et al. 1996; Kacher et al. 1996a, b). Liquid-liquid extractions with TiOA from 12 M HCl (Czerwinski et al. 1994a) confirmed the results of (Hulet et al. 1980). Cationic species were investigated by extraction into thenoyltrifluoroacetone (TTA). A distribution coefficient for Rf between those of the tetravalent pseudo-homologs Th and Pu indicated (Czerwinski 1992) that Rf is less affected by hydrolysis than Zr, Hf, and Pu.

Czerwinski et al. (1994b) performed a series of liquid-liquid extractions with tributylphosphate, TBP, in benzene to study the effect of HCl, Cl^- , and H^+ ion concentration between 8 M and 12 M on the extraction of Zr^{4+} , Hf^{4+} , Th^{4+} , Pu^{4+} , and Rf^{4+} . It was found that Rf extracts efficiently as the neutral tetrachloride into TBP from 12 M HCl (i.e., it behaves like Zr, Th, and Pu) while the extraction of Hf was relatively low and increased seemingly from 20% to 60% between 8 M and 12 M HCl. Extraction of Rf increased from 60% to 100% between 8 M and 12 M HCl, thus defining an extraction sequence $\text{Zr} > \text{Rf} > \text{Hf}$ for the group-4 chlorides. Surprising results were obtained when the chloride concentration was varied at a constant H^+ concentration of 8 M. Above 10 M Cl^- concentration, the extraction of Rf decreased and behaved differently from Zr, Hf, and Th, and resembled that of Pu^{4+} . This was interpreted in terms of stronger chloride complexing in Rf than in Zr, Hf, and Th, leading to the formation of RfCl_6^{2-} (Hoffman 1990), which is not extracted into TBP. Extraction studies at a constant concentration of 12 M Cl^- showed that Rf extraction is sharply increasing with increasing H^+ concentration between 8 M and 12 M (Czerwinski et al. 1994b). Such behavior is not exhibited by Zr and Hf. As some of these extraction experiments suffered from differences in the details of the chemical procedures applied to the different elements, for example, different contact

times and volumes used, it is important to confirm these very interesting findings in an experiment that establishes identical conditions for all homologous elements including Rf.

Kacher et al. (1996a) performed some additional chloride extractions into TBP/ benzene with Zr, Hf, and Ti. The reported low extraction yields of Hf by Czerwinski et al. (1994b) could not be reproduced by Kacher et al. (1996a) who reported that they observed that significant amounts of Hf (more than 50% in some cases) stick to Teflon surfaces. (They actually conducted their subsequent experiments with polypropylene equipment because only negligible adsorption was observed with polypropylene surfaces.) The Hf results from the experiments performed by Czerwinski et al. (1994b) were based on online data taken at the cyclotron where the activity was collected on a Teflon disk which according to (Kacher et al. 1996a) accounts for the seemingly low Hf extraction. Surprisingly, a similar loss of Rf due to adsorption in the experiments of Czerwinski et al. (1994b) was not suspected by Kacher et al., and so the latter authors, based on their new Zr-, Hf-, and Ti-results and on the old (Czerwinski et al. 1994b) Rf results, suggested a revised sequence of extraction into TBP/ benzene from around 8 M HCl as $Zr > Hf > Rf > Ti$. In a parallel study of liquid-liquid extractions into TBP/benzene from HBr solutions, extraction of Rf was found to be low and was only increased for bromide concentrations beyond 9 M (Kacher et al. 1996a). The extraction behavior of the group-4 elements into TBP from both HCl and HBr solutions was primarily attributed to their different tendencies to hydrolyze (Kacher et al. 1996a). The latter statement refers to concurrent work by Bilewicz et al. (1996) who studied the sorption of Zr, Hf, Th, and Rf on cobalt ferrocyanide surfaces. These ferrocyanides are known to be selective sorbents for heavy univalent cations such as Fr^+ , Cs^+ , and Rb^+ . However, some ferrocyanides such as Co ferrocyanide have been found to exhibit also particularly high affinities for tetravalent metal ions such as Zr^{4+} , Hf^{4+} , and Th^{4+} involving the formation of a new ferrocyanide phase between the 4+ cation and the $Fe(CN)_6^{4-}$ anion. The first hydrolysis step of a 4+ cation is shown in the following reaction

The left hand side of ► Eq. (20.10) shows the hydrated 4+ cation, whereas the right hand side the first hydrolysis product a 3+ cation. As 3+ cations are essentially not sorbed by ferrocyanide surfaces, the onset of hydrolysis at decreasing HCl concentration in the aqueous phase will be reflected by a rapid decrease of the sorbed activity. This decrease was observed by Bilewicz et al. (1996) below 3 M HCl for Rf, below 1 M HCl for Zr, and below 0.5 M HCl for Hf, establishing seemingly a hydrolysis sequence $Rf > Zr > Hf$. As hydrolysis increases with decreasing radius of the cation, the stronger hydrolysis of Rf is very surprising and in conflict with the results of Czerwinski (1992). Bilewicz et al. (1996) suggested as an explanation that the predominant coordination number (x in ► Eq. (20.10)) for Zr^{4+} and Hf^{4+} is 8, and changes to 6 for Rf due to relativistic effects making the $6d_{5/2}$ orbitals unavailable for ligand bonding of water molecules. Günther et al. (1998) have shown that this does not withstand a critical examination. It is the present author's opinion that some experimental deficiency and not the increased tendency of Rf to hydrolyze produced the surprising results of Bilewicz et al. (1996). For example, the contact time of the aqueous phase with the ferrocyanide surface was only 10 s in the Rf experiments. In a kinetic study, the authors found that Zr and Hf sorbed within 20 s and 40 s, respectively, while Th required more than 90 s to achieve nearly complete sorption (Bilewicz et al. 1996). It is conceivable that, within the 10 s interaction of the aqueous phase in the Rf experiments, no equilibrium was established thus making the Rf data meaningless.

A study of the extraction of fluoride complexes of Ti^{4+} , Zr^{4+} , Hf^{4+} , and Rf^{4+} into TiOA was also reported by Kacher et al. (1996b). This work presents some evidence for extraction of $^{261\text{a}}\text{Rf}$ into TiOA from 0.5 M HF; however, no quantitative assessment of the extraction yield or K_d value is made so that the conclusion of Kacher et al. (1996b) that the extraction into TiOA for the group-4 elements decreases in the order $\text{Ti} > \text{Zr} \approx \text{Hf} > \text{Rf}$ is not reproducible.

In view of the somewhat unsatisfactory situation with the conflicting Hf results by Czerwinski et al. (1994b) and Kacher et al. (1996a) and with the intention to establish an independent set of data characterizing the extraction sequence of Zr, Hf, and Rf from 8 M HCl into TBP, Günther et al. (1998) determined distribution coefficients of these elements from HCl solutions. In 8 M HCl, the K_d of Zr is 1,180 and that of Hf is 64. This difference makes possible a chromatographic separation of Hf from Zr in ARCA II on 1.6 mm i.d. \times 8 mm columns filled with TBP on an inert support. This separation was also studied with the short-lived ^{169}Hf from the $\text{Gd}(^{18}\text{O}, \text{n})$ reaction yielding $K_d = 53^{+15}_{-13}$ in agreement with the above results from batch extraction experiments. 78 s $^{261\text{a}}\text{Rf}$ was produced in the $^{248}\text{Cm}(^{18}\text{O}, 5\text{n})$ reaction at the Philips Cyclotron of the Paul Scherrer Institute, Switzerland, and from the distribution of α events between the Hf and Zr fraction, a K_d value of Rf in 8 M HCl of ~ 150 was determined. This gives the extraction sequence $\text{Zr} > \text{Rf} > \text{Hf}$. Such a sequence is expected from theoretical considerations (Günther et al. 1998; Pershina 1998a, b) of complex formation and the concurrent hydrolysis of complexes

To predict the equilibrium constant of \blacklozenge Eq. (20.11), one has to consider the difference in total energies of the (partially) hydrolyzed species on the left hand side of \blacklozenge Eq. (20.11) that are not extracted and the extractable MCl_4 . (It is assumed that the OH^- -containing species will not extract into the organic phase because of the strong hydrogen bonding interaction between OH^- and H_2O .) This can be done by quantum chemical calculations (Pershina 1996; Pershina and Fricke 1999), allowing to determine the differences in the Coulomb and the covalent parts of the binding energy separately. Calculations for Zr, Hf, and Rf are still to be done, but one can already draw qualitative conclusions based on a parallel study of the hydrolysis of chloro complexes of the group-5 elements Nb, Ta, Pa, and Db (Pershina 1998a, b). For group 5, the order of complex formation described by equilibria similar to the reaction (\blacklozenge 20.11) in 4–12 M HCl solutions was found to be $\text{Pa} > \text{Nb} > \text{Db} > \text{Ta}$ in excellent agreement with experimental data (Paulus et al. 1999a, b) to be discussed in \blacklozenge Sect. 20.6. This sequence is explained by dominant differences in the Coulomb part of the energy of reaction when OH^- groups are replaced by Cl^- anions. Earlier calculations (Pershina and Fricke 1994a) of MCl_4 ($\text{M} = \text{Zr}, \text{Hf}, \text{and Rf}$) have shown that the compounds are very similar, which can also be true for $\text{M}(\text{OH})_x\text{Cl}_{4-x}$. Knowing the analogy in the electronic structure of the halides and oxyhalides of groups 4 and 5 (Pershina 1996, 1998a, b) one can postulate the same order of complex formation $\text{Zr} > \text{Rf} > \text{Hf}$ according to \blacklozenge Eq. (20.11) as it was found for the corresponding group-5 elements. For both group 4 and 5, such a sequence is in full agreement with experimental data for Zr, Hf, and Nb, Ta, respectively, showing that compounds of the 5d elements are more hydrolyzed than those of the 4d elements and are hence less extracted. For these elements, the hydrolysis of complexes (Pershina 1998a, b; Pershina and Fricke 1999) is of opposite order to the hydrolysis of cations. This shows that the statements of Kacher et al. (1996a), concerning the seemingly low extraction of Hf and Rf as being due to their increased tendency to hydrolyze, are incorrect.

Fluoride complexation of the group-4 elements was studied by Bruchertseifer et al. (1989), Szegłowski et al. (1990), Pfrepper et al. (1997, 1998), and Strub et al. (2000). In the work of Szegłowski et al. (1990), $^{261\text{a}}\text{Rf}$ transported to the chemistry apparatus on line was continuously dissolved in 0.2 M HF, and the solution was passed through three ion-exchange columns. In the first cation-exchange column, the transplutonium elements produced directly in the $^{18}\text{O} + ^{248}\text{Cm}$ reaction were removed from the solution. In the next anion-exchange column, $^{261\text{a}}\text{Rf}$ was sorbed as RfF_6^{2-} , while the following cation-exchange column retained its cationic decay products. After the end of bombardment, the descendants ^{253}Fm and ^{253}Es were desorbed from the third column and detected off-line by α spectroscopy. Their detection was proof that Rf forms anionic fluoride complexes, which are sorbed on an anion-exchange resin.

By selecting conditions such that the retention time, t_r , is of the order of the nuclear half-life, $T_{1/2}$, Pfrepper et al. (1997, 1998) developed this technique further, thereby making it a quantitative technique capable of measuring K_d values of short-lived isotopes by online chromatography. Pfrepper et al. have verified the equivalence of \bullet Eqs. (20.8) and \bullet (20.9). They compared K_d values for Hf isotopes obtained, firstly, in batch experiments and by conventional elution chromatography in the anion-exchange system consisting of HS36 (a resin with the quaternary triethyl-ammonium group) and 0.27 M HF/ x M HNO_3 (where x is variable) with, secondly, K_d values obtained in the same system with the MCT technique. They used the short-lived Hf isotopes $^{165,166}\text{Hf}$ and detected the daughter nuclides $^{165,166}\text{Tm}$ and ^{166}Yb by γ -ray spectroscopy. In order to determine the ionic charge of the Hf fluoride complexes, the concentration of the counter ion NO_3^- was varied. K_d values were found to be 12.7 ± 1.8 ml/g with 0.2 M HNO_3 and 2.4 ± 0.8 ml/g with 0.5 M HNO_3 corresponding to an ionic charge of -1.9 ± 0.4 for the fluoride complex of Hf as determined from the slope of the plot of $\log K_d$ versus the logarithm of the concentration of the counter ion. From this it was concluded that Hf probably forms HfF_6^{2-} . This is evidenced also by \bullet Fig. 20.13 in which the K_d values obtained by the online MCT technique are compared with those from a series of batch experiments performed in parallel with the same anion-exchange resin. From the good agreement, it was concluded that with the MCT technique, determination of the ionic charge of complexes of transactinides must be feasible.

In the application of the MCT technique to $^{261\text{a}}\text{Rf}$, Pfrepper et al. (1998) used about 20 mg (11 mg) of the anion-exchange resin HS36 in the chromatographic column at an elution rate of approximately 0.35 ml/min of 0.27 M HF and 0.2 (0.1) M HNO_3 . The cation-exchange column (s) that sorbed the descendants 23 s ^{257}No , 3 d ^{253}Fm , and 20 d ^{253}Es contained 50 mg of the strongly acidic cation exchanger Wofatit KPS.

For the similar cation-exchange resin Dowex 50 \times 12, it was shown previously by Pfrepper et al. (1997) that, for HNO_3 concentrations <0.3 M, K_d values for trivalent rare earth cations exceed 10^4 ml/g resulting in a breakthrough volume in excess of 500 ml. Assuming the same conditions for their $^{261\text{a}}\text{Rf}$ experiment (Pfrepper et al. 1998), it was decided to renew the cation-exchange columns collecting the descendant fractions D_1 and D_2 every 12 h. This corresponded to eluent volumes of about 260 ml, while the breakthrough volume was estimated to be about 10^3 ml.

Thus, at first sight, breakthrough of the cationic “daughter nuclides” was safely prevented. $^{261\text{a}}\text{Rf}$ and $^{165-169}\text{Hf}$ were produced simultaneously by irradiation of a combined target of ^{248}Cm and $^{152,154,158}\text{Gd}$ with ^{18}O ions at the Dubna U-400 Cyclotron. In the γ -ray spectra of D_1 and D_2 , the nuclides ^{165}Tm , ^{166}Yb , ^{167}Tm , ^{169}Lu , and ^{169}Yb were detected as the decay products of $^{165,166,167,169}\text{Hf}$. K_d values on the order of 14.8 and 47 were determined in 0.27 M HF/0.2 M HNO_3 and 0.27 M HF/0.1 M HNO_3 , respectively, compatible with an ionic charge

■ Fig. 20.13

Value of $\log K_d$ of Hf in the system HS36-0.27 M HF- HNO_3 as a function of the HNO_3 concentration, measured in batch and online experiments (Reprinted with the permission of Oldenbourg Wissenschaftsverlag, München, (Pfrepper et al. 1997))

of the fluoride complex of -1.85 ± 0.1 . For ^{261}Rf , the α decays of its descendant ^{253}Es were evaluated yielding K_d values of about 14 and 50 in 0.27 M HF/0.2 M HNO_3 and 0.27 M HF/0.1 M HNO_3 , respectively, giving an ionic charge of -1.9 ± 0.2 . Pfrepper et al. (1998) concluded that Rf has properties of a close homologue of Hf and forms RfF_6^{2-} , the stoichiometry characteristic of Hf and other group-4 elements.

Kronenberg et al. (2004a) have observed that the K_d values of trivalent lanthanide (Tb^{3+}) and actinide cations (^{241}Am , ^{250}Fm) in mixed HF/0.1 M HNO_3 solutions on the cation-exchange resin Dowex 50W \times 8 exceed 10^4 ml/g only for HF concentrations below 10^{-2} M. For higher HF concentrations, the K_d values decrease to 2,000 in 0.05 M HF/0.1 M HNO_3 , 1,300 in 0.1 M HF/0.1 M HNO_3 , 700 in 0.5 M HF/0.1 M HNO_3 , and 500 in 1 M HF/0.1 M HNO_3 . A simultaneous rise of K_d values on the anion-exchange resin Dowex 1 \times 8 is observed (Kronenberg et al. 2000) for >0.05 M HF/0.1 M HNO_3 with values reaching 170 in 0.1 M HF/0.1 M HNO_3 , 1,600 in 0.5 M HF/0.1 M HNO_3 , and 2,500 in 1 M HF/0.1 M HNO_3 thus indicating that anionic fluoride complexes are formed. The K_d value in 0.27 M HF/0.1 M HNO_3 on a strongly acidic cation-exchange resin can be estimated to be on the order of 800. Thus, the breakthrough volume for lanthanides and actinides in the experiments by Pfrepper et al. was not >500 ml (Pfrepper et al. 1998) but rather <40 ml, that is, both the Hf and the Rf descendants were breaking through the cation-exchange columns in less than 2 h. It is impossible to reconstruct what this did to the K_d values in the work of Pfrepper et al. (1998); however, the enormous differences (orders of magnitude) between the K_d values of Hf and Rf in mixed HF/ HNO_3 solutions observed recently by Toyoshima et al. (2008) do cast doubt on the validity of the results by Pfrepper et al. (1998) where indistinguishable K_d values for Hf and Rf were reported.

Strub et al. (2000) have investigated in batch experiments K_d values of the long-lived tracers ^{95}Zr , ^{175}Hf , and ^{233}Th on a strongly acidic cation-exchange resin, Aminex A5, and on a strongly basic anion-exchange resin (Riedel-de H  en) in 0.1 M HNO_3 solutions containing variable concentrations of HF. On the cation-exchange resin, below 10^{-3} M HF, the K_d values for Zr, Hf,

and Th are $>10^3$ indicating the presence of cations. In the range $10^{-3} \text{ M} < [\text{HF}] < 10^{-2} \text{ M}$, the K_d values of Zr and Hf decrease due to the formation of neutral or anionic fluoride complexes. The behavior of Zr and Hf is very similar (Hf sticking to the resin even at slightly higher HF concentrations). The elution of Th from the resin is observed at more than one order of magnitude higher HF concentrations (see [Fig. 20.14](#)). These off-line data were compared with online data taken with ARCA II at the GSI Helmholtz center for heavy ion research, Darmstadt, UNILAC accelerator where short-lived Hf isotopes $^{166,167,168}\dots\text{Hf}$ were produced in xn-reactions of a ^{12}C beam with an enriched ^{158}Dy target. There is a general agreement between both sets of data.

On an anion-exchange resin, as expected, there is little sorption of Zr, Hf, and Th at low HF concentrations. In the range $10^{-3} \text{ M} < [\text{HF}] < 10^{-2} \text{ M}$, the K_d values of Zr and Hf in batch experiments rise simultaneously, that is, in the same range as they decrease on the cation-exchange resin. This shows that the disappearance of the cationic species at low HF concentrations is followed immediately by the formation of anionic fluoride complexes. For Th, the sorption on the anion-exchange resin stays low for all HF concentrations indicating that Th does not form anionic fluoride complexes.

In the Rf experiments (Strub et al. 2000) performed at the PSI Philips Cyclotron, ^{261}Rf was produced in the $^{248}\text{Cm}(^{18}\text{O},5n)$ reaction at 100 MeV. The target contained 10% Gd enriched in ^{152}Gd to produce simultaneously short-lived Hf isotopes that were used to monitor the behavior of Hf and to perform yield checks by γ spectroscopy. Rf and Hf were transported by a $\text{He}(\text{KCl})$ gas jet and were collected for 90 s by impaction inside ARCA II. The deposit was dissolved in 200 μl 0.1 M HNO_3/x M HF (for different values of x) and was fed onto the 1.6×8 mm cation-exchange column at a flow rate of 1 ml/min. The effluent was evaporated to dryness as sample 1. In order to elute remaining Rf and Hf from the column, a second fraction of 200 μl 0.1 M $\text{HNO}_3/0.1$ M HF was collected to strip all group-4 elements from the column. This fraction was referred to as sample 2.

In the anion-exchange experiments, Rf and Hf were transported, collected, and loaded onto the anion-exchange column as in the experiments with the cation-exchange columns. Again,

Fig. 20.14

Sorption of Zr, Hf, Th, and Rf on the cation-exchange resin Aminex A6 in 0.1 M HNO_3 at various HF concentrations. Off-line data are shown for Zr, Hf, and Th, and online data for Rf; re-evaluated data from (Strub et al. 2000)

the effluent was evaporated to dryness as sample 1. In order to elute remaining Rf and Hf from the column, a second fraction of 200 μl 5 M HNO_3 /0.01 M HF was used. This fraction was prepared as sample 2. K_d values are often calculated as follows:

$$K_d = \frac{A_s}{A_l} = \frac{A_{s0} V_1}{A_{l0} m_s} \quad (20.12)$$

with A_s specific activity in the solid phase (Bq/g), A_l activity concentration in the liquid phase (Bq/ml), A_{s0} activity in the solid phase (Bq), A_{l0} activity in the liquid phase (Bq), V_1 volume of the solution (ml), and m_s mass of the resin (g). The K_d values using Eq. (20.12) are obtained such that the activity of sample 1 is attributed to the liquid phase and the activity of sample 2 to the solid phase. However, in elution experiments, Eq. (20.12) yields only correct K_d values for the fortunate situation of equal activities in fraction 1 and 2, that is, cuts between fraction 1 and 2 at the maximum position of the elution curve. To circumvent this deficiency, K_d values shown in Fig. 20.14 were calculated by a computer program that simulates the elution process. The number of theoretical plates (obtained from the shape of tracer elution curves), the free column volume, the volume of fraction 1 and an assumed K_d value are the initial input parameters. In an iteration process, the K_d value is varied until the experimentally observed activity in fraction 1 results.

The results of the online experiments with Rf and Hf on cation-exchange columns are given in Fig. 20.14 together with the results of the off-line batch experiments. The online data for Hf are consistent with the off-line data.

The K_d values for ^{261}Rf at 5×10^{-4} M HF and at 10^{-2} M HF are lower limits as no ^{261}Rf decays were detected in sample 1. It is seen that the decrease of the K_d values for Rf occurs between 0.01 M HF and 0.1 M HF, that is, at one order of magnitude higher HF concentrations than for Zr and Hf. Under the given conditions, the behavior of Rf is intermediate between that of its pseudo-homologue Th and that of its group members Zr and Hf.

The results of the online experiments with the anion-exchange columns are as follows: While the off-line data for Hf clearly indicate that anionic fluoride complexes of Hf are formed for $>10^{-3}$ M HF, one observes that the Hf data taken online are somewhat lower. The reason for this discrepancy is unknown at present. Seemingly, the behavior of Rf is different from that of Zr and Hf, if compared with the off-line data, as there is almost no sorption of Rf on the resin. For HF concentrations for which maximum K_d values are observed for Zr and Hf, there is no indication of a rise in the K_d values for Rf.

This cannot mean that no anionic fluoride complexes exist for Rf at any HF concentration as this would be in contradiction with the results reported by Kacher et al. (1996b), Szegłowski et al. (1990), and Pfrepper et al. (1998). Therefore, the concentration of HNO_3 was varied (Strub et al. 2000) between 0.1 M and 0.01 M at a constant HF concentration of 0.05 M thus varying the concentration of NO_3^- , which acts as a counter ion competing for the binding sites on the anion exchanger. It was observed (Strub et al. 2000) that the K_d values of Hf and Rf rise with decreasing NO_3^- concentration indicating that negatively charged complexes are formed both for Hf and for Rf, but that the counter ion NO_3^- is apparently much more effective in removing Rf from the binding sites on the anion exchanger than in removing Zr and Hf.

This was the starting point for a new series of experiments with anion-exchange chromatography with Aminex A27 in which the HNO_3 and the HF concentration were varied systematically (Strub et al. 2001). The following observations were made:

1. There is a steep dependence of the $\log K_d$ values of Rf on the $\log [\text{NO}_3^-]$ concentration at fixed HF concentration (0.01 M).

2. At fixed $[\text{NO}_3^-]$ concentration (0.003 M), above 0.1 M HF, increasing the HF concentration leads to a decrease in the K_d values for Rf.

Observation (1) suggested that the NO_3^- ion acts as a counter ion competing for the binding sites on the anion-exchange resin with the Rf-fluoride complex. Based on observation (2), a second counter ion discussed by Strub et al. (2001) is the HF_2^- ion, that is, the dominant anion above an initial HF concentration of 0.3 M.

Note that in the work of Kronenberg et al. (2004a) there were two MCT experiments performed with ^{261}Rf using 0.5 M HF/0.1 M HNO_3 and 0.01 M HF, respectively. In the first case, the cation-exchange columns were filled with 330 mg of Dowex 50W \times 8 and were used for 3 h to prevent breakthrough of the cationic descendants. The anion-exchange column in between was filled with 50 mg of the anion exchange resin Dowex 1 \times 8 in the nitrate form. In the second case, the cation-exchange columns were filled with 68 mg Dowex 50W \times 8 and used for 4 h, and the anion-exchange column with 17 mg of Dowex 1 \times 8 in the fluoride form. Each experiment was run for 24 h at an average beam intensity of $3 \times 10^{12} \text{ s}^{-1}$.

The first experiment with 0.5 M HF/0.1 M HNO_3 was performed to corroborate the low K_d values obtained by Strub et al. (2000) with ARCA II on an anion-exchange resin. A total of 80 α decays were observed attributable to ^{253}Es in the sample 1 representing the liquid phase and no event in the strip fraction representing the solid phase. Taking zero to be compatible with three events at 95% confidence level in Poisson statistics, leads to an upper limit for the K_d value of Rf of <3 , which is rather consistent with the data of Strub et al. (2000), but not with the value in 0.27 M HF/0.1 M HNO_3 obtained by Pfrepper et al. (1998).

In the second experiment, performed in pure 0.01 M HF without any HNO_3 , 90 events attributable to ^{253}Es were observed in the strip fraction representing the solid phase and zero events in the liquid phase. This led to a lower limit for the K_d value on the order of 300 compatible with the one measured with ARCA II in pure 0.01 M HF (Strub et al. 2001).

In summary, one can state that the K_d values for Rf obtained with the MCT, that is, low in 0.5 M HF/0.1 M HNO_3 and high in 0.01 M HF, are consistent with the ones determined with ARCA II.

The formation of anionic chloride complexes of Zr, Hf, and Rf above 7 M HCl through 9.5 M HCl was shown in experiments with AIDA (Haba et al. 2002) indicating that the complexing strength in the group-4 elements decreases in the order $\text{Rf} > \text{Zr} > \text{Hf}$. A hypothetical Th-like or Pu-like behavior of Rf was probed with an anion-exchange resin in 8 M HNO_3 in experiments with AIDA. While Th(VI) and Pu(VI) form anionic complexes under these conditions and are sorbed on the anion-exchange resin, Rf remains in solution (Haba et al. 2002) as expected for a typical group-4 element with non Th-like and non Pu-like properties.

The anion-exchange chromatographic behavior of Rf was investigated by Haba et al. (2004) in 1.9–13.9 M HF and compared to that of Zr and Hf. As HF is a weak acid, equilibration among HF, H^+ , F^- , and HF_2^- in aqueous solution is established by the chemical equations

with $K_1 = 935 \text{ M}^{-1}$ and $K_2 = 3.12 \text{ M}^{-1}$ for the first \bullet Eq. (20.13) and the second \bullet Eq. (20.14) equilibria, respectively. The insert of \bullet Fig. 20.15 shows the variation of $[\text{HF}]$, $[\text{H}^+]$, $[\text{F}^-]$, and $[\text{HF}_2^-]$ as a function of the initial $[\text{HF}]_{\text{ini}}$. Above 1 M HF, the concentration of the HF_2^- anion is more than one order of magnitude higher than that of F^- , and $[\text{HF}_2^-]$ increases linearly with

■ Fig. 20.15

Variation of the distribution coefficient, K_d , of Zr and Hf on the anion-exchange resin CA08Y as a function of the initial HF concentration. The linear relation with a slope of -3.0 ± 0.1 is indicated by a dotted line. The insert shows the variation of $[\text{HF}]$, $[\text{H}^+]$, $[\text{F}^-]$, and $[\text{HF}_2^-]$ as a function of $[\text{HF}]_{\text{ini}}$ (Reprinted with the permission from (Haba et al. 2004). Copyright (2009) American Chemical Society)

increasing $[\text{HF}]_{\text{ini}}$. Thus, the decrease of the K_d values of Zr and Hf with increasing $[\text{HF}]_{\text{ini}}$ shown in Fig. 20.15 are explained as the displacement of the metal complex from the binding sites by HF_2^- as the dominant anionic species in solution. In Fig. 20.16, elution curves for Zr and Hf simultaneously produced are shown with (a) a 1.6 mm i.d. \times 7. mm column in 17.4 and 7.7 M HF and with (b) a 1.0 mm i.d. \times 3. mm column in 9.7 and 5.8 M HF. The percentages of the eluted activities are depicted and are nearly the same as expected from the same K_d values in the batch experiment, see Fig. 20.15. According to the Glöckauf equation of chromatography, the eluted activity $A(v)$ with the effluent volume v is

$$A(v) = A_{\text{max}} \exp \left\{ -N(v_{\text{peak}} - v)^2 / 2v_{\text{peak}}v \right\} \quad (20.15)$$

where A_{max} , N , and v_{peak} are the maximum peak height, the number of theoretical plates, and the peak volume, respectively. The results of the fit of Eq. (20.15) are shown as solid or dotted curves in Fig. 20.16. In the dynamic chromatographic system, the K_d value is

$$K_d = v_{\text{peak}} / m_r \quad (20.16)$$

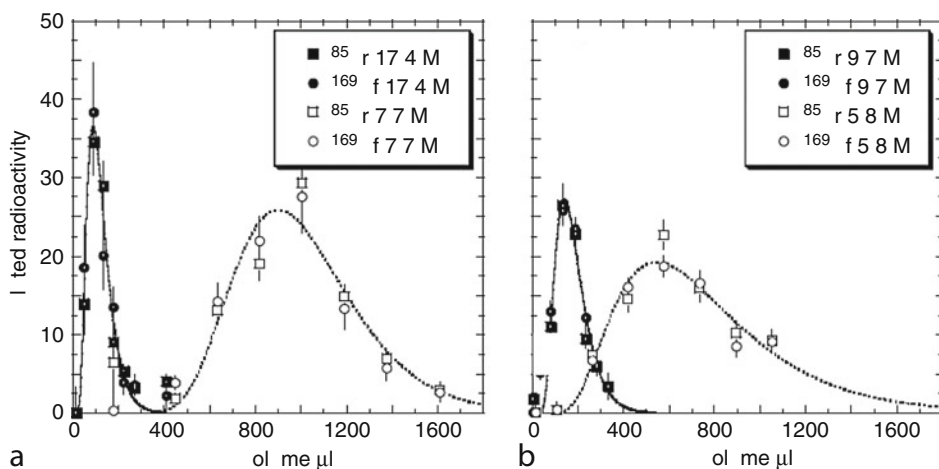

where m_r is the mass of the dry resin. In Fig. 20.17, the K_d values of Zr and Hf calculated with Eq. (20.16) are shown. The K_d values of the different column sizes are consistent with each other.

From the radioactivities A_1 and A_2 observed in fractions 1 and 2, respectively, the percentages %ads were evaluated using the equation

$$\% \text{ads} = 100 A_2 / (A_1 + A_2) \quad (20.17)$$

■ Fig. 20.16

Elution curves of Zr and Hf from (a) 1.6 mm i.d. \times 7.0 mm columns in 17.4 and 7.7 M HF and from (b) 1.0 mm i.d. \times 3.5 mm columns in 9.7 and 5.8 M HF. The solid and dotted curves are fits by the Glöckauf equation. The number of theoretical plates results as (a) 4.8 ± 0.5 and (b) 4.6 ± 0.5 (Reprinted with the permission from (Haba et al. 2004). ■ Fig. 20.18

%ads of Zr, Hf, and Rf on the anion-exchange resin CA08Y as a function of the initial HF concentration with (a) the 1.6 mm i.d. \times 7.0 mm columns and with (b) the 1.0 mm i.d. \times 3.5 mm columns (Reprinted with the permission from (Haba et al. 2004). Copyright (2009) American Chemical Society)

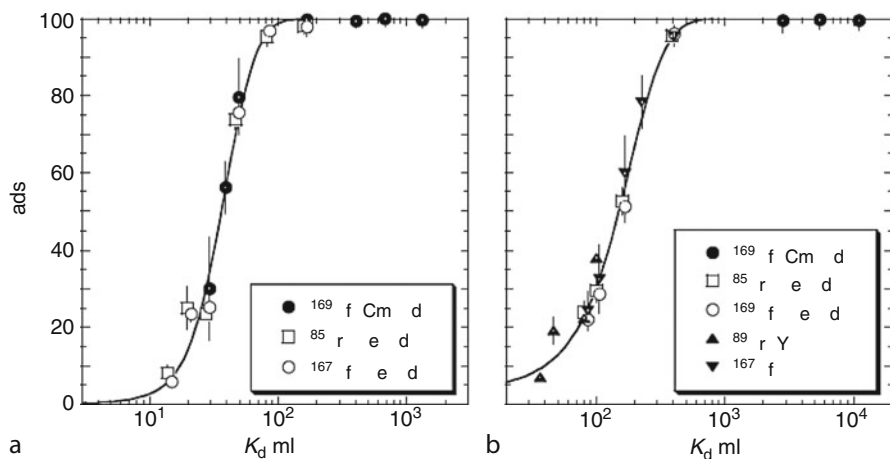

The %ads values of Zr, Hf, and Rf are shown in Fig. 20.18 as a function of $[HF]_{ini}$ for the 1.6 mm i.d. \times 7.0 mm columns (a) for the 1.0 mm i.d. \times 3.5 mm columns (b). The %ads values of Zr and Hf obtained by the online experiments decrease steeply with increasing $[HF]_{ini}$ above 8 M for the larger columns and above 5 M for the smaller ones, while the %ads of Rf decrease at much smaller $[HF]_{ini}$. In Fig. 20.19, the correlations between the %ads values shown in Fig. 20.18 and the K_d values from Fig. 20.15 are plotted with the same symbols as used in Fig. 20.18 and are fitted (solid curves) by

$$\%ads = 100 \exp[-a \exp\{-b(K_d - c)\}] \quad (20.18)$$

Assuming that the kinetics in the complexation and ion-exchange processes of Rf are as fast as those for Zr and Hf, the %ads of Rf from the dynamic column method have been transformed into K_d values using Eq. (20.18). This assumption has subsequently been verified by measuring the elution curve for Rf in 5.4 M HF and by deducing the K_d value according to Eq. (20.16) (Toyoshima et al. 2004). The results from Haba et al. (2004) for Rf are shown as diamonds in Fig. 20.20, together with those of Zr and Hf by the same symbols as used in Fig. 20.17. As shown by a solid line, the K_d values of Rf decrease linearly with increasing $[HF]_{ini}$ and are much smaller than those of Zr and Hf for the same $[HF]_{ini}$. The slope of -2.0 ± 0.3 of $\log K_d$ versus $\log [HF]_{ini}$ for Rf differs from the slope of -3.0 ± 0.1 for Zr and Hf, indicating that different anionic fluoride complexes are formed, that is, RfF_6^{2-} and ZrF_7^{3-} and HfF_7^{3-} . Relativistic molecular density functional calculations (Pershina et al. 2002) – where the free energy change for various fluorination of Rf was compared to those of Zr and Hf – indicated that the complex formation for Rf is much weaker in Rf compared to Zr and Hf in agreement with experiment.

■ Fig. 20.19

Variation of the %ads of Zr and Hf on the anion-exchange resin CA08Y with (a) the 1.6 mm i.d. \times 7.0 mm columns and with (b) the 1.0 mm i.d. \times 3.5 mm columns as a function of the distribution coefficient K_d . ■ Fig. 20.20

Variation of the distribution coefficient K_d of Zr, Hf, and Rf on the anion-exchange resin CA08Y as a function of the initial HF concentration. The linear relationships with slopes -2.0 ± 0.3 for Rf and -3.0 ± 0.1 for Zr and Hf are indicated by the solid and dotted lines, respectively (Reprinted with the permission from (Haba et al. 2004). Copyright (2009) American Chemical Society)

With reference to (Strub et al. 2000, 2001), Toyoshima et al. (2008) have re-examined the fluoride complexation of Rf in mixed HF/HNO₃ solutions by determining %ads values for Rf and correlating them with the relationship between K_d and %ads for Zr and Hf as in (Haba et al. 2004). The variation of the K_d values of Zr and Hf under static conditions and K_d values of Rf from column chromatography as a function of the equilibrated concentration of free F⁻ ($[F^-]_{eq}$) is shown in ▶ Fig. 20.21a. The solid, dashed, and dotted curves are results of theoretical calculations by Haba et al. in which the log K_d is related to the formation constants K_n ($n = 1-6$). From this, it is concluded that the maximum possible value of the formation constant K_6 of Rf is at least one order of magnitude smaller than K_6 of Zr and Hf. Under the assumption that the equilibrium constant of the exchange reaction of MF_6^{2-} with the anion-exchange resin for Rf is equal to those of Zr and Hf ($D_2 = 5 \times 10^5$), a K_6 for Rf results that is approximately three orders of magnitude smaller than those of the lighter homologs. In ▶ Fig. 20.21b, the slopes of the linear correlations of log K_d versus log $[NO_3^-]$ are plotted, which are consistently -2 , indicating that the stoichiometry of the fluoride complexes is MF_6^{2-} in the given range of $[F^-]_{eq}$. For Rf, this has been shown at a fixed equilibrated concentration

■ Fig. 20.21

(a) Variation of the K_d values of Zr and Hf under static conditions and of Rf in column chromatography as a function of the equilibrated concentration of F⁻ ($[F^-]_{eq}$). Values for Zr and Hf are shown for $[NO_3^-] = 0.01, 0.03, 0.1$, and 0.3 M. Values for Rf are shown for $[NO_3^-] = 0.01$ and 0.015 M. The solid, dashed, and dotted curves represent theoretical calculations of K_d values. (b) Variation of the slopes in the log K_d versus log $[NO_3^-]$ plot as a function of $[F^-]_{eq}$ (Reproduced with the permission of Oldenbourg Wissenschaftsverlag, München, (Toyoshima et al. 2008))

■ Fig. 20.22

Distribution coefficients, K_d of Zr and Hf under static conditions and those of Zr, Hf, and Rf from column chromatography as a function of the equilibrated concentration of NO_3^- ($[\text{NO}_3^-]_{\text{eq}}$) at fixed $[\text{F}^-]_{\text{eq}} = 3.0 \times 10^{-3}$ M. Linear relationships of the $\log K_d$ versus $\log [\text{NO}_3^-]_{\text{eq}}$ for Rf and the homologs are indicated by the solid and dashed lines, respectively (Reproduced with the permission of Oldenbourg Wissenschaftsverlag, München, (Toyoshima et al. 2008))

$[\text{F}^-]_{\text{eq}} = 3.0 \times 10^{-3}$ M, see Fig. 20.22. Here, again, the much weaker complexation of Rf by the fluoride ion is apparent compared to that of its homologs. A qualitative explanation comes from the Hard Soft Acid–Base (HSAB) concept. The small fluoride anions are hard donors and prefer the smaller acceptor ions Zr and Hf. The much larger (softer) Rf acceptor ion tends to prefer larger (softer, more polarizable) donor ligand ions like Cl^- , see (Haba et al. 2002).

The extraction behavior of Rf into tributylphosphate from hydrochloric acid, see (Günther et al. 1998), was re-examined in reversed-phase extraction chromatography by Haba et al. (2007). It was found that Zr shows the largest %ads values and that the values for Rf and Hf are close to each other in qualitative agreement with the previous work. A re-examination of the K_d values of Zr, Hf, Th, and Rf on a cation-exchange resin in 0.1 M HNO_3 as a function of the concentration of the fluoride ion by Ishii et al. (2008) is highly consistent with the results by Strub et al. (2000).

20.6 Element 105 (Dubnium)

20.6.1 Theoretical Predictions

In the periodic table, Fig. 20.1, element 105 is placed in group 5 below Ta, so that the electronic ground state configuration is expected to be $[\text{Rn}]5f^{14}6d^37s^2$. This is in agreement with early relativistic calculations (Desclaux 1973) and with a more recent MCDF calculation (Fricke et al. 1993). Thus, a significant contribution of the $7p_{1/2}$ state to the ground state is not expected for Db. Atomic and ionic radii and the first through fifth ionization potentials were calculated by Fricke et al. (1993). Differences in the chemical behavior of element 105 to

extrapolated properties of an eka-tantalum could result from a larger ionic radius, a different effective charge, and a different radial extension of the 6d orbitals which are most important in its molecular bondings (Pershina et al. 1992a, b, c; Fricke et al. 1993; Pershina and Fricke 1993, 1994a, b; Pershina 1998a, b). Redox potentials were estimated for the group-5 elements including the pseudo-homolog Pa on the basis of ionization potentials from MCDF calculations (Ionova et al. 1992; Fricke et al. 1993). It was shown that the stability of the pentavalent state is increasing from V to Db, while the stability of the tetra- and trivalent state is decreasing. Although it was found that the stability of the maximum oxidation state decreases when going from element 103 to 105, no extra stability of the trivalent state in element 105 was found (Ionova et al. 1992). It would be interesting to test this prediction in reduction experiments similar to the experiments performed on element 103 (Scherer et al. 1988).

DS DVM calculations allow the degree of covalency in the bonding and the effective charge on the central atom in halide and oxyhalide compounds of the group-5 elements (Pershina et al. 1992a, b, c; Pershina and Fricke 1993). From these, it was inferred (Pershina et al. 1992b) that DbBr_5 should be more volatile than its lighter homologs, whereas classical extrapolations within the periodic table would yield a lower volatility (Türler 1996).

The electronic structure of the group-5 anionic complexes $[\text{MCl}_6]^-$, $[\text{MOCl}_4]^-$, $[\text{M}(\text{OH})_2\text{Cl}_4]^-$, and $[\text{MOCl}_5]^{2-}$ was calculated with the DS DVM code (Pershina et al. 1994). By applying Born's theory of phase transition between the aqueous phase and the organic phase (mixed HCl/HF solutions and TiOA, see (Kratz et al. 1989), the extraction sequence $\text{Pa} > \text{Db} > \text{Nb}$ was predicted, which is the inverse sequence compared to that observed experimentally (Kratz et al. 1989). Due to the complicated situation in mixed HCl/HF solutions with possibilities to form mixed chloride/fluoride- or fluoride complexes, it was recommended to repeat the experiments in the pure HCl system (Pershina et al. 1994). While these new experiments were prepared (Paulus 1997), Pershina (1998a, b) considered hydrolysis and complex formation of Nb, Ta, Pb, and Pa in HCl solutions as competing processes in equilibria such as

Here, the hydrolyzed species on the left is the one staying in the aqueous phase, and the chloride complex on the right is expected to be extracted into the amine phase. Calculations of the electronic structure of the hydrolyzed species of Nb, Ta, Db, and Pa, and of their complexes in HCl solutions were performed (Pershina 1998a, b) using the DS DVM method. On the basis of results of these calculations, relative values of the free energy change of the reactions of complex formation were determined (Pershina 1998a, b). The order of complex formation above 4 M HCl was found to be $\text{Pa} \gg \text{Nb} > \text{Db} > \text{Ta}$. This sequence is predominantly defined by the electrostatic energy of the metal–ligand interaction. The hydrolysis of the chloride complexes, as a reverse process, was found to change as $\text{Ta} > \text{Db} > \text{Nb} \gg \text{Pa}$. Using finally Born's theory of metal-ion extraction, the following trend in the extraction of the anionic species from aqueous solutions containing >4 M HCl was predicted (Pershina 1998b): $\text{Pa} \gg \text{Nb} \geq \text{Db} > \text{Ta}$. This was the first time that detailed predictions of the aqueous-phase properties of these elements were made. It shows that a detailed analysis of the electronic structure of the compounds formed under specific conditions is necessary and leads to the prediction of an inversion of the trend of the properties when going from the 5d to the 6d elements. This has already been observed for the group-4 elements (Günther et al. 1998), and it is of importance to verify this experimentally for the group-5 elements.

20.6.2 Experimental Results

The volatilities of the chlorides and bromides of element 105 were first studied with $1.8 \text{ s } ^{261}\text{Db}$ in a similar thermochromatographic apparatus as used for element 104 (Zvara et al. 1974, 1976). Results from the volatility study of the bromides are shown in [Fig. 20.23](#). In these experiments, the spontaneous-fission track distribution detected on mica track detectors along the chromatographic column was assumed to characterize the behavior of element 105. The measured distribution of ^{261}Db was corrected for the much shorter half-life before comparing it with the adsorption zones of longer-lived tracer activities of various elements including $3.3 \text{ min } ^{169}\text{Hf}$ and $14.6 \text{ h } ^{90}\text{Nb}$. The distance between the integral curve for ^{90}Nb and the center of the shaded zone in [Fig. 20.23](#) is $60 \pm 10^\circ\text{C}$ and characterizes dubnium bromide as being less volatile than niobium bromide and close in volatility to hafnium bromide.

First isothermal gas chromatography experiments with the bromides of the group-5 elements Nb, Ta, and Db (Gäggeler et al. 1992b; Gäggeler 1994) were performed with an earlier version of the OLGA apparatus shown in [Fig. 20.5](#). The results are shown in [Fig. 20.24](#) where the chemical yield as a function of the isothermal temperature is a measure of the volatility. The yields for Nb were measured with HBr as brominating agent, for Ta, HBr plus BBr_3 vapor was used, and for Db both HBr and HBr plus BBr_3 vapor were applied. The solid curves are the results of Monte Carlo simulations with the free parameter $\Delta H_a^{\circ(T)}$ adjusted to the data by a least-squares fit.

Within the error limits, the bromides of Nb and Ta have the same volatility while the Db bromide is less volatile as already indicated by the thermochromatographic data (Zvara et al. 1976). Both sets of experimental data seem, at first glance, to disagree with results from

Fig. 20.23

Upper panel: Distribution of fission tracks (circles) attributed to element 105 bromides from three thermochromatographic experiments compared with the deposition zone of $14.6 \text{ h } ^{90}\text{Nb}$ (histogram) and the temperature gradient along the column. **Lower panel:** Integral distribution of $14.6 \text{ h } ^{90}\text{Nb}$ and of $3.3 \text{ min } ^{169}\text{Hf}$ (smooth solid lines) and the integral fission-track distribution (dashed step function). The shaded zone depicts the limits of the “corrected” position of the step function for element 105 after consideration of the difference in the half-life of ^{261}Db and the Hf and Nb isotopes (Adapted from Zvara et al. (1976))

■ Fig. 20.24

Relative yield of Nb (open triangles), Ta (full circles), and Db (squares) bromides as a function of temperature in the isothermal part of the gas-chromatography column. Inserted into the figure is information on the brominating agents and the adsorption enthalpies derived from Monte Carlo simulations (solid lines). After (Gäggeler et al. 1992b) (Reproduced with the permission of Oldenbourg Wissenschaftsverlag, München)

relativistic molecular calculations (Pershina et al. 1992b). Theory predicts that DbBr_5 has the highest covalency and lowest effective charge among the group-5 bromides, which should make DbBr_5 more volatile than its homologs. Also, a “nonrelativistic” thermodynamical model (Eichler 1994) leads to the prediction of a band of DbBr_5 volatilities that are close to those of NbBr_5 and TaBr_5 . This is depicted in Fig. 20.25.

The current interpretation of the low Db-bromide volatility is the possible formation, due to the presence of traces of oxygen in the system, of the oxytribromide DbOBr_3 instead of the pentabromide. This is supported by theoretical calculations, which showed for element 105 a much stronger tendency to form oxyhalide compounds than for Nb and Ta (Pershina et al. 1992c). While the generally lower volatility of the oxyhalide can be inferred from the DS DVM calculations, it remains open whether the DbOBr_3 volatility will be higher or lower than that of the Nb and Ta oxyhalides (Pershina et al. 1992c). Further experiments are needed to clarify the situation.

In a series of experiments investigating the volatility of the chlorides of the group-5 elements, it was observed that the dubnium chlorides are more volatile than the bromides, possibly similar in volatility to NbCl_5 (Kadkhodayan 1993; Türler 1996). This is in agreement with the finding that the group-4 and -5 chlorides are more volatile than the respective bromides. For Ta, only a species with a much lower volatility was observed, presumably TaOCl_3 (Türler 1996).

In the most recent experiment (Türler et al. 1996), either precautions were taken to keep the partial pressure of oxygen as low as possible or controlled partial pressures of free O_2 were

■ Fig. 20.25

Vapor pressure curves for Nb, Ta, and Db bromides. The curve DbBr_5 exp. was deduced from the experimental data shown in ▶ Fig. 20.24. The curve theor.-rel. is from Pershina et al. (1992b). The shaded area denoted theor.-non-rel. is from Eichler (1994)

Relative yields of 15 s ^{99g}Nb pentachloride and oxychloride as a function of isothermal temperature and O_2 "partial pressure." Full circles: $^{99g}\text{NbCl}_5$, $p(\text{O}_2) \leq 1$ ppmv, $\Delta H_a^{\circ(T)}(\text{NbCl}_5) = -80$ kJ/mol. Full squares: 50% $^{99g}\text{NbCl}_5 + 50\%$ $^{99g}\text{NbOCl}_3$, $1 \text{ ppmv} \leq p(\text{O}_2) \leq 80$ ppmv. Full diamonds: $^{99g}\text{NbOCl}_3$, $p(\text{O}_2) \geq 80$ ppmv, $\Delta H_a^{\circ(T)}(\text{NbOCl}_3) = -99$ kJ/mol. The solid lines are the results of the Monte Carlo model using $\Delta H_a^{\circ(T)}$ values which best fit the experimental data (Reproduced with the permission of Oldenbourg Wissenschaftsverlag, München, (Türler et al. 1996))

applied to study the volatility of the chlorides of niobium and dubnium. ▶ Figure 20.26 illustrates the response of Nb to the various oxygen concentrations. It shows that the concentration of O_2 and oxygen containing compounds (e.g., H_2O) is critical in volatility experiments with group-5 elements and needs carefully to be controlled.

For a “partial pressure” of oxygen below 1 ppmv (parts per million by volume), NbCl_5 is formed with purified HCl as chlorinating agent. For $p(\text{O}_2)$ between 1 ppmv and 80 ppmv two species of different volatilities (NbCl_5 and NbOCl_3) are observed. Both species were produced in about equal amounts, which resulted in a yield curve with two steps. Finally, above $p(\text{O}_2) \geq 80$ ppmv, NbOCl_3 was identified as the volatile species. The conditions at which the subsequent experiments with ^{262}Db were conducted were as close as possible to the conditions where NbCl_5 was formed in the test experiments. The relative yield curve for ^{262}Db is shown in [Fig. 20.27](#) in comparison with the yield curves for NbCl_5 and NbOCl_3 from [Fig. 20.26](#). For element 105, again a yield curve consisting of two steps is observed, suggesting that both DbCl_5 and DbOCl_3 were present (Türler et al. 1996). $\Delta H_a^{\circ(T)}(\text{DbOCl}_3) = -117$ kJ/mol was obtained in the application of the Monte Carlo model at the higher temperatures and only a lower limit of the absorption enthalpy $\Delta H_a^{\circ(T)}(\text{DbCl}_5) > -98$ kJ/mol can be given for the pentachloride. An investigation of the Ta volatility is needed to complete the picture. Also, future experiments should extend the yield measurements of Db chlorides to lower temperatures for a comparison with theoretical predictions. At this time, the data show that, indeed, dubnium has a strong tendency to form the oxychloride as predicted.

First studies of the aqueous phase chemistry of element 105 were conducted by Gregorich et al. (1988). Like Nb and Ta, Db was adsorbed on glass surfaces upon fuming with nitric acid. In 801 manually performed experiments, 24 α events due to the decay of 34 s ^{262}Db or its 3.9 s ^{258}Lr daughter including five $\alpha\alpha$ mother-daughter correlations were observed. In an attempt to study the extraction of the dubnium fluoride complex from 3.8 M HNO_3 /1.1 M HF into methyl isobutyl ketone (MIBK), no decays attributable to ^{262}Db could be observed.

Under these conditions, Ta extracts while Nb does not. From an extrapolation in group 5 it was expected that Db would behave more like Ta than Nb but, surprisingly, Db apparently did

Fig. 20.27

Relative yield of NbCl_5 (full circles) and NbOCl_3 (full diamonds) as a function of the temperature of the isothermal part of the gas-chromatography column (Türler et al. 1996). The data for dubnium (triangles) indicate that both DbCl_5 and DbOCl_3 were formed under the experimental conditions. The solid lines are the results of Monte Carlo simulations with the adsorption enthalpies given in the text (Reproduced with the permission of Oldenbourg Wissenschaftsverlag, München, (Türler et al. 1996))

not extract. The non Ta-like behavior of Db might indicate that Db forms polynegative anions like $[\text{DbF}_7]^{2-}$ under the chosen conditions. The higher charge would then prevent extraction even into solvents with a relatively high dielectric constant such as MIBK.

To investigate this unexpected finding and more facets of the dubnium chemistry, a large number of automated separations were conducted with the Automated Rapid Chemistry Apparatus ARCA II (Schädel et al. 1989). In the first experiments, extraction chromatography separations with the liquid anion exchanger TiOA on an inert support (Kratz et al. 1989) were performed. TiOA extracts all group-5 elements including Pa, irrespective of the formation of mono- or polynegative anions, from HCl solutions above 10 M. At lower concentrations, selective back extractions allowed to distinguish between the chemical behavior of Nb, Ta, Pa, and Db. Small amounts of HF (typically 0.02 M) were added to the HCl solutions as this is recommended in the literature (Korkisch 1989) to prevent hydrolysis and “to maintain reproducible solution chemistry” of the group-5 elements. Element 105 was shown (Kratz et al. 1989) to extract into the TiOA on the chromatographic columns in ARCA II from 12 M HCl/0.02 M HF as do Nb, Ta, and Pa, due to the formation of anionic halide complexes. In subsequent elutions, the elution positions of element 105 relative to those of Nb, Ta, and Pa were determined (Kratz et al. 1989) in 10 M HCl/0.025 M HF, in 4 M HCl/0.02 M HF, and in 0.5 M HCl/0.01 M HF (Zimmermann et al. 1993). Two thousand one hundred and ninety-eight collection and separation cycles on a 1 min time scale (Kratz et al. 1989; Zimmermann et al. 1993) were necessary to obtain the results shown in Fig. 20.28.

It is seen that element 105 shows a striking non Ta-like behavior and that it follows, at all HCl concentrations below 12 M, the behavior of its lighter homolog Nb and that of its pseudo-homolog Pa. From this similarity, it was concluded that the complex structure of Db was $[\text{DbOX}_4]^-$ or $[\text{Db}(\text{OH})_2\text{X}_4]^-$, and the preferential formation of oxyhalide complexes of element 105 was also predicted theoretically (Perschina et al. 1994). As explained in Sect. 20.6.1, due to the complicated situation in mixed HCl/Hf solutions, it was recommended (Perschina et al. 1994) to repeat the experiments in the pure HCl system.

The proximity of the Db behavior in the TiOA experiments to Pa was the reason for performing a series of extractions of Db into diisobutyl carbinol (DIBC), a secondary alcohol, which is a specific extractant for Pa. The extraction from concentrated HBr in ARCA II was followed by the elution of a Nb fraction in 6 M HCl/0.0002 M HF, and a Pa fraction in 0.5 M HCl. The number of ^{262}Db decays observed in the Nb fraction indicated that less than 45% of the Db was extracted into DIBC and the extraction sequence $\text{Db} < \text{Nb} < \text{Pa}$ was established (Gober et al. 1992). This was tentatively attributed to an increasing tendency of these elements to form non-extractable polynegative complex species in the sequence $\text{Pa} < \text{Nb} < \text{Db}$.

Another series of experiments with Db used its complexation by the α -hydroxyisobutyrate anion (α -HIB), $(\text{CH}_3)_2\text{COH-COO}^-$, which depends strongly on the charge of the metal ion (Schädel et al. 1992). Elutions from cation exchange columns in ARCA II with unbuffered 0.05 M α -HIB showed that Db, together with Nb, Ta, and Pa, elutes promptly (within 4 s), while tri- and tetravalent ions are strongly retained on the resin (Schädel et al. 1992). This provided an unambiguous proof that pentavalent Db is the most stable valence state in aqueous solution. These separations, being fast and very clean, were also used to detect the hitherto undiscovered isotope 27 s ^{263}Db produced in the $^{249}\text{Bk}(^{18}\text{O},4n)$ reaction (Kratz et al. 1992; Schädel et al. 1992).

As suggested in (Perschina et al. 1994), the amine extractions of the group-5 elements were systematically revisited by Paulus et al. (Paulus 1997; Paulus et al. 1999a, b). Perschina (1998a, b), by considering the competition between hydrolysis and halide complex formation,

■ Fig. 20.28

Percentage extracted activity of Nb, Ta, and Pa tracers (curves) as a function of HCl concentration in the system TiOA-HCl/0.03 M HF. The **bold bars** encompass the upper and lower limits deduced for the Db extraction from the elution positions in the chromatography experiments (Kratz et al. 1989; Zimmermann et al. 1993). The complete extraction of Db into TiOA from 12 M HCl/0.02 M HF is not indicated for clarity (Reprinted with the permission of Oldenbourg Wissenschaftsverlag, München, (Zimmermann et al. 1993))

predicted the extraction sequence $\text{Pa} \gg \text{Nb} \geq \text{Db} > \text{Ta}$, as mentioned above. K_d values for Nb, Ta, and Pa were measured in new batch extraction experiments with the quaternary ammonium salt Aliquat 336 and pure HF, HCl, and HBr solutions (Paulus 1997; Paulus et al. 1999a, b). Based on these results, new chromatographic column separations with ARCA II were elaborated to study separately the fluoride and chloride complexation of element 105. As an example, the separation of Eu-, Ta-, Nb-, and Pa tracers in the Aliquat 336/HCl system is shown in ► Fig. 20.29. After feeding of the activities onto the column in 10 M HCl (whereby the disturbing actinides modeled by trivalent Eu run through the column), Ta is eluted in 6 M HCl, Nb in 4 M HCl, and Pa in 0.5 M HCl (Paulus 1997; Paulus et al. 1999a, b).

One thousand three hundred and seven experiments were conducted with element 105 with a cycle time of 50 s. In the system Aliquat 336/HCl, after feeding of the activity onto the column in 167 μl 10 M HCl, a Ta fraction was eluted in 183 μl 6 M HCl as is shown in ► Fig. 20.29. This was followed by stripping of a combined Nb, Pa fraction from the column in 167 μl 6 M HNO_3 /0.015 M HF. From the distribution of α decays between the Ta fraction and the Nb, Pa fraction, a K_d value of 438^{+532}_{-166} for element 105 in 6 M HCl was deduced, which is close to that of Nb and differs from the values for Pa and Ta, see ► Fig. 20.30. Thus, the extraction sequence $\text{Pa} > \text{Nb} \geq \text{Db} > \text{Ta}$ is established exactly as theoretically predicted (Pershina 1998a, b).

In the system Aliquat 336/HF, the reaction products were loaded onto the column in 167 μl 0.5 M HF. In elutions with 133 μl 4 M HF (Pa fraction), and with 167 μl 6 M HNO_3 /0.015 M HF (combined Nb, Ta fraction) all α -decay events of element 105 were observed in the Nb, Ta

■ Fig. 20.29

Elution curves for trivalent cations (Eu), and for Ta, Nb, and Pa from Aliquat 336/Voltalef columns (1.6×8 mm) in ARCA II. The activities are fed onto the column in 10 M HCl. This is followed by separate elutions of a Ta fraction in 6 M HCl, of a Nb fraction in 4 M HCl, and of a Pa fraction in 0.5 M HCl (Reproduced with the permission of Oldenbourg Wissenschaftsverlag, München, (Paulus et al. 1999b))

fraction. This results in a lower limit for the K_d value of element 105 in 4 M HF of >570 , which is close to that of Nb and Ta ($\geq 10^3$) and differs markedly from that of Pa (~ 10).

It is satisfying to see that not only the extraction sequence in the system Aliquat 336/HCl is correctly predicted by theory (Pershina 1998b) but that the calculated free energy changes of the reactions of complex formation are on the order of 12 eV for the fluorides, 20 eV for the chlorides, and 22 eV for the bromides (Pershina et al. 1999) (not taking into account the Gibbs free energy of formation of H_2O which is 3 eV), which again is in agreement with the experimental findings: For the fluorides, the equilibrium is always on the right hand side of Eq. (20.19) even at low HF concentrations (Paulus 1997); for the chlorides, it takes >3 M HCl to form extractable chloride complexes and for the bromides, the threshold is shifted to >6 M HBr (Paulus 1997).

Anion-exchange chromatography of Db produced in the $^{248}\text{Cm}(^{19}\text{F},5n)^{262}\text{Db}$ reaction was investigated by Tsukada et al. (2009) together with the homologs Nb and Ta and the pseudo-homolog Pa with the anion-exchange resin CA08Y in 13.9 M HF solution. For Nb and Ta, elution curves were determined and K_d values were determined with fits by the Glöckauf equation. The latter were again correlated with %ads values, and the correlation was used to determine a K_d from the %ads values of ^{262}Db and ^{170}Ta in 13.9 M HF solution. The variation of the K_d values of Db, Nb, Ta, and Pa on the anion-exchange resin CA08Y as a function of $[\text{HF}]_{\text{ini}}$ are shown in Fig. 20.31. The results indicate that the sorption of Db on the resin is significantly different from that of the homologs and that the sorption decreases in the

■ Fig. 20.30

Distribution coefficients of Pa, Nb, and Ta in the system Aliquat 336/HCl. The K_d for Db in 6 M HCl is also indicated (Paulus 1997). The system shows the inverse extraction sequence as compared to the TiOA/HCl/HF system (● Fig. 20.28) as theoretically predicted (Pershina 1998b) (Reproduced with the permission of Oldenbourg Wissenschaftsverlag, München, (Paulus et al. 1999b))

sequence $Ta \approx Nb > Db > Pa$. The measurement of distribution coefficients at different HF concentrations is necessary to determine the chemical forms of the group-5 elements to compare the experimental adsorption sequence with that from theoretical predictions.

20.7 Element 106 (Seaborgium)

20.7.1 Theoretical Predictions

Relativistic molecular orbital calculations (Pershina and Fricke 1994a, 1995) with the DS DVM code have shown that the volatile species $SgCl_6$ as well as $SgOCl_4$ will decompose at high temperatures by analogy with $MoCl_6$ and $MoOCl_4$ transforming into compounds of Mo(V). Therefore, DS DVM calculations were performed of the electronic structure of the group-6 dioxodichlorides MO_2Cl_2 ($M = Cr, Mo, W, Sg$) and their analysis with respect to the stability of the compounds toward thermal decomposition. In ● Table 20.2, the Mulliken analysis data (Pershina and Fricke 1996; Pershina et al. 1996) effective charges Q_M , overlap populations, OP , and dipole moments, μ , are presented.

The trends in Q_M , OP , and the metal-ligand bond energies estimated on the basis of the data in ● Table 20.2, are reminiscent of those for the group-6 oxotetrachlorides, $MOCl_4$. However, the energy gaps ΔE between the highest occupied molecular orbital (HOMO) and the lowest unoccupied molecular orbital (LUMO) are much larger for the dioxodichlorides, MO_2Cl_2 , than for the oxotetrachlorides. This should prevent the dioxodichlorides from thermal

■ Fig. 20.31

Distribution coefficients K_d of Db, Nb, Ta, and Pa on the anion-exchange resin CA08Y as a function of $[\text{HF}]_{\text{ini}}$. The values of Db and Ta obtained from online column experiments are indicated by the closed symbols, while those of Nb, Ta, and Pa from batch experiments are shown by the open symbols. The K_d values of Rf, Zr, and Hf taken from (Haba et al. 2004) are also plotted (Reproduced with the permission of Oldenbourg Wissenschaftsverlag, München, (Tsukada et al. 2009))

■ Table 20.2

Effective charges, Q_M , overlap populations, OP , and dipole moments, μ , for MO_2Cl_2 (Pershina and Fricke 1996; Pershina et al. 1996)

	MoO_2Cl_2	WO_2Cl_2	SgO_2Cl_2
Q_M/e	1.03	1.08	0.97
OP ($M = 2O$)	1.07	1.38	1.48
OP ($M - 2Cl$)	0.64	0.86	0.85
OP (tot)	1.72	2.23	2.34
μ/D	1.04	1.35	1.83

dissociation and should make MoO_2Cl_2 , WO_2Cl_2 , and SgO_2Cl_2 much more stable than MoOCl_4 , WOCl_4 , and SgOCl_4 even though their $M\text{-Cl}$ bond strengths are similar.

The lower volatility of WO_2Cl_2 compared to that of MoO_2Cl_2 was associated (Pershina 1996; Pershina et al. 1996) with the larger dipole moment of the former compound. And from the trend of the dipole moments in Table 20.2, the following sequence in volatility was predicted: $\text{MoO}_2\text{Cl}_2 > \text{WO}_2\text{Cl}_2 > \text{SgO}_2\text{Cl}_2$.

These theoretical results (Pershina and Fricke 1994a, 1995, 1996; Pershina et al. 1996) have influenced the decision (Dressler et al. 1995) of the gas-phase chemists to use oxygen containing chlorinating agents, and the volatility data in ▶ Fig. 20.35 are in agreement with the prediction. Note that the dipole moments in the dioxodichlorides of the group-6 elements are the result of the ds hybridization in MO_2^{2+} giving rise to a cis structure of the oxygen ligands (Pershina and Fricke 1996).

DS DVM calculations (Pershina and Fricke 1994a, 1996; Pershina et al. 1996) confirmed the full analogy between SgO_2Cl_2 and MO_2Cl_2 ($\text{M} = \text{Mo}$ and W). Thus, one can also assume the same type of complexes of seaborgium in HCl and HF solutions as those of Mo and W. Results of the extraction of the Mo, W, and U species from aqueous HCl solutions into organic media have shown the opposite trend in the distribution coefficients, $K_d(\text{U}) > K_d(\text{Mo}) > K_d(\text{W})$, compared with HF solutions where $K_d(\text{U}) < K_d(\text{Mo}) < K_d(\text{W})$. Pershina (1996) associates this with two different extraction mechanisms. In the HCl case the mechanism of the formation of an adduct is valid:

The process of the molecule transfer (ΔG_t) between the aqueous and the organic phase in this case is defined by the strength of the dipole–dipole interaction of the $\text{MO}_2\text{Cl}_2(\text{H}_2\text{O})_2$ species with water molecules. The values of dipole moments obtained as a result of the DS DVM calculations (Pershina and Fricke 1996), ▶ Table 20.2, then define the distribution coefficients in 2–6 M HCl in the sequence $\text{U} > \text{Mo} > \text{W} > \text{Sg}$.

The absence of a dipole moment in $\text{UO}_2\text{Cl}_2(\text{H}_2\text{O})_2$ with a linear structure of the oxygen ligands explains its superior extractability. In HF solutions, anion exchange takes place (Pershina 1996) according to

Here, the free energy of transfer is determined by the sizes of the extracted species leading to the sequence $\text{U} < \text{Mo} < \text{W}$.

The distribution coefficient is finally dependent on the complex formation and on the partition of the complexes between the phases. Details of the electronic structure of the anionic complexes existing in HF solutions still need to be studied.

Based on MCDF calculations of the ionization potentials for all oxidation states of the group-4 elements (Johnson et al. 1999), Pershina et al. (1999b) made use of a linear correlation between the calculated ionization potentials and the redox potentials of the group-6 elements to predict the reduction potentials of the various oxidation states of seaborgium in acid solutions. For example, the reduction potential $E^\circ(\text{Sg}^{\text{VI}}/\text{Sg}^{\text{III}})$ is -0.46 V. Thus, it might be interesting to attempt to reduce seaborgium by contact with a strongly reducing metal such as Al ($E^\circ = -1.662$ V) in future experiments. Throughout the transactinide series, the stability of the maximum oxidation state decreases in the sequence $\text{Rf} > \text{Db} > \text{Sg}$.

Relativistic molecular density-functional calculations of the electronic structure of hydrated and hydrolyzed species have been performed by Pershina and Kratz (2001) for the group-6 elements Mo, W, and Sg. By use of the electronic density distribution data, relative values of the free energy changes and constants of hydrolysis reactions were defined. The results show hydrolysis of the cationic species with the formation of neutral molecules to decrease in the order $\text{Mo} > \text{W} > \text{Sg}$, which is in agreement with experiment for Mo, W, and Sg. For the

further hydrolysis process, with the formation of the anionic species, the trend is predicted to be reversed: Mo > Sg > W. A decisive energetic factor in the hydrolysis process is the predominant electrostatic metal–ligand interaction.

20.7.2 Experimental Results

First attempts to chemically characterize seaborgium were reported by Timokhin et al. in 1992 (Timokhin et al. 1996) and were completed in 1993 and 1995 (Yakushev et al. 1996; Zvara et al. 1998). The authors used the short-lived isotope $0.9\text{ s }^{263}\text{Sg}$ produced in the $^{249}\text{Cf}(^{18}\text{O},4n)$ reaction and their fast online thermochromatography equipment shown in Fig. 20.32. The recoils were thermalized and swept from the target chamber in 1 l/min argon gas directly into the thermochromatographic column; an open, 3.5 mm i.d. tube of fused silica, 120 cm in length. About 60% of the recoils reached the column, the rest deposited on the walls of the target chamber. At the column inlet, the flowing argon was mixed with the reactive gas supplied from the end part of the apparatus through an annular channel formed by the glass jacket of the column. 0.2 l/min of air saturated with SOCl_2 vapor was supplied to yield partial pressures of 20 mmHg ($\sim 2.7\text{ kPa}$ or 2.6 vol %) of SOCl_2 and 25 mmHg ($\sim 3.3\text{ kPa}$ or 3.3 vol %) of O_2 in the resulting carrier gas.

In test experiments with Mo and W radioisotopes with half-lives in the range of seconds to hours, Yakushev et al. (1996) generally observed two deposition zones, a “high temperature zone” at about 250°C and a “low temperature zone” at about 160°C . The distribution of the activities between these zones depended on the half-life such that the percentage deposited in the lower temperature zone increased with increasing half-lives of the nuclides. This was interpreted as evidence for a rapid formation of the dioxodichlorides, MO_2Cl_2 , that are subsequently relatively slowly converted into the more volatile oxotetrachlorides, MOCl_4 . For very short-lived species, a deposition on the quartz surface as the dioxodichloride was expected. Zvara et al. (1998) also report that, in their thermochromatography column, short-lived W isotopes reached their deposition zone in less than 0.8 s.

Fig. 20.32

Schematic representation (Zvara et al. 1998) of the thermochromatographic equipment used by Timokhin et al. (1996), Yakushev et al. (1996) and Zvara et al. (1998) (Reprinted with the permission of Oldenbourg Wissenschaftsverlag, München, (Zvara et al. 1998))

The inner surface of the fused silica column served as a solid state detector for spontaneous fission (SF) events. After the discovery of the α -emitting 0.9 ± 0.2 s ^{263}Sg by Ghiorso et al. (1974) with a cross section on the order of 0.3 nb, Druin et al. (1979), reported observation of a $0.64^{+0.32}_{-0.18}$ s SF activity assigned to ^{263}Sg with 0.6 nb cross section at 95 MeV. This was thought to be the origin of the fission tracks in the fused silica column, which were made visible by etching subsequent 5 cm segments of the column with HF and scanning the surface with an optical microscope. At room temperature, the detection efficiency with this technique is 65%. It decreases at higher temperatures due to annealing of the tracks.

Six experiments with the $^{249}\text{Cf}(^{18}\text{O},4n)^{263}\text{Sg}$ reaction were performed with a total number of ^{18}O ions (called “beam dose”) between 0.8×10^{17} and 2.6×10^{17} in each case. In the first two thermochromatographic runs, a quartz wool filter was present in the start zone as in most ancillary tests. No fission tracks were found in the column. In the four following experiments, this filter was omitted. In the fifth experiment, no chlorinating reagents were added and the column was kept at ambient temperature to test the behavior of the nonvolatile actinides. 18 SF events were detected within the first 15 cm of the column. The number of tracks found in runs 3, 4, and 6 are 10, 20, and 11, respectively, and these are mostly distributed along the first 20–120 cm of the column, see [Fig. 20.33](#).

The same data from runs 3, 4, and 6 are shown again in [Fig. 20.34](#) with corrections for the decreased detection efficiency due to annealing in the hotter part of the column. The thick solid line is a fit of the theoretical peak shape in nonequilibrium thermochromatography (Zvara 1990) to the corrected data. One notices a marked difference in the deposition temperatures of element 106 and ^{176}W . According to Zvara et al. (1998), this difference can hardly be associated with the different half-lives, 0.9 s versus 2.5 h, resulting in different migration times (Zvara 1985). Rather, according to Zvara et al. (1998), the different deposition zones for ^{263}Sg and ^{176}W point to nonidentical chemical states of the two homologs: The short-lived ^{263}Sg deposited as SgO_2Cl_2 and decayed long before this compound could be transformed into SgOCl_4 . The long-lived ^{176}W first rather quickly formed WO_2Cl_2 but was completely converted into the more volatile WOCl_4 . In the first two “unsuccessful” experiments, the retention time of seaborgium on the quartz wool filter was assumed (Zvara et al. 1998) to have exceeded the nuclear half-life of the seaborgium isotope(s). A longer retention time on the filters than in the open column was observed earlier by the authors in investigations of the group-4 and -5 elements and attributed to the large effective surface of the quartz filters (equivalent to several meters of an open column).

The work by Zvara et al. (Timokhin et al. 1996; Yakushev et al. 1996; Zvara et al. 1998) has been met with skepticism. This concerns both the assignment of the observed SF activity and the chemical state of the tungsten and seaborgium oxochlorides. The latter is discussed first.

As mentioned above, different deposition temperatures due to different half-lives are a well-known phenomenon (Zvara 1985). It is difficult to understand that the formalism to analyze thermochromatographic data has not been applied by Zvara et al. (1998) to correct quantitatively for the largely different half-lives of ^{263}Sg and ^{176}W and to extract the adsorption enthalpy. Also, before a statement about the possible chemical state of seaborgium is made, the data for short-lived isotopes of the homologous elements Mo and W should be presented and analyzed quantitatively with the formalism developed by Zvara (1985). The latter was used by Türler (1999) and applied to the data in [Fig. 20.34](#) resulting in values of $\Delta H_a^{\circ(\text{T})} = -110$ kJ/mol for ^{263}Sg and $\Delta H_a^{\circ(\text{T})} = -102$ kJ/mol for ^{176}W . These values are much higher than the values reported in (Türler et al. 1999), which are -98 kJ/mol for ^{265}Sg and -96 kJ/mol for ^{168}W .

■ Fig. 20.33

Distribution of fission tracks along the thermochromatographic column (Zvara et al. 1998). The *hatched* histograms stand for fission events detected in runs with the carrier gas argon (1 l/min) + air (0.2 l/min) + SOCl_2 (20 mmHg). The white (*not hatched*) histogram depicts the fission events observed in the run with pure argon in a cold column. The *dotted* curve gives the temperature profile along the column. The *solid* line indicates the distribution of gamma activity due to $2.5 \text{ h } ^{176}\text{W}$ in an arbitrary linear scale (Reprinted with the permission of Oldenbourg Wissenschaftsverlag, München, (Zvara et al. 1998))

■ Fig. 20.34

The data from ▶ Fig. 20.33 are represented with their correction for the relative detection efficiency (*dashed* histograms) due to annealing at elevated temperatures. The thick solid line is “the smoothed corrected thermochromatogram of element 106” (Zvara et al. 1998) (Reprinted with the permission of Oldenbourg Wissenschaftsverlag, München, (Zvara et al. 1998))

■ Fig. 20.35

Relative yield versus isothermal temperature for $^{104}\text{MoO}_2\text{Cl}_2$ (full diamonds, $T_{1/2} = 59$ s, $\Delta H_a^{\circ(T)} = -90$ kJ/mol), $^{168}\text{WO}_2\text{Cl}_2$ (open squares, $T_{1/2} = 51$ s, $\Delta H_a^{\circ(T)} = -96$ kJ/mol), and $^{265}\text{SgO}_2\text{Cl}_2$ (full triangles, $T_{1/2} = 7.4$ s, $\Delta H_a^{\circ(T)} = -98$ kJ/mol) (Reprinted with the permission of WILEY-VCH, STM Copyright & Licenses (Türler et al. 1999))

The other concern is with the assignment of the observed SF activity. The 70% SF branch deduced on the basis of cross section arguments by Druin et al. (1979) has never been confirmed. In the decay chains of $^{271}\text{110}$ as third generation α decays, 8 α decays of ^{263}Sg grouped around 9.248 MeV were measured (Hofmann et al. 1995a) in excellent agreement with the 9.25 MeV literature value (Ghiorso et al. 1974) for 0.9 s ^{263}Sg , but the half-life of $0.31^{+0.16}_{-0.08}$ s is different. Therefore, and because Hofmann et al. (1995a) did not observe the 9.06 MeV line (intensity ratio of the 9.25 MeV line to the 9.06 MeV line in the work of Ghiorso et al. (1974) is $\sim 9:1$), one must assign the two α lines to two different levels in ^{263}Sg . Both are populated in the $^{249}\text{Cf}(^{18}\text{O},4n)$ reaction, but only the 0.3 s level is populated by α decay in the decay chain of $^{271}\text{110}$. An upper limit for a fission or electron capture branch of the 0.3 s level of 12% was given by Hofmann et al. (1995a).

Hofmann et al. compared the decay pattern of ^{263}Sg with that of the next heavier $N = 157$ isotope $^{265}\text{108}$. Two α lines with energies of 10.31 and 10.58 MeV and an intensity ratio of 2:1 were measured in the case of the direct production in the reaction $^{58}\text{Fe} + ^{208}\text{Pb}$. Only the 10.58 MeV transition was observed in the α decays of $^{269}\text{110}$ (Hofmann et al. 1995b).

Therefore, two levels with approximately the same half-life of 1.5 ms exist in $^{265}\text{108}$. As fission was not observed, one can determine the α decay hindrance factors⁶ as 1.1 (10.31 MeV) and 5.0 (10.58 MeV) both being in agreement with favored α transitions. This also confirms the expectation, based on theoretical predictions (Cwiok et al. 1994), of the existence of isomeric states with similar decay properties. Theory predicts a very similar level structure for the lighter odd- A isotones. If this is the case in ^{263}Sg , the 0.9 s state should also decay by favored α transition. Also, a fission branch of more than 10% in ^{263}Sg would require an odd- N fission hindrance factor of less than 200 (usually on the order of 10^5 for odd neutrons). These

arguments by Hofmann et al. (1995a) do not rule out a large fission branch in $^{263\text{m}}\text{Sg}$ but make it seem unlikely.

A solution to these open questions was recently given by Gregorich et al. (2006) who measured a fission branch of 13% in 0.9-s $^{263\text{a}}\text{Sg}$. Starting from a cross section of 0.3 nb (Ghiorso et al. 1974) and an “effective” cross section of 0.15 nb in the experiment by Zvara et al. (1998), and using this fission branch of 13%, one calculates 32 SF events to be expected under the reported conditions, while twice as many SF events are shown in  Fig. 20.34.

Thus, if the assignment of the observed SF events in the thermochromatography experiments (Zvara et al. 1998) to the decay of 0.9 s $^{263\text{a}}\text{Sg}$ is questionable, it is of crucial importance to show that in the experiments, the other transactinide elements 104 and 105 are much less volatile than the studied 106 compound. Zvara et al. (1998) claimed that elements 104 and 105 do not form volatile compounds with a chlorinating, oxygen-containing carrier gas but the references given do not warrant such a claim. On the other hand, Türler et al. (1996) have shown that DbOCl_3 is volatile above 200°C, and an absorption enthalpy of -117 kJ/mol was deduced. From literature data, it is known that DbOCl_3 is more volatile than TaOCl_3 . Therefore, DbOCl_3 could have been volatile under the experimental conditions of the experiment even if it had been shown that Ta was not volatile. A volatile DbOCl_3 needs to be considered because one cannot exclude an EC decay branch in $^{263\text{a}}\text{Sg}$ leading to SF in ^{263}Db (Kratz et al. 1992) and, after α decay, to SF in ^{259}Lr (Gregorich et al. 1992). Such a “bizarre” explanation of the observed SF events in the seaborgium experiments (Zvara et al. 1998) is not ruled out by the evidence presented.

Also for rutherfordium, Jost et al. (1996) showed that ^{261}Rf is volatile in a carrier gas of 1 l/min He, 150 ml/min Cl_2 saturated with SOCl_2 , and 20 ml/min O_2 , that is, under conditions that are similar to the conditions of the thermochromatography experiments (Zvara et al. 1998). In summary, the conclusion by Zvara et al. (1998) that only element 106 can be responsible for the observed SF decays is not convincing. The evidence presented by Zvara et al. (1998) falls short of demonstrating that other sources of SF tracks are rigorously excluded.

In 1991, an international collaboration centered around the nuclear chemistry groups at GSI, Darmstadt, the University of Mainz, and PSI, Villigen, started to prepare their chemical characterization of seaborgium in a series of test experiments (see, e.g., Brüche et al. 1992; Gäggeler et al. 1992a, Hübener et al. 1992; Dressler et al. 1995; Günther et al. 1995). Generally, their experiments used gas-jet transportation systems and “external” detection systems in which the $\alpha\alpha$ -correlation technique with silicon detectors was used; both being “slow” as compared to the Dubna technique (Zvara et al. 1998). Therefore, based on the predicted enhanced nuclear stability near $N = 162$ and $Z = 108$ due to an especially large negative shell correction (Patyk and Sobiczewski 1991), it was hoped that more neutron-rich nuclides with presumably longer half-lives than the 0.9 s of $^{263\text{m}}\text{Sg}$ could be synthesized, for example, in the $^{22}\text{Ne} + ^{248}\text{Cm}$ reaction. Indeed, in 1993, working at the Dubna gas-filled recoil separator, a Dubna-Livermore collaboration succeeded to synthesize, as they believed, two new isotopes of element 106, ^{265}Sg , and ^{266}Sg , in the $^{248}\text{Cm}(^{22}\text{Ne}, 5n)$ and $^{248}\text{Cm}(^{22}\text{Ne}, 4n)$ reaction at 121 MeV and 116 MeV, respectively (Lazarev et al. 1994). They measured an α energy of 8.63 ± 0.05 MeV for ^{266}Sg and a half-life of 1.2 s for the spontaneously fissioning daughter, ^{262}Rf . For ^{265}Sg , they measured α energies between 8.71 MeV and 8.91 MeV and correlated α decays of the daughter $^{261\text{a}}\text{Rf}$ (8.29 MeV) and the grand-daughter ^{257}No (8.222, 8.27, and 8.32 MeV). The cross sections were reported to be 80 pb at 116 MeV and 60 pb at 121 MeV for production of ^{266}Sg and 260 pb at 121 MeV for production of ^{265}Sg . These were reported to have an estimated

uncertainty of a factor of ~ 3 . Using the phenomenological formula of Viola and Seaborg (Patyk and Sobiczewski 1991) they estimated a partial α half-life for ^{266}Sg of 10–30 s and of 2–30 s for ^{265}Sg , assuming a hindrance factor between 1 and 3. Measurements of the life times could not be performed as the implantation signals in the position-sensitive surface barrier detector were below the detection threshold. The estimated half-lives were felt to be rather encouraging for the planned chemistry experiments with these seaborgium isotopes. Note that due to the work by Dvorak et al. (2006, 2008) and Düllmann and Türler (2008), the assignments in (Lazarev et al. 1994) need to be reexamined.

In 1995, two of the developed techniques (Dressler et al. 1995; Günther et al. 1995) were eventually used to study the chemical properties of seaborgium. A short account of these successful first experiments and their results was published in (Schädel et al. 1997a). A more up-to-date report on the experiments, including the results of a follow-up experiment performed in 1996, is given here.

The choice of the chemical system was influenced by the wish to differentiate Sg from the group-4 elements and by theoretical predictions (Pershina and Fricke 1996) showing that SgO_2Cl_2 should be the most stable oxochloride compound. Thus, chlorinating oxygen containing reactive gases were selected. It was also predicted by calculating the dipole moments in the Mo-, W-, and Sg-dioxodichlorides (Pershina and Fricke 1996) that the volatility should decrease in the order $\text{Mo} > \text{W} > \text{Sg}$. With the aid of an empirical correlation between sublimation enthalpy ($\Delta H_s^{\circ(298\text{ K})}$) and adsorption enthalpy on quartz surfaces, $\Delta H_a^{\circ(T)}(\text{SgO}_2\text{Cl}_2)$, between -97 and -108 kJ/mol was predicted (Eichler et al. 1999a).

With the reaction oven temperature kept at 900°C and typically 100 ml/min Cl_2 saturated with SOCl_2 plus 2 ml/min O_2 , the chromatographic behavior of short-lived Mo isotopes from ^{235}U fission and of short-lived W isotopes produced at the PSI Philips cyclotron in the $^{152}\text{Gd}(^{20}\text{Ne}, xn)$ reaction was studied and values of $\Delta H_a^{\circ(T)}$ of -90 kJ/mol were measured for MoO_2Cl_2 and of -100 kJ/mol for the less volatile compound WO_2Cl_2 . Also, the yield versus temperature curve for ^{229}U from the $^{232}\text{Th}(\alpha, 7n)$ reaction was measured yielding a $\Delta H_a^{\circ(T)}$ of -91 kJ/mol indicative of the formation of UCl_6 (Gärtner et al. 1997). It was demonstrated that for isothermal temperatures above 275°C retention times less than 10 s in OLGA III are achieved.

In a first experiment in 1995 at the GSI UNILAC accelerator, a ^{248}Cm target of $950\text{ }\mu\text{g}/\text{cm}^2$ was bombarded with 121 MeV ^{22}Ne ions of 3×10^{12} ions s^{-1} . OLGA III was operated between 300°C and 400°C . As reactive agents, 100 ml/min Cl_2 saturated with SOCl_2 and 2 ml/min O_2 were added. Spontaneous fission decays and α decays were registered in ROMA. The separated activities were deposited on thin polypropylene foils ($30\text{--}40\text{ }\mu\text{g}/\text{cm}^2$) at the periphery of a 64-position wheel. Every 10 s, the wheel was stepped to move the collected activity between 7 pairs of PIPS detectors. All events were registered in an event-by-event mode. Due to a long-lived contamination from ^{212}Po in the 8.8 MeV region, where α decays of ^{265}Sg are expected, the significance of the observed event chains had to be improved. Therefore, a mother-daughter recoil mode for ROMA was implemented. In this mode, every second position on the wheel remained empty. Whenever an α particle with the decay energy of ^{265}Sg or ^{266}Sg (between 8.5 MeV and 8.9 MeV) was detected in a bottom detector, it was assumed that the daughter nucleus, ^{261a}Rf or ^{262}Rf recoiled out of the KCl deposit on the polypropylene foil (KCl was the aerosol in the recluster unit) into the top detector. Such an event initiated the daughter search mode by causing a single step. In this mode, the sources were removed from the detector pairs and empty positions were moved in-between. The system waited for 2 min for the decay of the daughter nuclides, before the parent mode was resumed.

Between 300°C and 400°C isothermal temperature, several $\alpha\alpha$ -correlations observed in the daughter mode allowed the clear identification of ^{265}Sg . In addition, one very significant triple correlation was observed in the parent mode (Gäggeler 1998).

In 1996 the experiment was continued (Gäggeler 1998) and the isothermal temperature was varied in order to determine $\Delta H_a^{\circ(T)}$ for the seaborgium compound. First, the volatility of WO_2Cl_2 was carefully re-examined under conditions that were identical to those of the actual Sg experiment. Short-lived W-isotopes were produced in the 119 MeV ^{22}Ne on ^{152}Gd reaction at the GSI UNILAC accelerator. A He/C-jet (1.0 l/min) was used to rapidly transport the reaction products to the chromatography apparatus. As reactive agents, 144 ml/min Cl_2 saturated with SOCl_2 at room temperature (20 ml/min) and 2 ml/min O_2 were added. The Sg experiment was performed with a mixed $^{248}\text{Cm}/^{152}\text{Gd}$ target ($690 \mu\text{g}/\text{cm}^2$ ^{248}Cm , $22 \mu\text{g}/\text{cm}^2$ ^{152}Gd) at ^{22}Ne beam energy of 123 MeV. The same quartz column with the same quartz wool plug in the same chromatography oven as in the preceding W experiment was used. Spontaneous fission decays and α decays were registered with ROMA. Every 10 s, the wheel was stepped to move the collected activity between 7 pairs of PIPS detectors. Again the mother-daughter recoil mode with a daughter search time of 200 s was implemented. Simultaneously, the yield of short-lived W was monitored with a HPGe detector, in order to ensure that the chemical separation was proceeding with high chemical yield.

The yield curve measured for $^{168}\text{WO}_2\text{Cl}_2$ ($T_{1/2} = 51$ s) is shown in  Fig. 20.35 together with the previously measured yield curve for $^{104}\text{MoO}_2\text{Cl}_2$ ($T_{1/2} = 59$ s) (Gärtner et al. 1997). With the Monte Carlo model, an adsorption enthalpy $\Delta H_a^{\circ(T)}(\text{WO}_2\text{Cl}_2) = -96$ kJ/mol was determined in good agreement with the previous measurement. For ^{265}Sg , at 350°C isothermal temperature and with a “beam dose” of 2.31×10^{17} ^{22}Ne ions, the results of the first experiment were confirmed by observing further ^{265}Sg α -decay chains (Türler et al. 1998). Without changing any of the other experimental parameters, the isothermal temperature was then lowered to 250°C, and a beam dose of 5.22×10^{17} was accumulated. Three decay chains of ^{265}Sg were observed, corresponding to a relative yield of $\sim 30\%$ as compared to the results at 350°C. For the simultaneously produced ^{168}W , a relative yield of $\sim 47\%$ was observed at 250°C as compared to the result at 350°C, which is in agreement with previous measurements. The relative yields for ^{265}Sg are also shown in  Fig. 20.35. Owing to the relatively large error bars on the two Sg data points, a careful statistical analysis was performed which resulted, within the Monte Carlo model, in a value of $\Delta H_a^{\circ(T)}(\text{SgO}_2\text{Cl}_2) = -98_{-5}^{+2}$ kJ/mol. Thus, the sequence in volatility of MO_2Cl_2 ($\text{M} = \text{Mo}, \text{W}, \text{Sg}$) is $\text{MoO}_2\text{Cl}_2 > \text{WO}_2\text{Cl}_2 \approx \text{SgO}_2\text{Cl}_2$. The probability that SgO_2Cl_2 is equally or even more volatile than MoO_2Cl_2 is less than 15% (Türler et al. 1999).

The experimentally determined $\Delta H_a^{\circ(T)}$ values, measured with trace amounts (at zero surface coverage), can be correlated with their macroscopic sublimation enthalpies ΔH_s (Türler et al. 1999). From an empirically derived linear correlation between ΔH_a and ΔH_s , the sublimation enthalpy of SgO_2Cl_2 can be estimated as ~ 127 kJ/mol. This is an important quantity to estimate the sublimation enthalpy of Sg metal. Seaborgium is estimated to have an equal or even higher sublimation enthalpy than W, the least volatile element in the periodic table (Türler et al. 1999).

The assignment of very few decay chains (Türler et al. 1998) to the isotope ^{266}Sg must be revised according to the more recent data by Dvorak et al. (2006) and Dvorak et al. (2008) showing that all decay chains observed in the reaction $^{248}\text{Cm}(^{26}\text{Mg}, \text{xn})^{270-x}\text{Sg}$, which were originally attributed to ^{266}Sg , originated from ^{265}Sg (Düllmann and Türler 2008).

The other gas chromatography approach that has been applied to seaborgium is the online high-temperature gas chromatography of group-6 elements in the $\text{O}_2\text{--H}_2\text{O(g)--SiO}_2\text{(s)}$ system. Hübener et al. (2001) have found that Mo and W are volatile in humid oxygen gas at relatively high temperatures and that the peculiar adsorption behavior both in the thermochromatography and in the isothermal gas chromatography (Hübener et al. 2001), for a detailed account see (Vahle 1996), required the assumption of a dissociative adsorption and associative desorption

also called “reaction gas chromatography.” ▶ Figure 20.36 shows as an example the relative elution yield of ^{169}W as a function of column temperature in isothermal online gas chromatography at $p(\text{H}_2\text{O}) = 780 \text{ Pa}$, $v_o(\text{He}) = 1 \text{ l/min}$, $v_o(\text{O}_2) = 0.5 \text{ l/min}$ (Vahle 1996). One sees from ▶ Fig. 20.36 that the experimental data cannot be reproduced by the conventional model assuming reversible adsorption. None of the dashed curves is capable of accounting for the experimental observation.

The solid line is the result of a Monte Carlo simulation for dissociative adsorption and associative desorption as formulated above with $\Delta H^\circ_{\text{diss,ads}} = -41 \text{ kJ/mol}$ and $\Delta S^\circ_{\text{diss,ads}} = -41 \text{ J K}^{-1} \text{ mol}^{-1}$. It is tempting to enlarge on this newly developed model.

The residence time of a molecule in the adsorbed state is a random variable. Its expectation value is given by the Frenkel equation

■ Fig. 20.36

Relative elution yield (Vahle 1996) of ^{169}W ($T_{1/2} = 76 \text{ s}$) as a function of isothermal temperature at $p(\text{H}_2\text{O}) = 780 \text{ Pa}$, $v_o(\text{He}) = 1 \text{ l/min}$, $v_o(\text{O}_2) = 0.5 \text{ l/min}$. The dashed lines were calculated with the conventional Monte Carlo model assuming reversible adsorption of $^{169}\text{WO}_2(\text{OH})_2$ with $\Delta H_a^{\circ(\text{T})} = -180 \text{ kJ/mol}$ through -240 kJ/mol in steps of 10 kJ/mol . The solid line is the Monte Carlo result for reaction gas chromatography with $\Delta H^\circ_{\text{diss,ads}} = 41 \text{ kJ/mol}$, $\Delta S^\circ_{\text{diss,ads}} = 41 \text{ J K}^{-1} \text{ mol}^{-1}$ (Adapted from (Vahle 1996))

$$\bar{\tau}_a = \tau_0 e^{-\frac{\Delta H_{\text{ads}}^0}{RT}}. \quad (20.23)$$

In the case of reversible adsorption, τ_0 is the vibrational period of the adsorbed particle perpendicular to the surface of the adsorbing solid; it is typically of the order 10^{-12} to 10^{-14} s. In the case of reaction gas chromatography, τ_a depends essentially on the kinetics of the rate-determining associative desorption and the collision probability of water molecules with the adsorbed species. The mean residence time in the adsorbed state then becomes

$$\bar{\tau}_a = \tau_0^* e^{-\frac{\Delta H_{\text{ads}}^0}{RT}}. \quad (20.24)$$

If the volatility of the gaseous compound ($\text{MO}_2(\text{OH})_{2(\text{g})}$) is much larger than that of the adsorbed species ($\text{MO}_{3(\text{ads})}$) the retention time t_r is equal to the total time of adsorption t_{ads} . This leads to the new expression for the retention time

$$t_r = \frac{LT_0\Phi}{v_0 T} \left\{ 1 + \frac{4}{d} \frac{c_{\text{ads}}^0(\text{MO}_3)}{c_{\text{gas}}(\text{H}_2\text{O})} \exp\left(-\frac{\Delta H_{\text{diss,ads}}^0}{RT}\right) \exp\left(\frac{\Delta S_{\text{diss,ads}}^0}{R}\right) \right\} \quad (20.25)$$

where L denotes the length of the isothermal part of the column, Φ denotes the cross section of the column, d is the inner diameter of the column, $T_0 = 298$ K, T is the isothermal temperature, $c_{\text{ads}}^0(\text{MO}_3)$ is the standard concentration of MO_3 in the adsorbed state, $c_{\text{gas}}(\text{H}_2\text{O})$ is the concentration of water molecules, $\Delta H_{\text{diss,ads}}^0$ is the standard enthalpy of the dissociative adsorption, and $\Delta S_{\text{diss,ads}}^0$ is the standard entropy of the dissociative adsorption. Two important things follow from the above equation:

1. An increase of the water partial pressure in the carrier gas leads to a higher collision probability of water molecules with the adsorbate.
2. The new quantity τ_0^* becomes

$$\tau_0^* = \sqrt{\frac{2\pi M}{RT}} \frac{c_{\text{ads}}^0(\text{MO}_3)}{c_{\text{gas}}(\text{H}_2\text{O})} \exp\left(\frac{\Delta S_{\text{diss,ads}}^0}{R}\right). \quad (20.26)$$

The latter equation means that, while τ_0 was only dependent on temperature and on properties of the adsorbing surface, τ_0^* depends on more parameters, which are connected to the transport process (molar mass of the transported species M , $c_{\text{gas}}(\text{H}_2\text{O})$ and $\Delta S_{\text{diss,ads}}^0$). Therefore, the values of τ_0^* can vary over large ranges and are always orders of magnitude longer than the values of τ_0 . For the transport of tungsten at a water partial pressure of 780 Pa, one obtains $\tau_0^* = 10^{-4}$ s.

The high temperatures visible in [Fig. 20.36](#) that are necessary to obtain high yields (and fast transport, see Vahle 1996) have presented a technological challenge. Nevertheless, the system has been advanced such that a first application to the study of seaborgium oxide hydroxides was conducted (Hübener et al. 2001) in which the formation of a volatile $\text{SgO}_2(\text{OH})_2$ could unambiguously be proven by the observation of two $^{265\text{b}}\text{Sg}$ α decays followed shortly by time-correlated fission of the $^{261\text{b}}\text{Rf}$ daughter. The original assignments to ^{266}Sg and the daughter ^{262}Rf have been corrected here according to the revised decay properties by Düllmann and Türler (2008).

The Automated Rapid Chemistry Apparatus, ARCA II (Schädel et al. 1989), that has been so successful in studying chemical properties of element 105 (Kratz 1994; Paulus et al. 1999a, b)

and recently also of element 104 (Günther et al. 1998; Strub et al. 2000, 2001) in aqueous solutions, was foreseen (Brüchle et al. 1992) to perform also the first aqueous chemistry with seaborgium.

Several chemical systems were tested with the fission products ^{93}Y , ^{97}Zr , and ^{99}Mo , and W isotopes produced in the $^{20}\text{Ne} + ^{152}\text{Gd}$ reaction (Brüchle et al. 1992) at the PSI Philips cyclotron. α -hydroxyisobutyric acid solutions of 5×10^{-2} M, pH = 2.65, or pH = 5 used to elute W in a rapid, one-stage separation from cation exchange columns provided a good separation from Hf and Lu. Likewise, solutions with 0.1 M HCl and various HF concentrations between 10^{-4} M and 10^{-2} M were eluting W rapidly while Hf was safely retained on the column below 10^{-3} M HF. Hf was observed to be partially eluted for $\geq 2.8 \times 10^{-3}$ M HF in 0.1 M HCl. Finally, the decision was made to use a solution of 0.1 M $\text{HNO}_3/5 \times 10^{-4}$ M HF to elute a seaborgium fraction from cation exchange columns (Günther et al. 1995) in order to avoid the formation of mixed chloride-fluoride complexes which are difficult to model. $[\text{MO}_2\text{F}_3(\text{H}_2\text{O})]^-$ is a likely form of the complexes that are eluted, but neutral species such as MO_2F_2 cannot be excluded. Some problems were encountered with adsorption of the activities on the slider in ARCA II. Among the various materials tested, titanium showed the lowest losses of W and Hf due to adsorption. Figure 20.37 shows the elution curve for short-lived W isotopes from the reaction of ^{20}Ne with enriched ^{152}Gd .

The activity was transported to ARCA II with a He(KCl)-jet within about 3 s and deposited on a titanium slider, dissolved and washed through the 1.6×8 mm chromatographic column (filled with the cation exchange resin Aminex A6, 17.5 ± 2 μm) at a flow rate of 1 ml/min with 0.1 M $\text{HNO}_3/5 \times 10^{-4}$ M HF. Eighty-five percent of the W are eluted within 10 s. No di- or

■ Fig. 20.37

Elution curve for W-tracer modeling the seaborgium separation (Schädel et al. 1997) in ARCA II using a solution of 0.1 M $\text{HNO}_3/5 \times 10^{-4}$ M HF with a flow rate of 1 ml/min. The 1.6 mm i.d. \times 8 mm columns are filled with the cation exchange resin Aminex A6 (Reprinted with the permission of Oldenbourg Wissenschaftsverlag, München)

trivalent metal ions and no group-4 ions are eluted within the first 15 s. Also uranium, in the form of UO_2^{2+} , is completely retained on the column.

In the seaborgium experiments (Schädel et al. 1997b), a $950 \mu\text{g}/\text{cm}^2$ ^{248}Cm target was bombarded with 3×10^{12} ^{22}Ne ions s^{-1} at 121 MeV. Three thousand nine hundred identical separations were conducted with a collection and cycle time of 45 s and a total beam dose of 5.48×10^{17} ^{22}Ne ions. The transport efficiency of the He(KCl) jet was 45%. On the average, counting of the samples started 38 s after the end of collection. The overall chemical yield was 80%.

Three correlated $\alpha\alpha$ -mother-daughter decays were observed that were assigned to the decay of ^{261}Rf and ^{257}No as the decay products of ^{265}Sg . The three correlated events have to be compared with an expectation value of 0.27 for random correlations. This gives a probability of 0.24% that the three events are random correlations. As the mother decays were not observed, it is important to note that ^{261}Rf and ^{257}No can only be observed if ^{265}Sg passed through the column because group-4 elements and No are strongly retained on the cation exchange columns in ARCA II. Most likely, the decay of ^{265}Sg was not observed because it decayed in the time interval between the end-of-separation and the start-of-measurement, which was equivalent to four half-lives. That the columns really retained ^{261}Rf was demonstrated recently in an experiment where ^{261}Rf was produced directly in the $^{248}\text{Cm}(^{18}\text{O}, \text{n})$ reaction at the PSI Philips cyclotron (Strub et al. 2000), and processed in the seaborgium chemistry in 0.1 M $\text{HNO}_3/5 \times 10^{-4}$ M HF. ^{261}Rf did not elute from the column and was subsequently stripped from the column with 0.1 M $\text{HNO}_3/10^{-1}$ M HF. From the observation of the three correlated α -decay chains of ^{265}Sg daughters it was concluded, that, for the first time, a chemical separation of seaborgium was performed in aqueous solution. Seaborgium shows a behavior typical of a hexavalent element located in group 6 of the periodic table and different from that of the pseudo-group-6 element uranium, which is fixed as UO_2^{2+} on the cation exchange column. Presumably, Sg forms $[\text{SgO}_2\text{F}_3(\text{H}_2\text{O})]^-$ or the neutral species $[\text{SgO}_2\text{F}_2]$, but due to the low fluoride concentration used, the anionic $[\text{SgO}_4]^{2-}$ ("seaborgate" in analogy to molybdate, $[\text{MoO}_4]^{2-}$, or tungstate, $[\text{WO}_4]^{2-}$) could not be excluded.

In order to get experimental information on this latter question, a new series of seaborgium experiments with ARCA II was performed in 1996 in which 0.1 M HNO_3 without HF was used as the mobile aqueous phase and Aminex A6 as stationary phase (Schädel et al. 1998). If the "seaborgate" ion was what was isolated in 1995, it was supposed to show up here again. A $691 \mu\text{g}/\text{cm}^2$ ^{248}Cm target containing $22 \mu\text{g}/\text{cm}^2$ enriched ^{152}Gd was bombarded with 123 MeV ^{22}Ne ions. The simultaneously produced ^{169}W served as a yield monitor. Forty-five second cycles were run in which the effluent was evaporated on thin ($\sim 500 \mu\text{g}/\text{cm}^2$) Ti foils mounted on Al frames. These were thin enough to be counted in close geometry by pairs of PIPS detectors thus increasing the efficiency for $\alpha\alpha$ -correlations by a factor of 4 as compared to the 1995 experiment. A beam dose of 4.32×10^{17} beam particles was collected in 4,575 separations. Only one $\alpha\alpha$ -correlation attributable to the $^{261}\text{Rf} - ^{257}\text{No}$ pair was observed. With an expected number of random correlations of 0.5 this is likely (the probability is 30%) to be a random correlation. From the beam integral and the overall yield as measured simultaneously for ^{169}W (27% including jet transportation and chemical yield), a total of five correlated events was to be expected. This tends to indicate that, in the absence of fluoride ion, there is sorption of seaborgium on the cation-exchange resin.

This non-tungsten-like behavior of seaborgium under the given conditions may be attributed to its weaker tendency to hydrolyze:

$$\vdots$$

The measured equilibrium constants for this stepwise deprotonation scheme for Mo and W have been collected from the literature (Pershina and Kratz 2001). They show that Mo is more hydrolyzed than W, and that the deprotonation sequence for Mo and W at pH = 1 reaches the neutral species $\text{MO}_2(\text{OH})_2(\text{H}_2\text{O})_2$. Assuming the deprotonation processes for Sg to be similar to those of Mo and W, Eqs. (20.27)–(20.30), Pershina and Kratz (2001) predict that the hydrolysis of the cationic species to the neutral species decreases in the order $\text{Mo} > \text{W} > \text{Sg}$, which is in agreement with the experimental data on hydrolysis of Mo and W and with the results for Sg (Schädel et al. 1998) for which the deprotonation sequence ends earlier with a cationic species such as $\text{SgO}(\text{OH})_3(\text{H}_2\text{O})_2^+$, which sorbs on a cation-exchange resin.

It is interesting to recall that a decreasing tendency to hydrolyze ($\text{Nb} > \text{Ta} > 105 > \text{Pa}$) was reported (Pershina 1998b) to determine the extraction of the group-5 chlorides into aliphatic amines. Thus, a similar behavior in the neighboring group-6 is apparent.

Looking back to the experiments in (Schädel et al. 1997b) where fluoride ions were present, having a strong tendency to replace OH^- ligands, it appears plausible that, in this preceding experiment, neutral or anionic species were formed:

Thus, the presence of fluoride ions seems to be an important prerequisite for planned experiments in which the K_a value of Sg on an anion-exchange resin is to be determined with the MCT technique (Pfrepper et al. 1998; Kronenberg et al. 2000) and to be compared to that of Mo and W.

20.8 Element 107 (Bohrium)

20.8.1 Theoretical Predictions

To assess the influence of relativistic effects on the volatility of BhO_3Cl , fully relativistic density-functional calculations of the electronic structure of the group-7 oxychlorides MO_3Cl ($\text{M} = \text{Tc}$, Re , and Bh) were performed by Pershina and Bastug (2000). These calculations show that the properties of Bh are very similar to those of the lighter homologs. BhO_3Cl is the most covalent

compound in the row TcO_3Cl , ReO_3Cl , and BhO_3Cl , and is relatively stable. In this molecular form, element 107 is the most stable in the highest oxidation state in the group.

Increasing values of dipole moments and electric dipole polarizabilities in the row TcO_3Cl , ReO_3Cl , and BhO_3Cl are the reasons for increasing molecule–surface interactions (Pershina and Bastug 2000), which means that volatility of the compounds changes in the following sequence: $\text{TcO}_3\text{Cl} > \text{ReO}_3\text{Cl} > \text{BhO}_3\text{Cl}$. Using a simple physisorption model for the molecule–surface interaction adjusted to the experimental adsorption enthalpy of ReO_3Cl , results in a value for the adsorption enthalpy of TcO_3Cl of -48 ± 2 kJ/mol in agreement with the experimental value of -51 ± 2 kJ/mol and in a predicted value for the adsorption enthalpy of BhO_3Cl of -78 ± 5 kJ/mol.

Also, classical extrapolations down the group using empirical correlations of thermochemical properties (Eichler et al. 2000a) predict BhO_3Cl to be more stable and less volatile than ReO_3Cl and TcO_3Cl . Bh is thus expected to behave chemically like a typical group-7 element and the volatility of its compound BhO_3Cl is expected to be the lowest within the group.

20.8.2 Experimental Results

The first unambiguous identification of an isotope of element 107 in the nuclear fusion reaction of ^{54}Cr with ^{209}Bi involved $^{262\text{m}}\text{Bh}$ (Münzenberg et al. 1981). The half-life of 8 ms determined for $^{262\text{m}}\text{Bh}$ and even the half-life of 440 ms for the more stable isotope ^{264}Bh (Hofmann et al. 1995c), are too short for an investigation of chemical properties. Therefore, searches for the presumably longer lived, more neutron rich nuclides ^{266}Bh and ^{267}Bh were performed for some time. Early searches applying gas chemical separation techniques for volatile oxide and oxyhydroxide compounds failed (Zvara et al. 1984; Schädel et al. 1995). Recently, the nuclide ^{267}Bh was discovered in the $^{249}\text{Bk}(^{22}\text{Ne}, 4n)$ reaction (Wilk et al. 2000). The production cross section of ^{267}Bh was about 60 pb at a beam energy of 117 MeV. Its half-life is 17^{+14}_{-6} s and the α -decay energy 8.83 ± 0.03 MeV. There was also evidence for the 5n-product ^{266}Bh having a much shorter half-life (Wilk et al. 2000).

In preparation of experiments investigating the chemical properties of bohrium, the adsorption data of the lighter homolog Re as oxide (ReO_3) and hydroxide (HReO_4) on quartz surfaces was studied (Eichler et al. 1999a). In online studies with short-lived Re isotopes, only the formation of the less volatile ReO_3 was observed with an adsorption enthalpy indistinguishable from those for PoO_2 and BiOOH . Po, Pb, and Bi nuclides are often formed in interactions of the heavy-ion beam with lead impurities in the target or target assembly. As these by-products would severely interfere with the unambiguous identification of ^{267}Bh due to their very similar α -decay energies, the high-temperature gas chromatography developed in (Eichler et al. 1999a) was considered less suitable for the chemical characterization of bohrium. Therefore, the oxychloride chemistry of the group-7 elements Tc and Re was investigated and the highly volatile compounds observed in O_2/HCl -containing carrier gas were attributed to MO_3Cl ($\text{M} = \text{Tc}, \text{Re}$) (Eichler et al. 2000a). Adsorption enthalpies on quartz surfaces of -51 kJ/mol and -61 kJ/mol were evaluated for TcO_3Cl and ReO_3Cl , respectively, and an excellent separation from the much less volatile compounds BiOCl and PoOCl_2 was achieved (Eichler et al. 2000a), which made this system the prime choice for experiments with bohrium.

A ^{249}Bk target ($670 \mu\text{g}/\text{cm}^2$) covered with a layer of ^{159}Tb was bombarded for 4 weeks at the Philips cyclotron of the Paul Scherrer Institute with typically 1.6×10^{12} ^{22}Ne particles per second at 119 MeV, producing 17 s ^{267}Bh in the $^{249}\text{Bk}(^{22}\text{Ne}, 4n)$ reaction (Eichler et al. 2000b).

^{176}Re was simultaneously produced in the $^{159}\text{Tb}(^{22}\text{Ne},5\text{n})$ reaction and served as monitor for the chemical separation process. Nuclear reaction products recoiling from the thin ^{249}Bk target were adsorbed on carbon aerosols in the He carrier gas and were transported to the online gas chemistry apparatus. There, the aerosol particles were collected on quartz wool at $1,000^\circ\text{C}$. HCl and O_2 were introduced to form the volatile oxychlorides as well as to oxidize the carbon particles. The chromatographic separation took place downstream in the adjoining isothermal section of the quartz column. The retention time of the compounds in the column is mainly dependent on the adsorption interaction with the chlorinated quartz surface at a given isothermal temperature and on the flow rate of the carrier gas. Oxychlorides leaving the column were attached to CsCl particles and transported to the detection system. Here, the CsCl particles were deposited on thin polyethylene foils mounted on the periphery of a stepwise rotating wheel. Every 10 s, the collected activity was stepped between successive pairs of silicon detectors measuring α and spontaneous fission decays. Four correlated decay chains of ^{267}Bh were observed at 180°C isothermal temperature, two at 150°C , and none at 75°C . The relative yields of ^{267}Bh observed at the three temperatures are shown in [Fig. 20.38](#) together with the data for ^{108}Tc and ^{169}Re .

The adsorption properties of BhO_3Cl were quantified by using the microscopic model of the adsorption process (Zvara 1985). The standard adsorption enthalpy of BhO_3Cl on the quartz surface resulted as $-75^{+9}_{-6}\text{ kJ/mol}$ (68% confidence interval) with $T_{1/2} = 17\text{ s}$ for ^{267}Bh . This value compares well with the predicted value of $-78 \pm 5\text{ kJ/mol}$ (Pershina and Bastug 2000) for BhO_3Cl , applying a physisorption model adjusted to the experimental adsorption enthalpy of ReO_3Cl . Thus, BhO_3Cl exhibits a stronger adsorption interaction with the chlorinated quartz surface than TcO_3Cl and ReO_3Cl as predicted.

■ Fig. 20.38

Isothermal gas chromatographic separation of the group-7 oxychlorides MO_3Cl ($\text{M} = \text{Tc}, \text{Re}, \text{Bh}$) (Eichler et al. 2000b). The error bars indicate a 68% confidence interval. The lines represent the results of the Monte Carlo modeling (Zvara 1985) giving standard adsorption enthalpies of -51 kJ/mol (TcO_3Cl), -61 kJ/mol (ReO_3Cl), and -75 kJ/mol (BhO_3Cl). The dashed lines show the calculated relative yield of BhO_3Cl concerning the 68% confidence interval of the standard adsorption enthalpy of BhO_3Cl ranging from -66 to -81 kJ/mol (Reprinted by permission from Macmillan Publishers Ltd.: (NATURE) (Eichler et al. 2000b), copyright (2009))

An empirical correlation between the standard adsorption enthalpy on quartz and the macroscopic standard sublimation enthalpy for chlorides and oxychlorides (Türler et al. 1999) allows estimating the standard sublimation enthalpy of BhO_3Cl as 89^{+21}_{-18} kJ/mol to be compared to the values of 49 ± 12 kJ/mol and 66 ± 12 kJ/mol for TcO_3Cl and ReO_3Cl , respectively (► Fig. 20.38).

20.9 Element 108 (Hassium)

20.9.1 Theoretical Predictions

As the presumably very volatile tetroxide of hassium is an attractive object for a chemical characterization, fully relativistic density functional calculations of the electronic structure of the group-8 oxides MO_4 ($M = \text{Ru}, \text{Os}, \text{and Hs}$) have been performed by Pershina et al. (2001a). They find that the covalence and stability of the tetroxides increase from OsO_4 to HsO_4 . By using various models of molecule–surface interaction and by adjusting the adsorption enthalpy for OsO_4 to the experimental value (-38 kJ/mol), standard adsorption enthalpies of -40.4 ± 1.5 kJ/mol and -36.7 ± 1.5 kJ/mol were predicted for RuO_4 and HsO_4 , respectively. Thus, HsO_4 has been expected to be as volatile as OsO_4 , with the difference in the adsorption enthalpy being on the order of the experimental uncertainty. The trend in the predicted volatility of the group-8 oxides is, therefore, $\text{RuO}_4 < \text{OsO}_4 \leq \text{HsO}_4$. This sequence would also correspond to the idea that increasing volatility corresponds to increasing covalence of the compounds. More recent theoretical developments triggered by the experimental results are discussed below.

20.9.2 Experimental Results

The discovery of Hs was reported in 1984 (Münzenberg et al. 1984) with the identification of ^{265}Hs with a half-life of 1.5 ms. In 1996, ^{269}Hs with a half-life of about 10 s was observed in the α -decay chain of $^{277}112$ (Hofmann et al. 1996). Its direct production should be possible in the $^{248}\text{Cm}(^{26}\text{Mg}, 5n)$ reaction with a cross section of a few picobarns.

Following the example of Zhuikov (Zhuikov et al. 1986), several groups have adopted the *in situ* production of volatile tetroxides directly behind the target by adding oxygen (typically 10%) to the carrier gas that contains no aerosol particles (Düllmann et al. 2002a, Kirbach et al. 2002; von Zweidorf et al. 2002). Typically, the reaction products were transported with the carrier gas through a quartz column containing a quartz wool plug heated to some 600°C at the exit of the recoil chamber providing a hot surface at which the oxidation of the group-8 elements to their tetroxides was completed. The latter were further transported through a Teflon capillary to the detection system. Using thermochromatography at low temperatures, Düllmann et al. measured the temperature at which HsO_4 deposits with their cryo online detector COLD, which also served as detection system for the isotopes $^{269,270}\text{Hs}$. COLD consists of 12 pairs of silicon PIN-diodes of $1 \times 3 \text{ cm}^2$ mounted at a distance of 1.5 mm inside a copper bar. A temperature gradient from -20°C to -170°C was established along the detector array.⁷ The efficiency for detecting a single α particle was 77%. COLD (Düllmann et al. 2002b) was an improved version of a previous setup called the cryo-thermochromatography separator CTS (Kirbach et al. 2002).

An alternative approach is being followed by von Zweidorf et al. (2002). In their experiment the tetroxides are allowed to deposit on a thin layer of humid NaOH faced at a distance of ca.

1 mm by an array of silicon PIN-diodes. This system has an efficiency of 45% for detecting a single α particle. For OsO_4 the deposition is due to the formation of an osmate (VIII) of the form $\text{Na}_2[\text{OsO}_4(\text{OH})_2]$ where OsO_4 acts as an acid anhydride.

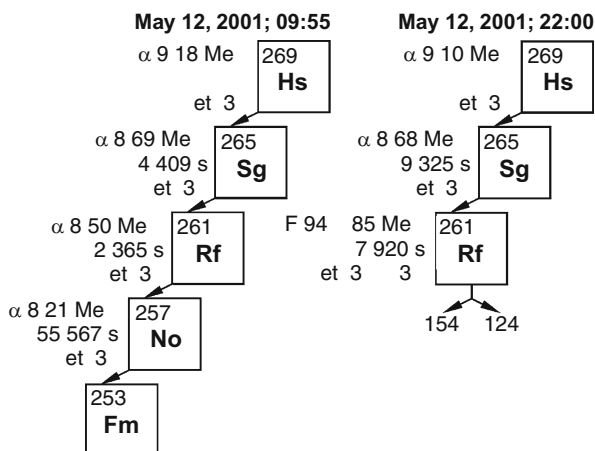

In the first experiment to characterize the volatility of HsO_4 the COLD array was used (Düllmann et al. 2002b). The experimental setup involved three banana-shaped ^{248}Cm targets mounted on a rotating target wheel that was bombarded with up to $8 \times 10^{12} \text{ } ^{26}\text{Mg}^{5+}$ ions per second, delivered by the UNILAC accelerator at GSI, Darmstadt. The projectile energy was $\sim 146 \text{ MeV}$ inside the ^{248}Cm targets. The functioning of the entire experiment was checked at the beginning and after the Hs experiment by mounting a ^{152}Gd target and by producing $19.2 \text{ s } ^{172}\text{Os}$, which has an α -decay branch of 1%. The experiment to produce Hs lasted 64.2 h during which a total of $1.0 \times 10^{18} \text{ } ^{26}\text{Mg}$ ions passed through the targets. Seven correlated decay chains were observed of which two representative ones are shown in Fig. 20.39.

The characteristics of the three first decay chains agree well with data (Hofmann et al. 1996) on ^{269}Hs and its daughter nuclides, while two other chains were attributed (Türler et al. 2003) to the decay of ^{270}Hs . The last two decay chains were incomplete and their assignment to either ^{269}Hs or ^{270}Hs was uncertain. More recently, the results reported in (Dvorak et al. 2006) and (Dvorak et al. 2008) strongly suggest that all decay chains observed in the original work by Düllmann et al. 2002b were starting with ^{269}Hs . All correlated α -decay chains were registered in detector pairs 2 through 4. The background count rate of α particles with energies of 8.0 through 9.5 MeV was so low that the probabilities that any of the five first chains and any of the two last chains are of random origin are less than 7×10^{-5} and 2×10^{-3} , respectively.

As depicted in Fig. 20.40, the α decay of one Hs atom was registered in detector 2, the decay of four atoms in detector 3, and the decay of two atoms in detector 4. The maximum of

Fig. 20.39

Two of the seven nuclear decay chains originating from Hs isotopes detected in COLD (Düllmann et al. 2002b). Indicated are the energies of α particles and fission fragments in MeV and the lifetimes in s. The detector in which the decay was registered is indicated where T stands for top detector and B for bottom detector. For each chain, the date and time of its registration are given. The two selected chains are typical in the sense that both show $3 \text{ s } ^{261}\text{bRf}$ as grand-daughter of ^{269}Hs decaying either by the emission of an 8.5 MeV α particle or by SF (Adapted by permission from Macmillan Publishers Ltd: (NATURE) (Düllmann et al. 2002b), copyright (2009))

■ Fig. 20.40

Thermochromatograms of HsO_4 and OsO_4 . Measured values are represented by bars (HsO_4 black, OsO_4 white). The dashed line represents the temperature profile. The maxima of the deposition zones are at $-44 \pm 6^\circ\text{C}$ for HsO_4 and $-82 \pm 7^\circ\text{C}$ for OsO_4 . Solid lines represent the results of Monte Carlo simulations with standard adsorption enthalpies of -46 kJ/mol for HsO_4 and -39 kJ/mol for OsO_4 (Reprinted by permission from Macmillan Publishers Ltd: (NATURE) (Düllmann et al. 2002b), copyright (2009))

the Hs distribution was found at a temperature of $-44 \pm 6^\circ\text{C}$, that for the Os distribution at $-82 \pm 7^\circ\text{C}$. The adsorption enthalpy was extracted from the data by a Monte Carlo simulation with the value of ΔH_{ads} being a free parameter. The results that best reproduce the experimental data are shown in Fig. 20.40 (solid lines) and suggest a value of the standard adsorption enthalpy of $-46 \pm 2\text{ kJ/mol}$ for HsO_4 and $-39 \pm 1\text{ kJ/mol}$ for OsO_4 on the silicon nitride surface of the detectors. For OsO_4 the value is in good agreement with that using quartz surfaces (Düllmann et al. 2002a). Therefore, a direct analogy between theory and experiment is expected because a comparable adsorption interaction of OsO_4 is ascertained for quartz and silicon nitride surfaces. The significantly lower volatility of HsO_4 as compared to that of OsO_4 has been a surprise as a similar or slightly higher volatility for HsO_4 had repeatedly been predicted (Pershina et al. 2001a, b; Pershina et al. 2005). The apparent discrepancy between experiment and theory has triggered new theoretical efforts (Pershina et al. 2008); in this work, fully relativistic four-component density functional theory calculations were performed on MO_4 ($\text{M} = \text{Ru}, \text{Os}, \text{and Hs}$). Implementation of the noncollinear spin-polarized approximation in the method and the use of large optimized sets of numerical basis functions resulted in a high accuracy of the calculated molecular properties, especially the molecular polarizabilities. The latter have fully reproduced the experimental values for RuO_4 and OsO_4 , and have shown a dramatic increase in the polarizability by 8.95 a.u. for HsO_4 in comparison with the old value (Pershina et al. 2005). This led to a new value for $\Delta H_{\text{ads}} = -45.4 \pm 1\text{ kJ/mol}$ for HsO_4 , which is now in perfect agreement with experiment.

It is noteworthy that the decay properties of ^{261}Rf in Fig. 20.39 are consistent with those observed in the decay chains of element 112 (Hofmann et al. 1996) but deviate from

experimental data where ^{261}Rf was produced directly. In the latter case, a half-life of 78 s and an α -particle energy of 8.28 MeV are observed (Kadkhodayan et al. 1996). Apparently, when ^{261}Rf is formed by α decay of precursors, the α -decay energy is 8.5 MeV, the half-life is about 3 s, and a SF branch of 91% is evident (Düllmann and Türler 2009). Dressler and Türler (2002) have tentatively assigned the hitherto known 78 s state to an $11/2^-$ isomeric state and the 3 s state to the $7/2^+$ ground state in ^{261}Rf .

In the work by von Zweidorf et al. (2004), ^{269}Hs was also produced in the $^{248}\text{Cm}(^{26}\text{Mg},5n)$ reaction. In the CALLISTO experiment (Continuously working Arrangement for cLuster-Less transport of In-SiTU produced volatile Oxides), an admixture of ^{152}Gd to one of the three banana shaped rotating target segments simultaneously produced α -emitting 19.2-s ^{172}Os and 22.4-s ^{173}Os . The evaporation residues were oxidized in situ behind the target in a mixture of He and O_2 and transported to a deposition and detection system. The latter consisted of 16 PIN diode detectors facing in close geometry a layer of NaOH which served, in the presence of a certain partial pressure of water in the transport gas, as a reactive surface for the deposition of the volatile tetroxides. For OsO_4 , the deposition involves the formation of a salt, an osmate (VIII). In analogy, the deposition of HsO_4 is likely to involve the reaction

Thus, CALLISTO has shown that HsO_4 like OsO_4 is an acid anhydride and forms with NaOH a hassate(VIII) in analogy to the known osmate(VIII), that is, a salt. [Figure 20.41](#) shows the distribution of the deposited amount of OsO_4 and HsO_4 as a function of the detector position. While the majority of the Os activity is centered in front of detector 1 and tails into the subsequent positions, the five α -decay chains of ^{269}Hs are centered in front of detector position 3. In (von Zweidorf et al. 2004) it was not claimed that this indicates a lower reactivity of HsO_4 with respect to moisturized NaOH as compared to OsO_4 , however, theoretical work by Pershina (2005) predicts interestingly that the hassate(VIII) should be more covalent than the osmate(VIII), and HsO_4 should react slightly weaker with NaOH (by less than 52 kJ/mol) than OsO_4 .

Fig. 20.41

Distribution of the deposited amount of OsO_4 and HsO_4 on a surface of NaOH facing a phalanx of 16 PIN diode detectors as a function of the detector position. While the $^{172,173}\text{Os}$ α activity is centered in front of detector 1, the ^{269}Hs decays are centered around position 3 (Reproduced with the permission of Oldenbourg Wissenschaftsverlag, München, (von Zweidorf et al. 2004))

20.10 Element 112 (Copernicium)

20.10.1 Theoretical Predictions

Based on relativistic calculations, Pitzer (1975) indicated the possibility that element 112 (copernicium, Cn, whose name and symbol was approved by IUPAC in February 2010) in its elementary state should be relatively inert – almost like a noble gas due to its closed electron shells $7s^2$, $6d^{10}$. Therefore, Cn should be more volatile than Hg.

A more recent fully relativistic treatment of the interaction of Cn with metallic surfaces such as Au or Pd, predicts weaker absorption of Cn than Hg on these metals (Perschina et al. 2004); however, due to metal–metal interaction, Cn was predicted to sorb at much higher temperatures than Rn, which sorbs only by van der Waals forces. The capability of Cn to form metallic bonds was also predicted by Eichler and Rossbach (1983). On the other hand, on chemically inert surfaces such as quartz or ice, mercury is found to be adsorbed only at very low temperatures (-100°C) (Soverna et al. 2005) to -160°C (Yakushev et al. 2001, 2003). Thus, the latter surfaces are much less suitable to distinguish between a volatile metal and a noble gas-like behavior of Cn, than sorption on, for example, a Au surface. Recent developments in the four-component Density Functional Theory, that is, the spin-polarized (SP) 4c-DFT allow to make very accurate predictions on the adsorption enthalpy of Cn on a Au surface, which is 20 kJ/mol weaker than that for Hg (Perschina et al. 2009).

20.10.2 Experimental Results

The first two attempts to chemically characterize element 112 with the use of the 3-min SF-isotope $^{283}\text{112}$ (Oganessian et al. 1999a, b, 2004a) were made by Yakushev et al. (2001 and 2003) at the FLNR in Dubna. Products from the $^{48}\text{Ca} + ^{238}\text{U}$ reaction including 49-s ^{185}Hg produced on a small amount of Nd added to the U target were transported in the elementary state in a He gas flow. In the improved second experiment, the 25 m long capillary, i.d., 2 mm, was connected to a detector array of eight pairs of Au-coated PIPS detectors at ambient temperature for the detection of Hg-like 112. Subsequently, the gas flow entered a $5,000\text{ cm}^3$ cylindrical ionization chamber for the detection of a gaseous element 112. This chamber had an aerosol filter at the entrance. A mixture of Ar and CH_4 was added as counting gas. The PIPS detectors and the ionization chamber were placed inside a barrel-shaped neutron detector with 126 ^3He long counters. In this experiment, 95% of the 49-s ^{185}Hg was found on the first pair of Au-coated PIPS detectors at a He flow rate of 500 ml/min. At a He flow rate of 250 ml/min, 99% of the ^{185}Hg deposited on the first detector pair. Eight SF-decays attributed to the decay of $^{283}\text{112}$ were registered in the ionization chamber and none in the PIPS detectors. It was concluded that element 112 does not form a strong metal–metal bond with Au and that it behaves more like a noble gas rather than Hg. A standard adsorption enthalpy for Cn of ≤ 0 kJ/mol was estimated as compared to -100 kJ mol^{-1} for Hg and -29 kJ/mol for Rn (Eichler and Schädel 2002). According to more recent Dubna results (Oganessian et al. 2004d) and GSI results (Hofmann et al. 2007), ^{283}Cn decays by α -particle emission with a half-life of about 4 s. Thus, the results of the first chemical experiments on element 112 are inconclusive.

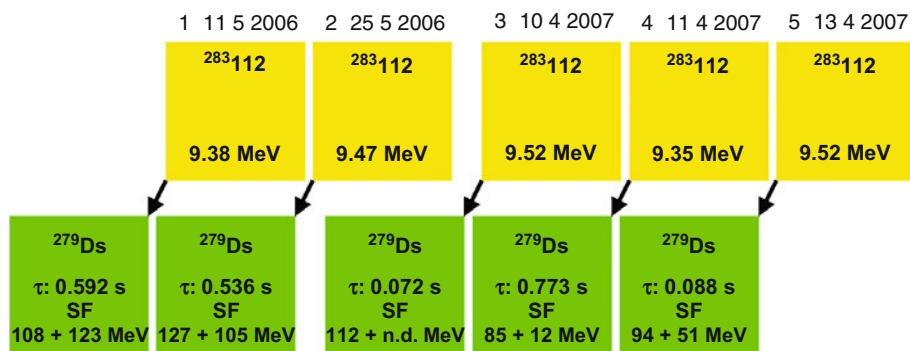

A second series of experiments started in 2003 at GSI (Gäggeler et al. 2004) again with the reaction of $^{48}\text{Ca} + ^{238}\text{U}$ to produce ^{283}Cn . Simultaneously, $^{184-186}\text{Hg}$ was produced on a small amount of Nd in the target as well as ^{220}Rn as a transfer product from U. The aim was to

measure the adsorption behavior of element 112 on Au in comparison with that of Hg and Rn. In a modified version of the COLD detector (Düllmann et al. 2002a), along a Au surface, a temperature gradient from +35°C to −185°C was established. Test experiments had determined the adsorption behavior of Hg and Rn on various transition metal surfaces with some interference due to an ice coverage at the low temperature end (Soverna et al. 2005). In the first experiment on element 112 (Gäggeler et al. 2004), the Au catcher was faced by 32 silicon PIN diodes. The following observations were made: Hg was mainly adsorbed on the Au opposite to the first detector with a tail to lower temperatures in agreement with a Monte Carlo simulation with a standard adsorption enthalpy of −101 kJ/mol. From the adsorption of Rn, beginning at detector 29 and peaking at detector 31, it was deduced that below −95°C, the Au surface was covered with a thin ice layer. At an expected background of 3 SF events, 5 SF events were observed scattered along the entire detector array. A cluster of 7 SF events – interpreted as candidates for 3-min ^{283}Cn – were observed at detectors 29 to 31, that is, in the position of the Rn. If true, this suggests that element 112 behaves as a noble gas. However, the collaboration decided to repeat the experiment with an improved setup in almost 4π geometry (Eichler et al. 2006) and improved sensitivity to shorter half-lives. However, also this experiment did not yield a conclusive result.

In 2006, a series of experiments at FLNR Dubna made possible the first unambiguous detection of element 112 after its chemical separation (Eichler et al. 2007a, b). These chemical experiments with element 112 were focused on the new decay pattern of ^{283}Cn with a half-life of about 4 s and an α -particle decay ($E_\alpha = 9.54$ MeV) to ^{279}Ds , which decays by SF with a half-life of 200 ms (Oganessian et al. 2004d; Hofmann et al. 2007) produced in the fusion reaction of ^{48}Ca with ^{238}U . Even larger production rates have been observed for ^{283}Cn by using the indirect production path $^{242}\text{Pu}(^{48}\text{Ca}, 3n)^{287}114$ ($T_{1/2} = 0.48$ s, $E_\alpha = 10.02$ MeV) \rightarrow ^{283}Cn (Oganessian et al. 2004d). This reaction was used in the subsequent work (Eichler et al. 2008). The chemical setup used in the experiments was based on the thermochromatographic in situ volatilization and online detection technique (IVO) in combination with the cryo-online detector COLD (Eichler et al. 2000b; Düllmann et al. 2002b; Eichler et al. 2006, 2007a, b). From the observation of only two atoms (► Fig. 20.42, chains 1 and 2), assigned unambiguously to ^{283}Cn , a first indication of a volatile metallic element 112 was obtained (Eichler et al. 2007a, b). In 2007, the

► Fig. 20.42

Detected α -SF decay chains assigned to the isotope ^{283}Cn ; n.d. = not determined (Reproduced with the copyright permission of Wiley-VCH, STM-Copyright & Licenses (Eichler et al. 2008))

collaboration was able to increase the overall efficiency by a factor of about three (Eichler et al. 2008) and observed three additional decay chains of ^{283}Cn (Fig. 20.42, chains 3–5). The thermochromatographic deposition patterns for ^{185}Hg , ^{219}Rn , and ^{283}Cn under varied experimental conditions are depicted in Fig. 20.43.

In the first experiment in 2006 (Eichler et al. 2007a, b), a carrier-gas flow of 860 ml/min and a temperature gradient between -24°C and -184°C was applied (Fig. 20.43). A spontaneous, diffusion-controlled deposition of ^{185}Hg was observed in the first eleven detectors. ^{219}Rn deposited almost entirely on the last nine detectors. One decay chain (chain 1) assigned to ^{283}Cn was observed in the second detector (-28°C) together with ^{185}Hg , that is, clearly distinct from ^{219}Rn .

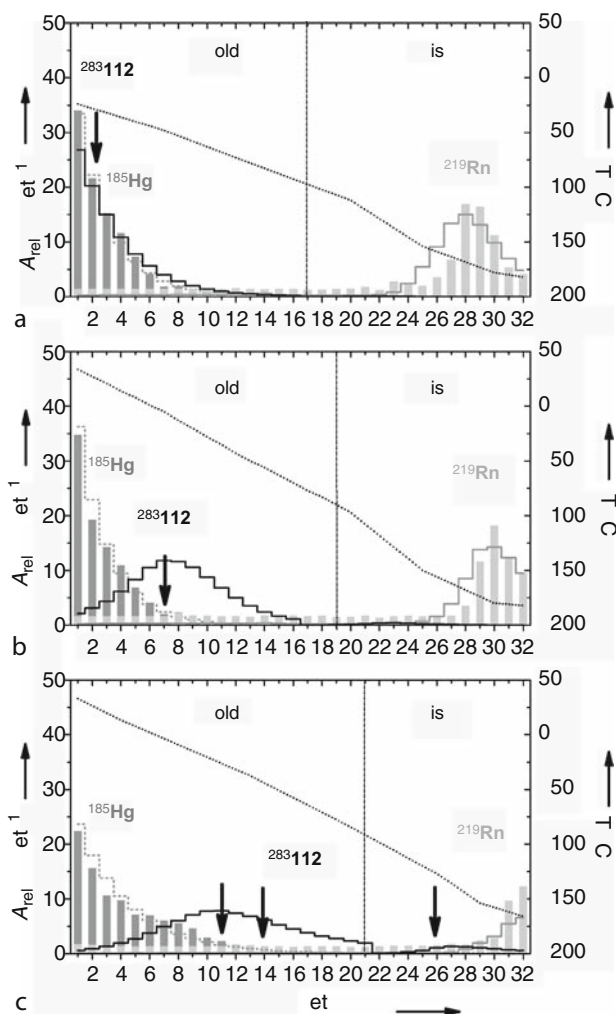

In the second part of the experiment in 2006 (Eichler et al. 2007a, b), a steeper temperature gradient between $+35^\circ\text{C}$ and -180°C (Fig. 20.43b) was established. The gas-flow rate was 890 ml/min. Thus, ^{185}Hg revealed a shorter deposition pattern up to detector eight consistent with an increased diffusion coefficient of Hg in the carrier gas. Only 70% of the ^{219}Rn deposited on the last six detectors due to the slightly increased temperature at the last detectors. A decay chain (chain 2) attributed to ^{283}Cn was observed in the seventh detector (-5°C), again clearly distinct from ^{219}Rn .

In 2007 (Fig. 20.43c), the gas-flow rate was increased to 1,500 ml/min in order to increase the transport efficiency. The temperature gradient was between $+32^\circ\text{C}$ and -164°C . As a result, the ^{185}Hg deposition region broadened considerably to 14 detectors. Only about 30% of the ^{219}Rn deposited on the last four detectors. The faster carrier gas transported three observed atoms of ^{283}Cn further down to detectors at lower temperatures. Chains 3 and 5 were detected in detectors 11 (-21°C) and 14 (-39°C). Chain 4 was detected in detector 26 (-124°C). From dew point measurements in the carrier gas, it has to be concluded that the detector surfaces held below -95°C were covered by a thin ice layer (Fig. 20.43a–c, vertical lines). Thus, it was concluded that four events (chains 1–3, and 5) are attributable to atoms of element 112 deposited on the gold surface, while chain 4 represents an atom of element 112 deposited on ice.

Monte Carlo simulations following (Zvara 1985) were applied to determine the most probable standard adsorption enthalpy on gold surfaces at zero coverage from the chromatographic deposition of Hg, Rn, and element 112 (Eichler et al. 2008). The diffusion controlled deposition of Hg (Fig. 20.43, gray dashed lines) yielded a lower limit for $-\Delta H_{\text{a}}^{\text{Au}}(\text{Hg}) > 65 \text{ kJ/mol}$, in agreement with literature data (Soverna et al. 2005). The deposition of ^{219}Rn (Fig. 20.43, gray solid lines) gave an adsorption enthalpy of $-\Delta H_{\text{a}}^{\text{Au}}(\text{Rn}) = 19 \pm 2 \text{ kJ/mol}$ in agreement with a value of $-20 \pm 2 \text{ kJ/mol}$ measured for Rn on ice (Eichler et al. 2000a). The Monte Carlo simulation of the deposition of ^{283}Cn (Fig. 20.43, black arrows), resulted in an adsorption enthalpy of element 112 on gold surfaces of $-\Delta H_{\text{ads}}^{\text{Au}}(\text{Cn}) = 52_{-3}^{+4} \text{ kJ/mol}$ (68% confidence interval). Using this value, the calculated deposition pattern (Fig. 20.43, black lines) indicates, for the highest gas flow, a probability of 15% for atoms of element 112 to reach detector 21 and to continue the chromatographic process on ice. This explains the observation of chain 4 by detector 26. The expected number of random correlations during the entire experiment was calculated to be 0.05. The enhanced adsorption enthalpy of element 112 on gold compared to a prediction using a physisorption model (Eichler and Schädel 2002) indicates a metallic-bond character of the interaction of element 112 with gold. The calculations of the Cn–Au interaction potential using density functional theory (Pershina et al. 2005; Pershina et al. 2007; Sarpe-Tudoran et al. 2007) predict a metallic-bond character but seem to overestimate somewhat the energetic content of this interaction. In summary, element 112 is chemically not as inert as a noble gas as suggested in 1975 (Pitzer 1975).

■ Fig. 20.43

Thermochromatographic deposition patterns of ^{185}Hg , ^{219}Rn , and ^{283}Cn in the COLD, dependent on experimental parameters. The measured relative activity per detector (A_{rel} , left hand axis) of ^{185}Hg (dark gray bars, MCS: gray dashed line) and ^{219}Rn (gray bars, MCS: gray solid line) is shown. The positions of the detected ^{283}Cn atoms are indicated (black arrows, MCS: black solid line). The temperature gradient is shown (black dashed line, right hand axis). Experimental parameters: (a) gas flow 860 ml/min, temperature gradient from -24°C to -184°C ; (b) gas flow 890 ml/min, temperature gradient from 35°C to -180°C ; (c) gas flow 1,500 ml/min, temperature gradient from 32°C to -164°C . The beginning of ice coverage of the detectors at -95°C is indicated by the vertical lines (Reproduced with the copyright permission of WILEY-VCH, STM Copyright & Licenses (Eichler et al. 2008))

An empirical link between the single-atom quantity ΔH_a and the volatility of macroscopic amounts of an element or compound, determined by the standard sublimation enthalpy ΔH_{aubl} , reveals linear relationships for various elements and compound classes on various surfaces (Eichler and Eichler 2003). A similar correlation was established between ΔH_a^{Au} values of elements and their ΔH_{subl} values (Eichler 2005). By using this correlation, the standard sublimation enthalpy can be estimated as $\Delta H_{\text{subl}}(\text{Cn}) = 38_{-12}^{+10}$ kJ/mol, indicating that element 112 is more volatile than its lighter homologs Zn, Cd, and Hg, reflecting an increasing stabilization of the atomic state due to relativistic effects in group 12 of the periodic table up to element 112.

20.11 Outlook

On behalf of the International Union of Pure and Applied Chemistry (IUPAC), the chemistry of the early transactinides Rf, Db, and Sg, has been critically evaluated by Kratz (2003a, b, c), with the result that for each of these elements there remain open questions that should be clarified in future experiments. The same holds, of course, for Bh and Hs. Nevertheless, it is fashionable to go ahead and design and prepare chemical experiments with even heavier elements.

For meitnerium, element 109, the isotope ^{270}Mt to be produced in the $^{238}\text{U}(^{37}\text{Cl}, 5n)$ or $^{248}\text{Cm}(^{27}\text{Al}, 5n)$ reactions is anticipated to have a half-life on the order of a second and should, thus, be suitable for chemical studies with one of the fastest separation techniques, for example, with SISAK.

Similarly to element 112, one can expect that element 114 will also have an enhanced volatility in the metallic state (Schwerdtfeger and Seth 2002) due to its ground state electron configuration with the quasiclosed electron shell $7s^2 7p_{1/2}^2$ caused by the large spin-orbit splitting of the 7p atomic orbitals and the strong relativistic stabilization of the $7p_{1/2}$ atomic orbital. Thus, the scheme of separation and identification can, in principle, be similar to that used by Eichler et al. (2008). Fully relativistic (four-component) density-functional theory calculations by Pershina et al. (2009) predict that element 114 should be gaseous in its elemental state but should be more reactive toward sorption on a gold surface than element 112. The trend in the binding energies with gold predicted is $\text{Pb} \gg 114 < \text{Hg} < \text{Cn}$. It is expected that element 114 should be observed in the thermochromatography experiments at the very beginning of the chromatography column with a warm end close to the position of Hg. It should be clearly distinguished from the more volatile element 112. At this time, it is one of the most challenging tasks for nuclear chemistry to verify this prediction.

Elements 108–116 are expected to be partially very noble metals. Thus, their electrochemical deposition on suitable electrode materials from aqueous solutions could be an attractive method for their isolation. It is known that the potential associated with the electrochemical deposition of radionuclides in metallic form from solutions of extremely small concentration is strongly influenced by the choice of the electrode material. This is reproduced by Eichler and Kratz (2000) in a model in which the interaction between the microcomponent A and the electrode material B is described by the partial molar adsorption enthalpy and entropy. By combination with the thermodynamic description of the electrode process, a potential is calculated that characterizes the process at 50% deposition:

$$E_{50\%} = E^\circ - \Delta H(A - B)/nF + T\Delta S_{\text{vibr}}(A - B)/nF - (RT/nF)\ln(A_m/1,000) \quad (20.34)$$

Here, $\Delta H(A - B)$ is the partial molar net adsorption enthalpy associated with the transformation of 1 mol of the pure metal A in its standard state into the state of “zero

coverage” on the surface of the electrode material B, ΔS_{vibr} is the difference in the vibrational entropies in the above states, n is the number of electrons involved in the electrode process, F is the Faraday constant, and A_m the surface of 1 mol of A as a monolayer on the electrode material B (Eichler and Kratz 2000). For the calculation of the thermodynamic functions in [Eq. \(20.34\)](#), a number of models were used by Eichler and Kratz (2000) and calculations were performed for Ni-, Cu-, Pd-, Ag-, Au-, and Pt-electrodes and the microcomponents Hg, Tl, Pb, Bi, and Po, thus confirming the decisive influence of the choice of the electrode material on the deposition potential. For Pd and Au, particularly large, positive values of $E_{50\%}$ were calculated, larger than the standard electrode potentials tabulated for these elements. This makes these electrode materials the prime choice for practical applications. An application of the same model for the superheavy elements still needs to be done, but one can anticipate that the preference for Pd and Au will persist. The latter are metals in which, due to the formation of the metallic bond, almost or completely filled d orbitals are broken up so that these metals tend in an extreme way toward the formation of intermetallic compounds with sp-metals. The perspective is to make use of these metals in the form of a tape on which the tracer activities are electrodeposited and the deposition zone is subsequently stepped between pairs of Si detectors for α and SF spectroscopy (Hummrich et al. 2008).

The coupling of chemistry devices to a physical pre-separator, mentioned shortly in [Sect. 20.4](#), opens completely new possibilities for chemical experiments. In experiments without pre-separation, the intense heavy-ion beam creates a plasma in the gas-filled recoil chamber where the fusion evaporation residues are thermalized. In contrast, a so-called recoil transfer chamber RTC behind a physical recoil separator is virtually beam-free and organic ligands can be directly introduced into the RTC, allowing in situ syntheses also of compound classes that would be destroyed by the beam. In a proof-of-principle experiment performed at the BGS in Berkeley, highly volatile β -diketonate complexes of the homologs of Rf, Zr, and Hf, were formed (Düllmann et al. 2009). It was thus shown that this technique indeed allows to expand the range of accessible chemical systems for transactinide research. As an exciting example, studies of organometallic compounds of transactinides appear feasible. First studies in this field could focus on group-6 hexacarbonyls with the ultimate goal of investigating Sg (CO)₆ and the group-8 metallocenes toward an experiment with hassocene, Hs(Cp)₂. Thus, a new interdisciplinary research field is about to open up bringing together experts from transactinide chemistry, organic, and organometallic chemistry, but also the spectroscopic community as the analog compounds with the lighter homologs will be amenable to, for example, XAS-spectroscopy helping to understand the structure of the new transactinide containing compounds.

1. The expressions “cold fusion” and “hot fusion” are explained in [Sect. 21.5 of Chap. 21 in this Volume 2](#) on “Superheavy Elements” (p. 929).
2. See also [Chap. 53 in Vol. 5](#) on “Radiochemical Separations by Thermochromatography” (p. 935).
3. PIPS detectors have been designed to replace SSB (silicon surface barrier) and DJ (diffused junction) detectors in alpha and beta/(conversion-)electron spectroscopies. Passivation normally means a SiO₂ layer on the surface, a key to low noise and relative ruggedness. Due to ion-implanted junctions, PIPS's have a very thin (<50 nm) and well-defined dead

- (window) layer, and those meant for alpha measurements have at least 140 μm (i.e., 140.000 nm) active layer, enough to stop up to 15 MeV alphas (p. 935).
4. See also ► [Sect. 52.2 in Chap. 52, Vol. 5](#), on “Solvent extraction and Ion Exchange in Radiochemistry” (p. 942).
 5. See ► [Fig. 9.1 in Chap. 9, Vol. 1](#), on “Stochastics and Nuclear Measurements” for choices of giving symmetric (\pm) or asymmetric (+ and $-$) error intervals (p. 944).
 6. See ► [Eq. \(2.63\) in Sect. 2.4, Chap. 2, Vol. 1](#), on “Basic Properties of the Atomic Nucleus” (p. 975).
 7. Modern silicon PIN diode detectors – P for p-type, I for intrinsic, N for n-type – have the same old sandwiched layer structure as the older Li-drifted ones; however, they can operate up to 150°C without being damaged. The operation principle is also the same. Being reversed biased, the high-resistivity I layer is completely depleted of free carriers, so when a radiation particle creates electron-hole pairs in the I layer, the electric field drives the holes to the N layer and the electrons to the P layer thus forming a current pulse, the height of which is proportional to the energy deposited in the active layer, that is, I (p. 986).
 8. To get the pressure in Pa, the values on the vertical axis are to be multiplied by ~ 133 (p. 934).

Acknowledgements

The author gratefully acknowledges the assistance of P. Sach-Muth in bringing the manuscript into its final form.

Abstract: The long quest to detect superheavy elements (SHEs) that might exist in nature and the efforts to artificially synthesize them at accelerators or in multiple-neutron capture reactions is briefly reviewed. Recent reports of the production and detection of the SHEs 113, 114, 115, 116, and 118 are summarized and discussed. Implications of these discoveries and the prospects for the existence and discovery of additional SHE species are considered.

21.1 Early Predictions of Superheavy Elements

The possibility of relatively stable elements well beyond uranium, the heaviest element found in large quantities in nature, was considered in the early 1950s. This interest was sparked by the totally unexpected discovery of the new elements 99 (einsteinium) and 100 (fermium) in debris from the first US thermonuclear device “Mike,” tested on Eniwetok Atoll in the South Pacific on November 1, 1952, by the Los Alamos Scientific Laboratory. Prior to that discovery, only the elements through californium (atomic number 98) were known. Scientists postulated that the enormous, nearly instantaneous, high neutron flux generated in the 10 Mt detonation of Mike resulted in the successive capture of at least 17 neutrons in the uranium-238 (^{238}U) present in the device. In this way, the heavier uranium isotopes through ^{255}U were produced and many of these isotopes decayed rapidly by successive emission of negatively charged beta particles to produce isotopes of known elements with atomic numbers of 93 through 98. The uranium isotopes of masses 253 and 255 decayed all the way to the new elements having proton numbers of 99 and 100 and mass numbers of 253 and 255 as shown in the schematic diagram in [Fig. 21.1](#).

Publication (Ghiorso et al. 1955) of these 1952–1953 discoveries of elements 99 and 100 by Berkeley, Argonne, and Los Alamos scientists was delayed until after the data were declassified in 1955. In that same year, John A. Wheeler published a paper (Wheeler 1955) on nuclear fission and nuclear stability in which he extrapolated the rates of spontaneous fission (SF) and other processes limiting nuclear stability to the region of very large masses. In a talk presented at the 1955 International Conference on the Peaceful Uses of Atomic Energy (Wheeler 1956) he showed a diagram of the estimated limits of nuclear stability within which half-lives would be greater than a ten-thousandth of a second. Although he cautioned that his extrapolations might be appreciably in error, he still concluded that it was reasonable to look for nuclei with masses perhaps twice as heavy as $^{256}\text{100}$, the heaviest nucleus known at the time, i.e., masses of 500 or more! He further suggested that massive neutron irradiation of existing heavy nuclides might be an appropriate method for building such superheavy nuclei.

The possible existence of superheavy elements was also discussed by Gertrude Scharff-Goldhaber (1957). She speculated that there might be another region of relative stability around $^{310}\text{126}$ because it might be expected to have two especially stable, spherical closed nuclear shells (similar to closed electron shells). These spherical shells, or “magic” numbers as they are often called, were thought to be at proton number 126 and neutron number 184, thus making $^{310}\text{126}$ a “doubly magic” nucleus.

Such ideas spurred the quest to produce still heavier elements in subsequent thermonuclear tests. Indeed, the rather long-lived nuclide ^{257}Fm (half-life: $T_{1/2} = 100$ days) was detected in later nuclear tests, indicating capture of at least 19 neutrons in uranium. However, attempts to produce and detect still heavier elements in underground nuclear tests conducted at the Nevada Test Site all failed, thus dashing hopes that heavier long-lived elements could be produced via this multiple neutron-capture process that, as it had been postulated, might

■ Fig. 21.1

“mimic” production of heavy elements in astrophysical processes. (See ► [Chap. 12 in this Volume.](#)) These unsuccessful attempts were reviewed by R. W. Hoff (1978) at a symposium held at Berkeley in 1978 to commemorate the 25th anniversary of the discovery of elements 99 and 100. He postulated that the neutron fluxes were high enough to have produced masses heavier than 257, but the measured SF half-lives of 0.4 ms for ^{258}Fm and 1.5 s for ^{259}Fm were so short that formation of masses heavier than 257 by additional neutron capture was effectively blocked. It was suggested that perhaps the very neutron-rich, long-lived ($T_{1/2} \approx 9,700$ years) nuclide, ^{250}Cm , formed in rather large quantities in these tests, might be recovered afterward. It could then be used as target material to produce superheavy elements (hereafter to be called SHEs) by bombardments at accelerators with projectiles as heavy as ^{238}U .

Myers and Swiatecki (1966) and Meldner (1967) predicted that an “Island of Superheavy Elements” well beyond uranium might exist around elements with atomic numbers 114 or 126. This raised the possibility that very long-lived SHEs might still exist on earth after having been formed during the last nucleosynthesis in the solar system some 4.5 billion years ago. Later theoretical studies based on new theories of nuclear structure (Strutinsky 1966; Nilsson et al.

■ Fig. 21.2

Contour plots of predicted half-lives of SHEs as a function of proton and neutron number according to (a) Fiset and Nix (1972) and (b) Randrup et al. (1974)

1969a; Fiset and Nix 1972; Randrup et al. 1974) confirmed that an island of nuclear stability stabilized by spherical nuclear shells should be centered around 110–114 protons and 184 neutrons. Such calculations led to the conclusion that these spherical closed nuclear shells or “magic numbers” should be nearly as strong as those at 82 protons and 126 neutrons found in doubly magic, stable (nonradioactive) lead-208 (^{208}Pb), the most abundant isotope of naturally occurring lead. Some calculations even indicated that element 110 with 184 neutrons ($^{294}110$) should be the longest-lived with a half-life in the range of hundreds of thousands to a billion years as shown in the contour plots (Fiset and Nix 1972; Randrup et al. 1974) in Fig. 21.2.

These elements near the predicted islands of nuclear stability around the spherical closed shells at proton numbers 110–114 (or even 126) and 184 neutrons are typically referred to as SHEs. Although arguments have been made (Armbruster and Münzenberg 1989) that the heavy elements that would not exist except for stabilization by nuclear shells, whether or not they are spherical, should be designated as SHEs, the term has usually been reserved for those elements in the region of the predicted spherical doubly magic nuclei.

A 1968 periodic table with the “Superactinide” series proposed by Glenn T. Seaborg (1968) is shown in Fig. 21.3. Seaborg stated that in placing what he called the “Superactinides” at the bottom of the periodic table under the lanthanides and actinides, he had tried for simplicity’s sake to conform as nearly as possible to the current form of the periodic table.

This 32-member “Superactinide” series would begin with element 122 and end with element 153 after filling of the $5g^{18}$ and $6f^{14}$ electron shells, perhaps in mixed electronic configurations. However, Seaborg cautioned that complications from intruding 7d and 8p electrons might also occur and cause deviations from this picture and from the predominantly trivalent character expected for this Superactinide series. The predicted SHE with atomic number 126 would be a member of this series. A few examples of some of the early searches for SHEs in nature and at accelerators will be described in the next sections of this chapter and are discussed in much more detail by Hoffman, Ghiorso, and Seaborg in the *Transuranium People: The Inside Story* (Hoffman et al. 2000).

21.2 Early Searches for SHEs

21.2.1 In Nature

Among the earliest searches for SHEs in nature were those conducted at Berkeley between 1968 and 1972 by S. G. Thompson's group (Nilsson et al. 1969b; Cheifitz et al. 1972). Searches were begun in natural ores for element 110 as eka-platinum and elements 111 through 114 as eka-gold, -mercury, -thallium, and -lead. Initially, they looked specifically for eka-platinum, element 110, using low background counting techniques and sensitive analytical methods. Among the most sensitive measurements are those based on evidence of SF decay. This process is very rare among the known naturally occurring radionuclides and even if SHEs decay by other modes, they were expected to end in SF. The results of the searches were negative, corresponding to a concentration of $<10^{-11}$ g/g. Later, they used their very high efficiency, large liquid scintillator system in an attempt to measure the high multiplicity of neutrons predicted (Nix 1969) to be emitted during the SF of spherical SHE nuclei in the region of element 114. In order to reduce effects from cosmic-ray background, they placed their detector some 250 m deep in a cross passage inside the Bay Area Rapid Transit (BART) system tunnel then under construction between Berkeley and Orinda, California. More than 40 large samples of ores, natural minerals such as galena and gold nuggets, manganese nodules from the ocean floor, moon rocks, and placer platinum were surveyed, but they found no evidence for

increased neutron emission. Assuming a half-life of a billion years, they set a limit of $<10^{-14}$ moles of SHEs per mole of sample.

In 1969, G. N. Flerov and coworkers (Flerov and Pereygin 1969) in Dubna, Russia, reported detecting fission tracks in lead glass, which they attributed to the possible decay of SHEs. Based on additional observations of fission events in lead ore samples, they concluded they had found SF events with an apparent half-life of 4×10^{20} years that they attributed to SHEs. However, other researchers (Price et al. 1970) were not able to observe any fission tracks in old lead- and gold-rich minerals and set lower limits that were in contradiction with the Flerov results.

G. Herrmann (1974) published a review of early searches for SHEs in nature and concluded that no positive results had yet been obtained in either terrestrial or extraterrestrial samples, although many extremely sensitive methods had been developed and used in the search.

In 1976, R. V. Gentry and others (Gentry et al. 1976; Fox et al. 1976) reported evidence for element 126 and possibly elements 116, 124, and 127 in several “Giant Halos” found in mica samples (see [Sect. 17.13 of Chap. 17 in this Volume](#) on pleochroic halos). Gentry suggested that these giant halos had to be caused by 12–14 MeV alpha particles, much higher than the known members of radioactive decay series, and might have been produced by SHEs. Measurements of miniscule samples containing a single giant halo were bombarded with low-energy protons and the induced X-rays were measured. These so-called PIXIE measurements indicated L X-rays at the appropriate energies for the SHEs 126 and possibly 116, 124, and 127 as well. These results created great excitement and elation in the community and, at first it appeared that at last there was some firm physical evidence for SHEs. Unfortunately, the ‘X-rays’ turned out to be nuclear gamma rays induced in cerium-praseodymium isotopes present in the inclusions, and yet another discovery disappeared.

21.2.2 At Accelerators

First attempts to produce SHEs “artificially” were also conducted at Berkeley in 1968 by S. Thompson and A. Ghiorso and coworkers (Thompson 1968; Bowman et al. 1968). They used reactions of heavy ion projectiles with heavy actinide targets, e.g., $^{40}\text{Ar} + ^{248}\text{Cm} \rightarrow ^{288}114$, followed by neutron emission. No SHEs were detected and only limits could be set on the production cross sections and half-lives. (See [remark #33 in Chap. 9 of Vol. 1](#) on estimating such limits.)

Marinov et al. (1971a) published an article in *Nature* in January 1971, claiming production of element 112, eka-mercury, after they observed SF events in a mercury fraction chemically separated from the products of a long irradiation of tungsten with 24 GeV protons. The production mechanism was presumed to be secondary reactions with suitable targets of the heavy recoil products from the interactions of the high-energy protons. Later experiments showed (Marinov et al. 1971b) that some 70% of the observed SF activity was due to contamination from ^{252}Cf , and subsequent attempts by members of the group to repeat the initial results were unsuccessful. Subsequent more sensitive experiments (Bimbot et al. 1971; Batty et al. 1973) also proved to be negative.

Flerov and Oganessian (1972) reported detecting SF activity with a half-life of about 150 days in sulfide fractions containing osmium and bismuth separated from the products of long bombardments of ^{238}U with a variety of ions as heavy as ^{136}Xe . However, the average number of neutrons per fission was typical of actinides rather than SHEs so, again, another report seemed

unlikely. Attempts were initiated to try to produce SHEs in uranium + uranium collisions at the Universal Linear Accelerator (UNILAC) in Darmstadt, Germany, and in reactions of ^{48}Ca projectiles with ^{248}Cm at the SuperHILAC at Berkeley, but no positive results were obtained.

21.3 Summary of Results to 1978

The quest for SHEs continued in spite of the negative results, and in 1978 a large International Symposium on Superheavy Elements (Lodhi 1978) was held to assess the results and to consider future experiments. Most of the researchers working in the field and many other interested scientists attended. Some 15 countries and 50 different institutions were represented. The results of both searches in nature and attempts to synthesize SHEs were summarized. The quest had been extended by Anders et al. (1975) to investigations of anomalous stable xenon ratios arising from fission of SHEs in meteorites, but the results were model-dependent and controversial. The detection of neutrons from SF found in separated samples of hot springs water from the Cheleken Peninsula by Flerov and his group (Flerov 1977) was nonspecific as pointed out by D. C. Hoffman (Hoffman 1978; Hoffman et al. 1980) and remained inconclusive. Investigations of the reaction of ^{48}Ca with ^{248}Cm at Berkeley (Hulet et al. 1977; Illige et al. 1978; Otto et al. 1978) continued to prove fruitless, and resulted only in pushing the limit on the production cross section still lower to 0.1 nanobarn (nb) (10^{-34} cm^2). In the closing summary of the Superheavy Elements Symposium, G. A. Cowan (1978), suggested using uranium beams to bombard ^{248}Cm , or even ^{250}Cm , recovered from underground nuclear tests. The conclusion was that there was still no positive evidence for the discovery of SHEs either in nature or in the products of accelerator bombardments. With the reduction of most of the half-life predictions from 10^9 down to 10^4 years, or even only a year depending on estimates of SF half-lives, most plans for future attempts to find SHEs were focused on production at accelerators.

21.4 Searches for SHEs Since 1978

In 1981, Herrmann summarized (Herrmann 1981) the results of searches for SHEs in damped collisions of ^{238}U with ^{238}U carried out at the UNILAC at Darmstadt utilizing their unique high-energy uranium beams to bombard uranium targets. A wide variety of radiochemical separation techniques and a rotating-wheel system were used to search for elements 108 to 118 and even 126. These experiments were also to no avail and upper limits of 10^{-32} , 10^{-33} , and 10^{-35} cm^2 were set on the cross sections for half-lives of 1 to 100 ms, 100 ms to 1 day, and 1 day to 1 year, respectively. However, he predicted that the planned increases in fluence levels would permit reaching cross sections below these levels. Subsequently, the search for the production of SHEs in damped collisions (see [Chap. 3 in Vol. 1](#)) with ^{238}U (6.2–7.3 MeV/nucleon) at the UNILAC was extended to ^{248}Cm targets (Kratz et al. 1986) because this reaction was predicted to have a higher cross section. Comprehensive aqueous- and gas-phase radiochemical separation techniques were used to isolate SHE fractions that were then assayed for SF activity, including fission-fragment total kinetic energies, and neutron emission. Again, the results were negative with upper cross-section limits of $\sim 10^{-33} \text{ cm}^2$ for half-lives of minutes to hours and $\sim 4 \times 10^{-35} \text{ cm}^2$ for half-lives from days to several years.

About the same time, a large collaboration (Armbruster et al. 1985) of nuclear scientists, both chemists and physicists, from groups in the USA, Germany, and Switzerland conducted an exhaustive “final” investigation of the reaction of ^{248}Cm with ^{48}Ca projectiles in 1982–1983 first at the SuperHILAC at Berkeley, USA, and then at the UNILAC in Darmstadt, Germany. The earlier attempts at Berkeley (Hulet et al. 1977; Otto et al. 1978; Illige et al. 1978) and Dubna (Oganessian et al. 1978) using bombarding energies corresponding to excitation energies of the compound system of 33–53 MeV had all been negative. Therefore, the new experiments were conducted with excitation energies between 16 and 40 MeV, close to the reaction barrier, in an attempt to keep the excitation energy as low as possible in order to minimize losses due to prompt fission.

The recoil fragment separators, Small Angle Separator System (SASSY) at the SuperHILAC, Lawrence Berkeley Laboratory (LBL) and Separator for Heavy Ion Reaction Products (SHIP) at the Universal Linear Accelerator (UNILAC) at the Gesellschaft für Schwerionenforschung (GSI), Darmstadt, Germany, were used to search for nuclides with half-lives as short as microseconds. In addition, both online and off-line radiochemical separation techniques were utilized to search for species with half-lives as short as a few seconds and as long as years. Again, no evidence was found for SHEs with production cross sections larger than 0.1–0.01 nb over a half-life range of 1 μs to 10 years.

Searches for naturally occurring SHEs in *Atlantis II* hot brine reported by Flerov et al. (1979), Halperin et al. (1981), and Feige et al. (1987) also all proved to be negative. By the end of 1987, no credible evidence for SHEs, either in nature or artificially produced, remained and the quest was essentially abandoned.

21.5 Discovery of Elements 107 Through 112

Meanwhile, between 1981 and 1984, three new elements, bohrium (107), hassium (108), and meitnerium (109) were discovered (see Chap. 19 in this Volume.) A timeline of the discovery of the transuranium elements is shown in Fig. 21.4. They were produced (Münzenberg et al. 1981, 1982a, b) at the UNILAC using so-called cold fusion production reactions suggested by Oganessian et al. (1975). Targets of doubly magic stable ^{208}Pb or nearby stable ^{209}Bi were bombarded with the appropriate heavy-ion projectiles (e.g., enriched stable ^{54}Cr and ^{58}Fe ions). These “shell-stabilized” targets react with the stable projectiles to give a compound nucleus that is the sum of their proton and neutron numbers. The resulting compound nuclei are produced with much lower excitation energies than those resulting from “hot fusion” reactions in which unstable heavy actinide targets are used. These “cold” compound nuclei are much more likely to de-excite by emitting only a single neutron, and thus, being less likely to be destroyed by fission, they have larger production cross sections. The isotopes $^{262}107$, $^{265}108$, and $^{266}109$ were separated and identified using the in-flight “separator for heavy-ion reaction products” (SHIP), built at GSI under the direction of Peter Armbruster. The names and symbols bohrium (Bh) for 107, hassium (Hs) for 108, and meitnerium (Mt) for 109 were officially adopted for these elements along with rutherfordium (Rf) for element 104, dubnium (Db), formerly called hahnium (Ha) for element 105, and seaborgium (Sg) for 106 by the International Union of Pure and Applied Chemistry (IUPAC) in August 1997 (CNIC 1997).

Evidence for different isotopes of element 110 was reported by several groups of scientists in 1995–1996. Ghiorso et al. (1995a, b) reported production of a single atom of $^{267}110$ in the $^{209}\text{Bi}(^{59}\text{Co},n)$ cold fusion reaction, Lazarev et al. (1996) reported evidence for decay of

■ Fig. 21.4

Timeline of discovery of transuranium elements. The claimed discovery date is indicated rather than the date discovery was confirmed and approved by the IUPAC. Solid lines indicate confirmed elements, dashed lines indicate unconfirmed elements

the neutron-rich nuclide $^{273}_{110}$ produced in the hot fusion reaction $^{244}\text{Pu}(^{34}\text{S}, 5n)$, and Hofmann et al. (1995a) reported evidence for isotopes of element 110 produced in cold fusion reactions. More details on these reports are given in Hoffman (1998).

After many improvements to SHIP, an international team led by S. Hofmann conducted experiments at GSI in 1995 and claimed discovery of element 110 (Hofmann et al. 1995a) produced in the cold-fusion reaction $^{208}\text{Pb}(^{62}\text{Ni}, n)^{269}_{110}$. They reported observation of $^{269}_{110}$ based on four chains that decayed by alpha emission to known daughter nuclides. They proposed the name darmstadtium (Ds), which was approved by the IUPAC in August 2003. The second chain could not be found in subsequent re-examination of the data (Hofmann et al. 2002), but IUPAC ruled that the remaining three chains constituted adequate proof.

In the subsequent experiments conducted in 1995, discovery of element 111 produced via the cold-fusion reaction $^{209}\text{Bi}(^{64}\text{Ni}, n)^{272}_{111}$ was also claimed (Hofmann et al. 1995b) based on observation of three decay chains identified using SHIP. The name “roentgenium” (Rg) in honor of Wilhelm Conrad Roentgen was proposed for element 111 and announced on the 100th anniversary of Roentgen’s 1895 discovery of X-rays. The IUPAC considered the data of high quality but inconclusive because no known daughters were identified in the reported decay chains.

In 2004, Morita et al. (2004a) used the same reaction as the GSI group to produce $^{272}_{111}$. They observed 14 alpha-decay chains in total, thus providing much new information about its decay properties, clearing up some of the ambiguities and confirming the discovery of $^{272}_{111}$ and the alpha-decay properties previously reported by Hofmann et al. (1995b, 2002). The name “roentgenium” with symbol Rg was finally officially approved by IUPAC in November 2004.

Continuing their experiments at GSI using the SHIP separator, Hofmann et al. (1996) identified two decay chains attributed to element 112 produced via the $^{208}\text{Pb}(^{70}\text{Zn}, n)^{277}_{112}$

reaction. Hofmann et al. (2002) later reanalyzed their 1996 data and subsequently reported that one of the decay chains attributed to element 112 could not be found in the original data and performed additional experiments to obtain more data for the isotopes of element 110 through 112 to support their originally reported discoveries. Again, Morita et al. (2005, 2007a) at RIKEN repeated the GSI experiments on production of element 112. Their observation of two of the same decay chains as reported by the GSI team was important in the ultimate assignment of discovery of element 112 to the GSI team of Hofmann et al. (2002).

A Joint Working Party (JWP) appointed by the International Unions of Pure and Applied Chemistry (IUPAC) and Pure and Applied Physics (IUPAP) assigned priority of discovery in May 2009 of element 112 to the international group of scientists led by S. Hofmann (Hofmann et al. 1996, 2002) working at GSI. The discoverers proposed the name “copernicium” with the symbol “Cp” after the Polish astronomer Nicolaus Copernicus. However, the proposed symbol was amended to be “Cn” because Cp for “cassiopeium” had earlier been proposed for element 71. That discovery could not be confirmed, and element 71 was later named lutetium by the acknowledged discoverers. The approval process was initiated by IUPAC in July 2009 and completed in March 2010 (Tatsumi and Corish 2010). The names and symbols for the transactinides approved as of 2010 are shown in [Table 21.1](#). The updated 2010 Periodic table of the Elements is shown in [Fig. 21.5](#).

One of the most significant things about the elements 107 through 112 is that they decay predominantly by alpha emission rather than SF, contrary to earlier predictions. These discoveries helped to give scientists renewed hope that it would be possible to reach the predicted island of SHE stability around element 114. The newly discovered nuclides also helped to substantiate the theoretical model and calculations of A. Sobiczewski and his group (Smolańczuk et al. 1995; Sobiczewski 1997) at the Soltan Institute for Nuclear Studies in Warsaw that predicted a doubly magic deformed region of extra stability around proton number 108 and neutron number 162 in addition to the island of spherical stability around $Z = 114$ and $N = 184$.

Table 21.1

List of IUPAC approved transactinides (TANs) 104–112 (Elements 104–109 approved August 30, 1997)

Z	Name	Symbol
104	Rutherfordium	Rf
105	Dubnium (Hahnium) [#]	Db (Ha) [#]
106	Seaborgium	Sg
107	Bohrium	Bh
108	Hassium	Hs
109	Meitnerium	Mt
110 ^a	Darmstadtium	Ds
111 ^b	Roentgenium	Rg
112 ^c	Copernicium	Cn

^aIUPAC approved August 2003.

^bIUPAC approved November 2004.

^cIUPAC approved March 2010.

[#]Used in publications on chemical properties prior to 1997.

21.6 Reports of Discoveries of SHEs

21.6.1 1999–2003

After the discovery of element 112 in 1996, researchers at GSI attempted to produce element 113 but were unsuccessful. Extrapolation from their previous experiments with lead and bismuth targets led them to believe that the cross sections for producing the elements beyond 112 had dropped so low that they needed to further upgrade and increase the efficiency of their SHIP system before continuing the search.

Bombardment of ^{208}Pb with 449 MeV ^{86}Kr projectiles to produce $^{293}118$ by a 1n out reaction was predicted by Smolańczuk (1999a, b) to have a large production cross section and decay via a unique chain of six high-energy alpha emitters with rather short half-lives. In 1999, the reaction was investigated by researchers at Lawrence Berkeley National Laboratory (LBNL) using the recently completed Berkeley Gas-filled Separator (BGS) at the 88 in. cyclotron. Because of the odd neutron in these nuclides, the half-lives might be as much as a factor of ten longer than these predictions. Due to the very low excitation energy of only 13.3 MeV calculated for the compound nucleus, emission of two neutrons is energetically forbidden, and single neutron emission is much more probable than alpha or proton emission from the compound nucleus. Ninov et al. (1999) reported finding three such decay chains with a cross section of a few picobarns in initial experiments conducted in April and May 1999, but upon re-examination of the original data, these results could not be verified. Later experiments

conducted in 2001 (Gregorich et al. 2003) showed no evidence for these decay chains and an upper limit of about 1 pb for production of this decay chain in the reaction of ^{208}Pb with 449 MeV ^{86}Kr projectiles was set.

Concurrently, under the leadership of Yu. Ts. Oganessian, researchers from the Joint Institute of Nuclear Research (JINR), Dubna, Russia, and the Lawrence Livermore National Laboratory (LLNL) heavy element group used the Dubna gas-filled recoil separator (DGFRS) to investigate production of heavier elements via the “hot fusion” reaction. In bombardments of rotating ^{244}Pu targets with ^{48}Ca projectiles accelerated in the Dubna U-400 heavy ion cyclotron, they found evidence for a single decay chain that they attributed to element 114 in data obtained from some 40 days of running time during November and December 1998. This corresponds to a cross section of about 1 pb or less. Based on the bombarding energy of 236 MeV and the characteristics of the observed alpha-decay chain, they originally attributed the event to $^{289}114$, which corresponded to the calculated maximum for the 3n evaporation reaction of the $^{244}\text{Pu} + ^{48}\text{Ca}$ reaction (Oganessian et al. 1999c). They reported observation of only one alpha-decay chain, a long chain ending with SF of $^{277}108$. The measured time intervals between successive decays and the corresponding alpha-decay energies indicated relatively long half-lives for $^{289}114$ (2–23 s), $^{285}112$ (20–200 min), $^{281}110$ (1–12 min), and $^{277}108$ (16 min). The half-lives they reported for $^{285}112$ and $^{281}110$ are nearly a million times longer than those of the heaviest previously known isotopes ($^{277}112$ and $^{273}110$) of these elements. Because this reaction was not previously studied, the method of genetic correlations to known nuclei for the identification of the parent nucleus could not be used, but the assignment of this one decay sequence to $^{289}114$ seemed reasonable based on predicted excitation functions for the $^{244}\text{Pu} + ^{48}\text{Ca}$ reaction. Evidence for $^{288}114$ via the 4n out reaction was subsequently observed in a continuation of the previous experiment that ran from June through October 1999, using the same bombarding beam energy as the first experiment (Oganessian et al. 2000a). Two decay sequences with similar decay characteristics were observed consisting of an implanted ion, two subsequent alpha-decays and terminated by a spontaneous fission. The decay chains were different than those observed during the first run. Based on previous experimental data as well as theoretical calculations, it was assumed that evaporation of either three or four neutrons from the $^{292}114$ compound nucleus would be expected with similar probabilities (on order of one picobarn) over the range of excitation energies observed in both experiments, $E^* = 31.5\text{--}39$ MeV (Oganessian et al. 2000a). Therefore, observation of two neighboring isotopes of element 114 in these experiments at the same beam energy was not unexpected. The new chains obviously originated from a different parent nucleus than that previously observed during the first $^{244}\text{Pu} + ^{48}\text{Ca}$ reaction that were originally attributed to $^{289}114$. The new nuclides observed in the second experiment were characterized by higher alpha-decay energies and terminated by SF at an earlier stage in the sequence. Comparison of the two chains-supported assignment of the first reported decay chain (three alpha-decays followed by SF) to the odd-mass nucleus $^{289}114$ and the shorter chains consisting of two alpha-decays followed by SF to even-even $^{288}114$ (Oganessian et al. 2000a). However, in further measurements of the $^{244}\text{Pu} + ^{48}\text{Ca}$ excitation function over a range of higher beam energies (see ▶ Sect. 21.6.2), the one event originally attributed to $^{289}114$ could not be reproduced and that result has never been confirmed. The original assignment of $^{288}114$ has since been changed to $^{289}114$ based on excitation function data described in ▶ Sect. 21.6.2.

In mid-April 1999, a multinational collaboration, also led by Oganessian, reported indirect evidence for two events of $^{287}114$ from the $^{242}\text{Pu}(^{48}\text{Ca}, 3\text{n})$ reaction using the Dubna electrostatic recoil vacuum separator VASSILLISSA. These results were published (Oganessian et al. 1999b)

in July 1999. In one event, a 10.29 MeV alpha particle was followed 1.3 s later by SF, while in the other event an escape peak with an alpha energy of only 2.31 MeV followed by SF was detected. The SF lifetimes for the two events were 9.3 and 3.8 min, which the authors claim correspond to the same SF activity (within the limits of the reported uncertainties) of about 1.4 min that they produced previously in the reaction of ^{238}U with ^{48}Ca projectiles (Oganessian et al. 1999a) and had attributed to $^{283}112$. In these experiments with the ^{242}Pu target, it was postulated that $^{283}112$ would be observed as the alpha-decay daughter of $^{287}114$. Based on the two SF events observed in the $^{242}\text{Pu} + ^{48}\text{Ca}$ reaction and the two events attributed to $^{283}112$ produced via the $^{238}\text{U}(^{48}\text{Ca},3n)$ reaction, the SF half-life of $^{283}112$ was estimated to be approximately 3 min (Oganessian et al. 1999b). However, later measurements of the $^{242}\text{Pu} + ^{48}\text{Ca}$ excitation function showed that the reported decay properties of $^{287}114$ were not correct, and the parent 114 nucleus actually decays through a chain consisting of two alpha particles followed by SF with the much shorter SF half-life of only a few seconds (Oganessian et al. 2004b). The shorter $^{283}112$ half-life was later reproduced by Hofmann et al. (2007), which supported the revised $^{287}114$ decay properties (see ▶ Sect. 21.6.2).

In 2000, the Dubna–LLNL collaboration reported evidence for the production of $^{292}116$ in the $^{248}\text{Cm}(^{48}\text{Ca},4n)$ reaction at a center-of-target beam energy of 240 MeV (Oganessian et al. 2000b, Oganessian 2001). One decay chain was observed consisting of an evaporation residue followed by two alpha particles and partial energy deposition of a third alpha followed by a spontaneous fission. The half-life estimated from this one event was ~ 33 ms; a cross-section limit was not given as the experiment was in progress during the reported observation of this nuclide, but subsequent excitation function measurements indicate it was likely on the order of 1 pb (Oganessian et al. 2004b). The daughter nuclides appeared to decay with the same properties as those observed in the second reported $^{244}\text{Pu} + ^{48}\text{Ca}$ experiment where the $^{288}114$ assignment was originally proposed (Oganessian et al. 2000a). Therefore, this first reported isotope of element 116 was assigned to $^{292}116$, but was later changed to $^{293}116$ when it was realized that the assignments of the first two reported isotopes of element 114 were incorrect (see ▶ Sect. 21.6.2 for more details). The earlier experiments of Armbruster et al. (1985) described in ▶ Sect. 21.4 reported no evidence for production of SHEs with cross sections larger than 0.1 nb (100 pb) to 0.01 nb (10 pb) over a half-life range of μs to 10 years. However, these experiments did not have sufficient sensitivity to detect SHE nuclides at the picobarn cross-section level and are not in conflict with the above results.

21.6.2 2004–2009

The complete excitation function of the $^{244}\text{Pu} + ^{48}\text{Ca}$ fusion reaction was not measured until 2004 by Oganessian et al. (2004a). The ^{244}Pu targets were bombarded with ^{48}Ca ions at beam energies ranging from 243 to 257 MeV; these were higher than those studied previously during the first two reported observations of element 114 (Oganessian et al. 1999c, 2000a). At a ^{48}Ca energy of 243 MeV, decay chains consisting of two consecutive alpha-decays followed by SF were observed and had identical decay properties to the two chains previously reported at the lower bombarding energy of 236 MeV that were originally assigned to $^{288}114$ (Oganessian et al. 2000a). In addition, at all three of these higher bombarding energies, very short decay chains consisting of a single alpha-decay followed by SF were observed, and at the highest beam energy of 257 MeV, one chain was detected that included two sequential alpha-decays ending with a SF with decay properties that differed from any of the previous observed

chains (Oganessian et al. 2004a). It was assumed that the longer decay chains observed at the lowest and highest beam energies belonged to odd-mass isotopes of 114, while the short alpha-SF chains originated from an even-even nucleus. Based on predicted excitation functions for the $^{244}\text{Pu} + ^{48}\text{Ca}$ reaction, it now appeared that the single chain observed at the highest bombarding energy was likely due to the previously unreported isotope $^{287}\text{114}$ produced via the 5n evaporation channel and the alpha-SF chain, therefore, originated from $^{288}\text{114}$ produced via the 4n channel. These assignments meant that the decay chains originally attributed to $^{288}\text{114}$ (Oganessian et al. 2000a) were actually from a different isotope, and based on the measurement of the excitation function, the assignment was changed instead to the 3n evaporation product, $^{289}\text{114}$, which would be consistent with a longer, odd-mass decay chain (Oganessian et al. 2004a). The single decay chain originally reported as $^{289}\text{114}$ (Oganessian et al. 1999c) was never duplicated experimentally, and, based on the results subsequently reported by Oganessian et al. (2004a), was probably not due to an isotope of element 114. Maximum cross sections for the production of 114 isotopes via the $^{244}\text{Pu} + ^{48}\text{Ca}$ reaction were reported to be: 2 pb (3n), 5 pb (4n), and 1 pb (5n).

Likewise, the complete excitation function of the $^{242}\text{Pu} + ^{48}\text{Ca}$ reaction was subsequently measured in 2004 over a range of beam energies from 235 to 250 MeV (Oganessian et al. 2004b). During a subsequent experiment, the $^{238}\text{U} + ^{48}\text{Ca}$ reaction was also studied over a range of beam energies from 230 to 240 MeV in order to identify the potential alpha-decay daughter of $^{287}\text{114}$, $^{283}\text{112}$ (Oganessian et al. 2004b). Fifteen decay chains consisting of two alpha-decays followed by SF were observed at three beam energies (235, 238, and 244 MeV) during bombardment of ^{242}Pu with ^{48}Ca . The decay properties matched those reported as $^{287}\text{114}$ produced via the $^{244}\text{Pu}(^{48}\text{Ca},5\text{n})$ reaction (Oganessian et al. 2004a). This assignment was also supported by the direct production of the $^{283}\text{112}$ daughter via the $^{238}\text{U}(^{48}\text{Ca},3\text{n})$ reaction (Oganessian et al. 2004b). $^{283}\text{112}$, produced both directly and as the daughter of $^{287}\text{114}$, was observed to decay in both cases via alpha-decay with a half-life of 4 s followed by a very short SF (Oganessian et al. 2004b). These results disagreed with the original report of $^{283}\text{112}$ (Oganessian et al. 1999b), which indicated that it decayed via SF with a lifetime on the order of several minutes. The alpha-decay of $^{283}\text{112}$ was later confirmed by Hofmann et al. (2007) but the 3 min SF activity was not observed. Hofmann et al. (2007) measured two decay chains from the $^{238}\text{U}(^{48}\text{Ca},3\text{n})$ reaction, confirming data previously reported for this isotope by Oganessian et al. (2004b). Two other events were observed consistent with a 50% SF branch for $^{283}\text{112}$. Decay chains for the observed element 114 isotopes based on the original measurements of their direct production via $^{242,244}\text{Pu} + ^{48}\text{Ca}$ reactions with their current proposed isotopic assignments are shown in [Fig. 21.6](#).

Evidence for $^{286}\text{114}$ was first reported by Oganessian et al. (2004a) as the daughter of $^{290}\text{116}$ produced in the $^{245}\text{Cm}(^{48}\text{Ca},3\text{n})$ reaction shown in [Fig. 21.7](#). The assignment was later substantiated in measurements of cross sections for the $^{48}\text{Ca} + ^{242}\text{Pu}$ reaction (Oganessian et al. 2004b). The maximum cross section measured for production of $^{286}\text{114}$ is approximately 4.5 pb for the $^{242}\text{Pu}(^{48}\text{Ca},4\text{n})$ reaction.

Additional isotopes of element 116, $^{290}\text{116}$, and $^{291}\text{116}$, were observed in the reaction of ^{48}Ca with ^{245}Cm (Oganessian et al. 2004a), with cross sections of about 1 pb at a bombarding beam energy of 243 MeV. Once the final assignments of $^{288}\text{114}$ and $^{289}\text{114}$ were determined by Oganessian et al. (2004a; see discussion above) it was realized that the daughter of what was originally believed to be $^{292}\text{116}$ had decay properties that, in fact, matched those of $^{289}\text{114}$ produced in the $^{244}\text{Pu} + ^{48}\text{Ca}$ reaction (Oganessian et al. 2004a). Therefore, the assignment of the element 116 isotope originally observed in the $^{248}\text{Cm} + ^{48}\text{Ca}$ reaction was changed to

■ Fig. 21.6

Decay chains for $^{286}_{114}$ (Oganessian et al. 2004b), $^{287}_{114}$ (Oganessian et al. 2004a), $^{288}_{114}$ (Oganessian et al. 2004a), and $^{289}_{114}$ (initially reported as $^{288}_{114}$ by Oganessian et al. 2000a, later changed to $^{289}_{114}$ in Oganessian et al. 2004a) as measured from the direct production reactions shown on the figure. Half-lives calculated from average lifetimes; observed alpha energies in megaelectron volts are given. Yellow squares indicate alpha-decay and green squares indicate SF

■ Fig. 21.7

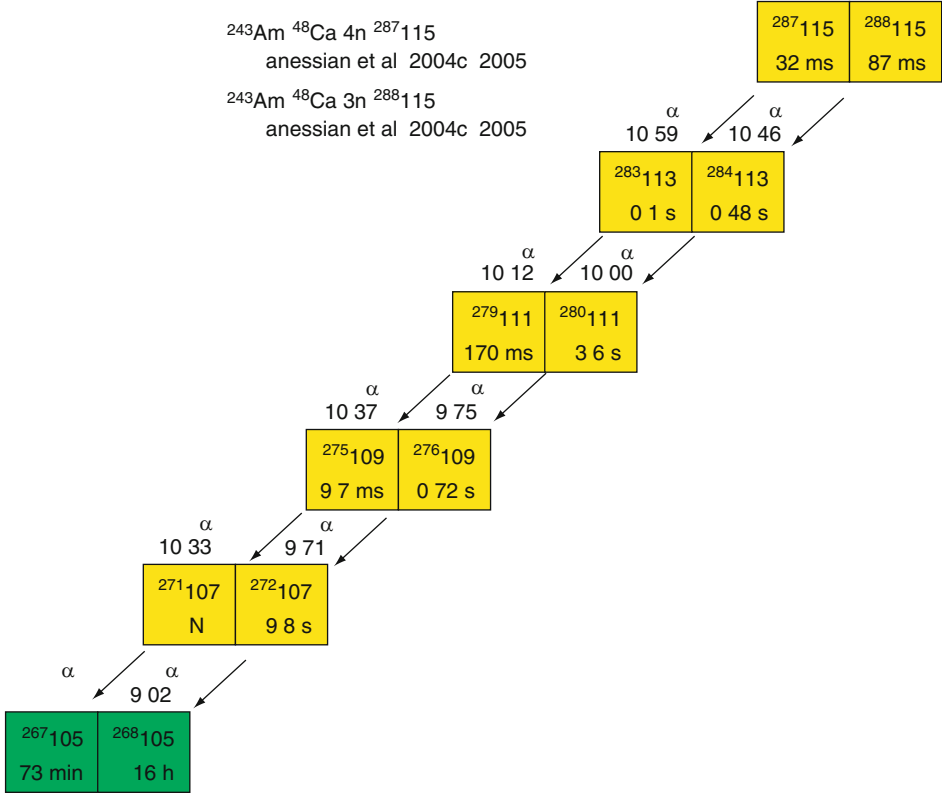

Decay chains for $^{290}_{116}$ (Oganessian et al. 2004a), $^{291}_{116}$ (Oganessian et al. 2004a), $^{292}_{116}$ (Oganessian et al. 2004b), and $^{293}_{116}$ (initially reported as $^{292}_{116}$ by Oganessian et al. 2000b, Oganessian 2001, later changed to $^{293}_{116}$ in Oganessian et al. 2004a) as measured from the direct production reactions shown on the figure. Half-lives calculated from average lifetimes; observed alpha energies in megaelectron volts are given. Yellow squares indicate alpha-decay and green squares indicate SF

$^{293}_{116}$, and $^{292}_{116}$ was later reported in the measurement of the $^{248}\text{Cm}(^{48}\text{Ca},4n)$ reaction at 247 MeV with a cross section of about 1 pb (Oganessian et al. 2004b). Decay chains for the four observed isotopes of element 116 based on the original measurements of their direct production via $^{245,248}\text{Cm} + ^{48}\text{Ca}$ reactions ($^{290,291,292,293}_{116}$) with their current proposed isotopic assignments are shown in Fig. 21.7.

The next reported discovery of a SHE was in 2004 when the Dubna–LLNL collaboration reported the observation of element 115 and its decay daughter 113 for the first time (Oganessian et al. 2004c, 2005). Targets of ^{243}Am were bombarded with 248 MeV ^{48}Ca projectiles resulting in a total beam dose of 4.3×10^{18} ^{48}Ca ions. Three decay chains consistent with the decay of $^{288}_{115}$ and its daughter $^{284}_{113}$ formed via the $^{243}\text{Am}(^{48}\text{Ca},3n)$ reaction were reported resulting in a cross section of about 3 pb. One additional decay chain corresponding to the decay of $^{287}_{115}$ and its daughter $^{283}_{113}$ produced via the $^{243}\text{Am}(^{48}\text{Ca},4n)$ reaction was observed at an increased beam energy of 253 MeV giving a production cross section of about 1 pb (see Fig. 21.8).

Fig. 21.8
Reported decay chains for $^{287,288}_{115}$ (Oganessian et al. 2004c, 2005). $^{271}_{107}$ was not detected (ND). Half-lives calculated from average lifetimes; observed alpha energies in megaelectron volts are given. Yellow squares indicate alpha-decay and green squares indicate SF

The long-lived (16 h) ^{268}Db decay daughter of $^{288}_{115}$ (Oganessian et al. 2004c) was later isolated via chemical methods (Dmitriev et al. 2005) during a subsequent ^{48}Ca bombardment of ^{243}Am . During this procedure, the reaction products that came from the ^{243}Am were caught in a copper block placed directly behind the target. The block was removed after 24 h of irradiation and the surface was removed using a microlathe. The copper was then dissolved in nitric acid and run through a column of Dowex 50×8 cation-exchange chromatography resin. The Groups 4 and 5 elements were eluted together with hydrofluoric acid (Dmitriev et al. 2005; Oganessian et al. 2005; Schumann et al. 2005). The entire effluent was evaporated on a thin polyethylene foil for subsequent alpha and SF counting. The entire procedure from end of bombardment to the beginning of counting was approximately 2–3 h (Oganessian et al. 2005). Fifteen spontaneous fission events were observed with a measured half-life of 32 h (Oganessian et al. 2005), which was consistent within experimental uncertainties with the 16 h half-life observed for ^{268}Db produced as a decay product of the reported $^{288}_{115}$ chain shown in [Fig. 21.8](#) (Oganessian et al. 2004c). However, the chemical method used would not differentiate the Group 4 from Group 5 elements (Schumann et al. 2005). Identification of the atomic number cannot be made via spontaneous fission alone, especially in a case where contamination from other elements may have been present. The cross section for the production of $^{288}_{115}$ via the $^{243}\text{Am}(^{48}\text{Ca}, 3n)$ reaction was determined during the off-line chemical separation to be approximately 4 pb based on the assumption that the 15 observed SF events were from ^{268}Db and not another fissioning nuclide present in the final chemical fraction (Oganessian et al. 2005). This cross section was consistent with the 2.7 pb cross section measured via direct production (Oganessian et al. 2004c).

In a subsequent experiment performed by the LLNL–Dubna collaboration (Stoyer et al. 2007; Wilk et al. 2008), five SF events were detected in an experiment in which the reaction products collected in the copper catcher block were chemically separated to first isolate the Group 5 elements from other interfering products, and then the Group 5 fraction was further separated into Nb- and Ta-like fractions in order to evaluate whether the previously observed fission events were from ^{268}Db , which would be expected to behave as a Group 5 element. After removing the surface of the copper and dissolving it as before, the solution was sorbed on an inert Kel-F resin coated with methyl isobutyl ketone (MIBK). Several chemical fractions were collected by performing gradient elutions with varying concentrations of HCl and HF (Wilk et al. 2008). The Groups 4 and 5 elements were shown to be in different fractions based on the location of tracer radionuclides (^{89}Zr , $^{92\text{m}}\text{Nb}$, ^{177}Ta , ^{175}Hf , ^{167}Tm , and ^{169}Yb) added prior to the start of chemistry (Stoyer et al. 2007). The Group 5 elements were further separated in Nb- and Ta-like fractions through the use of graded HCl/HF elutions followed by a warm-water wash, which removed all of the tantalum (Wilk et al. 2008). All fractions were evaporated onto thin polyethylene foils for subsequent alpha and SF counting. The entire procedure from the end of irradiation to the beginning of counting took approximately 2 h. The five observed SF events all appeared in the Ta fraction, suggesting that the fissions originated from a Group 5 element. The lifetimes of the fission events were between 16 and 37 h. When one incorporates all of the fission events from direct production (Oganessian et al. 2004c) and the two subsequent off-line chemistry experiments (Oganessian et al. 2005; Stoyer et al. 2007; Wilk et al. 2008), the half-life of ^{268}Db is 28 h (Stoyer et al. 2007). The chemistry experiments provide indirect evidence that the daughter activity may come from the same long-lived dubnium nuclide that is part of the element 115 decay chain ([Fig. 21.8](#)). However, direct production will ultimately be required to confirm assignment of $^{288}_{115}$.

Direct production of two different isotopes of element 113 has also been reported. Morita et al. (2004b, 2007b) reported production of two events of $^{278}113$ via the $^{209}\text{Bi}(^{70}\text{Zn},n)$ cold fusion reaction with the extremely small production cross section of only about 31 fb in two separate experiments at a beam energy of 353 MeV at the Riken Linear Accelerator Facility. These were attributed to $^{278}113$ based on alpha-decay to the previously reported isotopes ^{266}Bh (approximately 1 s; Wilk et al. 2000) and ^{262}Db (34 s). Oganessian et al. (2007a) reported observation of two decay chains of $^{282}113$ produced via the $^{237}\text{Np}(^{48}\text{Ca},3n)$ reaction at a bombarding energy of 244 MeV, corresponding to a production cross section of 0.9 pb. Decay chains for these experiments to produce isotopes of 113 are shown in Fig. 21.9.

Eichler et al. (2007a, b) studied the production of $^{287}114$ via the $^{242}\text{Pu}(^{48}\text{Ca},3n)$ reaction using thermochromatographic separation methods. The reaction products were volatilized and the $^{283}112$ decay daughters were subsequently collected and measured on a detector surface cooled with a temperature gradient from $+35^\circ\text{C}$ to -186°C . The observed decay chains attributed to $^{283}112$ (9.5 MeV alpha-decay with a half-life of about 4 s) were consistent with those reported by Oganessian et al. (2004b) as decay products of $^{287}114$ observed during measurement of the $^{242}\text{Pu} + ^{48}\text{Ca}$ excitation function (Oganessian et al. 2004b). These experiments of Eichler et al. provide indirect proof of production of element 114 through the measurement of its $^{283}112$ decay daughter.

Most recently, a group at LBNL (Stavsetra et al. 2009) has reported production of one event each of $^{286}114$ and $^{287}114$ produced via the $^{242}\text{Pu} + ^{48}\text{Ca}$ reaction with decay properties

Fig. 21.9

Reported decay chains for Element 113. Left: $^{278}113$, two events reported (Morita et al. 2004b, 2007b). Right: $^{282}113$ (two events, Oganessian et al. 2007a). Half-lives calculated from average lifetimes; observed alpha energies in megaelectron volts are given. Yellow squares indicate alpha-decay and green squares indicate SF

■ Fig. 21.10

Reported decay chain for $^{294}_{118}$ (Oganessian et al. 2006). Half-lives calculated from average lifetimes; observed alpha energies in megaelectron volts are given. Yellow squares indicate alpha-decay and green squares indicate SF

consistent with those reported by Oganessian et al. (2004b). These experiments are the first to provide direct confirmation of production of element 114.

In 2006, Oganessian et al. (2006) reported the observation of three similar decay chains originating from element 118 produced via the $^{249}\text{Cf}(^{48}\text{Ca}, 3n)^{294}_{118}$ reaction at two different excitation energies (29 and 34 MeV) with a cross section of approximately 0.5 pb. The assignment of element 118 to the new decay chains was supported by the genetic correlation with a previously identified isotope of element 116 measured in the $^{245}\text{Cm}(^{48}\text{Ca}, 3n)^{290}_{116}$ reaction (Oganessian et al. 2004a) and its corresponding decay daughters. The decay chain for $^{294}_{118}$ is shown in ► Fig. 21.10.

21.7 Theoretical Predictions for Half-Lives and Nuclear Properties of Transactinide Elements (2003–2009)

Although most nuclear models indicated that half-lives and production rates rapidly decrease beyond Sg, some theoretical calculations (Sobiczewski 1997) predicted a region of nuclear stability around ^{270}Hs , a doubly magic deformed nucleus with 108 protons and 162 neutrons. One of the challenging experiments proposed for the future was to produce isotopes in this region for study of their properties. In recent studies by Dvorak et al. (2006, 2008), the new isotope ^{271}Hs (half-life ~ 4 s) was produced via a 3n out reaction in the bombardment of ^{248}Cm with ^{26}Mg projectiles at below Coulomb barrier energies. The measured cross section of a few picobarns was comparable to the maximum cross sections for the previously known 4 s ^{269}Hs , as well as for the isotope ^{270}Hs , which alpha-decays with a half-life of about 23 s and is an ideal candidate for chemical studies. These experiments suggest that the 3n reaction may be useful

for making more neutron-rich transactinides using relatively light heavy ion beams and actinide targets.

These and other studies and reanalysis of data for Sg decay products of Hs alpha-decay by Düllmann and Türler (2008) have shown that the originally reported 21 s ^{266}Sg (Türler et al. 1998) was in error and was actually due to ^{265}Sg , which has two isomeric states with half-lives of 8.9 s and 16.2 s, respectively. The good news is that the 8.9 s ^{265}Sg isomer is produced preferentially via the $^{248}\text{Cm}(^{22}\text{Ne}, 5n)$ reaction with an estimated cross section of a few hundred picobarns! Now it should be quite feasible to perform more “in-depth” detailed studies of the chemistry of Sg, such as stability of its oxidation states both in solution and in gas-phase studies and complex formation under a variety of conditions.

A review of predicted chemical properties including ionization potentials, ionic radii, and redox potentials for Sg and lighter Group 6 elements is given in Hoffman et al. (2006). These indicate that the (VI) oxidation state will be the most stable both in solution and in the gas phase and that Sg^{4+} will be even less stable than Ta^{3+} and W^{4+} . It will be especially interesting to compare actual comprehensive measurements of the chemical properties of Sg with those of lighter Group 6 homologues and with the predictions of modern relativistic atomic and molecular calculations that include the influence of relativistic effects on chemical properties.

The early predicted doubly magic spherical region of hypothetical long-lived SHEs shown in  Fig. 21.2 has never been reached although some of the recently reported heaviest isotopes of elements 112–118 produced in fusion reactions of heavy actinide nuclei with ^{48}Ca projectiles show significant increases in stability as the number of neutrons increases. Oganessian (2007b) has given a comprehensive review of the reported properties of the heaviest nuclides. He also discusses the theoretical predictions about the “island of stability.”

Zagrebaev and Greiner (2008) considered the use of multinucleon transfer reactions in low-energy collisions of heavy ions for the production of new heavy isotopes along the closed shell at 126 neutrons, which is important in the *r*-process of nucleosynthesis. They predicted that more than 50 new nuclei might be produced in collisions of ^{136}Xe projectiles with ^{208}Pb targets with cross sections of at least a microbarn and although SHEs would not be reached the information gained might be of some value in planning future SHE experiments and would add to the general information on reaction mechanisms.

Pei et al. (2009) investigated isentropic fission barriers using self-consistent nuclear density functional theory and the relationship between isothermal and isentropic descriptions. They found that the dependence of isentropic fission barriers on excitation energy changes rapidly and that shell effects are still important even for compound nuclei with large excitation energy. Fission barriers for nuclides produced in cold fusion reactions and those synthesized in hot fusion reactions are predicted to exhibit quite different behavior. For nuclei around $^{278}112$ produced in cold fusion reactions, they predict a more rapid decrease in the fission barriers with excitation energy compared to nuclei around $^{292}114$ produced in hot fusion reactions. Research to provide reliable theoretical estimates of compound nucleus survivability is in progress.

In a 2005 review article, Ćwiok, Heenan, and Nazarewicz (2005) present new theoretical results for properties of even–even heavy and SHE element nuclei with $94 \leq Z \leq 118$ and with $134 \leq N \leq 188$. They use self-consistent formalism and a modern nuclear energy density functional to formulate the following major conclusions concerning SHEs: (1) SHE nuclei around $Z = 116$ and $N = 176$ are expected to exhibit coexistence of oblate and prolate shapes,

in contrast to actinide and transfermium nuclei which have well-deformed elongated shapes; (2) Inclusion of triaxial shapes in the calculations dramatically reduces barriers between prolate and oblate shapes; (3) Gradual changes are expected along the triaxial energy surfaces although in special cases prolate and oblate shapes may be well separated. The heaviest isotopes recently reported by the Dubna–LLNL group are predicted to belong to a transition region that is subject to dramatic shape changes and/or triaxial softness. These shape effects are predicted to affect the alpha-decay energies, and half-lives may be lengthened due to hindrances in decay rates between parents and daughters with different shapes. Their predictions that the long-lived SHEs can exist in a variety of shapes and in some cases even in metastable states, and the formation of shape isomers will make positive identification of new species even more difficult than formerly anticipated.

21.8 Future

The 1970s predictions of exceedingly long half-lives for nuclei in the region around the spherical doubly magic superheavy nucleus $^{298}114$ have been drastically reduced. For example, calculations of Smolańczuk (1997) indicated that the spherical doubly magic superheavy nucleus $^{298}114$ would decay predominantly by alpha emission with a half-life of only about 12 min, but that $^{292}110$ might alpha-decay with a half-life of about 50 years. Theoretical calculations (Smolańczuk 2001; Chasman and Ahmad 1997) also indicated that nuclei with half-lives of microseconds or longer would exist all along the way to the predicted islands of stability. A 1978 contour plot with some of the nuclei reported in this “transition” region as of mid-2002 is shown in [Fig. 21.11](#).

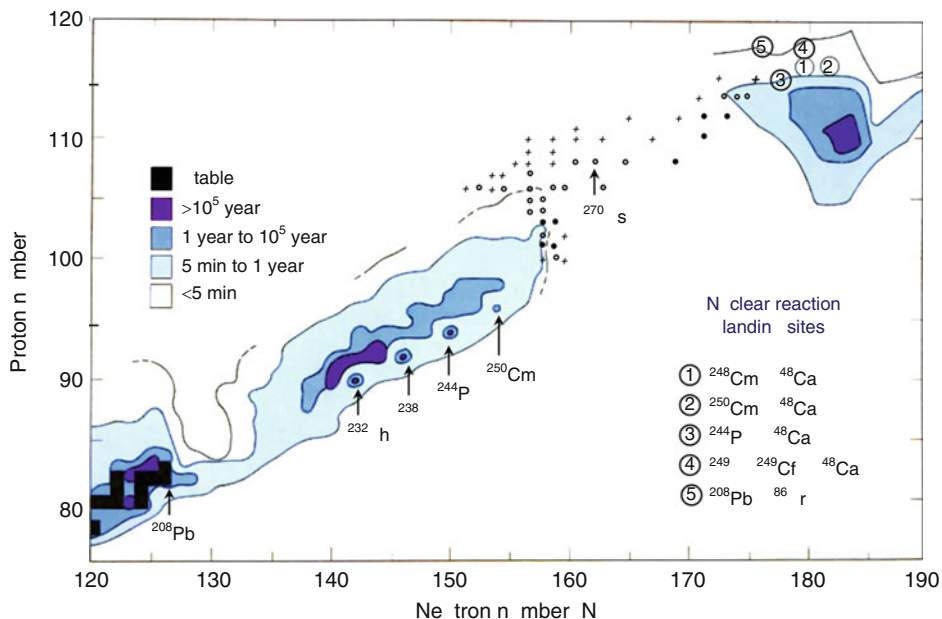

A large number of isotopes have been added to those shown as of mid-2002 for Sg (106) and beyond in [Fig. 21.9](#) of the authors’ previous SHE paper (Hoffman and Lee 2003). Many assignments have changed, some have been dropped entirely, and a host of others have been added and still await confirmation. [Figure 21.12](#) shows a similar representation of the isotopes *reported* (not necessarily confirmed) for Sg(106) through element 118 as of mid-2009 (Düllmann 2009).

Four isotopes each of elements 113 and 114, two of element 115, four of element 116, and one of element 118 have now been reported. It should be noted that none have yet been reported for element 117. Earlier calculations by Smolańczuk (1997) indicated that some of these nuclei would be expected to be nearly spherical with deformation energies ranging from only about 0.1 MeV for $^{292}116$ to 0.2–0.3 MeV for the 114 isotopes, compared to zero deformation energy for the spherical doubly magic $^{298}114$ and 7.8 MeV (Sobiczewski et al. 2001) for the doubly deformed magic nucleus, $^{270}108$. Thus, the nuclei in this region may qualify as spherical SHEs even though they do not have the full complement of 184 neutrons.

A Dubna–LLNL team (Oganessian et al. 2009) recently reported an unsuccessful attempt to synthesize element 120 at Dubna via the $^{244}\text{Pu}(^{58}\text{Fe},\text{xn})^{302-x}120$ reaction. The sensitivity of the experiment corresponded to a cross section of ~ 0.4 pb for the detection of one decay. The production cross section of the evaporation residues in this reaction appeared to be lower by more than an order of magnitude compared to that of the same target with ^{48}Ca . They considered various explanations for this and concluded that additional attempts to synthesize element 120 in this reaction would require much increased sensitivity and proposed

■ Fig. 21.11

Plot of heavy element topology from 1978 showing some landing points for proposed reactions. New heavy element isotopes reported as of mid-2002 are indicated with symbols denoting the following half-life ranges: + = 0.1 ms to 0.1 s; o = 0.1 s to 5 min; • = >5 min

that a more mass-asymmetric reaction, e.g., $^{248}\text{Cm} + ^{54}\text{Cr}$ or $^{249}\text{Cf} + ^{50}\text{Ti}$ might be more favorable.

Subsequent to the authors' mid-2002 review (Hoffman and Lee 2003), some 30 new heavy element isotopes have been reported. However, the longest lifetimes (not yet confirmed) reported to date by the Dubna–LLNL team for elements Rg through element 118 are: ^{280}Rg , 3.6 s; $^{285}\text{112}$, 29 s; $^{284}\text{113}$, 0.5 s; $^{289}\text{114}$, 2.6 s; $^{288}\text{115}$, 0.087 s; $^{293}\text{116}$, 0.05 s; 117, not yet reported; $^{294}\text{118}$, 0.09 ms. All of these decay via emission of an alpha particle. None are confirmed as yet, and none decay to any currently known isotopes, although some of the results for production of element 114 have been duplicated by other groups. Making it still more difficult is that using currently known reactions, accelerators, and detection techniques only an atom every few days may be produced! The half-lives quoted above for Rg, 112, 114, and possibly 113 are long enough for chemical studies provided techniques can be developed to deal with or enhance the low production rates. On the positive side, it has already been demonstrated that it is possible to perform studies of chemical properties at the picobarn level for nuclides with half-lives of seconds. Perhaps some of the predicted longer-lived metastable states and shape isomers of SHEs can be produced with large enough production rates to permit identification and characterization of their nuclear decay properties. It has also been proposed (Armbruster 2008) that the magic proton shell should be shifted from $Z = 114$ to $Z = 122$, which would present an additional challenge for experimentalists to try to produce still more proton rich nuclei.

Fig. 21.12

Chart of the Isotopes for Sg (106) through element 118 reported as of mid-2009 adapted from compilation of C. E. Düllmann, mid-2009 (Düllmann 2009)

[illegible]

Although it now is predicted that many additional, relatively long-lived SHE species can exist, new production reactions, imaginative techniques for optimizing overall yields, and methods for “stockpiling” long-lived products for off-line studies must be devised if these exciting new phenomena are to be fully explored.

22 Appendix to Part II – Table of Nuclides

R. B. Firestone

Lawrence Berkeley National Laboratory, Berkeley, California, USA

22.1	<i>Introduction</i>	<i>1034</i>
22.2	<i>Editors' Notes</i>	<i>1034</i>

Abstract: This chapter presents the table of nuclides, i.e., experimental nuclear data concerning isotopes and isomers of the elements.

22.1 Introduction

The table of nuclides shown below is arranged by elements with the atomic number Z starting from 0 (neutron). It lists all isotopes and isomers with half-lives >1 ms for which some experimental data are available.

The data including nuclear spin and parity ($J\pi$) are taken from the Nuclear Wallet Cards (Tuli 2000) and from the Evaluated Nuclear Structure Data File (ENSDF 2002).

Q -values (decay energies for different decay modes) for beta minus ($Q\beta^-$), electron capture ($Q\epsilon$), alpha ($Q\alpha$), and proton decay (Qp) are from Audi and Wapstra (1995). Systematic values are shown in square brackets.

Representative IUPAC isotopic compositions (abundances) of the elements (Rosman and Taylor 1997) are shown in curly brackets. Principal gamma rays and alpha particles for radioactive decay from ENSDF are given. Up to four gamma rays and two alpha particles with intensity greater than 10% of the most intense transition are shown.

Apart from the symbols printed in bold face above (and some trivial cases), the following abbreviations are used in [Table 22.1](#):

- **BR**: percent branching ratio
- β^- (β^-), ϵ (electron capture and/or β^+), **IT** (isomeric transition), and **SF** (spontaneous fission)
- β^- or ϵ delayed n, p, or α emission (β^-n , ϵn , $\epsilon\alpha$, etc.)

22.2 Editors' Notes

A *nuclide* is an atomic species as determined by its atomic number (proton number) Z and mass number (nucleon number) $A = Z + N$, where N is the number of neutrons in its nucleus. Atomic species with the same nuclear composition but different nuclear energy states with measurable lifetime are considered independent nuclides “in their own right.” Nuclides can be classified in different ways. Nuclides having the same atomic number Z (but different mass number A) represent the same chemical element and are called the *isotopes* of that element. Nuclides with the same mass number A (but different atomic number Z) are called *isobars*. Nuclides of the same number of neutrons N (but different atomic number Z) are called *isotones*. Nuclides of the same nuclear composition but different nuclear states are referred to as (nuclear) *isomers*. The terms *isotope*, *isotopic*, *isobar*, *isobaric*, *isotone*, *isotonic*, *isomer*, and *isomeric* can also be applied to *nuclei*, but the terms *nuclide* and *nuclidic* can only be applied to *atoms*.

Abstract: Ionizing radiation causes chemical changes in the molecules of the interacting medium. The initial molecules change to new molecules, resulting in changes of the physical, chemical, and eventually biological properties of the material. For instance, water decomposes to its elements H_2 and O_2 . In polymers, degradation and crosslinking take place. In biopolymers, e.g., DNS strand breaks and other alterations occur. Such changes are to be avoided in some cases (radiation protection), however, in other cases they are used for technological purposes (radiation processing). This chapter introduces radiation chemistry by discussing the sources of ionizing radiation (radionuclide sources, machine sources), absorption of radiation energy, techniques used in radiation chemistry research, and methods of absorbed energy (absorbed dose) measurements. Radiation chemistry of different classes of inorganic (water and aqueous solutions, inorganic solids, ionic liquids (ILs)) and organic substances (hydrocarbons, halogenated compounds, polymers, and biomolecules) is discussed in concise form together with theoretical and experimental backgrounds. An essential part of the chapter is the introduction of radiation processing technologies in the fields of polymer chemistry, food processing, and sterilization. The application of radiation chemistry to nuclear technology and to protection of environment (flue gas treatment, wastewater treatment) is also discussed.

23.1 Introduction

Radiation chemistry implies the study of chemical effects of interactions of ionizing radiation with materials. The term ionizing radiation in a wider sense is applied to photons or particles having sufficient energy to ionize the molecules of the medium: it involves photons with energies ranging from the first ionization energy of the medium (~ 10 eV) up to several MeV, as well as energetic charged particles, electrons, positrons, accelerated heavy ions, etc. The result of the energy absorption is breaking or rearrangement of chemical bonds. High-energy photons, charged species with sufficiently high energy and neutrons may be absorbed by the nuclei and cause nuclear reactions. This is the field of nuclear physics and nuclear chemistry or radiochemistry and these effects are not considered in radiation chemistry (Hummel 1992).

The field of radiation chemistry has been intensively investigated for about 100 years. However, there is a basic change in the approach. Until the 1950s and 1960s the main aim was to know more about the basic processes of absorption of radiation energy and about the chemical consequences of irradiation (Kroh 1989). In recent years, radiation chemistry is more and more becoming a quite generally applicable method of reaction kinetics by which important kinetic parameters can be measured and reaction mechanisms can be clarified (Tabata 1991a, b; Mayer 1999). Irradiation techniques are often applied as essential parts of technology, e.g., in polymer processing, food processing, sterilization, wastewater and flue gas treatment (Spinks and Woods 1990; Woods and Pikaev 1994). In the field of biological applications, the radiotherapy for cancer treatment should be mentioned. Therefore, this chapter is written not only for radiation chemists, but also for those whose main interests are in related fields, e.g., chemical kinetics, photochemistry, polymer science, radiation biology, radiation physics, radiation technology, radiochemistry, or nuclear technology.

23.2 Sources of Radiation

The sources of ionizing radiation used for research or industrial irradiation purposes can be divided into two groups: sources containing radionuclides, such as ^{60}Co , ^{137}Cs , or the ^{90}Sr – ^{90}Y pair, and machine sources of radiation, such as X-ray equipment or electron accelerators. Without going into details, this chapter will briefly mention those characteristics of some of the radioactive nuclides and accelerators, which are important from the point of view of using them for irradiation purposes.

23.2.1 Radionuclide Sources

^{60}Co is most widely used γ -radiation source for experimental and industrial purposes. It has a half-life of 5.27 years and emits two high-energy photons, 1.17 and 1.33 MeV per disintegration. The isotope is produced by neutron irradiation in $^{59}\text{Co}(n,\gamma)^{60}\text{Co}$ reaction in nuclear reactors. ^{59}Co is usually irradiated in the form of pellets and then these pellets are encapsulated in stainless-steel containers. For research purposes, generally 3.7×10^{13} – 3.7×10^{14} Bq (10^3 – 10^4 Ci) activity sources are used. The commercially available irradiation facilities are often self-shielded, portable although they may weigh several tons. In the industrial irradiation facilities the activity is generally in the 1.85×10^{15} – 3.7×10^{16} Bq (5×10^4 – 10^6 Ci) range. These facilities have irradiation chambers of the size of a room, 15–50 m². Shielding is provided by massive concrete walls, and the operators enter the irradiation chamber through a labyrinth. In the industrial irradiation facilities many tons of goods, e.g., medical products and agricultural products are treated every day. There are about 200 industrial γ -facilities worldwide (Machi 1998). The irradiation facilities used in cancer therapy usually have activities around 3.7×10^{14} Bq (10^4 Ci).

Less frequently, the fission product ^{137}Cs is used for γ -irradiation (γ -ray energy: 0.66 MeV, half-life: 30 years). ^{137}Cs is separated from spent fuel by reprocessing. It is usually applied in the form of cesium chloride sealed in stainless steel capsules.

From the β -ray emitters ^{90}Sr should be mentioned. This nuclide is also obtained from spent fuel by reprocessing. It emits β^- rays with 0.545 MeV maximum energy and a half-life of 28 years. ^{90}Sr disintegrates to its daughter nuclide ^{90}Y , which is also β^- emitter with a half-life of 64 h, maximum energy 2.25 MeV.

23.2.2 Machine Sources

In the pioneering period of radiation chemical research, the radiation emitted by X-ray equipment was often utilized for irradiation purposes. Nowadays particle accelerators, and first of all *electron accelerators* are the main machine sources of radiation (Spinks and Woods 1990).

In the *Van de Graaff accelerators*, a high-voltage electric field (up to several million volts) accelerates the electrons emitted by the hot cathode. (See more about Van de Graaff accelerators in ► Sect. 50.2.3.2, Chap. 50, Vol. 5, on “Particle Accelerators.”) The maximum energy of electrons is limited by the high-voltage insulation: most accelerators work between 1 and 5 MeV electron energy. These machines normally produce a continuous beam, but some of the accelerators were modified to deliver pulses in the subnanosecond – microsecond ($1 \text{ ns} = 10^{-9} \text{ s}$, $1 \mu\text{s} = 10^{-6} \text{ s}$) range. Van de Graaff type accelerators are also used to accelerate particles other

than electrons, e.g., protons, He^{2+} , or C^{6+} ions: these accelerators are the principal radiation sources in heavy ion radiolysis studies.

Pulse radiolysis studies in several laboratories are carried out by using pulsed field emission accelerators. In these accelerators that are known as *Febetron accelerators* (brand name, Field Emission Corporation, McMinnville, OR), similarly to the Van de Graaffs, electric field is used for electron acceleration. Charging a large number of high-capacity condensers in parallel and then discharging them in series produces the accelerating voltage. In contrast to most other accelerators, in these machines the electrons are produced at a field emission cathode. The pulse length is generally a few nanoseconds and the system is capable of giving very high electric currents in the 1,000 A range.

In *linear accelerators* (LINAC) a microwave produced by a magnetron or klystron power generator is used to accelerate the electrons entering the accelerator tube after a 50–100 keV preacceleration by static electric field. (Magnetron and klystron are different types of microwave generators. The LINAC mentioned here is basically the same as the diaphragm waveguide used for the acceleration of positrons as shown in [▶ Fig. 27.8 in Chap. 27](#) on “Positron Annihilation Spectroscopies.” The radiofrequency (RF)-based linear accelerator shown in [▶ Fig. 50.17, Chap. 50, Vol. 5](#), on “Particle Accelerators,” is also referred to as LINAC; it is used for the acceleration of protons and still heavier ions.) The accelerator tube is a few meters long segmented waveguide. The electrons injected into the waveguide, after a bunching process, ride on the crest of waves traveling along the guide and are accelerated to high energies up to several times 10 MeV (Spinks and Woods 1990). Two microwave frequencies, $\sim 1,400$ MHz (L-band) and $\sim 2,800$ MHz (S-band) are most commonly used. The accelerated electrons are delivered in pulses of nanoseconds or microseconds duration with a repetition rate of 50–500 Hz. For scientific purposes, low-power accelerators are usually applied, whereas for industrial irradiations high-power machines, 10–100 kW, are also available. In the high-power accelerators used for industrial irradiation, the beam can be magnetically deflected to sweep a larger irradiation area.

In both the S-band and L-band accelerators, the electric pulse exhibits a fine structure due to the bunching of electrons in the microwave field. The bunching results in trains of 10–30 ps ($1 \text{ ps} = 10^{-12} \text{ s}$) electron pulses: the individual pulses are separated by ~ 350 or ~ 710 ps. The individual pulses give a unique possibility to carry out picosecond pulse radiolysis experiments (Jonah 1975; Kobayashi and Tabata 1989). The first picosecond pulse radiolysis experiments were realized using trains of pulses. Combination of the trains of pulses with a stroboscopic detection allowed a time resolution in the 10 ps range. A technique called “subharmonic prebunching” is used to produce single picosecond pulses for pulse radiolysis purposes. With the help of a further technique called pulse compression pulses in the femtosecond range ($1 \text{ fs} = 10^{-15} \text{ s}$) were also produced (Uesaka et al. 2001; Muroya et al. 2001; Aoki et al. 2001). Because it involves more accelerating structures with multiple frequencies and phase relationships, and high-performance electron gun to inject electrons, subharmonic prebunching adds a lot of cost and complexity of operation of the LINAC facility (Wishart 2008). Consequently only a few prebunched LINACs were built for pulse radiolysis purposes.

During the late 1980s and into the 1990s, a new technology was introduced for generation of picoseconds electron beams. Instead of emission from a hot cathode to produce the electron beam, a metal or semiconductor cathode is struck with an ultraviolet (UV) laser pulse to emit electrons via photoelectric effect: the emitted electron pulse is as short as the incident laser pulse. Since the photocathode-based picosecond systems are simpler than the prebunched thermal emission setups, the newer picosecond pulse radiolysis systems are using this technique (Barbara 1998; Aoki et al. 2001; Wishart 2008).

Recently laser plasma LINAC accelerators are under development (Barbara 1998; Uesaka et al. 2001; Wishart 2008). In these systems a very intense terawatt (TW) femtosecond laser pulse hits the gas flow (helium) in a supersonic gas jet. The extremely strong electromagnetic field of the laser radiation strips the electrons off the helium atoms and accelerates them to very high energies in a process called wake-field acceleration. The wave energy is transferred to longitudinal electron momentum. The electrons have a broad energy distribution up to 30 MeV energy. This wide energy range is – at present – a disadvantage, limits the ability to transport the electrons from the point of generation.

The electron accelerators mentioned before, with the exception of LINACs, are used for scientific purposes. For industrial (processing) purposes high-power, 100 kW–1 MW, accelerators, which work with high, 20–80% electrical efficiency, are needed. The type of the accelerator selected for a given task depends on the thickness of the product to be irradiated.

In polymer processing, flue gas treatment, and wastewater treatment, medium-energy (0.5–5 MeV) electron accelerators are usually utilized. (Lower energy electrons are unsuitable because of their lower penetration.) In the medium energy range, very often transformer type accelerators are applied that use direct current voltage for the acceleration. The direct current voltage supplies are based on oil- or gas-filled transformers with rectifier circuits. When the voltage level is less than 700 keV, a high-voltage cable may be used to connect the power supply and the accelerator head. Between 700 keV and 5 MeV, high-voltage generators are utilized. In such generators, inductance and capacitance couplings make it possible to multiply the alternating current voltage up to 5 MeV. These machines work with 100–400 kW power and high electrical efficiency of 60–80%.

As mentioned before, high-power LINACs are also available for industrial purposes. In the accelerator tube of LINACs the electrons gain energy from the high-frequency microwave field in several resonant cavities. The new types of medium and large (>5 MeV) energy, high-power, high-frequency (>100 MHz) industrial accelerators use a single large resonant cavity and the electron passes through the cavity several times. In the case of the compact Rhodotron accelerators, when the electron crosses the resonant cavity, it gains ~1 MeV of energy each time. Ten passes and nine bending magnets are needed to obtain 10 MeV electron beam energy. These types of machines are produced up to 700 kW power and the electrical efficiencies are around 30–40% (Haji-Saeid 2007).

23.3 Energy Deposition, Ionization

Since in the radiation chemical practice mostly accelerated electron irradiation and γ -ray irradiation are applied, a brief summary will follow on the energy absorption of these particles in matter. The basic particle–matter interaction types are discussed in ► Chap. 8 of Vol. 1; that chapter approaches this problem from the side of the particle and concentrates on the question how the particle loses its energy. The main interaction types will also be mentioned here; however, the details will only be discussed in connection with the question of how the molecules gain energy from the energetic particles.

23.3.1 Energy Deposition

When they penetrate matter, the high-energy photons or electrons interact with the molecules of the medium. As a consequence of the inelastic collisions the particles lose energy with

concomitant formation of energy-rich excited or ionized molecules. These excited or ionized molecules will be referred to as activated molecules.

High-energy electrons interact either with the Coulomb field of the nucleus of the atom or with the electron shell in elastic or inelastic interactions. By passing through the electric field of an atomic nucleus, the high-energy electron can be decelerated leading to continuous bremsstrahlung. In interactions with the electron shell characteristic X-rays may form. The absorption of energy of X-rays and bremsstrahlung is similar to the absorption of γ -radiation energy. In inelastic collisions with the electrons of the medium the high-energy electron loses energy and slows down, and ionization or excitation of the absorbing material results. In the course of elastic scattering the direction of motion changes without conversion of kinetic energy into any other form of energy. The electron energy and the nature of absorbing material determine the relative frequencies of the different interactions.

High-energy photons interact with the medium by the photoelectric effect, Compton scattering, and by electron–positron pair production (see [Chap. 8, Vol. 1](#)). The threshold energy of the pair production (1.02 MeV) is twice the rest-mass energy of electron (0.51 MeV). This interaction type has importance at energies considerably higher than the threshold energy and especially in materials containing heavy elements. The photoelectric effect is predominant at low energies. In the latter interaction, an electron is ejected from the atom or molecule with a kinetic energy equal to the energy of photon minus the binding energy of the electron. In the Compton effect only a part of the incident photon energy is used to eject electron from the atom or molecule. The lower-energy photon thus produced may take part in further Compton or photoelectric interactions. As a consequence of energy degradation process of a high-energy γ -photon, a large number of energetic electrons are produced. Activated molecules are mostly produced in the interactions of these fast electrons with the atoms or molecules in the medium (Spinks and Woods 1990; Mozumder 1999, 2004). From the point of view of energy dissipation, four cases may be distinguished:

- Case a**, Activated molecule formation in the interactions of very high-energy particles (photons, electrons) with the atoms and molecules (hard collisions);
- Case b**, Interactions of the so-called fast electrons (electrons with several hundred – several thousand eV energy) with the atoms and molecules of the medium;
- Case c**, Reactions of slow electrons (energy between ca. 5 and 100 eV) with the atoms and molecules;
- Case d**, Scattering of very low-energy electrons (<5 eV) in the medium.

In the interactions of the very high-energy electrons (**Case a**) large amount of energy is transferred to the electron of the interacting molecule. For such energetic charged particle–electron interactions the classical model, which treats the system as a fast-moving charged particle passing along the free electron at rest, gives a good description. As a result of the Coulomb interaction the free electron is set in motion at the expense of the momentum (and the energy) of the fast-moving charged particle. The “probability” dP for a charged particle with charge ze and speed u to transfer energy between Q and $Q + dQ$ to an electron of the medium when passing unit distance is given by the model as

$$dP = NZ \frac{2\pi e^4 z^2}{(4\pi\epsilon_0)^2 m_e u^2} \times \frac{dQ}{Q^2}, \quad (23.1)$$

where m_e is the electron mass. In the equation NZ , the product of the number density of molecules, N , and the number of electrons in one molecule, Z , is the electron number density.

The quantity dP/NZ has a dimension of $(\text{length})^2$ and it is called the differential cross section for the events per electron (Hummel 1992).

For low values of Q , i.e., when Q is comparable to the binding energy of the electron, the picture of a collision with a free electron at rest is not any more correct. For such so-called *soft collisions* a model is applied, which involves resonance-like absorption of energy by the molecules. A visual picture given by Bednar in a conference paper (Bednar 1983) may help to understand the essence of the model. In the gas phase, the fast electron passing by the molecule M induces in the molecule a strongly time-dependent electric polarization (► Fig. 23.1). This time-dependent polarization is experienced by the molecule as electromagnetic waves with a range of frequencies. Some of the electrons of the molecule may start oscillating and a resonant excitation or ionization may occur.

The transit time of a fast electron with a kinetic energy in the 10^2 – 10^4 eV range (**Case b**) nearby the molecule is in the 10^{-18} s range. This is actually similar to the time needed for electric transition induced by the absorption of a photon of ~ 10 eV energy. The impulse action of the fast charged particle is practically equivalent to the absorption of energy from the electromagnetic field. In the charged particle action, like in photolysis, the optical selection rules also have an effect on the nature of the electric transitions. These selection rules determine which transition is symmetry or spin, allowed or forbidden. As regards the spin, according to the general rule, during the transition the multiplicity does not change. Since in the ground state most of the atoms and molecules have singlet multiplicity, after the promotion of an electron to a higher unoccupied atom or molecule orbital, the singlet multiplicity remains. However, there are some important differences between photon absorption and fast electron interactions. In photolysis the total energy of the photon is absorbed by the molecule and usually a given excitation or given ionization occurs. In the fast electron interactions the energy gained by the molecule varies from the energy of the lowest excited state to very high energy.

■ Fig. 23.1

Interaction of a passing electron (e) with a molecule (M). Fast electrons exert an impulse action on the molecule, whereas in the case of slow electrons the effect is elongated

According to Platzman's optical approximation theory (Platzman, 1962) the "probability" of picking up energy between Q and $Q + dQ$ is given by the equation

$$dP = \frac{2\pi e^4 z^2}{(4\pi\epsilon_0)^2 m_e u^2} \frac{df}{dQ} \frac{N}{Q} \ln(2m_e u^2 / Q) dQ, \quad (23.2)$$

In the equation the quantity df/dQ is the so-called *differential oscillation strength*. df/dQ is proportional to the optical absorption coefficient. The logarithmic term varies only slowly with Q , therefore the probability of resonant transition is roughly proportional to the $(df/dQ)/Q$ ratio, i.e., it is proportional to the ratio of optical absorption coefficient and the transition energy. If the optical absorption spectrum is accurately known, this equation gives a possibility for the calculation of the transition probabilities and also the yields of the different excited molecules (Hatano 1968, 1999; Makarov and Polak 1970; Kouchi and Hatano 2004).

The reciprocal energy dependence strongly limits the energy absorption at high energies: most of the energy absorption occurs between 10 and 40 eV. In this energy range there is a high probability for the formation of "superexcited" molecules (Makarov and Polak 1970; Robin 1974, 1975, 1985; Hatano 1999). The "*superexcited*" molecules are neutral excited molecules, but their excess energy is higher than the ionization threshold. The lifetime of the superexcited molecules is generally short. They may disappear in auto ionization, in conversion to lower energy excited molecules or in direct dissociation to fragments (Makarov and Polak 1970; Hatano 1999).

As described previously, the fast electrons slow down gradually losing ~ 10 – 40 eV energy in each interaction. As the kinetic energy of the incident particle drops below a certain value, ~ 100 eV (**Case c**), there is no more possibility of a "sudden" energy transfer like with a fast particle (Bednar 1983). Therefore, the optical approximation loses its validity, and optically not allowed transitions may also occur in the energy transfer process: there is a direct possibility for excitation to triplet excited states.

When the energy of the electron drops below ~ 5 eV (**Case d**) there is no more possibility for energy loss in electron excitation processes. The electron scatters in the medium losing energy in very slow energy transfer processes to the vibration/rotation levels of the molecules.

The total energy lost per unit path length by the primary charged particle is obtained by the sum of integrating over all losses occurring in hard and soft collisions. The total energy lost per unit path is called the *linear energy transfer* (LET). In water, the mean LET for fast electrons is ~ 0.2 eV nm $^{-1}$. When 5.3 MeV α particles are applied for irradiation LET-value is much higher, 43 eV nm $^{-1}$. LET is proportional to the square of the charge of the particle, z^2 , and inversely proportional to the square of its speed, u^2 .

In radiation chemistry, the intermediates form with a strongly nonhomogeneous distribution in the matrix (Freeman 1987). At the beginning of an electron track, when the energy is high, the intermediates are sparsely populated. When, however, the electron slows down to low energies, the local intermediate density is high. The energetic electrons along the track produce also secondary electrons (δ electrons) of lower energy that also cause ionization and excitation in the medium. However, due to the lower energy their tracks are shorter. When the electron energy is ~ 100 eV, its range in condensed phases is short and there is a high probability that the electron transfers excitation or ionization energy to a molecule close to the original ionization. In this way a small cluster or *spur* of ionized or excited molecules forms. (The "spur" concept plays an important role in the "spur model" of positronium formation described by [Eq. \(27.2\)](#) in [Chap. 27](#), on "Positron Annihilation Spectroscopies.") In the spur the intermediates

mutually influence each other's reaction possibilities. According to a more strict definition (Freeman 1968) even a single ionization producing a geminate ion pair create a spur: a spur is a grouping of reactive intermediates in which there is a significant probability that some of the intermediates will react with each other before they can diffuse into the bulk medium. Cloud chamber measurements showed that in water vapor 44% of the spurs contain one, 22% two, and 13% three ion pairs.

In condensed phases there are two to four activated molecules in one spur corresponding to ~ 100 eV energy loss. δ electrons in the 100–500 eV range produce larger spurs that may be called *blobs*. δ electrons in the 500 eV–5 keV range can generate short tracks, or above 5 keV branch tracks.

If a mixture of compounds is irradiated the fraction of the total absorbed energy transferred to each component of the mixture is determined by the mole fraction (x) of the component and by its energy absorption characteristics. To a first approximation the yield of product P, $G(P)$, formed in a mixture of A and B is given by the equation

$$G(P) = G(P)_A \varepsilon_A + G(P)_B \varepsilon_B, \quad (23.3)$$

$$\varepsilon_A = \frac{(1-x)Z_A}{(1-x)Z_A + xZ_B}, \quad (23.4)$$

where $G(P)_A$ and $G(P)_B$ are the yields of P product from A and B, and ε_A and ε_B are the electron fractions of A and B, respectively (*linear mixing rule*). (The radiation chemical yield, or G-value, is defined later by [Eq. \(23.15\)](#).) The electron fraction in a binary mixture is defined by [Eq. \(23.4\)](#), Z_A and Z_B are total numbers of electrons in molecules A and B, respectively.

23.3.2 Formation and Decay of Ion Pairs

As discussed previously, the absorption of the energy of high-energy particles in the medium mostly causes (directly or through a superexcited state) ionization of molecules. In gas phase, the ejected electron can easily escape the Coulomb field of the positive ion. Therefore, the charges become homogeneously distributed in the medium: charge recombination occurs randomly (homogeneous recombination). In contrast to the gas phase, in condensed phases the fate of the ion pairs and the nature of the recombination are strongly dependent on the properties of the medium. In the low-permittivity hydrocarbons, most of the ejected electrons lose the kinetic energy in interactions with the surrounding molecules and return to the geminate ion. Such recombination is called *geminate recombination*.

According to *Onsager's theory* the electron escape probability, $\Phi(r)$, is a function of the permittivity of the solution

$$\Phi(r) = \exp\left(\frac{-e^2}{4\pi\varepsilon_0\varepsilon_r kT}\right), \quad (23.5)$$

where e is the elementary charge, ε_r is the relative permittivity, ε_0 is the vacuum permittivity, and r is the distance between the ion and the electron. The *critical distance*, $r_c = e^2/(4\pi\varepsilon_0\varepsilon_r kT)$, where the energy of Coulomb interaction between electron and positive ion is equal to the thermal energy is 25–32 nm in hydrocarbons. When $r > r_c$ the fate of the electron mainly depends on the thermal diffusion. When $r < r_c$ the Coulomb interactions are predominant. In alkanes, 2–30% of the ejected electrons escape the positive ion and undergo homogeneous recombination (Freeman 1987).

The free ion yields strongly depend on the molecular structure; in linear alkanes the yields are low, the yields increase with the increasing branching. There is a positive correlation between the free ion yields and the mobility of electrons in the hydrocarbons. Since the yield and mobility of electric charge carriers in insulators like hydrocarbons is very important from both theoretical and practical point of view, a large number of papers were devoted to this subject and there are some good review papers as well (Hummel and Schmidt 1974; Holroyd 1987; Holroyd and Schmidt 1989; Holroyd 2004).

In liquid water at room temperature, the critical distance is only $r_c = 0.7$ nm. Most of the ejected electrons (dry electrons) have sufficient kinetic energy to get away from the positive ions. After thermalization, the electron orients the surrounding water molecules and forms the so-called hydrated electron (e_{aq}^-). The properties of this species, the hydrated electron, are now well known. Its reactions with a large variety of solutes were investigated in many hundred papers (Buxton et al. 1988).

➤ Table 23.1 shows the ionization potentials and the mean energies needed for ionization in the gas phase (W -values). The W -values are between 21 and 36 eV, and they are much higher than the ionization potential values. The high difference is partly because a considerable part of energy absorbed is used for excitation and also to the fact that ionization does not solely occur with the lowest energy electron.

23.4 Techniques in Radiation Chemistry

Two main different experimental approaches are used to investigate radiation chemical reactions. One of them is applied to detect, qualitatively or quantitatively determine intermediates and final products that are stable and do not change during the time of measurement. Such intermediates are ions or free radicals “frozen” in solid matrices. The other approach uses time dependent measurement in order to observe intermediates or the build up of final products (pulse radiolysis).

23.4.1 Steady-State Techniques

The final products of radiolysis reactions are analyzed by the usual analytical techniques, like spectrophotometry, gas chromatography, high-performance liquid chromatography (HPLC), and others. In the radiolysis investigations the conversion is generally very low, being on the order of 0.0001–0.01, therefore sensitive analytical techniques are needed. A new generation of techniques, for instance chromatographic and electrophoresis analytical instrumentation based on diode-array technology now makes it possible to examine radiation chemical processes below 10 Gy dose (Barbara 1998).

In radiolysis reactions, excited molecules, cations, free electrons, anions, and radicals are the main intermediates. For the study of radical anions, cations and radicals formed in a solid matrix, e.g., in polymers, electron paramagnetic resonance (EPR) spectroscopy is used since the 1950s. Anion and cation species can also be studied by UV spectroscopy. Absorption spectra of many organic radical anions and cations were measured in tetrahydrofuran or in halogenated hydrocarbon matrices (Shida 1988).

A widespread technique for studying the intermediates is the *scavenger method*. Yields of some of the products decrease, those of others increase or remain unchanged in the presence of

■ Table 23.1

Ionization potentials and the average value of radiation energy spent for producing a single ion pair (W -value) in the gas phase

Molecules	Ionization potential, eV	W -value, eV
Inorganic molecules		
H ₂	15.4	36.5
O ₂	12.1	30.8
CO ₂	13.8	33.0
N ₂ O	12.7	32.6
H ₂ O	12.6	29.6
NH ₃	10.2	26.6
Hydrocarbons		
Methane	12.7	27.3
Ethane	11.7	25.0
<i>n</i> -Hexane	10.17	22.61
3-Methylpentane	10.05	22.67
2,3-Dimethylbutane	10.00	22.80
2,2-Dimethylbutane	10.04	22.88
Cyclohexane	9.88	25.05
Ethylene	10.52	24.6
Benzene	9.25	20.9
Other organic molecules		
Methanol	10.08	
Ethanol	10.5	24.8
Acetone	9.7	

The W values compiled have been measured using electromagnetic radiation; however, the W values are nearly independent of the energy and type of radiation.

Blaunstein and Christophorou (1971), Christodoulides et al. (1984), Spinks and Woods (1990), Tabata (1991a).

scavengers, and new components appear among the products as a result of the scavenging process (Tabata 1991a). A general problem of the scavenger experiments is the practical impossibility of finding specific additives that react only with one type of intermediate being present during radiolysis. For instance, substances generally used as radical scavengers may also react with electrons, since both radical scavenging and electron scavenging are related to the electron affinity of the substance.

For *scavenging excited molecules* compounds with low excitation energies are used, e.g., aromatic hydrocarbons. These compounds in the excited state exhibit strong fluorescence that can be used to detect excited molecule quenching (Földiák 1981).

Electron scavenging is often carried out using N₂O additive. At room temperature it dissolves in water in 0.025 mol dm⁻³ concentration. In reaction with hydrated electrons, N₂O transforms to N₂ and OH (Schuler and Albarran 2002):

In hydrocarbons N_2 , H_2O , and in small amounts alcohols (e.g., in cyclohexane cyclohexanol) form as a result of electron scavenging. Alkyl halides are often used as electron scavengers in hydrocarbon systems, e.g., methyl bromide:

The methyl radical thus formed may abstract a hydrogen atom in organic solvents and the methane yield represents the electron scavenging yield. In the presence of radioactive I_2 the scavenging yield is calculated from the amount of radioactive methyl iodide formed (Warman et al. 1968, 1969).

It is much more difficult to find good *positive-ion scavengers* than electron scavengers. In ammonia and in hydrocarbons, cyclopropane may be used for this purpose.

Generally, charge scavenging and charge geminate recombination are in competition. It has been found that in saturated hydrocarbons and often in other solvents as well, the scavenged yield can be represented by a simple expression called Warman–Asmus–Schuler equation (Warman et al. 1968, 1969)

$$G(\text{scavenged species}) = G_{\text{fi}} + G_{\text{gi}} \frac{(\alpha c)^n}{1 + (\alpha c)^n}, \quad (23.9)$$

where n is around 0.5. G_{fi} and G_{gi} are the yields of ion pairs undergoing homogeneous (free ion) and inhomogeneous (geminate ion) recombination. The α parameter is a measure of the efficiency of the scavenging reaction.

The *detection of free radicals* and the determination of their yields can be achieved by using unsaturated hydrocarbons (e.g., ethylene) or other substances with unsaturated bonds or with unpaired electron (iodine, oxygen, nitrogen monoxide, benzoquinone, stable free radicals, etc.) as scavengers. The reactions of molecular iodine were often studied by applying radioactive iodine. Iodine reacts with many radicals with diffusion-controlled rate coefficient (LaVerne and Woinárovits 1994)

Radical scavengers are generally applied in $10^{-3} \text{ mol dm}^{-3}$ concentration. This concentration is sufficient to scavenge all the radicals that escape the spur or track; however, at this concentration level the scavenger cannot compete effectively with the reactions taking place in regions where several radical species are in close proximity, or with abstraction, or addition reactions of hot radicals.

23.4.2 Pulse Radiolysis, Technical Realization, and Detection Systems

The intermediates of radiolysis processes can be studied directly by the pulse radiolysis method. In pulse radiolysis experiments a short ps–μs pulse of electrons accelerated to several MeV energy is directed into a cell that contains the sample to be irradiated (Ebert et al. 1965; Baxendale and Busi 1982; Tabata 1991b; Mayer 1999; Wishart 2008). By the method the time dependence of the buildup and decay of intermediates and stable products are followed by

various detection systems. For the observation of intermediate and possibly end products, optical absorption and emission spectroscopy have been used since the early 1960s. In addition to absorption and emission, light scattering, direct current (DC), alternating current (AC), microwave conductivity, polarography, and EPR and nuclear magnetic resonance (NMR) monitoring techniques are also often used for detection. An excellent description of these methods is given in the *Proceedings of the NATO Advanced Study Institute* held at Capri, Italy, 1981 (Baxendale and Busi 1982). Patterson (1987), and more recently Karolczak (1999) also published a book chapter on the different monitoring techniques. The latter works mention some new techniques as well, like detection based on resonance Raman spectroscopy, time-resolved circular dichroism, or time-resolved X-ray absorption measurements. In the book *Pulse Radiolysis* edited by Tabata (1991b), the experts, sometimes inventors of the technique describe some selected pulse radiolysis techniques together with applications. Herkstroeter and Gould (1993) published a detailed description of the optical detection. Recently, Wishart (2008) summarized the ultrafast detection techniques in pulse radiolysis.

Since optical detection systems are used in most of the pulse radiolysis laboratories (and often the other methods are regarded as subsidiary detection techniques), this subsection only describes the principles and typical implementation of optical systems. The method, also called kinetic spectrophotometry or time-resolved spectrophotometry, differs from the conventional spectrophotometric technique since it uses a single path: the reference level is obtained as the light level passes the sample prior to irradiation. This is the basis for the high sensitivity of kinetic spectrophotometry: changes less than 1% in the transmitted light level are measured accurately. Averaging of a large number of traces is possible when using a computerized data acquisition system. The second important difference as compared to conventional spectrophotometry is the short response time. This setup, without the analyzing light, can also be used for emission measurements, although for the latter simpler systems are also used showing considerable advantages.

A schematic illustration of a pulse radiolysis setup is shown on  Fig. 23.2. In the usual arrangements the measuring system is divided into two parts. The first part, including the light source for the sample illumination, the lens system, the shutter preventing the heating, photolysis of the sample, light filters, and the measuring cell itself, is housed in the irradiation room. The measuring cell should be positioned in the beam so as to achieve an approximately homogeneous irradiation. The other parts of the setup are outside the radiation shielding concrete wall and the Faraday cage protecting against electromagnetic interference. These include the monochromator, the photodetector, the oscilloscope/digitizer, and the computer system for data acquisition and processing. Light is usually transmitted from the irradiation room to the measuring room through a hole in the shielding by means of mirrors and lenses. Less frequently light guide cable is used.

To achieve high sensitivity, the optical system should pass high light intensity at a given wavelength. For this, high-output lamps are needed. As light source, high-pressure xenon lamps are often used, the ones having approximately $1 \times 2 \text{ mm}^2$ illuminating area are the most widespread. Another advantage of the xenon lamps is that their light output can be increased considerably for several milliseconds by pulsing the arc current. During the pulse the arc dimensions do not change appreciably, and the increased power is mainly due to the increased luminosity of the arc. As an additional advantage, light density considerably increases in the ultraviolet part of the spectrum, where, under normal operation, the intensity is rather weak. With commercially available lamps, several thousand pulses can be delivered without substantial deterioration of lamp performance. In practice, mostly 150–1,000 W air-cooled or

■ Fig. 23.2

Schematic representation of pulse radiolysis with kinetic spectroscopic detection

water-cooled xenon lamps are used. The pulsing units contain capacitive pulse forming network; the discharge through the lamp is controlled by a thyristor.

Radiation resistance is an essential requirement for all the optics in the radiation field, this requirement is satisfied by using high purity fused synthetic quartz.

The transient changes of the optical absorption are monitored by photodetectors. The time dependence of the detector signal is monitored on an oscilloscope. Nowadays the signals in the ns–s range are digitized by transient digitizers, or digitizing oscilloscopes. Mostly photomultipliers or photodiodes are used as photodetectors. The photodiodes possess lower noise and higher quantum efficiency as compared to the multipliers, but they require a separate amplifier. Amplification occurs on the dynodes in the photomultipliers. Typical values are in the 10^3 – 10^9 range.

When light strikes the photocathode of a photomultiplier, photoelectrons are continuously produced but the instantaneous rate of production shows a statistical fluctuation because the photons of incident light arrive at random. This fluctuation of photoelectron formation is the reason for the fluctuations known as *shot noise*. The root mean square fluctuation of the cathode current, ΔI_c , is given as

$$\Delta I_c = \sqrt{2eI_c\Delta f}, \quad (23.12)$$

where I_c is the cathode current, e is the elementary charge, and Δf is the bandwidth of the detection system. The multiplier dynodes amplify this noise together with the signal.¹ For ideal

amplifiers $\Delta I_c/I_c$ equals $\Delta I_a/I_a$, where ΔI_a is the root mean square fluctuation of the anode current I_a . The signal at the oscilloscope is given as $I_a R$, where R is the load resistor. The sensitivity of the fast kinetic spectrophotometry is limited first of all by this shot noise. The signal to noise ratio, S/N is given as

$$\frac{S}{N} = \frac{I_c}{\Delta I_c} = \sqrt{\frac{I_c}{2e\Delta f}} \quad (23.13)$$

Decreasing of the shot noise is possible either by increasing the analyzing light intensity or by decreasing the bandwidth of the detection system (but this is practical only for signals in the microsecond range or longer).

As mentioned previously, in order to increase the sensitivity of the measurement, one can use pulsed analyzing light. The resulting small transient signal superimposed to a high DC level can only be measured accurately if it is separated from the DC component. A widespread method for doing this is called “backing-off” (► Fig. 23.3). In this procedure one circuit compensates, the other circuit measures the DC level.

The transient signal, separated from the DC level, is monitored on the oscilloscope and digitized. Several implementations of the backing-off method are described.

By kinetic spectrophotometers, the time-dependent absorbance (A) of the observed species is measured. According to the *Beer–Lambert law*

$$A = \lg \frac{I_0}{I} = \lg \frac{100\%}{T} = \varepsilon_\lambda c l, \quad (23.14)$$

■ Fig. 23.3

Effect of “backing-off” on the light intensity signal. The *upper figure* shows the oscilloscope screen with the pulsed light. The transient light intensity disturbance caused by the light absorption of the intermediate (shown in the circle) is enlarged by the “backing-off” method as shown in the *lower figure*

Where I_0 and I are the intensities of the incident and the transmitted light, respectively, T is the transmission in percentage, ϵ_λ is the molar extinction coefficient at wavelength λ , c is the concentration, and l is the optical path-length in the cell.

In the traditional experiments the time dependence is measured at a given wavelength. The spectrum of the intermediates can be composed from a series of measurements taking the absorbance at a constant time after the pulse. A complete spectrum can be measured in a single step by using gated diode-array detectors. However, their time resolution is not sufficient for very fast measurements. In the 100 ps–100 ns time range streak camera may be used for taking the spectrum. (A streak camera is an instrument making unnecessary the usual process of converting light to electronic signals then converting them back again to light.)

There are two optical detection techniques, which were used to provide picosecond time resolution. One is a system with a very fast photodetector: extremely fast phototube detectors and high-bandwidth oscilloscopes (≥ 6 GHz) offer resolution in the visible range down to 80 ps, which is still slower than the capabilities of the accelerator to produce short electron pulses (Wishart 2008). Detectors in other wavelength regions are slower and have complex responses. The other technique is the stroboscopic pulse radiolysis in which very short electron pulses and very short analyzing light pulses are used. In the latter as the analyzing light Cherenkov radiation may be used. Cherenkov light pulses probe the time profile of the transient produced by electron irradiation by varying the time between electron beam and Cherenkov light pulses. The stroboscopic technique can be combined both with multibunched beams and with single fine structure pulses. In the stroboscopic pulse radiolysis system, since the time response is independent of the time response of the photodetector, detectors with slow time response may be used. In the twin LINAC system operating at the University of Tokyo one accelerator is used for the irradiation and the other one to produce the Cherenkov light for analysis. There are two possibilities for the measurements. When the time interval between electron pulse and Cherenkov light is scanned at a fixed wavelength of Cherenkov light a time profile of an absorbing intermediate can be obtained. On the other hand, when the time interval between electron pulse and Cherenkov light is fixed and the wavelength of analyzing light is scanned a spectrum at a fixed time can be obtained (Tabata 1991b; Muroya et al., 2001; Uesaka et al. 2001; Aoki et al. 2001).

23.5 G-Value, Absorbed Dose

In order to quantify the radiation chemical effects of ionizing radiation one has to know the amount of molecules transformed or produced and the quantity of absorbed radiation energy that caused this effect. The ratio of the two is the radiation chemical yield, also called the G-value.

23.5.1 G-Value

The radiation chemical yield, $G(X)$, is defined as the quotient of the amount $n(X)$ of a substance of a specified entity, X , produced, destroyed, or changed by radiation, by the mean energy imparted, E , to the irradiated matter

$$G(X) = \frac{n(X)}{E}. \quad (23.15)$$

Hence, the SI unit of the G -value is mol J^{-1} . In most of the literature up to the 1990s, the G -value was expressed as the number of molecules produced, destroyed, or changed per 100 eV of energy absorbed. The conversion to SI units is as follows (Spinks and Woods 1990):

$$1 \mu\text{mol J}^{-1} = 9.65 \text{ molecules } (100 \text{ eV})^{-1}, \quad (23.16)$$

$$1 \text{ molecule } (100 \text{ eV})^{-1} = 0.1036 \mu\text{mol J}^{-1}. \quad (23.17)$$

23.5.2 Dosimetric Quantities

Since only the absorbed fraction of the incident radiation flux can induce physical or chemical changes, the absorbed energy, in other words the absorbed dose is an important quantity. The absorbed dose or simply the dose is defined as the mean energy, dE , imparted to an incremental quantity of matter, divided by the mass of that matter:

$$D = \frac{dE}{dm}. \quad (23.18)$$

(See for more details ► Chap. 47, Vol. 5, on “Dosimetry and Biological Effects of Ionizing Radiation”).

The preferred SI unit of the *absorbed dose* is the *gray* (Gy), which expresses in joule per kilogram (J kg^{-1}) the energy imparted to unit mass: $1 \text{ Gy} = 6.24 \times 10^{15} \text{ eV g}^{-1}$. In the radiation safety practice often milligray units are applied ($1 \text{ mGy} = 10^{-3} \text{ Gy}$), whereas in the radiation technological applications kilogray and sometimes megagray units are also used ($1 \text{ kGy} = 10^3 \text{ Gy}$, $1 \text{ MGy} = 10^6 \text{ Gy}$). The former absorbed dose unit, *rad*, was defined as 100 erg g^{-1} or $10^{-2} \text{ J kg}^{-1}$, therefore $1 \text{ Gy} = 100 \text{ rad}$ (Holm and Berry 1970; Kase et al. 1985; McLaughlin et al. 1989).

The energy absorbed by the unit mass in unit time is called the *absorbed dose rate* (\dot{D}); it is expressed in Gy s^{-1} , Gy min^{-1} , or in Gy h^{-1} units:

$$\dot{D} = \frac{dD}{dt}. \quad (23.19)$$

23.5.3 Dosimetry of γ -Ray and Electron Irradiation

The dosimeters developed for measuring absorbed doses are often classified into two groups based on the principle of operation: physical and chemical dosimeters. The physical dosimeters detect some physical effect induced by high-energy particles: e.g., calorimeters measure the part of the absorbed radiation energy transformed to thermal energy.

Most of the chemical dosimeters consist of a bulk component, often a liquid in which practically the total energy imparted by the ionizing radiation is deposited, and a solute that reacts with the radiation-induced species formed by the reaction of the bulk component to produce the observed chemical change.

In the following text, a few dosimeter systems will be mentioned that are commonly used in radiation chemistry. For a more detailed treatment of chemical and physical dosimetry, see ► Chap. 49 in Vol. 5 on “Dosimetry Methods.” However, more attention will be paid to pulse dosimetry that is used in pulse radiolysis investigations.

The most well-known liquid chemical dosimeter, the Fricke solution is based on the radiation-induced oxidation of ferrous ions, Fe(II), to ferric ions, Fe(III), in acidic media (E1026: Fricke Reference Standard Dosimeter, ASTM standard). The standard Fricke solution consists of $0.001 \text{ mol dm}^{-3}$ ferrous ammonium sulfate ($\text{Fe}(\text{NH}_4)_2(\text{SO}_4)_2(6\text{H}_2\text{O})$), or ferrous sulfate ($\text{FeSO}_4(7\text{H}_2\text{O})$), and 0.4 mol dm^{-3} H_2SO_4 in aerated aqueous solution. It is applicable for measuring doses in the 40 to 400 Gy range.

The dose is often measured by the alcoholic chlorobenzene dosimeter (ISO/ASTM 51538: Ethanol-Chlorobenzene Dosimetry System). This system is based on radiolytic formation of hydrochloric acid in aqueous ethanol solution of chlorobenzene. Usually the solution has the composition: 24% monochlorobenzene, 72% ethanol, and 4% water. The chloride ion yield, $G(\text{Cl}^-) = 0.59 \text{ } \mu\text{mol J}^{-1}$, is essentially independent of dose up to $\sim 100 \text{ kGy}$.

In radiation processing practice the dose is sometimes measured by means of the alanine-EPR ($\text{CH}_3\text{CH}(\text{NH}_2)\text{COOH}$) dosimetry system (ISO/ASTM 51607: Alanine-EPR Dosimetry). The operation of the dosimeter is based on the generation of $\text{CH}_3\text{CH}^\bullet\text{COOH}$ radicals by ionizing radiation. The read-out is made with electron-paramagnetic-resonance analysis. The nominal absorbed dose range is $1\text{--}10^5 \text{ Gy}$, with linear responses up to $\sim 10^4 \text{ Gy}$.

23.5.4 Pulse Dosimetry

In pulse radiolysis, the dose measurement should be carried out in the measuring cell under identical conditions with the experiments. Therefore, for dosimetry purposes it is advisable to use the same detection system that is also utilized in the measurements. In practice mostly the thiocyanate dosimeter and, less frequently, the hydrated electron dosimeter is used in pulse radiolysis studies (Fielden 1982).

The $(\text{SCN})_2^{\bullet-}$ ions produced in the pulse irradiation of potassium thiocyanate (KSCN) aqueous solution show transient optical absorption with a maximum at $\sim 475 \text{ nm}$.

The ions are produced in the reaction

The dosimetry is usually made in 0.01 mol dm^{-3} air- or oxygen-saturated solution. Since the $(\text{SCN})_2^{\bullet-}$ ions disappear in a fairly slow bimolecular reaction with a rate coefficient of $3 \times 10^9 \text{ mol}^{-1} \text{ dm}^3 \text{ s}^{-1}$, this system is applicable for measuring high-dose pulses. The dose can be calculated from the increase of absorbance at 475 nm , ΔA , using $G\varepsilon = 2.6 \times 10^{-4} \text{ m}^2 \text{ J}^{-1}$ (Buxton and Stuart 1995)

$$D = \frac{\Delta A}{G\varepsilon l \rho}, \quad (23.22)$$

where ε is the molar absorption coefficient at the wavelength of measurement, l is the light path in the optical cell, and ρ is the density. For long pulses with high dose, corrections are to be applied, since a fraction of the $(\text{SCN})_2^{\bullet-}$ ions reacts during the pulse. The correction amounts to 8% for $2.6 \text{ } \mu\text{s}$, 100 Gy pulses.

Hydrated electrons, e_{aq}^- , are produced in the radiolysis of water. Their broad optical absorption exhibits a maximum at 720 nm . Dosimetry is usually carried out in a solution containing $10^{-4} \text{ mol dm}^{-3}$ of sodium hydroxide and $10^{-2} \text{ mol dm}^{-3}$ of ethanol (Fielden 1982).

Hydrated electron is reactive toward most solutes, and for this reason the concentrations of hydroxonium ion, oxygen, and other contaminants should be kept at a low level. Due to the large value of $G\epsilon = 5.2 \times 10^{-4} \text{ m}^2 \text{ J}^{-1}$ in the ns domain doses as low as 0.05 Gy can be measured.

23.6 Water and Aqueous Solutions

Due to the intensive investigations more is known about radiation chemistry of water than any other liquid (Buxton 1987). Many of the principles of radiation chemistry as applied to the liquid phase have been developed in the course of studies on the radiation chemistry of water and aqueous solutions. Water and aqueous solutions have been studied because of the part they play in chemistry in general and in radiochemistry in particular, because they are readily available and not too difficult to work with, and because water is a polar liquid that responds in characteristic ways to radiation. A practical motivation for the studies has been the desire to understand the effect of radiation on biological systems. Irradiation of water and several aqueous systems is an important consideration in various aspects of nuclear technology (Swallow 1973).

23.6.1 Intermediates and Final Products in Pure Water

In the radiolysis of pure water the intermediates, hydrated electron (e_{aq}^-), hydroxyl radical (OH), and hydrogen atom (H) are well characterized. The intermediates mainly form as a consequence of ionization of water molecules. There is no unequivocal evidence that excited-state water molecules play any significant role in radiolysis (Draganic and Draganic 1971; Buxton 1982, 1987; Swallow 1982):

The radical cation $\text{H}_2\text{O}^{+\bullet}$ formed in reaction (23.23) may migrate over a distance of a few water molecules by resonance electron transfer, but since $\text{H}_2\text{O}^{+\bullet}$ is a strong acid within 10^{-14} s it gives a proton to one of the surrounding water molecules according to Eq. (23.25). The electron released in reaction (23.23) loses its kinetic energy in collisions with surrounding water molecules (dry electron) and in less than 10^{-12} s is localized in a potential energy well as a result of molecular dipoles rotating under the influence of the negative charge. Thus in reaction (23.26) the smallest anion, the solvated (hydrated) electron forms. In the recent publications the hydrated electron is sometimes called aqueous electron.

The excited water molecules, H_2O^* , formed in reaction (23.24), decompose to OH radical and H atom in reaction (23.27). The latter species also forms in hydrated electron reaction with hydroxonium ions in reaction (23.28).

The final products H_2 and H_2O_2 (and in its decomposition product O_2) form in the reactions of the intermediates

These reactions partly occur in the spur and there is a strong competition between spur reactions and diffusion out of the spur. This process, the so-called spur expansion, is finished in about 10^{-7} s. Scavengers being present in 10^{-4} – 10^{-3} mol dm^{-3} concentration react only with those intermediates that escape spur reactions. The yields of the e_{aq}^- , OH, and H intermediates in neutral and slightly alkaline solutions are usually taken as 0.28, 0.28, and $0.057 \mu\text{mol J}^{-1}$. In order to efficiently interfere with the spur processes scavenger concentrations in the mol dm^{-3} range should be applied.

The OH radical is a strongly oxidizing species, while e_{aq}^- and H show strongly reducing character. In research investigations, it is of special interest to have a more restricted radical source than the mixture of the three intermediates. This can be achieved by using special additives, as it will be shown below.

23.6.2 Reactions of e_{aq}^- , H, and OH Intermediates with Solutes

The *hydrated electron* is strong reducing agent with a standard reduction potential (vs. NHE) of $E^\circ = -2.9$ V. When the OH radicals disturb the observation of e_{aq}^- reactions, the OH radicals are eliminated using saturated H-atom-containing compounds, like *tert*-butanol

An advantage of alcohols is their good water solubility. The radical formed from *tert*-butanol is a nonreducing radical; it is rather inert in reactions with most organic solutes. This can be verified by saturating the *tert*-butanol-containing solution with N_2O . In such solution the *tert*-butanol radicals are the major radicals present. A disadvantage of *tert*-butanol is that $\bullet\text{CH}_2\text{C}(\text{CH}_3)_2\text{OH}$ may react with the radical under investigation.

The radicals formed from primary or secondary alcohols are reducing radicals. For instance, the α -hydroxyisopropyl radical that is produced by hydrogen abstraction from the secondary alcohol isopropanol is a powerful reducing agent:

This radical may transfer an electron with a high rate coefficient: the reaction often gives the same radical as formed by the e_{aq}^- attack (Buxton 1982; Swallow 1982).

A further possibility of eliminating OH radicals is their reaction with formate ions. These ions also eliminate the H atoms:

$CO_2^{\bullet-}$ has a similar reducing capacity as the α -hydroxyisopropyl radical. The hydrated electrons have a very wide and intense visible infrared (IR) light absorption band centered at $\lambda \approx 720 \text{ nm}$, $\epsilon_{720\text{nm}} \approx 1,850 \text{ m}^2 \text{ mol}^{-1}$. The band is asymmetric; it has a long tail on the high-energy side. Thousands of rate coefficients of hydrated electron attack were measured following the decay of hydrated electrons in pulse radiolysis experiments (Buxton et al. 1988). These coefficients are often high, and for many compounds they are in the diffusion-controlled region (► Table 23.2).

For instance, in the case of e_{aq}^- reactions with metal ions

the rate coefficients (k_{37}) are very often above $10^{10} \text{ mol}^{-1} \text{ dm}^3 \text{ s}^{-1}$. When S^{n+} and $S^{(n-1)+}$ are Ag^+ and Ag^0 , respectively, $k_{37} = 3.7 \times 10^{10} \text{ mol}^{-1} \text{ dm}^3 \text{ s}^{-1}$. For the Cd^{2+}/Cd^+ pair k_{37} is $5.4 \times 10^{10} \text{ mol}^{-1} \text{ dm}^3 \text{ s}^{-1}$. Such reactions are used to produce metal ions with unusual valence state (e.g., dispersed atoms), which, in some cases are not accessible by other methods. The atoms aggregate forming a colloid, which, when stabilized by surfactant, may show unusual catalytic properties (Belloni et al. 1998; Belloni and Mostafavi 2004).

► Table 23.2

Rate coefficients of e_{aq}^- , H atom and OH radical reactions with some molecules, ions, and radicals, $\text{mol}^{-1} \text{ dm}^3 \text{ s}^{-1}$

	e_{aq}^-	H	OH
e_{aq}^-	5.5×10^9	2.5×10^{10a}	3×10^{10}
H	2.5×10^{10}	7.8×10^9	7×10^9
OH	3×10^{10}	7×10^9	5.5×10^9
Fe^{2+}	1.6×10^8	7.5×10^6	3.2×10^8
H_2O_2	1.1×10^{10}	9×10^7	3×10^7
Benzene	1.1×10^7	9.1×10^8	7.8×10^9
Ethanol	$<10^5$	1.7×10^7	1.9×10^9
Acrylamide	1.7×10^{10}	7.5×10^9	5.9×10^9
Tryptophan	3×10^8	2×10^9	1.3×10^{10}
Thymine	1.8×10^{10}	5.7×10^8	5.4×10^9

^a $e_{aq}^- + H + H_2O \rightarrow H_2 + OH^-$.

Buxton (1982, 1987, 2001), Buxton et al. (1988), <http://www.rcdc.nd.edu>.

Among the e_{aq}^- reactions one should also mention the reaction with nitrous oxide, N_2O that gives N_2 molecule, hydroxyl radical, and hydroxyl ion (► Eqs. (23.6) and (► 23.7)). In reaction of e_{aq}^- with dissolved O_2 superoxide anion, a reducing radical with $E^\circ(O_2/O_2^{\bullet-}) = -0.33$ V forms

where $O_2^{\bullet-}$ is the anionic form of perhydroxyl radical (HO_2^{\bullet}). In living organisms the $O_2^{\bullet-}$ anion is of considerable importance where it can form in enzymatic reactions that do not involve ionizing radiation (von Sonntag 1987a, 2006).

In reactions with organic molecules e_{aq}^- reacts as nucleophilic reagent: it attacks molecules with low-lying molecular orbital, like aromatic hydrocarbons, conjugated olefinic molecules, carboxyl compounds, and halogenated hydrocarbons (Swallow 1982; Buxton 1982, 1987; Buxton et al. 1988). In the latter case, addition is usually followed by halide ion elimination, so the reaction can be considered as a dissociative electron capture. For instance, the reaction with chlorobenzene yields phenyl radical and chloride ion

Hydrated electron reacts with aldehydes and ketones with high rate coefficients of several times $10^9 \text{ mol}^{-1} \text{ dm}^3 \text{ s}^{-1}$. The electron is accommodated on the carbonyl oxygen. However, in reaction with carboxylic acids and esters or amides, the rate coefficient is low, $\sim 10^7 \text{ mol}^{-1} \text{ dm}^3 \text{ s}^{-1}$. The low rate coefficient is attributed to a mesomeric effect, which creates a new reaction center with low reactivity (Hart et al. 1967) (► Fig. 23.4).

For acrylate type compounds, in which there is a double bond in α position relative to the carboxylic group, the rate coefficient is again high. It shows that the conjugation between the vinyl and carbonyl group destroys the mesomeric effect (Bíró et al. 1996):

The yield of *hydrogen atoms* in neutral or alkaline solutions is very low, $G = 0.057 \mu\text{mol J}^{-1}$. In acidic solutions due to the conversion of hydrated electrons to H atoms in reaction (► 23.28) the yield can be as high as $G = 0.34 \mu\text{mol J}^{-1}$. Therefore, the H atom reactions are

■ Fig. 23.4

Mesomeric effect in carboxylic acid esters and amides

mostly studied in acidic *tert*-butanol-containing solutions. This additive is used to convert the OH radicals to the less reactive *tert*-butanol radicals in reaction (23.33); the reactivity of H atoms with *tert*-butanol is very low. The H atoms (and also the OH radicals) do not absorb the light in a readily accessible region of the spectrum. Therefore, in pulse radiolysis experiments the reaction product of the H atom reaction or competitive techniques are used to determine the rate coefficients.

The H atom is slightly less powerful reducing agent than e_{aq}^- ($E^\circ = -2.4$ V and -2.9 V, respectively). It reduces the metal ions with lower reduction potentials, e.g., in reaction with Cu^{2+} Cu^+ forms

The H atom reacts (with diffusion-controlled rate coefficient) with dissolved oxygen according to Eq. (23.42) forming perhydroxyl radical

There are two main reaction types of H atom reactions with most organic molecules: H atom abstraction (from saturated molecules) and H atom addition (to the double bonds of unsaturated molecules). For instance:

The *hydroxyl radical* is the main oxidizing radical in irradiated aqueous solution. In N_2O saturated solution (see reactions (23.6) and (23.7) also) the yield of OH radicals reacting with a solute of $10^{-3} \text{ mol dm}^{-3}$ concentration is usually taken as $G \approx 0.57 \mu\text{mol J}^{-1}$. In these solutions the H atoms are not eliminated and they also contribute to the reactions in the solution with a yield of $0.057 \mu\text{mol J}^{-1}$. In strongly alkaline solution OH converts to O^- ion with a pK -value of 11.9 (Buxton 1987):

In reactions with inorganic ions generally hydroxyl ion and the oxidized form of the inorganic ion is produced, e.g., Fe^{2+} transforms to Fe^{3+} (Eq. (23.46)). Very often, both with inorganic and organic ions, the reaction takes place with a two-step addition/elimination mechanism due to the large solvent reorganization energy in the formation of the hydrated hydroxide ion. For instance, the reaction with Fe^{2+} probably also occurs through an adduct intermediate

The reaction between OH radicals and phenols and phenolates also takes place with addition/elimination mechanism. The intermediate, a cyclohexadienyl-type radical, decomposes in acid/base catalyzed H_2O/OH^- elimination to phenoxyl radical (Land and Ebert 1967; Steenken 1987, 1996; Ashton et al. 1995; Roder et al. 1999)

With organic compounds, which do not contain double bond, the OH radicals usually react with hydrogen atom abstraction; see, e.g., reactions (23.33) and (23.34).

The OH reactions are usually studied in N_2O saturated solutions. In such solutions the conversion of hydrated electrons to hydroxyl radicals is a two-step process with the formation of intermediate O^- ions (reactions (23.6) and (23.7)). At higher solute concentrations, above $10^{-3} \text{ mol dm}^{-3}$, the intermediate O^- ions may also react with the solute to not negligible extent and some fraction is not converted to OH radical in reaction (23.7). When the rate coefficient of the OH reaction is measured with the usual thiocyanate competitive technique (see also reactions (23.20) and (23.21)), this reaction may cause an artifact, causing overestimation of the rate coefficient (Schuler and Albarran 2002)

$$\frac{1}{[(\text{SCN})_2^{-\bullet}]} = \frac{1}{[(\text{SCN})_2^{-\bullet}]_0} + \frac{1}{[(\text{SCN})_2^{-\bullet}]_0} \frac{k_{49}}{k_{20}} \frac{[\text{S}]}{[\text{SCN}^-]}, \quad (23.50)$$

where S is the solute molecule and the radical OHS^\bullet is the product of the $\text{OH} + \text{S}$ reaction. In Eq. (23.50) $[(\text{SCN})_2^{-\bullet}]_0$ and $[(\text{SCN})_2^{-\bullet}]$ are the concentrations of $(\text{SCN})_2^{-\bullet}$ ions produced by a constant pulse in the absence and presence of the solute S. $[\text{S}]$ and $[\text{SCN}^-]$ are the concentrations of the solute and thiocyanate ion. If O^- reacts also with the solute S, $[(\text{SCN})_2^{-\bullet}]$ becomes smaller yielding a formally higher k_{49}/k_{20} ratio. In the older literature k_{49} values above $1.5 \times 10^{10} \text{ mol}^{-1} \text{ dm}^3 \text{ s}^{-1}$ were also published (Buxton et al. 1988). Nowadays it is generally accepted that the upper limit is smaller. The reaction between OH radicals and phenols or some other aromatic hydrocarbons is suggested to be truly diffusion controlled, so it shows the upper limit. According to Roder et al. (1999) the upper limit is $\sim 1.4 \times 10^{10} \text{ mol}^{-1} \text{ dm}^3 \text{ s}^{-1}$. Ashton et al. (1995) measured $\sim 1.2 \times 10^{10} \text{ mol}^{-1} \text{ dm}^3 \text{ s}^{-1}$, whereas Schuler and Albarran (2002) suggested a k_{max} of $\sim 1 \times 10^{10} \text{ mol}^{-1} \text{ dm}^3 \text{ s}^{-1}$.

For the conversion of e_{aq}^- to OH sometimes hydrogen peroxide is used. The rate coefficient determined in the presence of H_2O_2 is somewhat smaller than that determined in N_2O saturated solutions (Schuler and Albarran 2002):

The OH radical is a strongly oxidizing species with a reduction potential of $E^\circ(\text{OH}/\text{OH}^-) = 1.9 \text{ V}$. Often milder and more selective oxidants are needed. The techniques producing oxidants with lower reduction potentials are worked out very well. Some examples (see also Table 23.3) are shown below:

23.6.3 Water as Reactor Coolant

Water is the most widespread coolant in nuclear reactors because of its low cost, good thermal properties, high moderating capacity, etc. However, it has two serious disadvantages, in its

■ **Table 23.3**

Standard reduction potentials vs. normal hydrogen electrode (NHE) of some radicals used in radiation chemical studies

Pair	E°, V
$\text{aq}/\text{e}_{\text{aq}}^-$	−2.9
$\text{H}_{\text{aq}}^+/\text{H}$	−2.4
$\text{CO}_2/\text{CO}_2^{\bullet-}$	−1.9

^aThis reduction potential relates, by definition, to O_2 saturated solution. For comparison with other values that are based on molarities, a value of −0.179 V should be taken (von Sonntag 2006).

Steenken (1985a), Neta et al. (1988), Wardman (1989), <http://www.rcdc.nd.edu>.

decomposition explosive mixture of H_2 and O_2 forms, and it is corrosive.² The yield of products (H_2 , O_2 , H_2O_2) strongly depends on the radiolysis conditions and also on the solutes present in water. When these products remain in the water, the decomposition yield is very low due to back reactions that reform water molecules from radiolysis products (Földiák 1986; Woods and Pikaev, 1994)

Reaction (23.58) removes oxygen from the system thus decreasing the corrosion and the radioactivity in the cooling water. The rate coefficients given above refer to room temperature reactions. Nowadays a large number of rate coefficients are available on higher temperature reactions in liquid water up to 300°C (Buxton 2001; Katsumura 2004; Baldacchino and Hickel 2008). By increasing the temperature the rate coefficients change according to the Arrhenius law up to 200°C–300°C. The radiolysis yields of the radical species are similarly increasing with the temperature. This increase is probably due to the acceleration of diffusion with the temperature.

Above 374°C and 22.1 MPa, the liquid and gas phases of water are merged in a single phase called supercritical water. The properties of supercritical water are very much different from that of the liquid water: the density of supercritical water is low and it is pressure dependent.

The permittivity in supercritical water is much less than in liquid water, therefore inorganic acids, bases, salts have low dissociation constants in it. Because supercritical water as coolant has been proposed for Generation IV reactors, there is an increasing interest in its radiation chemistry. Due to the extreme conditions, high temperature, and high pressure, special irradiation cells are needed for the investigations and work in the field is still at the beginning steps. The available experimental results show a strong pressure dependence of the yields. It is not clear yet whether this dependence is related to the change of the density of the medium or to the pressure activation of the reactions. The absorption spectrum of the hydrated electron shifts to longer wavelength with the temperature; above 300°C, the absorption maximum is around 1,200 nm. Since the extinction coefficient also varies with the pressure, the yield determination is rather complicated. As for the rate coefficients above 300°C, little experimental results have been published, again not only temperature, but also pressure dependence was reported (Katsumura 2004; Baldacchino and Hickel 2008).

23.7 Radiation Chemistry of Inorganic Solids

The radiation chemistry of inorganic solids may be regarded as a branch of solid-state physics to which subject it has made substantial contribution (Grigoriev and Traktenberg 1996). The study of radiation effects in solids is of vital importance for nuclear technology, and also relevant to several other fields, e.g., semiconductor technology. The irradiation effect in polymers is discussed in [Sect. 23.9.2](#).

23.7.1 Ice

Radiation chemistry of ice, i.e., solid water, is described in two newer book chapters (Kroh 1991; Wypych 1999), but it was also discussed in many former books on radiation chemistry. Here also, as with liquid water fast kinetic spectroscopic techniques were used to identify the early processes. Pulse radiolysis measurements have been carried out mostly with single crystal ice, which is sufficiently transparent. As it is common in solid-state radiation chemistry some of the intermediates remain trapped in the matrix and can be studied by means of standard spectroscopic techniques like optical absorption and EPR spectroscopy: using these techniques hydroxyl radicals, hydrogen atoms, and trapped electrons were identified at low temperature. The intermediates disappear upon warming up the solid sample. The hydrogen atoms formed at -269°C completely disappear when the solid is warmed to -196°C . The hydroxyl radicals produced at the latter temperature decay between -170°C and -140°C .

By means of pulse radiolysis, two types of localized excess electrons were identified in the irradiated ice. One of them has a visible absorption band with a maximum at $\sim 630\text{ nm}$ (e_{vis}^-); the other has an intense band in the infrared region with $\lambda_{\text{max}} \approx 2,350\text{ nm}$ (e_{ir}^-). The two bands have different decay times and show different sensitivities to the experimental conditions. Buxton et al. (1977) suggested that the electron trap, which leads to e_{vis}^- is vacancy produced by irradiation. The other band, e_{ir}^- , represents an electron localized at a natural cavity in the ice.

The yield of radiation chemical decomposition of water molecules is lower in ice than in liquid or gaseous state. For instance in neutral water the G -value of water decomposition is $G(\text{H}_2\text{O}) = 0.43\text{ }\mu\text{mol J}^{-1}$ at 20°C , whereas it is $0.1\text{ }\mu\text{mol J}^{-1}$ in ice at -10°C . Excited molecules

were not detected in solid water. It is assumed that the excitation energy is dissipated in the solid without producing any net chemical change (Spinks and Woods 1990).

23.7.2 Metals, Semiconductors

Since metals consist of a regular array of positive ions with a pool of mobile, loosely bound electrons, an electron rapidly fills the positive hole left by ionization. For this reason in metals, and also in similar inorganic ordered solid systems, excitations and ionizations are without any significant effect. Radiation effects in metals and semiconductors are interpreted in terms of displacement of atoms, i.e., in terms of radiation-induced dislocations in the ordered system. Such dislocations may cause embrittlement in metals used in nuclear reactor technique. In semiconductors, irradiation produces additional crystal defects, in this way the irradiation changes the concentration, mobility, and lifetime of charge carriers, and thus the electrical behavior of the material. In several countries electron accelerators are used to manufacture diodes and thyristors with short switching times. The radiation-induced centers are annealed at temperatures (250°C–300°C) higher than the usual working temperature of these devices (Spinks and Woods 1990; Woods and Pikaev 1994).

During irradiation of alkali halide crystals, different F centers form and the transparent crystals become colored (Robinson and Chandratillake 1987; Kroh 1991). During annealing these crystals, and also annealing irradiated aluminum oxide, fluorescence photons are emitted. This phenomenon is utilized in thermoluminescence dosimetry (TLD). (See [Sect. 49.3.2.2 in Chap. 49, Vol. 5](#), on “Dosimetry Methods.”) The thermoluminescence of irradiated quartz crystals is used for dating archeological objects.

23.8 Organic Systems

High-energy particle-induced reactions of organic molecules have been intensively studied since the beginning of radiation chemical investigations. In the field of alkane radiolysis, the interest was mainly due to their application as insulators in electric devices or components of lubricants in machines working in radiation field. Alkanes were often used as model compounds in studying inherent problems of radiolysis processes (e.g., spur reactions) or the processes taking place during radiation processing of polymers. The radiolytic reactions of olefins were often studied from the point of view of polymer chemistry. The main reason for the very frequent investigation of aromatic hydrocarbons is their high radiation resistance and their ability to protect other organic substances from decomposition. Several books, book chapters, or review articles were published on the radiolysis of hydrocarbons (Williams 1963; Topchiev 1964; Freeman 1968; Gäumann and Hoigné 1968; Földiák 1981; Hummel 1992; Shkrob et al. 2001). The vacuum ultraviolet (VUV) photochemistry of many of these compounds was also investigated both in gas and liquid phases and these studies are of great help to understand their radiolysis decomposition (Ausloos and Lias 1974; Ausloos et al. 1983; Wojnárovits 2004).

Radiation chemistry of several other classes of organic compounds, e.g., alkyl halides, alcohols, aldehydes, and carboxylic acids was also thoroughly investigated. A reason for the work in the field is that simple organic compounds provide models for polymers and for the

generally more complex compounds, which are of biological interest (Swallow 1973; Milinchuk and Tupikov 1989).

23.8.1 Saturated, Unsaturated, and Aromatic Hydrocarbons

The lowest ionization energies of alkanes in the gas phase are around 10 eV, in the liquids these values are ca. 1.5 eV lower. The lowest singlet excitation energies are 6.5–7.0 eV, and the lowest triplet energies are ca. 1 eV lower (Rothman et al. 1973; Wojnárovits and Földiák 1991). At the same time the energies of C–C bonds and C–H bonds are in the 3.5–4 eV and 3.8–4.5 eV ranges, respectively, i.e., the bond energies are much lower than the lowest excitation and ionization energies. Therefore, practically all activated molecules undergo chemical decomposition. Polymerization type reactions, albeit they were detected, have a minor role in alkane radiolysis (Földiák 1981).

The excited singlet states of alkanes show a weak fluorescence with wavelength of maximum around 200–230 nm and a quantum yield of $\phi = 0.001$ –0.02 (Rothman et al. 1973). The lifetimes of the excited states are generally around 1 ns (Hermann et al. 1985). In gas phase, the lifetime decreases with the decreasing pressure probably due to decreased collisional deactivation of vibrationally excited S_1 molecules. In liquid phase, a characteristic temperature dependence of the fluorescence lifetime was detected (Flamigni et al. 1982; Dellonte et al. 1984; Wickramaaratchi et al. 1985).

The radiation chemistry of *gaseous methane* was often studied. Radiolysis decomposition results in the formation of hydrogen, ethane, and ethylene as main products; longer chains and even polymer-like products also form in low yields (► Table 23.4) (Yang and Manno 1959; Hummel 1970; Lias and Ausloos 1975; György 1981).

The yield of ethylene and those of the higher-molecular-weight products show a strong dependence on the experimental conditions, first of all on the conversion. This is due to the higher reactivity of intermediates with final products than with methane itself. By applying a large variation of techniques, such as VUV photolysis, high-pressure mass spectroscopy, pulse radiolysis, ion–cyclotron resonance spectroscopy, and scavenger experiments, neutral (H , CH_2 ,

► Table 23.4

CH_3^\bullet , $\text{C}_2\text{H}_5^\bullet$) and charged intermediates (e^- , CH_3^+ , CH_4^+ and CH_5^+) were identified. The proposed reaction scheme is rather complicated

The high reactivity of ethylene in radical reactions explains its conversion sensitivity. The polymer with an approximate composition of $\text{C}_{20}\text{H}_{40}$ is proposed to form in subsequent ion-molecule reactions like (23.65) and (23.67).

Cyclohexane at room temperature may be regarded as a typical liquid alkane. In the molecule all of the C–C bonds and all of the C–H bonds are identical and consequently the product distribution is relatively simple. Hydrogen, hydrogen-deficient cyclohexene, and bicyclohexyl form as main degradation products (Ho and Freeman 1964; Holroyd 1968; Wojnárovits 1981; Ausloos et al. 1983; LaVerne and Wojnárovits 1994) (Table 23.5). The

yield of ring decomposition products in condensed phases is little, but the yields are higher in gas phase irradiation especially at low pressures. As intermediates of reactions in condensed phases several research groups identified free electrons, cyclohexyl radical cations, and cyclohexyl radicals. Radical scavenging experiments indirectly reveal also the formation of thermal H atoms:

Reaction (► 23.79), the unimolecular H₂ elimination is a typical decomposition mode of the alkane excited molecules in the S₁ excited state: the yield is ~0.12 $\mu\text{mol J}^{-1}$. The cyclohexyl radical yield is much higher, 0.56 $\mu\text{mol J}^{-1}$, more than twice the yield of scavengeable hydrogen atoms ($G \approx 0.15 \mu\text{mol J}^{-1}$). Therefore, cyclohexyl radicals should be produced in reactions, which do not involve thermal hydrogen atoms. In the earlier literature reaction (► 23.77) was suggested to proceed via “hot” hydrogen atoms. Later works suggest the $c\text{-C}_6\text{H}_{13}^{+\bullet}$ cation as the intermediate that forms in an ion–molecule reaction (Shkrob et al. 2001)

The cyclohexyl radicals in liquid phase disappear in self-termination reactions (LaVerne and Wojnárovits 1994) forming cyclohexene and bicyclohexyl in 1.1/1 ratio via the reactions (► 23.81a) and (► 23.81b) (Cramer 1967). In solid cyclohexane, the cyclohexyl radicals, as EPR evidences show, remain trapped in the matrix. They disappear during the phase transition when the solid is warmed up.

In the radiolysis of liquid cyclohexane and a few other cyclic alkanes high mobility cations form (Zador et al. 1973; De Haas et al. 1975, 1976; Shkrob et al. 2001). Their mobility is approximately one order of magnitude higher than the molecular diffusion. During the 35 years that have passed since the discovery lot of papers were devoted to the problem. These papers discussed the questions: (a) the nature of the fast-moving species and (b) whether all of the cations that form in radiolysis of these cyclic alkanes have high mobility or only a part of them. As regards the second question, nowadays most of the papers agree that in cyclohexane radiolysis not all of the cations have high mobility (Shkrob et al. 1996). The high-mobility charge carrier may be the $c\text{-C}_6\text{H}_{12}^{+\bullet}$ radical cation (according to some suggestions this species is supposed to be in vibrationally excited state), which moves with a resonance-like transfer from ion to molecule (without losing the excess energy, Brede et al. 1978).

Other papers suggest the $c\text{-C}_6\text{H}_{11}^+$ or the $c\text{-C}_6\text{H}_{13}^+$ ion as the fast-moving species (Shkrob et al. 2001). In the case of the $c\text{-C}_6\text{H}_{13}^+$ ion a proton transfer may explain the experimental findings:

In the radiolysis of *liquid n-alkanes* both the yields of hydrogen ($G \approx 0.5 \mu\text{mol J}^{-1}$) and C–C bond decompositions ($\sim 0.17 \mu\text{mol J}^{-1}$) remain essentially constant when the carbon atom number increases from C_4 to C_{17} . It should be noted that neither the C–H nor the C–C breaks occur randomly. The frequency of C–H decompositions at the secondary carbon atoms is ~ 3 times more frequent than at the primary carbons. The fragmentation of the carbon skeleton occurs preferentially in its central region, elimination of the methyl group is relatively infrequent (Holroyd 1968; György 1981; Wojnárovits and Schuler 2000).

In the radiolysis of *crystalline n-alkanes* preferred H-atom elimination from the penultimate position was observed. This is attributed to ion–molecule reaction that is promoted by the crystalline structure. An interesting even–odd alteration of the yields was also reported (Ichikawa and Yoshida 1992).

In the radiolysis of *liquid branched alkanes*, the C–H decomposition yields are smaller than in the radiolysis of *n-alkanes*, and this decrease is compensated by the increase in the yields of C–C breaking products. Radical scavenging experiments revealed that in branched alkanes a tertiary C–H bond decomposes ~ 14 times more frequently than a primary C–H bond. The decomposition of a secondary C–H bond is ~ 3 times more frequent than that of a primary C–H bond (Földiák et al. 1976; Hummel 1992; Wojnárovits and Schuler 2000; Schuler and Wojnárovits 2003). C–C bonds attached to tertiary or quaternary carbons also have high decomposition frequencies. In *2-methylpentane* (► Fig. 23.5) the C–C bond between carbon atoms 2 and 3 decomposes 3 times more frequently than the bond between 3 and 4, and 6 times more frequently than the bond between 4 and 5.

The summarized yields of primary C–H and C–C decompositions are nearly constant in the radiolysis of liquid alkanes with a yield of $0.67 \pm 0.06 \mu\text{mol J}^{-1}$. Primary decomposition yields do not contain the yields of molecules decomposed in secondary reactions like H atom abstraction (see reaction (► 23.80)) (György 1981; Wojnárovits 1981).

■ Fig. 23.5

2-Methylpentane

In *alkenes* the lowest energy excitations and ionizations are strongly localized in the vicinity of the double bond (Hirayama and Lipsky 1975). Their lowest energy singlet and triplet excitations are ~ 6 and 4 eV, i.e., these values are much smaller than the corresponding values in the *n*-alkanes. The double bonds help to stabilize the molecule against radiolysis, and the primary decomposition yields of alkenes are all smaller than the yields of alkane primary decompositions. Hydrogen yields in the radiolysis of alkenes are ca. one order of magnitude smaller than in the radiolysis of alkanes (Meisels 1970; Cserép 1981; Alfassi 1989). The low yield is partly attributed to the fact that the double bonds can easily scavenge H atoms (and also other radicals). According to Hatano (1968) the H_2 in alkene radiolysis originates from hot H atom reactions. These hot H atoms may form in direct decomposition of superexcited molecules.

In the case of chain-end olefins, the terminal radical addition is strongly preferred to the nonterminal addition

Allylic interaction has a special importance in the chemistry of alkenes (Cserép 1981). By splitting the C–H or the C–C bond in β position to the double bond, a resonance-stabilized allylic radical forms (► Fig. 23.6). The allylic C–H and C–C decompositions have higher yields than the other C–H and C–C decompositions. Allylic radicals mostly disappear from the solution in very slow combination reactions.

■ Fig. 23.6

Allylic radical formation in alkene radiolysis

Several groups investigated the reactions of radical cations in liquid alkenes. In pulse radiolysis studies the radical cations show a strong absorption band around 280 nm, which is attributed to the $\pi-\pi^*$ transition of the alkene monomer radical cation. Monomer radical cations “dimerize” with diffusion-controlled rate coefficients with the olefin molecules: the dimer cations have broad absorption bands in the 600–800 nm range (Mehnert et al. 1981, 1985; Alfassi 1989). Dimerization may proceed via a hydride ion (H^-) transfer in the transition-state of radical–molecule reaction (► Fig. 23.7):

Monoalkene dimers form after neutralization. This mechanism explains the experimental finding that in the radiolysis of 1-alkenes mostly linear monoalkene dimers are produced. The

■ Fig. 23.7

Dimerization of alkene radical cations

further condensation reactions are much slower and may yield trimers, tetramers, etc. Oligomerization may also proceed with a radical chain mechanism; the initiating radicals can form in reaction (1.86a and 1.86b). However, under the usual radiation chemical conditions the reactions mostly terminate in dimers or oligomers and real macromolecular polymers practically do not form (Alfassi 1989).

The buildup reactions dominate the radiation chemistry of *acetylenes*: in acetylene radiolysis benzene and the oligomer cuprene are the main products (Cserép 1981).

Aromatic hydrocarbons have extraordinarily high radiation resistance in condensed phases (Hoigné 1968; Roder 1981), which is attributed to the conjugated π electron structure. This conjugated system redistributes the energy absorbed over the whole molecule. Thus, the probability of energy localization on a single bond is very low. The energies of the lowest singlet excited and triplet states are low, 4–5 and 3–4 eV, respectively, and the excited state lifetimes are long. The lowest singlet states have lifetimes in the 1–500 ns range, the triplets live up to seconds (Birks 1970; Berلمان 1971). The long lifetimes give a possibility for losing the excess energy in fluorescence/phosphorescence or in quenching processes. The bond dissociation energies in aromatics are relatively high, in benzene $D(\text{C}-\text{C}) \approx 8$ eV and $D(\text{C}-\text{H}) \approx 4.8$ eV.

The yield of H_2 in the γ -radiolysis of benzene is only $0.004 \mu\text{mol J}^{-1}$, i.e., it is ca. 100 times smaller than the $G(\text{H}_2)$ of liquid cyclohexane. It should be noted, however, that the H_2 yield is much higher when instead of γ rays high LET α rays or accelerated heavy ions are used for irradiation (LaVerne and Schuler 1984). The major products from benzene and also from other aromatic hydrocarbons are dimers and higher-molecular-weight compounds that are called “polymer.” The yield of dimers and the “polymer” in γ -radiolysis of benzene is $\sim 0.08 \mu\text{mol J}^{-1}$.

Biphenyl and its higher homologues and the polynuclear hydrocarbons are extremely radiation resistant and they were tested as coolants and moderators in nuclear reactors. For these purposes, different mixtures of aromatic hydrocarbons and hydrogenated aromatic hydrocarbons were applied.

The aromatic rings can act as energy sinks for energy absorbed by other parts of the molecule and therefore in condensed phases the radiolytic yields from alkylbenzenes are not much higher than from benzene itself. Although some increase in the side-chain

decomposition is found as the chain became longer. This protecting effect of aromatic rings is exerted not only on side chains attached to aromatic rings, but it is also observed in mixtures of aromatic hydrocarbons and *n*-alkanes. Practically there is not much difference between the so-called intramolecular and intermolecular protecting effect (Zeman and Heusinger 1966). The intermolecular protecting effect is interpreted in terms of energy and/or charge transfer from the saturated molecule to the aromatic molecule

23.8.2 Other Organic Molecules

In *alkyl chlorides, bromides, and iodides* the carbon–halogen bonds (C–X) are weaker than either the C–C or the C–H bonds. During irradiation mostly carbon–halogen dissociation occurs forming alkyl radical and X or X[−] (Spinks and Woods 1990). Reaction (23.90) is due to the high electron affinity of Cl, Br, and I atoms, 3.61, 3.36, and 3.06 eV, respectively.

The primary decomposition yields in the radiolysis of alkyl halides are probably similar to the yields observed in the radiolysis of saturated hydrocarbons: *G*(primary decomposition) $\approx 0.6\text{--}0.7 \mu\text{mol J}^{-1}$. However, the yields of the measured products often reflect smaller primary decomposition yield due to “back” reactions, these reactions reform the structures of the original molecules. Typical examples are the radiolysis of iodomethane and carbon tetrachloride, for instance. In the radiolysis of the former in liquid phase, both through the neutral and ionic decomposition channels methyl radical and iodine atoms are produced. During the subsequent reactions, due to “back” reactions, only small amounts of ethane and molecular iodine form (*G* ≈ 0.12 and $0.13 \mu\text{mol J}^{-1}$)

Similar products as in the radiolysis of CH₃I, C₂H₆ and I₂ also form in the decomposition of CCl₄, *G*(C₂Cl₆) $\approx G$ (Cl₂) $\approx 0.07 \mu\text{mol J}^{-1}$.

An interesting aspect of the radiolysis of longer-chain alkyl bromides and chlorides is the high yield of isomerization (*G*(isomer) $\geq 6 \mu\text{mol J}^{-1}$: e.g., 1-chloroalkane isomerizes to 2-chloroalkane). These reactions are attributed to free-radical chain reactions, which involve intramolecular shift of a halogen atom.

From the *oxygen-containing* compounds much attention was paid to the radiolysis of alcohols. Their relative permittivities are between those of the hydrocarbons (~ 2) and water (~ 80). The behavior of alcohols in radiation chemistry is in many respects similar to that of water. The electrons ejected from alcohol molecules can be trapped in solid alcohol matrices and can be observed by optical absorption techniques. In liquids, pulse radiolysis measurements confirmed the presence of solvated electrons, for instance in methanol $\lambda_{\max} = 630$ nm, $\epsilon_{\max} = 1,700$ m² mol⁻¹, $G(e_{\text{solv}}^-) \approx 0.5$ $\mu\text{mol J}^{-1}$ in the picosecond time range. On the other hand, as main product of decomposition, H₂ gas forms with a yield comparable to the yield observed in liquid *n*-alkane radiolysis ($G(\text{H}_2) \approx 0.5$ $\mu\text{mol J}^{-1}$) (Freeman 1970, 1974; Spinks and Woods 1990).

Radiolysis of liquid methanol gives hydrogen, formaldehyde, and glycol as major products with yields (liquid phase) 0.55, 0.21, and 0.38 $\mu\text{mol J}^{-1}$, respectively. In the radiolysis of ethanol, hydrogen, acetaldehyde and 2,3-butan diol are the main products. The diols are mainly α -diols indicating that a common radiation chemical reaction of alcohols is loss of an α -hydrogen atom to give α -hydroxyalkyl radical.

In the radiolysis of aliphatic carboxylic acids, carboxylic acid esters and amides preferred formation of α -carboxyalkyl type radicals (e.g., $\text{R}^1\text{CH}^\bullet\text{COOR}$) are observed.

23.8.3 Ionic Liquids

Ionic liquids (ILs) are a class of organic salts that are liquid at or near room temperature. The cation parts of ILs are tetravalent ammonium ions with asymmetric substitution: tetralkyl ammonium ion, imidazolium ion, or pyrrolidinium ion (► Fig. 23.8). The most widely used ILs have positive ions as asymmetric derivatives of *N,N'*-dialkylimidazolium. As the anion counterpart a great number of negative ions are used including BF_4^- , PF_6^- , or $\text{N}(\text{CN})_2^-$.

The ionic liquids are generally nonvolatile, noncombustible, highly conductive, recyclable, and capable of dissolving a wide variety of materials. Therefore, they have been proposed as “green solvents” for chemical reactions and separation purposes. ILs can be used for extraction of metal species from aqueous media, encouraging the potential use of ionic liquids for the reprocessing of spent nuclear fuel: actually these unusual liquids are being suggested as next-generation diluents for extractions in nuclear cycle separations (Shkrob et al. 2007). The critical mass calculations of Harmon et al. (2001) showed the minimum critical concentrations in

■ Fig. 23.8

Tetralkyl ammonium ion, imidazolium ion, and pyrrolidinium ion

F_4^- PF_6^- $\text{N}(\text{CN})_2^-$ CF_3^- 2^- 2N^- etc

some ionic liquids for Pu are at least one order of magnitude higher than in aqueous solution. Successful use of ionic liquids in radiation-filled environments requires an understanding of ionic liquid radiation chemistry.

Ionic liquids have dramatically different properties compared to conventional molecular solvents. Pulse radiolysis of ionic liquids containing tetralkyl ammonium cation $[R_4N]$ $[(CF_3SO_2)_2N]$, $[R_4N][N(CN)_2]$, and $[R_4N][(CF_3SO_2)_2N]$, $[R_4N][N(CN)_2]$ produce solvated electrons that absorb over a broad range in the near infrared and persisting for hundreds of nanoseconds. Systematic cation variation shows that the spectroscopic properties of solvated electrons depend strongly on the lattice structure of the ionic liquid. The rate coefficients of solvated electron reactions with O_2 , and CO_2 and aromatic acceptors measured in several ionic liquids indicate that the diffusion rate for the solvated electron in ionic liquids can be significantly lower than those of small neutral molecules or radicals such as H-atom, in contrast to the situation in molecular solvents. In general the diffusion constants of charged and neutral reactants differ considerably in ionic liquids, which could lead to a means of controlling reactivity through rational selection of ionic liquid properties (Wishart et al. 2006; Asano et al. 2008).

In ionic liquids containing imidazolium cation, the dry electron produced in ionization before full solvation is rapidly scavenged by the cation forming imidazolyl radicals (Wishart and Neta 2003). Secondary reactions of these radicals may lead to the formation of carbene and imidazolyl dimerization products. According to the work of Berthon et al. (2006) the main radical intermediates due to the transformation of 1-butyl-3-methylimidazolium cation ([bmim]) are the methylimidazolium radical cation arising from the scission of the butyl chain on the N atom, the butylmethylimidazolium radical cation forming in homolytical dissociation of the H-C2 bond attached to the ring and a cation radical formed by loss of an H-atom from the butyl chain. Recombinations of the N atom centered radicals yield aromatic dimers with nitrogen heteroatoms, which have high molar absorption coefficients in the ultraviolet-visible (UV-VIS) optical spectra. This accounts for a significant darkening of the imidazolium type ionic liquids when they are subjected to the effect of ionizing radiation (Qi et al. 2008).

Radiation-induced degradation of the negative ion may lead to different radicals. Fragmentation of $[(CF_3SO_2)_2N]^-$ produces CF_3^\bullet radicals through the dissociation of the $(CF_3SO_2)_2N^\bullet$ “hole” radicals (Grodzowski and Neta 2002).

Generally very small amounts of products form in the radiolysis of ILs. Studying the decomposition of several ILs it was concluded that less than 1% of the liquid underwent decomposition when exposed to a dose of 400 kGy. So the chemical properties are only slightly affected by the irradiation.

On the other hand, radiolysis causes a significant increase in the viscosities of ILs. Generally the conductivity decreases as the viscosity increases.

23.9 Radiation Chemistry of Polymers

The use of high-energy radiation in polymer chemistry is one of the major industrial applications of radiation. Main advantages of ionizing radiation initiation include (Charlesby 1960, 1987; Chapiro 1962) the following:

1. Absence of any residual from the decomposition of chemical catalyst.
2. Very wide range of initiation rates.

3. Little or no temperature effect, so the temperature can be selected, e.g., to optimize the propagating reaction.
4. There is no danger of runaway reaction due to the energy released in the propagation reacting back to enhance the initiation rate of the catalyst.
5. Unusual features, e.g., initiation in the solid. Polymerization and cross-linking simultaneously.
6. Sometimes sterile end product is synthesized, which is important for biomedical applications.

The explanation for the success of using irradiation techniques for both polymers and biopolymers is usually that they involve macromolecules in which minute chemical changes at the appropriate places have great influence on the morphology. A single bond altered in about 10^5 may convert a free flowing polymer from a fluid to elastic solid. An even smaller change may be lethal in biological systems (Charlesby 1987).

23.9.1 Polymerization, Kinetics, and Mechanism

Polymerization is a synthesis of high-molecular-weight compounds by successive addition of a low-molecular-weight compound to an active site at the end of the growing polymer chain. Monomers are mainly compounds containing multiple bonds (e.g., --C=C-- , $\text{--C}\equiv\text{C--}$). Polymerization of a monomer comprises three major steps, initiation, propagation, and termination. In radiation-induced polymerization, attention is essentially confined to the first step (Charlesby 1960, 1987; Chapiro 1962; Dole 1973; Wilson 1974; Makhliis 1975; Alfassi 1989; Ivanov 1992; Singh and Silverman 1992; Clough and Shalaby 1996; Knolle and Trautman 1999; Clough 2001). During irradiation both charged intermediates (electrons, anions, cations) and neutral radicals form in the matrix. So the radiation-induced polymerization can propagate by anionic, cationic, or radical mechanisms. Sometimes two or three processes occur simultaneously. The relative importance of each mechanism depends on the chemical nature of the monomer, the solvent, the temperature, and the type and concentration of additives. For instance, halogenated solvents facilitate cationic mechanism since the electron capture reaction (see reactions (23.8) and (23.90)) lengthens the lifetime of cations. On the contrary, in amine or amide solvents, the quaternary ammonium-type ion formation act as positive charge stabilizer thus enhancing the possibility of anionic polymerization. More often the radiation-induced polymerization takes place predominantly by free-radical mechanism.

When a monomer or its solution is irradiated with a low-LET (γ or electron) radiation, the radicals formed from the monomer (M) or the solvent (S), to a first approximation, may be assumed to be dispersed essentially uniformly throughout the liquid (Swallow 1973)

The radical R^\bullet adds to the double bond of a monomer molecule initiating by that a polymerization chain reaction. The final step is chain termination, which, in homogeneous

liquid phase, occurs by disproportionation or combination reaction of two radicals giving a “dead” polymer P:

The rate of the stationary free-radical polymerization, R_p , is described by the equation

$$R_p = k_p \sqrt{\frac{R_i}{k_t}} [M], \quad (23.100)$$

where k_p is the rate coefficient of propagation, k_t is the rate coefficient of the termination reaction of two radicals, and R_i is the rate of initiation. Equation (23.100) contains two rates and two rate coefficients. There are several methods for the determination of individual rates or rate coefficients, or their combinations. For instance, by means of radical scavenging techniques, R_i can be determined. Measurement of the monomer consumption may give a possibility for the calculation of R_p . Radical concentration measurement may supply the $k_p/(k_t)^{1/2}$ ratio. Recently for the reliable determination of k_p a technique based on pulsed laser polymerization has been developed (Brandrup et al. 1999).

As mentioned before the temperature has little effect on the rate of radiation-induced radical polymerization. The overall activation energy of the process is calculated by the equation

$$E = \frac{E_i}{2} + E_p - \frac{E_t}{2}, \quad (23.101)$$

In radiation-induced polymerization, the activation energy of initiation, E_i , is close to zero, since the decomposition G -values of forming radicals ($G \approx 0.1\text{--}0.5 \mu\text{mol J}^{-1}$) are practically independent of the temperature. The activation energy of termination, E_t , is generally very low, whereas E_p , the activation energy of propagation in radical polymerization is generally in the $20\text{--}30 \text{ kJ mol}^{-1}$ range (Brandrup et al. 1999).

The rate of initiation R_i is proportional to the G -value of radical formation in the system, i.e., it is proportional to the dose rate. Therefore, the overall rate of polymerization R_p is proportional to the square root of the dose rate (Eq. (23.100)).

The rate coefficient of propagation, k_p , strongly depends on the nature of the monomer (Brandrup et al. 1999). Table 23.6 shows the k_p and k_t rate coefficients for a few monomers that are often polymerized by ionizing radiation initiation.

Table 23.6

Rate coefficients of chain propagation and termination during bulk polymerization of monomers and the G -values of initiation

Monomer	$k_p, \text{mol}^{-1} \text{ dm}^3 \text{ s}^{-1}$	$k_t, \text{mol}^{-1} \text{ dm}^3 \text{ s}^{-1}$	$G, \mu\text{mol J}^{-1}$
Butyl acrylate	6,800	6.4×10^6	
Methyl methacrylate	310	6.6×10^7	0.5–1.0
Acrylamide	18,000	1.5×10^7	
Methacrylamide	80	1.7×10^7	
Vinyl acetate	4,600	2.2×10^8	1.0
Styrene	40	6×10^7	0.07

Temperature $\sim 25^\circ\text{C}$.

Swallow (1973), Tabata (1991a), Brandrup et al. (1999).

Rates of termination reactions are generally assumed to be strongly influenced by diffusion: most of the rate coefficients are in the $k_t \approx 10^6\text{--}10^8 \text{ mol}^{-1} \text{ dm}^3 \text{ s}^{-1}$ range. This diffusion-limited behavior is also shown by the conversion and solvent dependence of k_t . During polymerization in bulk the viscosity of the liquid gradually increases with the conversion, which results in decreasing diffusivity and decreasing k_t . In solution polymerization k_t decreases with the solvent viscosity.

At high conversion, the growth of viscosity hinders the termination by radical–radical reactions, but it has less effect on the propagation reaction, because diffusion of small monomer molecules is not so much affected by viscosity. Hence, both the rate of polymerization and the molecular weight of the polymer show an increase, there is auto acceleration at high conversion. This effect is known as *gel-effect* or *Tommsdorf-effect*, which is usually accompanied by a sudden rise of temperature (Swallow 1973). Such effect was observed in many systems, for instance in the γ -ray induced steady-state bulk polymerization of methyl methacrylate (Luthjens et al. 2001).

Auto acceleration at relatively high conversion can also be caused by formation of free radicals from the polymer that has been produced (Woods and Pikaev 1994). The yield of radicals from the polymer, which is usually a saturated chain, may be higher than the yield from the unsaturated monomer leading to an increase in the rate of polymerization due to the increased radical population. Termination reactions of these radicals with chain-end radicals give rise to branched chains (graft homopolymer), while self-termination of mid-chain radicals brings about cross-links.

Ionic polymerization is understood much less than free radical one and the results are less reproducible due to considerable variations caused by small concentration of impurities (Alfassi 1989). Cationic polymerization can be described by using the scheme

The free electron produced in reaction (23.102) may react to form a non-propagating species. The positive ion can initiate polymerization by adding on another monomer molecule (see reaction (23.103)) or by transferring a proton to a monomer. The latter mechanism is suggested for liquid isobutene polymerization at low temperature (Spinks and Woods 1990)

Reaction (23.105) describes a termination reaction with an impurity X present. Impurity termination in free-radical polymerization can also take place, but in free-radical chain

reactions any impurity is generally consumed at the beginning of irradiation. In ionic polymerization, however, the impurity appears to be regenerated in charge neutralization. Based on the scheme, the polymerization rate (R_p) is described by the equation

$$R_p = k_p \frac{R_i}{k_t[X]} [M]. \quad (23.109)$$

An important characteristic of ionic polymerization is that the propagation rate coefficients are several orders of magnitude higher than for free-radical polymerization. In the equation $k_t[X]$ is the bimolecular termination rate coefficient multiplied by the impurity concentration. This equation shows that the rate of polymerization is proportional to the first power of initiation rate, i.e., to the first power of dose rate. Water is a common chain breaker of cationic polymerization since it replaces the cation by a hydroxonium ion. As a proton donor it also inhibits the anionic polymerization

where $(-H)$ indicates removal of a H atom from the n mer.

If during cationic polymerization the impurity concentration is very low, termination reactions between the propagating cation and negatively charged species (e^- , M^- , M_n^-) should also be considered:

At low impurity content, the polymerization takes place with kinetics that is characteristic of free-radical polymerization (► Eq. (23.100)). Such behavior was observed, for instance, in the cationic polymerization of styrene (Swallow 1973).

When the monomer is irradiated in a solvent such as water or alcohol, the radical or ionic intermediates formed from both the monomer and the solvent may initiate polymerization. The yield of initiating particles, to a first approximation, is expected to be proportional to the sum of the yields of intermediates in the irradiation of pure monomer or solvent, respectively, multiplied by their electron fractions (linear mixing rule, see ► Eqs. (23.3) and (23.4) in ► Sect. 23.3.1). In practice, however, the yield of initiation may be lower or higher than it is expected assuming linearity. This is due to energy or charge transfer between the components of the mixture. In dilute solutions (e.g., in water) it is commonly assumed that initiation occurs only by the intermediates of the solvent decomposition.

Vinyl monomers are often polymerized in aqueous solutions with the aim of producing hydrogels (Rosiak et al. 2002). Hydrogels are cross-linked hydrophilic polymers (polyvinyl alcohol, polyacrylamide, poly-2-hydroxyethylmethacrylate, methylcellulose, etc.) that can swell (and not dissolve) in water and retain more than 100% water in their volume (Ivanov 1992; Martelli et al. 1999). Because of their high water content, hydrogels usually show good biocompatibility. Some hydrogels show sensitivity to environmental conditions, and respond with high volume changes to small changes in temperature, pH, solute concentration, electrical, magnetic field, etc. For example, the crosslinked polymer of *N*-isopropyl acrylamide (NIPAAm) shows good thermal reversibility. Below the so-called lower critical temperature (LCST) 32°C it absorbs ~10 times more water molecules than the number of monomer units in the polymer. Above LCST the polymer shrinks and expels the water molecules. Hydrogels find a number of practical applications including controlled drug delivery, separation, and surface coatings on artificial organs.

During the usual synthesis conditions in aqueous solutions mainly the OH, H, and e_{aq}^- intermediates of water radiolysis (see ▶ Sect. 23.6.1) initiate the polymerization reaction, e.g., in the case of NIPAAm (Nagaoka et al. 1992; Strauss et al. 1998):

where R is the $-NH-CH(CH_3)_2$ group. The α -carboxyalkyl type radical produced in these reactions adds to a monomer molecule and the chain reaction starts.

With the progress of polymerization, the concentration of monomer molecules in the solution decreases and that of the prepared polymer chains increases. So the probability of forming a radical site on the polymer chain in hydrogen atom abstraction reaction of OH and H is increasing. These intermediates mostly abstract the tertiary H atom of the isopropyl group. The reaction of these mid-chain radicals with each other gives H type cross-links, their reaction with chain-end (propagating) radical yields T type branches. Through these reactions cross-linked polymer network forms.

▶ Figure 23.9 shows the synthesis of hydrogel microgels with a diameter of $\sim 2 \mu\text{m}$. Aqueous solution of the monomer (in the figure ethylene glycol dimethacrylate) is irradiated in oxygen-free aqueous solution. The micro-squares are collected by centrifuging. After washing and drying, the micro-squares may be used for chromatographic separation (Graselli et al. 2001).

23.9.2 Radiation Effects in Polymers

As mentioned before, small chemical changes in an irradiated polymer can modify its physical properties substantially. The most important chemical effects are cross-linking, which is

■ Fig. 23.9

Synthesis of hydrogel micro-squares

analogous to dimerization, and degradation, which is analogous to main chain scission. In most polymers, one of these processes predominates. In general, polymers with only secondary and tertiary carbon atoms in the main chain tend to cross-link, while degradation with main-chain scissions occurs if the chain includes quaternary carbon atoms. Polymers that predominantly undergo cross-linking on exposure to ionizing radiation include polyethylene, polyamides, and polyesters. Mainly degradation takes place in polyisobutylene, polymethacrylate, polymethacrylamide, and polytetrafluoroethylene (Swallow 1973; Ivanov 1992).

The changes and yields in polymer irradiation are often similar to those found with lower-molecular-weight compounds with similar structural features. The radiolysis of linear polyethylene is similar to that of the *n*-alkanes, polystyrene resembles the alkylbenzenes, and polymethyl methacrylate behaves like a branched chain ester. Lower-molecular-weight compounds are often used to model processes taking place in polymer irradiation.

23.9.2.1 Main Chain Scission

Radiation-induced degradation of polymers is inherently different from thermal degradation. As it was shown on the example of polyisobutylene in thermal decomposition, which occurs at higher temperature, a chain reaction of depolymerization is involved, releasing considerable amounts of monomer. The radiation-induced degradation is carried out at lower temperature. Since each scission during irradiation is an independent event, this number cannot exceed the number of primary excitations and ionizations. Thus, the degradation can be easily controlled through the dose of irradiation. $G(\text{scission})$ is independent of molecular weight and radiation intensity.

In addition to main chain scission or cross-linking, gas formation is also observed as a result of irradiation. The gas in the hydrocarbon-based polymers mostly consists of hydrogen. The amount of gas produced depends on the nature of the polymer and also on dose, temperature, type of radiation, etc. In the case of polyethylene the G -value of gas production is high, $G \approx 0.32 \mu\text{mol J}^{-1}$, comparable to the gas yields observed in the radiolysis of liquid *n*-alkanes $G \approx 0.5\text{--}0.6 \mu\text{mol J}^{-1}$. In the radiolysis of polystyrene and polymethylstyrene the yield of gaseous products is only $G \approx 0.01 \mu\text{mol J}^{-1}$, that value is typical of aromatic compounds. The benzene rings attached to the main chain exert a protective effect against both the C–H and the C–C decompositions in the chain.

Polytetrafluoroethylene (Teflon) belongs to the group of degrading polymers when irradiated. It is relatively radiation resistant in the absence of oxygen, but rapidly deteriorates in air or oxygen atmosphere. The decomposition takes place with chain mechanism with participation of alkoxy radicals. In practice, radiation-induced degradation is used to produce powdered Teflon. The process requires several hundred kGy dose and the powder is used as lubricant after blending with other materials.

23.9.2.2 Cross-Linking

Irradiation of degrading polymers leads to loss of mechanical properties such as strength. On the contrary, irradiation of cross-linking polymers increases the viscosity and also the mechanical strength.

The irradiation of polyethylene and its copolymers has been the most commercially successful of all applications of radiation in the polymer field (Charlesby 1987). Upon warming, the unirradiated polyethylene softens between 70°C to 90°C and turns to a viscous liquid at 115°C–125°C. After irradiation with a dose of ~20 kGy the polymer is form-stable to about 250°C.

Other physical changes consequent on cross-linking include a lower solubility in solvents and several orders of magnitude higher viscosity. The yield of cross-linking is $\sim 0.15 \mu\text{mol J}^{-1}$. It is accompanied by C–H bond rupture with the formation of H_2 gas and vinylene ($-\text{CH}=\text{CH}-$) unsaturation with yields of $G \approx 0.3$ and $\sim 0.15 \mu\text{mol J}^{-1}$, respectively. As intermediates alkyl radicals, radical cations, and trapped electrons are suggested (Brede et al. 1989; Spinks and Woods 1990; Shkrob and Trifunac 1995).

Cross-linking is due to the dimerization of adjacent free radicals (► Fig. 23.10):

Vinylene probably forms in disproportionation reaction, but unimolecular H_2 elimination from an excited state should also contribute to the yield.

There are several possibilities for the formation of adjacent radical pairs. They may be produced in spurs where in the energy deposition processes at least two activated molecules are populated in each other's vicinity. A radical pair may form if the detached H atom abstracts hydrogen from a neighboring polymer chain, or if a radical center migrates along the polymer chain until it encounters a radical on a neighboring chain. Ion–molecule reactions of the type shown here may also yield neighboring radical pairs (► Fig. 23.11):

Memory effect is a particularly interesting property of irradiated polyethylene and a few other polymers. During processing, polyethylene is irradiated in the required shape, it is then expanded with warming up to the softening temperature, and cooled down in the expanded form. During cooling the crystals reform and hold the polyethylene in this new configuration.

■ Fig. 23.10

Reactions of adjacent free radicals

■ Fig. 23.11

Formation of H_2 molecule in ion–molecule reaction

When warmed up again above its softening temperature, the polymer regains the original size and shape “prescribed” during irradiation. The memory effect has found a lot of practical applications, e.g., shrink film, used for food packaging and, shrinkable connectors in cable and other electrical installations, and other devices in which a controlled shape change is triggered by a simple temperature change.

Irradiation techniques can readily be used to produce grafted copolymers. During grafting, side chains (composed of B monomer units) are attached to the polymer chain formed from monomer units A (► Fig. 23.12).

Several methods are used to produce grafted polymers by irradiation. One of the methods uses simultaneous irradiation of polymer A immersed in monomer B: the radicals formed on A initiate polymerization of B as side chains. During the process some homopolymerization of B and cross-linking or scission also take place. In order to reduce homopolymerization and cross-linking radical scavengers, such as the Mohr-salt, may be applied. In another method, polymer A is irradiated resulting in the formation of radicals on the backbone chain. If this irradiated polymer is now dipped in monomer B, the trapped radicals react with B and provide the initiating centers for the branches. If the irradiation of polymer A is carried out in the presence of oxygen, peroxide groups form on the surface. Then the irradiated polymer A is placed in monomer B and heated to produce the grafted system. These peroxide groups decompose on heating to provide radicals for initiation of the polymerization of B.

In practice, grafting is often used for making biocompatible surfaces on polymers with good mechanical properties and also for the immobilization of bioactive materials such as enzymes or antigens on a polymer surface.

Radiation-induced curing of polymer coatings is a special field of paint-and-varnish technology. The coatings are applied in the form of a thin film on the corresponding support: paper, cloth, polymer, wood, metal, ceramics, etc. In the industrial use, accelerators with electron energy of 150–600 keV are applied. Apart from the traditional accelerators with beam scanning, a new accelerator family was developed with a hot cathode in the form of 1–2 m long tungsten wire. Advantages of radiation processing are the high rate of polymerization, which is achieved without the application of heat and without the use of solvents. The varnishes used in industrial technology are usually based on oligomer–monomer mixtures. The composition of the mixture basically determines the properties of the surface: hardness, elasticity, etc. Application of acrylates is quite common: apart from monofunctional monomers often di- or trifunctional monomers are also added to the mixture, e.g., 1,6-hexanediolacrylate, triethylene glycol acrylate. In this way during the polymerization, polymer network forms (Takács et al. 1989; Takács and Hedvig 1991; Takács 1992; Ivanov 1992).

In addition to the previously mentioned “classical type” polymer processing technologies a large number of new techniques were also developed. A family of these techniques uses swift

During grafting, side chains built from monomer units B are attached to the polymer chain formed from monomer units A

heavy ions with extremely high LET values to irradiate polymer films (polyethylene terephthalate, polycarbonate, polyvinylidene fluoride, and polyamide) perpendicularly to the surface. The high LET radiation strongly degrades the polymer along the particle path (narrow channel). After irradiation the film is etched by wet chemical treatment that reveals pores of which the shape, surface density, and dimensions can be controlled by choosing appropriate conditions. The treated polymer film can be used as micro filter in the desalination process of seawater or in dialysis.

The membrane with the nanometer-sized holes can be used as template of metallic replicas. The holes are filled up with some metal atoms by electrolysis in a galvanic cell, and after deposition, the membrane is removed mechanically or by a suitable solvent. In these ways, little rods with a few μm length and few times 10 nm diameters are produced (Tagawa et al. 2004; Coqueret 2008). By grafting environmental sensitive polymers on the surface of the holes, the permeability of the membrane can be regulated by external signal (temperature, pH, etc.). The operation of such systems may mimic the operation of biological membranes.

23.10 Biological Molecules

Radiation chemistry of biological molecules and radiobiology has been intensively studied since the biological effect of radiation was first observed just after the discovery of ionizing radiation. The books, conference proceedings, review articles, etc., published related to these topics probably could fill a small library (for instance Bensasson et al. 1985, 1993). Excellent books on the subject were published by von Sonntag in 1987 and 2006 with titles *The Chemical Basis of Radiation Biology* and *Free-Radical-Induced DNA Damage and its Repair: A Chemical Perspective*. These books cover practically all aspects of radiation chemistry of biologically important molecules. Besides introducing some basic results in the field, some references will also be mentioned.

Radiation chemistry of biological molecules may be investigated from different aspects. One of the aspects is how to protect living organisms from ionizing radiation, i.e., radiation safety. The other aspect is just the opposite, how the effect of radiation can be enhanced, e.g., in cancer treatment. By using radiation chemical methods it is relatively easy to produce and investigate the reactions of certain reactive short-lived species that are also produced in living organisms, e.g., the superoxide radical anion, $\text{O}_2^{\bullet-}$. In this respect radiation chemistry is a tool for studying biologically important reactions.

Studies on model compounds of biopolymers are usually made in the solid phase that shows the direct effect or in dilute aqueous solutions where the indirect effect is dominating. In the latter case the radicals of water radiolysis, e_{aq}^- , OH and H, induce the chemical changes. In vivo the state of biopolymers is somewhere between the two extremes. Usually the deoxyribonucleic acid (DNA) is regarded as the target molecule whose damage is mostly responsible for the deactivation of irradiated cells (von Sonntag 1987a, 2006; Mae 1987; von Sonntag and Schuchmann 2001).

23.10.1 DNA and Its Constituents

Most of what is known about the mechanisms leading to various types of DNA damages has been obtained by studying low-molecular-weight model systems. In aqueous solutions all the

three water radicals react with high rate coefficients with the four bases of DNA, adenine, cytosine, guanine, and thymine. However, the sugar part, deoxy-d-ribose, is only attacked with higher rate coefficient by OH radicals, as a consequence of which a hydrogen atom is eliminated. Further reactions of this radical may lead to breakage of the sugar–phosphate bond (strand break) or to base release. A large number of rate coefficients on the reactions of water radicals with DNA constituents were compiled in the work of Buxton et al. (1988). In 1986 von Sonntag and Schuchmann (1986), in 1987 von Sonntag (1987b), and von Sonntag and Ross (1987) published updated review and bibliographies on the radiolysis of nucleic acids and their base constituents. Critical evaluation of the results obtained with DNA and its constituents is given in the two books mentioned (von Sonntag 1987a, 2006).

The OH radicals are suggested to be the most damaging species in aqueous solutions, the OH attack may result in multiple lesions, e.g., base damage, sugar damage, DNA + DNA cross-linking, etc. The main reaction of OH with the bases is addition to the double bonds. The radical thus formed in reaction with pyrimidines in the presence of oxygen rapidly converts to peroxy radical. In the subsequent reactions the double bond saturates. Reactions of OH radicals with purine bases lead to the destruction of the imidazole ring. Due to these reactions altered bases form, but they may remain attached to the DNA chain. Other possibility is that the altered bases or their radiation-modified products are released from the polynucleotide chain by rupture of the *N*-glycosidic bond. This reaction may induce a strand breakage.

Any lesion within the DNA, in principle, can be lethal for the cell. In 1987, von Sonntag (1987a) suggested a hierarchy of the various lesions from the point of view of lethality. This hierarchy starts with base damage and single-strand breaks as the least dangerous damages, and finishes with such changes when both strands of the DNA are altered simultaneously, e.g., double-strand breaks, or base damages on opposite strands. The yield of single-strand breaks is estimated in the range $G = 0.02\text{--}0.08 \mu\text{mol J}^{-1}$, whereas the yield of double-strand breaks is an order of magnitude smaller.

23.10.2 Polysaccharides

Cellulose is the most abundant organic compound, comprising at least 50% of all carbon in vegetation. This biopolymer is composed of D-glucose units. The purest source of cellulose is cotton, which contains at least 90% of cellulose. The primary structure of cellulose allows extensive interactions between chains resulting in a highly crystalline supramolecular structure (crystallinity is 60–70%, cellulose I). In order to make available additional surfaces or to alter the crystal structure, cellulose is usually “activated” by various physical and chemical methods (alkali treatment).

The radiation chemistry of cellulose has been investigated mainly with the aim of enhancing the enzymatic degradation. Research work has also been motivated by the possibility of textile improvement by irradiation (dyeability) and also by radiation sterilization of cellulose-containing packaging materials, foodstuffs, etc. A further aspect of the radiation chemistry of cellulose is the production of copolymers: grafting may be carried out by the preirradiation method (► Sect. 23.9.2.2). In this case the radicals produced during irradiation, or by the thermal decomposition of the peroxides formed in radical-oxygen reactions, initiate the polymerization.

Under the effect of irradiation, cellulose may undergo degradation or cross-linking (Charlesby 1960). Above 10 Gy dose the main radiation effect is degradation, which is most likely due to splitting of the glucosidic bond: using a γ dose of 15 kGy the degree of polymerization of cotton–cellulose decreases from ca. 1,200 to 300. Another consequence of radiation treatment is the increase of carbonyl content, which shows oxidative degradation. By EPR method radicals were identified as intermediates of the transformation. The radicals are produced not only in the amorphous region but also in the crystalline region (Hebeish and Guthrie, 1981; Krassig 1996). These radicals, in the presence of vinyl monomers, can initiate reactions to yield grafted cellulosic fibers with special properties.

As mentioned before, chemical changes are observed even after low-dose irradiation, however, up to a dose of 500 kGy no change in the crystalline content was detected. It is assumed that the radiation-induced defects inside the crystallites do not induce destruction of the crystalline structure. However, the defects may change the intermolecular hydrogen bonding system, which keeps together the crystal lattice layers. In this way irradiation causes an increased accessibility, especially to treatments that are able to disrupt highly ordered, hydrogen-bonded cellulose structures. Therefore, when irradiated cellulose substrates are subjected to treatment with chemicals of high swelling power, such as NaOH solutions, increased alkali solubility and transformation of cellulose I crystal structure to cellulose II structure is observed (Dyer and Daul 1998; Takács et al. 2001). This has some technological importance: for instance, irradiation of pulp prior to viscose processing may result in reduced consumption of chemicals and time.

23.10.3 Amino Acids, Peptides

In peptides, amino acids are joined by peptide bonds to form the polypeptide chain. The e_{aq}^- , OH, and H radicals react with the amino acids and with the polypeptide chain with high rate coefficients that are close to the diffusion limit. OH radicals and, less frequently, H atoms abstract a hydrogen atom from the polypeptide chain (from the carbon atoms) or from the side chains, but they can also add to the rings of the aromatic amino acids. The radical site produced on the main chain may move along the chain by an internal hydrogen abstraction mechanism. If the H atom is abstracted from an S–H bond the radical migration stops, since the S–H bond is much weaker than the C–H bonds. This reaction is the basis of repair mechanism. The radicals may terminate in radical–radical reactions.

The hydrated electrons react with the carbonyl groups of the peptide chain or with disulfides and the protonated imidazole ring of histidine. It is assumed that the main sites of electron attachment are the surface peptide groups, and this is followed by internal electron migration into a potential sink, either to histidine or to a disulfide bridge (Mae 1987). As a final result of irradiation action on peptides in aqueous systems (and also in solid state) fragmentation of the peptide chain and cross-linking takes place.

23.10.4 Lipids

During irradiation of lipids in the presence of oxygen, the alkyl-type radicals formed on the fatty-acid chain quickly react with O_2 forming peroxy radicals. By abstracting an H atom from another fatty-acid molecule, the alkyl-type radical is regenerated and the peroxy radical is

converted to hydroperoxide. Thus a chain reaction starts in which lipid hydroperoxides form. The hydroperoxides have low thermal stability and easily decompose to toxic aldehydes and ketones. Antioxidants being present in lipids, for instance vitamin E (tocopherol), inhibit the chain reaction (Mae 1987; von Sonntag 1987a).

23.11 Radiation Applications

As discussed in the previous paragraphs, irradiation brings about physical and chemical changes in the material irradiated, and some of these processes can be applied to solve industrial problems. In [Sect. 23.9](#), some radiation technologies used in polymer chemistry were mentioned; some further industrial applications of irradiation will follow here. Synthetic and radiation processing aspects of irradiations are nicely summarized in the books of Bradley (1984), Spinks and Woods (1990) and Woods and Pikaev (1994). The most important practical applications and their advantages are summarized in [Table 23.7](#).

23.11.1 Radiation Synthesis

In the early period of radiation chemical investigations, the yields of many chemical reactions of industrial importance were determined since the applicability of radiation-induced reactions to synthetic work strongly depends on the yield. For instance, the radiation chemical yields of such reactions as

are low, $G < 0.5 \mu\text{mol J}^{-1}$. Therefore, the industrial application of radiation-induced syntheses of ammonia, hydrazine, and ozone is impractical, in contrast to some suggestions in the 1950s (Woods and Pikaev 1994). When the reaction takes place with a chain mechanism, the G -values can be much higher. Such chain reactions were mentioned before in connection with the isomerization of longer alkyl chlorides or bromides ([Sect. 23.8.2](#)) or with polymerization ([Sect. 23.9.1](#)). Often radiation initiation is advantageous because it can be carried out at lower temperature or without the addition of catalyst or chemical initiator giving a higher purity product.

Many radiation-induced chain reactions of synthetic importance are discussed in the book *Applied Radiation Chemistry* written by Woods and Pikaev (1994), in the *Radiation Chemistry Handbook* edited by Tabata (1991a), and also in a book chapter published by Takamuku and Yamamoto (1991). Earlier reviews on the subject were published by Bansal and Freeman (1971), and also by Chutny and Kucera (1974). A few examples will be mentioned here.

■ Table 23.7

Industrial applications of radiation processing

Product	Product improvements and advantages	Process
Wire and cable insulation; plastic insulating tubing; plastic packaging film	Shrinkability; impact strength; cut-through-, heat-, solvent-, stress-, cracking resistance; low dielectric losses	Cross-linking, vulcanization
Foamed polyethylene	Compression; tensile strength; reduced elongation	
Natural and synthetic rubber	High-temperature stability; abrasion resistance; cold vulcanization; elimination of vulcanizing agents	
Stack gases	Elimination of SO ₂ and NO _x	Chemical reaction
Solid-state semiconductors	Reduced switching time; stabilization of integrated circuit gain; reduced Zener diode noise level	Crystalline alteration
Precious and semiprecious gems, crystal, glass	Permanent coloring	
Adhesives: pressure sensitive, flock, laminate	Increased bonding; chemical-, chipping-, abrasion-, weather resistance; elimination of solvents; 100% convertibility of coating; high-speed cure; flexibility in handling techniques; low energy consumption; room-temperature cure; no limitation on colors	Curing, polymerization
Coatings; paints and inks on woods, metals and plastics		
Wood and organic impregnates	Mar-, scratch-, abrasion-, warping-, swelling-, weather resistance; dimensional stability; surface uniformity; upgrading of softwoods	
Cellulose	Enhanced chemical accessibility	Degradation
Textiles and textile fibers	Soil-release; shrink-, weather resistance; improved dyeability; static dissipation; thermal stability	Grafting
Film and paper	Surface adhesion; improved wettability	
Potatoes; wheat; rice, onions; cod and redfish; chicken; strawberries	Extended storage and shelf life	Sterilization, disinfecting
Wastewater	Safe disposal of wastewater solids; agricultural use of sewage sludge	
Medical supplies and disposable containers	Processing of heat-sensitive materials; high-speed in-line production; low energy consumption	Sterilization

Tabata (1991a), Spinks and Woods (1990), Woods and Pikaev (1994), Machi (1998).

Radiation-initiated chain reaction between H₂ and Cl₂ proceeds with a chain length over 10,000:

Radiation initiation has been used most successfully to induce free-radical chain reactions in organic substrates. The radiation-induced addition of HBr to ethylene is mentioned in many books. This reaction was used by Dow Chemical Company to produce bromoethane for a number of years:

Termination here and also in HCl production takes place with radical–radical reactions or with reaction of the radicals with impurities.

A few other reactions have also been developed to pilot plant or industrial scale including, e.g., chlorination, bromination, or sulfochlorination of hydrocarbons, oxidation of some organic compounds (Spinks and Woods 1990; Woods and Pikaev 1994).

Radiation-initiated cracking of hydrocarbons has been the subject of many studies. Irradiation reduces the temperature needed for chain reactions and also has an effect on the composition of products. The relatively high yield of unsaturated products under suitable conditions make the radiation-initiated process a possible source of feedstock for petrochemical industry (Spinks and Woods 1990; Zaikin and Zaikina 2008).

23.11.2 Applications of Radiation Chemistry to Nuclear Technology: The Purex Process

Some part of the spent fuel of atomic reactors is reprocessed separating uranium, plutonium, and the fission products, in order to produce new fissionable fuel or to collect some part of the valuable fission products. While several reprocessing methods have been proposed, the Purex process is the most widely used all over the world. The process uses 30% tributyl phosphate, TBP, as extractant in dodecane or kerosene solvent that is used to decrease the viscosity and the density of the liquid. The mixture is easily separated from water. The spent fuel is dissolved in concentrated nitric acid and the aqueous solution is mixed with the organic extractant. U and Pu present in the aqueous phase in the forms UO_2^{2+} and Pu^{4+} are extracted to the organic phase, the fission products remain in the aqueous solution. After reduction of Pu^{4+} by chemical or electrochemical method, Pu^{3+} goes back to the aqueous phase, while the uranium remains in the organic phase (Benndict et al., 1981; Choppin et al. 1995; Katsumura 2004).

It is obvious that during separation the organic phase is under the effect of intensive γ , β , and α radiation fields. Therefore, radiation resistance is a very important issue. TBP decomposes to products dibutyl phosphate ($G \approx 0.2 \mu\text{mol J}^{-1}$), monobutyl phosphate ($0.02 \mu\text{mol J}^{-1}$), and gaseous hydrogen ($0.15 \mu\text{mol J}^{-1}$). In addition to these main components some minor products, butane, butene, $\text{C}_1\text{--C}_3$ hydrocarbons, butanol, and phosphoric esters are also observed. Dibutyl phosphate is suggested to form in solvated electron reaction

During Purex process thermal degradation and hydrolysis of TBP also takes place. The thermal degradation yields a large number of products including butane, butene, N_2 , NO_2 , CO_2 , NO, and butanol. The specific concern is the dealkylation of the phosphate ester since the dialkyl phosphoric acid ester, formed in the reaction, is capable of nonspecific interactions with metal ions (Katsumura 2004; Shkrob et al. 2007).

The radiolytic decomposition of pure dodecane under oxygen-free conditions takes place with a yield of 0.6–0.7 $\mu\text{mol J}^{-1}$. The decomposition leads mainly to dehydrogenation with a yield of $\sim 0.5 \mu\text{mol J}^{-1}$. In the process hydrogen, dodecenes, and dimers are produced. In addition to the main components, a large number of C_1 – C_{11} fragmentation products and C_{13} – C_{23} buildup products were also observed. The intermediate products are hydrogen atoms, $\text{C}_{12}\text{H}_{23}^\bullet$ parent, and smaller fragment alkyl radicals (Földiák 1981; Wojnárovits and Schuler 2000). In the dodecane-alkyl phosphate system there is an efficient energy and charge transfer from the alkane to the phosphate resulting in radiation protection of the alkane and fragmentation of the phosphate (Shkrob et al. 2007).

In aqueous nitric acid solution, the nitrate ions reacting with hydrated electrons generate NO_2^\bullet radicals through the reactions of $\text{NO}_3^{2-\bullet}$ and HNO_3^\bullet . In the further reactions NO_2 partly transforms to nitrite and nitrate ions. In concentrated nitric acid solution, the reaction of OH radicals gives NO_3^\bullet radicals.

As final products of irradiation of concentrated nitric acid solutions HNO_2 , H_2 , and O_2 form. Their yields strongly depend on the concentration.

Since during the Purex process TBP, alkane, and aqueous nitric acid solution are in mixture or contact condition, the radiation chemical transformations depend on the composition, concentration of nitric acid, contaminant metal ions, irradiation conditions, and oxygen concentration (Tripathi and Ramanujam 2003; Katsumura 2004). Under aerated condition, the organic radicals react with oxygen forming peroxy radicals. After successive reactions a variety of alcohols, ketones, peroxides, and carbonyl compounds form. The ratio of nitration products to oxidation products is ~ 0.8 , and the ratio increases if there is no sufficient supply of O_2 .

Under irradiation there is an increase in the density and viscosity, which is attributed to the polymerization and nitration of the hydrocarbon diluent. The increase in the density becomes more significant with increasing nitric acid content of the solvent and absorbed dose, which leads to much sharper increase in the viscosity. Various possible hydrogen-bonding modes seem to play a major role in enhancing the viscosity of the system (Tripathi and Ramanujam 2003).

As mentioned before (in Sect. 23.8.3) ionic liquids are considered to be the next generation of diluents of TBP in the fuel reprocessing cycle. The ionic liquid diluents of interest consist of large hydrophobic cations and anions that are stable under oxidizing conditions ($1\text{--}2 \text{ mol dm}^{-3} \text{ HNO}_3$) and do not chelate metal ions. Among the investigated ionic liquid diluents are [bmim][PF₆], [bmim][BF₄], and [bmim][(CF₃SO₂)₂N]. In the radiolysis of the ionic liquid–TPB system the yield of radiation-induced fragmentation of the trialkyl phosphate does not exceed 1–4% of that of the solvent, even when the concentration of the solvent is 20–40% by mass. Although the radiation stability of ILs appears to be inferior to the presently used alkane solvents, these IL diluents protect the extractant against radiation damage, unlike such alkane diluents. Dissociative electron attachment (e.g., $\text{PF}_6^- + e^- \rightarrow \text{PF}_5^- + \text{F}^-$) to the extractant and its subsequent dealkylation do occur, but it is a minor reaction, even at the higher end of the concentration range (Shkrob et al. 2007).

23.11.3 Radiation Processing

Radiation technologies applying gamma sources and electron accelerators for material modification are well-established processes. There are over 160 industrial gamma irradiators and 1,300 industrial electron accelerators in operation worldwide. A new advancement in the field of radiation sources engineering is the development of high-power direct e^-/X conversion sources based on electron accelerators.

23.11.3.1 Application of Ionizing Radiation for Environmental Protection

Strategies to tackle environmental pollution have been receiving increasing attention throughout the world in recent years. Radiation processing using electron beam accelerators and gamma irradiators has shown very promising results in this area.

Electron irradiation of flue gases produced by coal power stations in order to reduce the emission of sulfur and nitrogen oxides after a few pilot plant installations has reached the industrial stage (Chimielewski 2002; Chimielewski et al. 2004; Namba et al. 2004). Before irradiation, water and ammonia are added, the gas stream is cooled to 50°C–100°C, and the ammonium nitrate and sulfate formed during the treatment are separated from the gas stream in electrostatic precipitators: the powdered material collected is used as fertilizer. The reaction mechanism is rather complex, in modeling studies over 100 reactions are considered. In addition to the gas phase reactions, some transformations also take place in water droplets by a solution kinetic mechanism. The primary active species, ions, radicals, excited atoms, and molecules form essentially by interaction of radiation with N_2 , O_2 , and H_2O . The primary species undergo fast neutralization, ion–molecule and dissociation reactions to produce a set of reactive radicals (OH , HO_2^\bullet , and $O(^3P)$ (oxygen atom in triplet state)), which react with the pollutant molecules (Markovic 1986; Busi et al. 1987; Woods and Pikaev 1994; Namba et al. 2004; Haji-Saeid 2007). The most important reactions are as follows:

In the reaction set M and M^\dagger stand for the so-called third molecule in the ground and in some energy-rich state. The colliding third molecule carries away some part of the reaction heat.

Electron beam technology for flue gas treatment was developed in Japan in the early 1970s. The process was later used at pilot plant scale plants in Germany, Japan, the Republic of Korea, and the USA. In Poland the process has been demonstrated to be successful at the Kaweczyn power station in a pilot plant installation with a throughput of $20,000 \text{ Nm}^3 \text{ h}^{-1}$.³ Pilot plant installation with a throughput of $20,000 \text{ Nm}^3 \text{ h}^{-1}$ was also constructed in Bulgaria at the Maritsa East 2 power station.

Industrial scale electron beam gas treatment installations are currently (2007) in operation in coal fired plants in Poland (Pomorzany) and China (Chengdu). The Pomorzany plant treats approximately $270,000 \text{ Nm}^3 \text{ h}^{-1}$ with SO_2 and NO_x removal efficiencies up to 95 and 70%.

A typical installation consists of four main parts:

1. Flue gas conditioning unit,
2. Ammonia storage and feed system,
3. Process vessel with accelerator system,
4. By-product collection and storage unit.

These units and the general schema of the flue gas treating system are shown on [Fig. 23.13](#).

Another possible application of the flue gas treatment technology is for the removal of volatile organic compounds (VOCs) and polycyclic aromatic hydrocarbons (PAHs), e.g., in flue gas treatment facilities of municipal waste incinerator plants.

The recognition that the polluted waters may pose a serious threat to humans has led technologists to look for cost effective technologies for their treatment. A variety of methods based on biological, chemical, photochemical, and electrochemical processes are being explored for decomposing the chemical and biological contaminants in *wastewater treatment*.

■ Fig. 23.13

General scheme of a flue gas purification plant

The first studies of the radiation treatment of wastes, principally for disinfection, were carried out in the 1950s. In the 1960s, these studies were extended to purification of water and wastewater. Laboratory research on industrial wastewater and polluted groundwater was conducted in the 1970s and 1980s. In the 1990s, several plants, including mobile electron beam facilities, were built for extended research. Studies in recent years have demonstrated the effectiveness of ionizing radiation such as, gamma rays and electron beams in combination with other treatments, in the decomposition of refractory organic compounds in aqueous solutions, and in the effective removal or inactivation of various microorganisms and parasites. The application of electron beam processing for drinking water, wastewater, and groundwater treatment offers the promise of a cost effective process (IAEA 2008).

Radiation processing aims at the degradation of pollutants at a faster rate than with conventional processes. Processing of wastewater generally has maximum efficiency at pollutant concentration of 10^{-3} mol dm $^{-3}$ or less. Treatment of such wastewater is simple, requires a low dose (~ 1 kGy) and provides almost complete elimination of odor, color, taste, and turbidity. In general, pollutant transformation involves the following pathways: chain oxidation, formation of insoluble compounds, coagulation of colloids, and enhancement of pollutant biodegradability.

The *toxic metals* present in industrial effluent streams include heavy metals such as silver, lead, mercury, nickel, zinc, and chromium. These heavy metals accumulate in soil and are eventually transferred to the human food chain. In irradiation treatment the general strategy is the reduction of higher oxidation state ions to lower oxidation state ions: in lower oxidation state the solubility is usually lower, so often the reduced ions can be separated by precipitation. The reduction is done by the hydrated electron and hydrogen atom (under oxygen-free conditions) and/or by other reducing-type radicals formed in hydroxyl radical + alcohol or in hydroxyl radical + acetic acid reaction (see for instance reaction (23.34) and (23.144)) (Haji-Saeid 2007; Chaychian et al. 1998; Belloni and Mostafavi 2004; Belloni and Remita 2008).

The hydrated electrons readily reduce the silver ions to silver atoms. The atoms aggregate and finally form a black precipitate

In acidic media, e.g., in the presence of acetic acid, the toxic Cr(VI) compounds can easily be reduced to poorly soluble Cr $^{3+}$ ions. The reduction occurs with a multistep mechanism through the reaction of H atoms. The α -carboxyalkyl radicals formed in OH + acetic acid reaction after forming a complex Cr(VI)-CH $_2$ COOH and dissociation also contribute to Cr(VI) reduction

The Pb $^{2+}$ ions reacting with hydrated electrons transform to Pb $^+$ ions: Pb $^+$ ions in disproportionation reaction convert to Pb $^{2+}$ ions and Pb 0 atoms. The H atoms also contribute to the reduction. However, in the presence of dissolved oxygen, the zerovalent lead oxidizes

back to Pb^{2+} , for this reason during the reaction, precipitation and filtering oxygen-free conditions are needed.

Mercury is precipitated in the form of poorly soluble Hg_2Cl_2 : the processes of precipitation will be demonstrated with the example of the aqueous solution of HgCl_2 treated in the presence of small concentrations of isopropanol or ethanol.

The precipitation of metals from $10^{-3} \text{ mol dm}^{-3}$ concentration solutions takes place with 99% efficiency, precipitation of Cr(VI) and Hg(II) needs a few kGy dose; for the elimination of lead ions with the same concentration an order of magnitude higher dose is needed (Chaychian et al. 1998).

Many organic substances such as surfactants, lignin, pesticides, and dyes do not degrade by conventional biochemical methods, or they degrade very slowly. Biodegradation of wastewater depends on the oxidation level and structure of pollutants, preliminary oxidation, and fragmentation of biologically resistant molecules improves their biodegradability (Emmi and Takács 2008; IAEA 2008).

Aqueous effluents that can be degraded by irradiation fall into two categories: industrial wastewater, and natural and contaminated water including effluents from municipal treatment plants. The main differences between the two groups are the concentration of pollutants and the level of microbial infection, both of which are higher in the first group of effluents; however, disinfection is the main focus for the second group. Owing to the great variety of wastewaters generated by the industry, there is no universal treatment process for industrial wastewaters.

After intensive research and pilot plant installations the first full-scale industrial plant was reported for the purification of wastewater generated at the Voronezh (Russia) synthetic rubber plant. Irradiation is used to convert the non-biodegradable emulsifier or Nekal into a biodegradable form. Nekal is a mixture of isomeric isobutyl-naphthalene sulfonates. The installation has two 50 kW capacity electron accelerators and treats 2,000 m^3 effluents per day (Woods and Pikaev 1994).

Advances to molecular design of dyes have improved their photostability and stability toward aerobic degradation or common oxidants, for these reasons the removal of dyes from wastewaters is extremely difficult. Effluents of textile dyeing and finishing industries are known to have considerable color, suspended solids, chlorinated organic molecules, surfactants, some heavy metals and to have variable pH, temperature, and chemical oxygen demand (COD). Especially reactive azo dyes cause special environmental concern: their precursors and their degradation products, such as aromatic amines, are considered highly carcinogenic. (Azo dyes are chemical compounds bearing the functional group $\text{R}-\text{N}=\text{N}-\text{R}'$ in which R and R' are aryl groups. Because of the electron delocalization through the $\text{N}=\text{N}$ group these compounds have

vivid colors, such as red, orange, or yellow. Azo dyes generally are bound to the textile fibers through secondary bonds (the structure of a simple azo dye, Acid Orange 7 (AO7) is shown below, ► Fig. 23.14). The reactive dyes have active groups for chemically bonding to the textile). Consequently, dyes have to be removed from industrial wastewater before discharging. Since the traditional elimination methods (e.g., biodegradation) are not efficient enough there is demand for establishing new efficient ways for disposal and treatment of azo dye containing wastewater by new oxidation/reduction processes. Such processes can be initiated by highly reactive radicals. The so-called advanced oxidation processes (AOP) work on this principle and apply highly reactive OH radicals for the reaction produced, e.g., in photo Fenton reaction (UV light-assisted decomposition of H_2O_2), photocatalytic reaction with suspended semiconductor such as TiO_2 (yielding also OH radicals) or ionizing radiation-induced decomposition of water. Due to the intensive research on the field of radiation-induced degradation of azo dyes, the basic processes of the undergoing reactions are now clarified (Wojnárovits and Takács 2008).

The reactive intermediates formed in water radiolysis (e_{aq}^- , H and OH) react with the dye molecules with high, practically diffusion-controlled rate coefficient forming dye radicals. e_{aq}^- and H attack principally the azo bond, whereas the OH radicals mainly react with the aromatic rings. Large number of parallel and consecutive reactions is involved in discoloration and mineralization (degradation to CO_2 , H_2O , N_2 , NO_x , SO_4^{2-}). The products were individually identified in very few cases. As intermediate products, compounds with destroyed $-\text{N}=\text{N}-$ bond, hydroxylated dye molecules, dimers, molecules with opened rings, aldehydes, ketones, and carboxylic acids form. The process of mineralization is usually followed by such techniques as chemical or biological oxygen demand, and total carbon content measurement. Discoloration is highly effective when e_{aq}^- and H are the reaction partners (in the absence of oxygen); however, for mineralization OH radicals and oxygen are required (oxidative degradation).

In order to treat industrial wastewater of dyeing factories the first pilot plant (output $1,000 \text{ m}^3 \text{ day}^{-1}$) was established in the area of Daegu Industrial Complex, Daegu, Republic of Korea. The pilot plant was operating with ELV accelerator (energy 1 MeV, beam power 40 kW) for large-scale test of combined electron-beam and biological treatment of industrial textile dyeing wastewater (Han et al. 2002). According to the pilot-plant investigations of the dyeing complex wastewater equal purification degree corresponds to 17 h of bio-treatment without preliminary irradiation and about 8 h of bio-treatment with preliminary electron-beam treatment and absorbed dose 1–2 kGy. Based on the experiences gained with pilot plant a full-scale electron beam plant was constructed to treat $10,000 \text{ m}^3 \text{ day}^{-1}$ textile wastewater. This full-scale plant, since its start in 2006, has demonstrated that the established radiation

► Fig. 23.14
Acid Orange 7 (AO7)

technology is cost effective when compared to conventional treatment. The regular operation of this facility provides operational data on reliability and additional data for a detailed economic evaluation.

Several reactor types have been suggested for industrial application. One of the best designs is shown in ► Fig. 23.15. The injected wastewater forms a wide continuous layer, which is irradiated by a transverse electron beam. The thickness of the water jet is tied to the beam energy, i.e., to the penetration of the accelerated electrons. The width of the water jet corresponds to the width of the beam window. The water jet type reactor makes possible electron beam treatment at high rates of wastewater flow (Haji-Saeid 2007).

Pilot-and industrial-scale plants for radiation disinfection of *sewage sludge* are in operation in several countries. Sewage is water born waste from domestic premises and industry. Since it carries human waste, it is a source of various human pathogens that need to be controlled for safe disposal. The sludge resulting from municipal wastewater treatment is in the form of a liquid or semisolid liquid that typically contains 1–20% solids by weight, depending on the operations and processes used. Many researchers have shown that sewage sludge can be disinfected by exposure to ionizing radiation, and that irradiation often facilitates dewatering by accelerating sedimentation and filtration. A dose of 2–3 kGy destroys more than 99.9% of the bacteria being present in sewage sludge and leads to the almost complete removal of helminthes eggs and to the inactivation of the agents that cause diseases in animals. Doses of this magnitude are employed for the radiation treatment of sewage sludge at an industrial plant in Geiselbullach, Germany (Lessel and Suess 1984), and slightly higher doses (4 kGy) are used at a pilot plant near Boston in the USA (Trump et al. 1984). Higher doses are needed to inactivate more radiation-resistant organisms. Doses of 10 kGy were used at a sewage treatment plant in Albuquerque, USA (Sivinski 1983), and at an installation in Ukraine (Vysotskaya 1983).

The first plant in Geiselbullach started in 1973 and was used for research and demonstration purposes, not much later an industrial plant went into operation. The pilot plant in Albuquerque operated between 1978 and 1985 and was used for research. In Vadodara, India, a sludge treatment plant for processing 110 m³ of liquid sludge a day has been in operation since 1992 (Rawat et al. 1997; Gautam et al. 2005). The treatment plants mentioned work with ⁶⁰Co or ¹³⁷Cs radionuclides.

■ Fig. 23.15

Wastewater reactor with perfect displacement

A pilot plant using an electron accelerator as radiation source was built in Boston in 1976 and later it was modified to obtain 655 m³ of disinfected sludge per day. In the 1980s, similar facilities were brought into service near Miami (USA), and in Takasaki (Japan, Hashimoto and Kawakami 1984). Construction of an industrial scale plant treating 600 m³ dewatered sludge per day (18% solids content) is planned in Israel (Haji-Saeid 2007).

The operational experiences of the sewage treatment plants using γ - or electron irradiation have shown that the process is simple, effective, and easy to integrate into the existing sewage treatment plants. The irradiated sludge, being pathogen free, after composting can be beneficially used as manure in agricultural fields, as it is rich in soil nutrients. Since the irradiated sludge is free of bacteria, it can also be used as a medium for growing bacteria that are useful for soils to produce biofertilizer that can enhance crop yields (Haji-Saeid 2007).

23.11.3.2 Food Irradiation

Irradiation of food and food components has been the subject of intensive studies since the 1950s and radiation processing of selected foods has been approved by many countries (Elias and Cohen 1983, 1987; Farkas 1988, 2004). During irradiation, the temperature of the irradiated material rises only by a few degree Celsius, therefore irradiation treatment is regarded as isothermal process. Because of the negligible heat effect, irradiation treatment kills the cells of microbes contaminating frozen foods without thawing them up, or, those in fresh food without changing the original physical state of the product. Irradiation needs less energy than thermal treatment; irradiation may be carried out either in bulk or after packaging thus avoiding recontamination or reinfestation of the product. In contrast to the usual chemical treatment processes, no toxic chemicals such ethylene oxide, carcinogens, or mutagens need be used. However, the vitamin content of the food may be reduced due to irradiation, e.g., vitamin C and vitamins A and E may act as radical scavengers. It should be noted, however, that such vitamins are also damaged by other methods of food processing (Mozumder 1999).

The purpose of irradiation can be (a) delaying or preventing sprouting, inactivation of molds and bacteria to prolong shelf life, (b) elimination of insects and parasites, (c) delaying ripening of foods, and (d) production of sterile products, which can be used without refrigeration.

Inhibition of sprouting in onions, potatoes, and the like needs the lowest dose, 0.12–0.15 kGy. Next is the elimination of insects and parasites in cereals, fruits, dried fish, and fresh meat requiring 0.1–1.0 kGy. Delay in physiological processes in fresh fish, meat, and meat products needs ~ 1 kGy. 1.0–5.0 kGy will be needed to prolong the self-life of fresh fish, meat, and meat products. Control of pathogenic microorganisms and spoilage decontamination in seafood, poultry, spices, and animal feed require 3–10 kGy. 10–50 kGy may be needed for sterilization and elimination of viruses in poultry, meat, seafood, prepared foods, hospital diets, and foods for astronauts (radappertization). When meat is irradiated at higher doses there are some flavor changes due to lipid peroxidation. The high-dose treatment must be delivered to a vacuum-packed and deeply frozen (-30°C) product to avoid unwanted changes.

Food processing is usually carried out by ^{60}Co γ rays or less frequently by accelerated electrons. The electron energy should not exceed 10 MeV: below 10 MeV, electrons do not induce appreciable radioactivity in irradiated food. When not the electron itself, but the X-rays generated by electron impact on heavy metals (bremsstrahlung) is used for food treatment, then the electron energy should be kept below 5 MeV. Typical irradiation facilities used for food

irradiation (and also for sterilization of medical products, polymer processing, etc.) consist of a chamber containing the radiation source, some sort of conveyor systems to transport products inside and outside the shielding walls, and sophisticated control and safety system. Irradiation facilities are built with several layers of redundant protection to detect or eliminate equipment malfunctions and protect employees from accidental exposure (Farkas 2004).

The radiobiological effect in foods was first explained by the direct target effect theory. According to the theory, the biological effects are due to direct action of radiation on important molecules on sensitive parts of cells. Later it was shown that a considerable part of biological effects is due to indirect processes, e.g., reactions of reactive intermediates formed in water radiolysis (Elias and Cohen 1983, 1987; Farkas 1988, 2004).

Toxicological, nutritional, and microbiological tests support the safety of irradiated food for consumption and some 50 countries granted national clearances of irradiation of at least one or more food items of food classes (Farkas 2004). Legislator authorities require that irradiated food products be labeled. In general, the international food irradiation symbol, the so-called Radura logo (► Fig. 23.16) is required with a statement that the product has been intentionally subjected to radiation.

Regarding packaging material for irradiated foods, most commonly used food packaging material are suitable for the purpose. However, irradiation of prepackaged food requires approval of its packaging material.

Due to the public concern it is desirable to develop simple methods for the identification of irradiated food products. Because of the low yields of products formed it is a rather complicated problem. One of the standardized methods, electron spin resonance (EPR) technique, permits identification of food that contains a hard dry matrix, e.g., bone (Raffi and Kister 2008). When food containing bone is irradiated, free radicals are produced and trapped in the in the crystal lattice, which can be detected by EPR spectroscopy.

Thermoluminescence measurements observing crystal defects in, e.g., quartz grains being as impurity on the surface of some foods (vegetables) can also be successfully applied (Farkas 2004). Another standardized method is based on the irradiated fat-containing foods using the mass-spectrometric detection 2-alkyl-cyclobutanones after gas chromatographic separation (► Fig. 23.17 (Delincée 2002)).

23.11.3.3 Sterilization of Medical Products and Drugs

One of the most successful applications of radiation technology has been the sterilization of medical supplies. Sterilization was introduced by the mid-1950s, at present, ~30% of all

■ Fig. 23.16
Radura logo

■ Fig. 23.17

2-Alkylcyclobutanone

medical, single-use disposable products are sterilized by irradiation. Of the different kinds of disposables mainly surgical gowns, gloves, syringes, bandages, sutures, dressings, catheters, and transfusion sets are sterilized by irradiation (IAEA 1975, 1990; Woods and Pikaev 1994).

The aim of the irradiation is to kill or inactivate the microorganisms. The exact mechanism of the process is less known, although it is almost certainly connected with the radiation-induced damage of the DNA and perhaps also with the damage of cytoplasmic membranes (Farkas 2004). The radiation sensitivity was shown to increase with the amount of DNA in the nucleus of the microorganism.

In principle there is an exponential relationship between the microorganism survival and the absorbed dose. However, the practically measured survival curves often deviate from the linear relationship on the log survival-absorbed dose plots. At the beginning of the treatment there is a shoulder: initially the survival decreases less steeply than at higher doses. It indicates that more than one lesion is required to kill the microorganism; the shoulder is due to repair processes within the cells.

Generally a reduction of 10^{-6} in microorganism level is required. Since sterilization is equivalent to disruptive action of large biological molecules, relatively small doses are needed for the process making radiation sterilization economically feasible. The minimum absorbed dose required by the authorities in different countries varies somewhat, but it is mostly around 25 kGy. In case of highly radiation resistant microorganisms, higher doses may be required.

When compared with the traditional sterilization methods, such as heating in an autoclave, ethylene oxide, or formaldehyde treatments several advantages of radiation technology should be mentioned

1. Since there is a simple relationship between sterility and, absorbed dose, sterility is controlled by the dose value, which, in turn, is usually controlled by the conveyor speed. Therefore, long-lasting microbiological tests are required only occasionally. It increases the safety of sterilization and simplifies the process. The process is continuous, allowing smooth product flow and requiring minimum human handling.
2. The products can be sterilized after packaging, which gives some flexibility of operation.
3. Irradiation avoids the use of toxic chemicals, e.g., ethylene oxide, or high temperatures in an autoclave.
4. In case of irradiation treatment, new materials can be used for the medical devices (e.g., syringe).

The various materials (often polymers) have to be chosen such that they are sufficiently radiation resistant to withstand the sterilization dose. Under the dose conditions, needed for sterilization some polymers such as polyethylene, polystyrene, poly(ethylene terephthalate), polyurethanes, and epoxides may be stable, whereas others such as polypropylene, poly(methyl methacrylate), polyvinyl chloride (PVC) may not. When the radiation stability of the plastic

material is poor, some additives are included in order to improve the radiation stability (Woods and Pikaev 1994; IAEA 1975, 1990).

Most of the irradiation in the field of sterilization is carried out by ^{60}Co irradiation facilities; however, sometimes electron accelerators are also used for this purpose.

A new field of radiation application is the *radiation sterilization of drugs*. The requirement for sterility of drugs depends on type of administration. It concerns mostly ophthalmic preparations, sterile topical products, and injectable solutions. In some cases, radiation sterilization appears to be an attractive alternative to other types of sterilization, e.g., heat sterilization. For drugs the usual requirement (six orders of magnitude decrease in the microorganism level) is achieved by applying an absorbed dose of 25 kGy.

When drugs in the solid state (tablets, powders, suspensions) are sterilized, the drug molecules are directly ionized and excited by the ionizing radiation: the diffusion of the reactive species is hindered by the solid and they cannot diffuse, except for the mobile deliberated electrons and hydrogen atoms. The reactive species, mostly radicals, are trapped by the solid matrix and they react with high probability with each other reestablishing the initial molecules. For this reason the drug transformation yield is usually very low ($<0.1\%$). In fact, until the 1990s the analytical techniques failed to detect final products present in traces. Due to the development of highly sensitive analytical techniques, nowadays the radiation chemistry research is directed toward the reaction mechanisms and analysis of final products in terms of their potential toxicity. The impurity concentration in drugs is generally higher than the concentration of the newly formed radiolytic products, moreover during radiolysis usually the same products form as the impurities making product determination more difficult (Tilquin 2008).

When the drug is sterilized in aqueous solution most of the energy of ionizing radiation is absorbed by water and the reactive intermediates of water radiolysis, discussed in [Sect. 23.6.1](#), react with the microorganisms and also with the drug molecules. In solutions the drug undergoes decomposition with a high yield, unless by adding a protective agent or by freezing the solution (Woods and Pikaev 1994; Tilquin 2008). As radioprotectors some vitamins or 1,2-propanediol may be used. When an aqueous solution of a pharmaceutical is frozen, the polycrystalline solid contains both ice and solute phases. Since the phases are separate, the indirect effect of the intermediates of water radiolysis on the drug molecules is reduced. So freezing increases the radiation stability of aqueous pharmaceutical preparations. Sterilization of frozen materials is described as cryoradiation sterilization (Woods and Pikaev 1994).

23.12 Editors' Note

1. See [Fig. 9.21 in, Vol. 1 Chap. 9](#), on “Stochastics and Nuclear Measurements,” for a schematic representation of the “smearing” of a signal while it gets amplified by subsequent dynodes (p. 1279).
2. See [Chap. 57 in Vol. 6](#) on “Technical Application of Nuclear Fission.” The problems caused by oxygen formation are commented on in Sect. 57.4.2.1 on “The pressurized water reactor (PWR)” (p. 1290).
3. Nm^3 stands for normal cubic meters, where “normal” refers to standard temperature and pressure of the gas (p. 1318).

Abstract: Various aspects of hot atom chemistry are described, reviewing it from fundamentals to applications. In gas, liquid, and solid systems, recoil atom reactions show characteristic features. Chemical behavior of implanted atoms that is specific to them and somewhat different from that of ordinary recoil atoms is also described. Examples of radioisotope enrichment are included.

24.1 Introduction

It is usually considered that hot atom chemistry deals with chemical effects of nuclear transformations, which result in the formation of “hot atoms” with high kinetic energy or high electric charge. However, in some cases “hot atoms” with high energy can be generated by nonnuclear means (photochemical method, beam acceleration, etc.). These nonnuclear hot atoms are included in up-to-date hot atom chemistry concepts in this chapter.

The recoil phenomenon, which is intimately related to hot atom chemistry, was first observed by H. Brooks (1904) in 1904 at the McGill University (► Table 24.1). She noticed severe contamination with radioactivity of ^{214}Pb and ^{214}Bi in the ionization chamber she used. In 1905, Rutherford (1951) (Nobel Prize 1908) who supervised her work concluded that the phenomenon observed by her was based on the recoil energy of the residual nucleus introduced by α particle emission on the nuclear disintegration of ^{218}Po (in other words, implantation in the wall material occurred). Then the technique using nuclear recoil was successfully employed by Hahn (Nobel Prize 1944) and Meitner (1909) for the separation of short-lived ^{210}Tl (half-life 1.32 min) in 1909. The same technique was absolutely effective to separate a new element Np ($Z=93$) from fission fragments with high kinetic energy when uranium ($Z=92$) was irradiated with neutrons by Mcmillan (Nobel Prize 1951) and Abelson (1940).

Following the above mechanical use of nuclear recoil, purely chemical effects of nuclear recoil were observed by Szilard and Chalmers (1934a, b) in 1934. They used (n, γ) reaction of iodine in ethyl iodide. The product of neutron capture, ^{128}I , could be chemically extracted into an aqueous phase after mixing ethyl iodide with water.

This was the starting point of the so-called hot atom chemistry, which formed a unique branch of nuclear and radiochemistry thereafter.

Although Szilard wrote only two papers on this subject, he was regarded as the father of hot atom chemistry. His finding was further confirmed by Fermi (Nobel Prize 1938) and coworkers (Amaldi et al. 1935) who pointed out that recoil energy of a few hundred eV due to γ emission is enough to break chemical bonds in neutron-irradiated inorganic compounds such as permanganate.

It was then recognized that chemical bond rupture can be caused not only by high kinetic energy, but also by high electric charge. In 1939, Segrè (Nobel Prize 1959), Halford, and Seaborg (Nobel Prize 1951) observed separation of ^{80}Br (the ground-state isomer of $^{80\text{m}}\text{Br}$) from $^{80\text{m}}\text{Br}$ -labeled organic bromide (Segrè et al. 1939). The same kind of ^{80}Br separation was reported by Devault and Libby (1939) (Nobel Prize 1960) independently. The nuclear isomeric transition $^{80\text{m}}\text{Br} \rightarrow ^{80}\text{Br}$ does not produce high kinetic energy but high electric charge by emission of Auger electrons through internal conversion associated with the isomeric transition.

The reason for bond rupture by high electric charge was clarified more clearly later. Snell and Pleasonton (1955) measured charge distribution after nuclear decay by mass spectrometry. Chemical effects of high charge in molecular systems were studied by Wexler (1961a) in detail,

■ Table 24.1

Milestones in the development of hot atom chemistry

Year	Name	Nationality	Discoveries or events
1904	H. Brooks	Canada	Contamination of ionization chamber (attributed to nuclear recoil by E. Rutherford in 1905)
1909	O. Hahn & L. Meitner	Germany	Recoil separation of RaC''
1934	L. Szilard & T. A. Chalmers	Hungary	Chemical separation of recoil ^{128}I from neutron-irradiated $\text{C}_2\text{H}_5\text{I}$
		UK	
1935	E. Amaldi et al.	Italy	Chemical effect of (n,γ) reaction attributed to recoil by γ emission
1939	E. Segrè et al.	Italy, USA	Chemical effect of isomeric transition attributable to high electric charge

1998	T. Miyazaki et al.	Japan	Quantum mechanical tunneling effect for hot tritium reaction

and the "explosion model" proposed by Carlson (Carlson and White 1968) reasonably explained the ruptured product distribution.

After the bond-rupture studies by Szilard and Chalmers (1934a, b) and by Fermi and coworkers (Amaldi et al. 1935), chemists became interested in chemical reactions of recoil atoms. In organic substances, a variety of hot atom chemical products labeled with radiohalogens were detected by Glückauf and Fay (1936). Lu and Sugden (1939) suggested

that the reactions of recoil halogen atoms occurred in an organic liquid cage. They found a scavenger effect on the reaction yield.

Later, Libby (1940) noticed the importance of reentry reaction, that is, the reaction leading to a parent chemical form. In this case, a permanganate fraction (“retention” as he called it) in neutron-irradiated potassium permanganate (KMnO_4) was the main subject of discussion.

Libby (1947) proposed a billiard ball collision model to understand hot atom chemical reaction in solid inorganic compounds. It was, in fact, the first attempt of modeling in the history of hot atom chemistry, even though it is by no means valid in our present knowledge. This model explained the “retention” by assuming that energy loss is maximum for the struck atom of similar mass, and this kind of billiard ball collision leads to the “retention” most effectively. So, the permanganate fraction labeled with ^{56}Mn , for example, was important in neutron-irradiated KMnO_4 according to his model.

However, Libby’s model was criticized by some authors later. Among them, there was Willard (Goldhaber and Willard 1953) who proposed an alternative “random fragmentation model” on the basis of experimental observation of scavenger effect in organic liquids and a variety of products. He thought of an important role of radical scavenger in the cage surrounding the recoil atom concerned.

Instead of using condensed phases, two giants of hot atom chemistry, Wolfgang and Rowland (Nobel Prize 1995) studied hot tritium reaction in a gaseous phase in the 1960s. This reaction system, attractive because of its simplicity (using a radioisotope of hydrogen in a gaseous medium), was suitable to solve the problem of mechanisms of hot reactions. Moderator gas such as helium was available for slowing down hot tritium atoms, and the results could be interpreted similarly to the neutron slowing down process already consolidated in nuclear reactor technology. Wolfgang observed that hot reaction yields could be effectively suppressed by adding the moderator gas helium to the reaction system. The contribution of thermal reaction, which would have disturbed the determination of the reaction yield, could be eliminated in the presence of a scavenger such as oxygen. Wolfgang and coworker (Henchman and Wolfgang 1961) proposed an “impact model” to explain substitution and abstraction yields in rather mechanistic manner.

On the contrary, Rowland and coworkers (Lee and Rowland 1963) inferred that collision of a hot tritium atom with a target molecule to react was relatively “soft” as if cushions were inserted (*cushioning collision model*). He revealed (Root et al. 1965) that the abstraction leading to formation of HT (a molecule consisting of a hydrogen atom and a tritium atom) was remarkably affected by chemical binding energy between carbon and hydrogen atoms in the target molecule.

Wolfgang turned to chemical accelerator work afterward probably because he could not be content with ordinary hot atom chemistry using nuclear reactions. His brilliant papers (Wolfgang 1969) on ADAM and EVA chemical accelerators provoked strong interests among researchers of reaction dynamics in physical chemistry. Especially the latter machine, which was able to specify reaction energy and angle, was much more valuable in obtaining exact information on hot reaction compared to ordinary hot atom chemical experiments using nuclear technique. He was among the constructors of modern chemical dynamics, but he died before his time. While Wolfgang engaged in the study of ion-neutral (molecule) reaction, neutral–neutral reaction was studied by Y.T. Lee (1975) (Nobel Prize 1986) who had been involved in hot atom chemistry.

After the hot tritium reaction studies, Rowland also shifted his interests to atmospheric chemical reactions. He pointed out the danger of the possible destruction of the ozone layer

surrounding the earth by man-made fluorine compounds (Molina and Rowland 1974). His prophetic warning was recognized as a realistic one later by the observations of geophysicists, and the Nobel Prize was awarded to him. It was not in the field of hot atom chemistry; however, without his career in hot atom chemistry, he could not have accomplished his Nobel Prize work.

So, the readers of this chapter should realize that hot atom chemistry was the field in which many Nobel Prize laureates were interested, even though hot atom chemistry itself was not the subject of Nobel Prize.

Some remarks have to be added on hot atom chemistry in solids, which is more or less connected with solid-state physics. Maddock and coworker (Maddock and deMaine 1956) noticed that annealing phenomena occurred in the chemical distribution of neutron-irradiated chromate crystals. This type of study was further extended and elaborated by others, for example, Lindner and Harbottle (1961) studied phosphate compounds. A series of investigations on the appearance (threshold) energy were carried out by Yoshihara et al. (Yoshihara and Kudo 1970) who found that the threshold energy was greater than the energy of Frenkel pair formation in typical crystals. It is worth noting that implantation reactions having similarity to hot atom chemical reactions could be utilized in the synthesis of labeled compounds by Baumgärtner and Reichold (1961). This reaction was interesting for it resulted in enhancement of the reaction yield probably because of shock-wave-like action (Yoshihara et al. 1992). Mixed crystal studies of solid hot atom reactions were performed by Müller and Hagenlocher (1990) who put emphasis on the “lattice disorder” in irradiated crystals.

The International Hot Atom Chemistry Symposium began in 1959 and ended in 1987. Frankly speaking, the boom of hot atom chemistry was over, although still some important works are to be noted. Hot atom chemistry has already gathered lots of information on the chemical effects of nuclear transformations, which may be available for other radio- and nuclear chemists. It is reasonable to believe, however, that hot atom chemistry also has future possibilities in the field of nonnuclear chemical processes.

24.2 Recoil Energy and Charge Distribution

24.2.1 Recoil Energy

To estimate the recoil energy, which is endowed to the hot atom in nuclear transformation, one needs some basic knowledge about nuclear reactions. In the nuclear reaction

where A and B are the reacting nuclei, C and D are the produced nuclei, and Q is the energy released, the energy and momentum are conserved. In nuclear decay processes (including those from compound nuclei), mathematical treatments are rather simple and it is easy to calculate recoil energy.

For nuclear disintegration such as α decay, calculation of recoil energy (E_R) of the residual nucleus is as follows:

$$E_R = M_\alpha E_\alpha / M_R, \quad (24.2)$$

where M_α is the mass of the α particle, E_α is the kinetic energy of the emitted α particle, and M_R is the mass of the residual nucleus. The relation holds good, in principle, in all the cases of

naturally occurring α emitters. In the case of RaA (i.e., ^{218}Po) for which Brooks (1904) observed serious contamination with its daughter nuclides, the calculated result using [Eq. \(24.2\)](#) is 112 keV, which is comparable with or higher than the bombarding energies used in modern implantation technology.

[Equation \(24.2\)](#) can also be applied to other cases of nuclear processes in which compound nucleus formation and subsequent decay are concerned. For the nuclear reaction $^6\text{Li}(n,\alpha)\text{T}$ with the Q -value 4.78 MeV, the recoil energy (E_{T}) of tritium T is as follows:

$$E_{\text{T}} = M_{\alpha}E_{\alpha}/M_{\text{T}} = Q M_{\alpha}/(M_{\alpha} + M_{\text{T}}) \quad (24.3)$$

where E_{α} and M_{α} are α energy and mass, respectively, and M_{T} is the mass of tritium. Similarly, the recoil energy (E_{R}) of the nucleus produced in the (n,p) reaction induced by thermal (i.e., low-energy) neutrons is expressed as

$$E_{\text{R}} = M_{\text{p}}E_{\text{p}}/M_{\text{R}}, \quad (24.4)$$

where M_{p} is the mass of the proton, E_{p} is its energy, and M_{R} is the mass of the recoil atom. In the case of (n, γ) reactions induced by thermal neutrons it is necessary to take the momentum of the photon into consideration. Therefore, the final formula to calculate recoil energy of the recoil atom is

$$E_{\text{R}}/\text{eV} = 537 \frac{(E_{\gamma}/\text{MeV})^2}{M_{\text{R}}/\text{u}}, \quad (24.5)$$

where E_{γ} is the energy of the emitted photon, E_{R} is the recoil energy of the product, and u is the atomic mass unit. For nuclear fission induced by thermal neutrons (or spontaneous nuclear fission), the fragments A and B move to opposite direction with almost equal momentum. So the energy of the fragment A (E_{A}) is expressed as

$$E_{\text{A}} = Q M_{\text{B}}/(M_{\text{A}} + M_{\text{B}}), \quad (24.6)$$

where Q is the total energy generated in fission, and M_{A} and M_{B} are masses of the fragments A and B, respectively. In this case, the contribution of fission neutron in the reaction is neglected for simplicity.

For β -decay processes (both β^{-} and β^{+}) neutrino emission accompanied with electron emission as well as relativistic effects should be taken into account. Thus, the formula for the maximum recoil energy E_{R} is expressed as follows:

$$E_{\text{R}}/\text{eV} = 537 \frac{(E_{\beta}/\text{MeV})(1.02 + E_{\beta}/\text{MeV})}{M_{\text{R}}/\text{u}}, \quad (24.7)$$

where E_{β} is the maximum kinetic energy of the emitted electron and M_{R} is the mass of the recoil atom.

In *electron capture (EC) decay*, recoil by neutrino emission should be considered. Assuming the rest mass of the neutrino is zero, the recoil energy expression is similar to that in the photon emission in (n, γ) reaction in [Eq. \(24.5\)](#).

$$E_{\text{R}}/\text{eV} = 537 \frac{(E_{\nu}/\text{MeV})^2}{M_{\text{R}}/\text{u}}, \quad (24.8)$$

where E_{ν} is the neutrino energy. For the $^{37}\text{Ar} \rightarrow ^{37}\text{Cl}$ decay, Snell and Pleasonton (1955) measured experimentally E_{R} using their mass spectrometer. The measured value (9.63 ± 0.06 eV) was in good agreement with the calculated one.

For isomeric transitions when the excitation energy of the nucleus is carried away by a γ photon, the formula for the recoil energy is the same as in the case of the thermal (n, γ) reaction (2.5):

$$E_R/\text{eV} = 537 \frac{(E_\gamma/\text{MeV})^2}{M_R/\text{u}}. \quad (24.9)$$

However, it should be noted that this is only valid for photon emission. It will be more complicated, if Auger electron emission accompanied with photon emission is taken into account. Calculated recoil energy values for typical nuclear processes are shown in [Table 24.2](#) (Yoshihara 1984).

Assuming isotropic emission of ejected particles in the $A + x \rightarrow B + y + Q$ type reaction, average recoil energy $\langle E_R \rangle$ of B was calculated by Libby (1947). The expression is as follows:

$$\langle E_R \rangle = E_\mu \left\{ \frac{M\mu}{(M+m)^2} + \frac{m(M+m-\mu)}{(M+m)^2} \left[1 + \frac{Q}{E_\mu} \left(\frac{M+m}{M+m-\mu} \right) \right] \right\} \quad (24.10)$$

where E_μ is the kinetic energy of the bombarding particle x with mass μ , M is the mass of the recoiling atom B, m is the mass of the emitted particle y, and Q is the overall mass difference in

Table 24.2

Calculated (maximum) recoil energies for typical nuclear processes

Nuclear process	Examples	E_R (eV)
α decay	$^{238}\text{U}-^{234}\text{Th}$	7.17×10^4
	$^{219}\text{Rn}-^{215}\text{Po}$	1.27×10^5
	$^{218}\text{Po}(\text{RaA})-^{214}\text{Pb}$	1.12×10^5
Thermal neutron (n, α)	$^6\text{Li}(\text{n},\alpha)\text{T}$	2.73×10^6
Thermal neutron (n,p)	$^3\text{He}(\text{n},\text{p})\text{T}$	1.95×10^5
	$^{14}\text{N}(\text{n},\text{p})^{14}\text{C}$	4.5×10^4
	$^{35}\text{Cl}(\text{n},\text{p})^{35}\text{S}$	3.1×10^4
Thermal neutron (n, γ)	$^{31}\text{P}(\text{n},\gamma)^{32}\text{P}$	1.05×10^3
	$^{37}\text{Cl}(\text{n},\gamma)^{38}\text{Cl}$	5.27×10^2
	$^{79}\text{Br}(\text{n},\gamma)^{80}\text{Br}$	4.17×10^2
	$^{127}\text{I}(\text{n},\gamma)^{128}\text{I}$	1.96×10^2
Nuclear fission (thermal neutron, spontaneous)	$^{235}\text{U}(\text{n},\text{f})$	$(6-10) \times 10^7$
β decay	$^3\text{H}-^3\text{He}$	3.6
	$^{32}\text{P}-^{35}\text{S}$	77.5
	$^{36}\text{Cl}-^{36}\text{Ar}$	18.4
	$^{90}\text{Sr}-^{90}\text{Y}$	5.10
	$^{210}\text{Bi}-^{210}\text{Po}$	6.45
Electron capture	$^{37}\text{Ar}-^{37}\text{Cl}$	9.67
Isomeric transition	$^{69\text{m}}\text{Zn}-^{69}\text{Zn}$	1.5

terms of energy (Q -value). For the angle θ between the incident particle x and the emitted particle y , the recoil energy E_R is expressed by the equation

$$E_R = \langle E_R \rangle - A \cos \theta \quad (24.11)$$

where

$$A = \frac{2E_\mu}{(M+m)^2} \left\{ Mm\mu(M+m-\mu) \left[1 + \frac{Q}{E_\mu} \left(\frac{M+m}{M+m-\mu} \right) \right] \right\}^{1/2}. \quad (24.12)$$

In the molecular entity, however, the recoil energy of the recoiling atom is not fully effective to break chemical bonds. This was pointed out by Suess (1940) who calculated the energy available for internal excitation, E_i , as

$$E_i = E_R M_2 / (M_1 + M_2), \quad (24.13)$$

where E_R is the recoil energy of the hot atom with mass M_1 and the mass of the attached atom (or group) is M_2 . Thus, for example, the recoil energy of ^{128}I produced in molecular HI is of poor efficiency in breaking the chemical bond. According to ▶ Eq. (24.13), it is only 0.78%. The maximum energy of the γ quantum in $^{127}\text{I}(\text{n},\gamma)^{128}\text{I}$ is 6.83 MeV, and the recoil energy E_R is 196 eV using ▶ Eq. (24.5). Therefore, E_i (energy available for the chemical bond rupture) for HI is 1.53 eV or 2.45×10^{-19} J. On the other hand, HI bonding energy is 295 kJ/mol, that is, 4.90×10^{-19} J per molecule, which is larger than the energy available. So, it is predicted that the HI bond escapes rupture, in agreement with experimental observation. In the case of ethyl iodide, $\text{C}_2\text{H}_5\text{I}$, in the Szilard–Chalmers experiment, E_i is calculated to be 36.4 eV, which is enough for the rupture of the C–I chemical bond (274 kJ/mol or 1.08 eV per one molecule).

24.2.2 Electric Charge Distribution

Ionization of outer electrons can occur if the moving atom has sufficiently high kinetic energy. The first approach to this problem was demonstrated by Bohr (1940) who postulated that the atom will lose its outermost orbital electron when the speed (u_R) of the atom is greater than that of the orbital electron (u_e). Therefore, the lower limit of the speed, which results in ionization, is determined by the following equation:

$$\frac{1}{2} m_e u_e^2 = I_p, \quad (24.14)$$

where m_e is the electron mass, and I_p is the ionization potential. For the condition $u_R = u_e$ one gets from ▶ Eq. (24.14):

$$I_p = m_e E_R / M, \quad (24.15)$$

where M and E_R are the mass and the (recoil) energy of the atom, respectively. For the atom produced by high-energy reaction, the recoil energy would be in the range of some hundred MeV. Carlson et al. (1970) calculated that the average charge would be between +16 and +17 for iodine at energy of 100 MeV. This estimate was in good agreement with experimental one (+17) obtained by Datz et al. (1971) in gases. However, in solids, the value was much higher (+26). The reason for this was discussed by Betz and Grodzins (1970).

There are other mechanisms for ionization of atoms, when a vacancy in the inner shell of an atom is formed in the moment of electron capture or internal conversion. The initial vacancy in

the inner electron shell is followed by successive electron emission from outer shells (vacancy cascade). In this process, the vacancy in the inner shell is filled by an electron from the adjacent outer shell, and the energy difference of these shells causes the emission of an electron from the same outer shell. The outer shell possesses, therefore, two vacancies, which will be filled by outer electrons. If this process is repeated thereafter, the number of vacancies will be twice. The multiplication of electron vacancies will attain saturation because the atom has only limited number of electrons. This is called the Auger process. The Auger processes may compete with radiative processes, but the probability for Auger processes is greater than radiative processes (X-ray emission) except for K and L shells of heavy elements.

➤ **Figure 24.1** shows a typical example of a vacancy cascade in xenon. Carlson and Krause (1965) compared the charge spectrum obtained by Monte Carlo calculation with experimental results obtained for krypton. The theoretical and experimental results are in agreement as seen in ➤ **Fig. 24.2**.

The other cause of ionization is electron shake-off. The charge spectrum observed for this process is entirely different from that for the vacancy cascade.

When the central charge of an atom changes suddenly, for example, as in the case of β^- and β^+ decays, there is a finite probability that an electron in a given orbital goes to an excited level of the continuum. Therefore, the electron will be shaken-off, as if fruits of a tree fall down by shaking. The shake-off probability P_{nlj} for the ionization of an electron from orbital nlj is

$$P_{nlj} = 1 - \left[\left| \int \psi_{nlj}^* \psi_{nlj} d\tau \right|^2 \right]^N \quad (24.16)$$

■ **Fig. 24.1**

Typical vacancy cascade in Xe as the result of an initial L vacancy. Black circles represent electrons, white circles represent vacancies, and white circles with black circles show the cases that a subsequent Auger process has filled a vacancy

■ Fig. 24.2

Charge distribution of Kr ions resulting from irradiation of Kr by Mo K X-rays compared with calculated spectrum

where ψ_{nlj} and ψ'_{nlj} are the single-electron wave function for the initial and final states of atomic orbitals nlj , respectively. N is the number of electrons in the orbital of the initial state. The overlap $\psi'^* \psi$ is not unity because the final state has a different central potential. For β^- decay, the nuclear charge changes by +1 and for β^+ decay by -1 (in α decay: -2). Generally speaking, the shake-off probability is not so large: it is usually 10% or less for β^- and β^+ decays.

As a summary of charge distribution after nuclear decay, ▶ Fig. 24.3 shows various cases in monatomic or polyatomic gases (inclusive of solid surface emission for α decay and heavy ion nuclear reaction).

24.3 Enrichment of Radioisotopes by The Szilard–Chalmers Processes

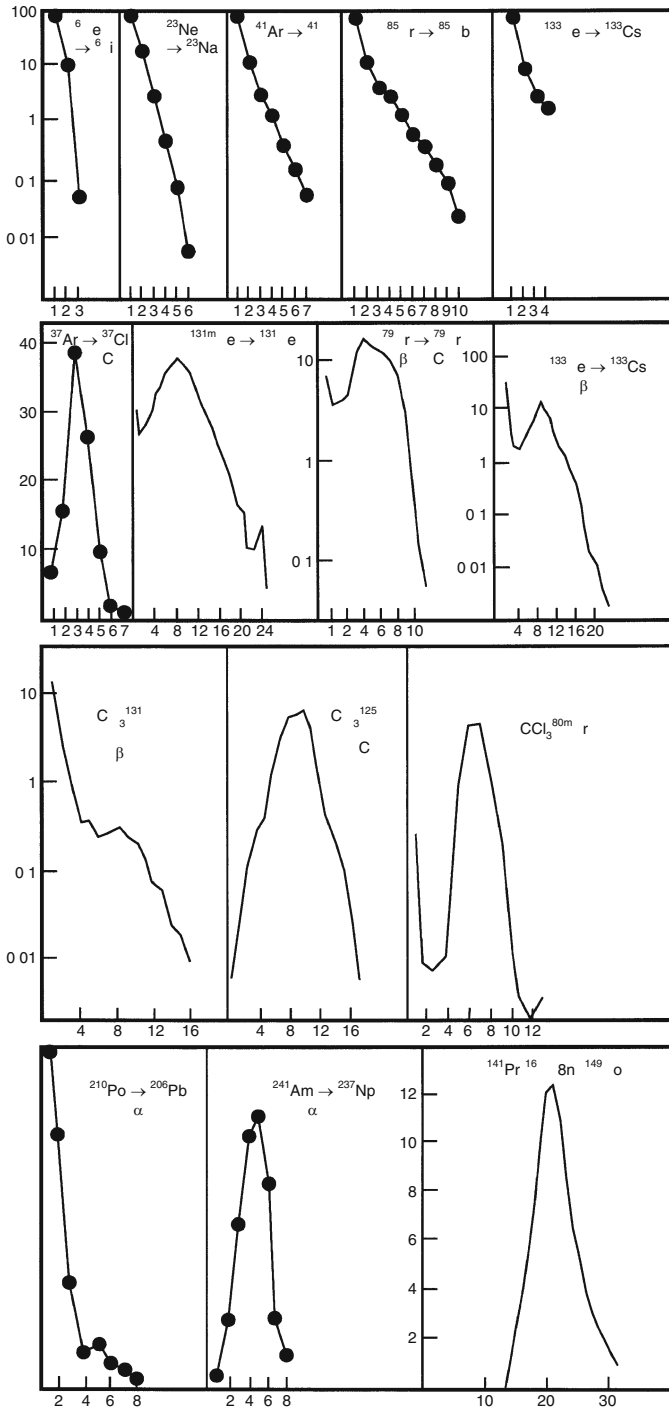

Before nuclear reactors became available for radioisotope production, the Szilard–Chalmers process mentioned in ▶ Sect. 24.1 was very important for its availability to prepare radioisotopes with high specific activity. This unique technique survived for many years after the first nuclear reactor started to operate in 1942. The activity A of a radionuclide produced by activation can be expressed as

$$A = N\sigma f(1 - e^{-\lambda t}) \quad (24.17)$$

where N is the number of the target atoms being irradiated, σ is the nuclear reaction cross section of activation, f is the projectile flux density (in the case of nuclear reactors, neutron flux density), λ is the decay constant of the produced radioisotope, and t is the irradiation time.

■ Fig. 24.3

Charge distribution after nuclear decay

When the atomic number of the produced radioisotope is equal to that of the target element, the specific activity A_s is

$$A_s = A/W \quad (24.18)$$

where W is the mass of the element irradiated. Considering $W = NG/6.02 \times 10^{23}$, where G is the atomic weight of the irradiated element,

$$A_s = 6.02 \times 10^{23} \sigma f (1 - e^{-\lambda t}) / G. \quad (24.19)$$

Equation (24.19) shows that the specific activity of the produced radioisotope is characterized by the curve with a saturation value $A_{\text{sat}} = 6.02 \times 10^{23} \sigma f / G$ with an initial slope $A_{\text{sat}} = 6.02 \times 10^{23} \lambda \sigma f / G$ (Fig. 24.4).

One can use the half-life $T_{1/2}$ instead of λ , which is expressed as

$$\lambda = 0.693 / T_{1/2} \quad (24.20)$$

In the dawn of the history of nuclear science, the neutron flux density (f) of Ra–Be source was only 10^2 – 10^4 n cm $^{-2}$ s $^{-1}$. The total activity produced by such neutron sources via (n, γ) reaction was very low and so was the specific activity of the radionuclides. The Szilard–Chalmers process, however, could dramatically increase the specific activity: the improvement could reach orders of magnitude. In the measurement of β radioactivity, which was a frequent task in early days of nuclear science, samples with low specific activity brought sometimes troublesome problems of self-absorption corrections. By the introduction of the Szilard–Chalmers process, however, this difficulty could be avoided, because the measurement could be performed within small statistical errors using a sample with high specific activity. Therefore, the Szilard–Chalmers process became one of the useful means of preparation of radioisotopes for measurement, as Szilard and Chalmers (1934b) recognized the importance of this technique in their early work.

Fig. 24.4

Radioactivity accumulation curve

In fact, even the very low neutron flux in the upper atmosphere could be measured by $^{80\text{m}}\text{Br}$ radioactivity using this technique by Von Halban Jr et al. (1939) who used ethyl bromide as a target material for the production of the radioisotope from (n,γ) reaction.

It is true, however, that the advent of modern nuclear reactors changed this situation. The neutron flux attained to $10^{11} - 10^{15} \text{ n cm}^{-2} \text{ s}^{-1}$. So, the total activity and the specific activity increased strikingly. Without the Szilard–Chalmers process, the specific activity of the aimed radioisotope was high enough for many purposes.

Even though the specific activity of nuclear-reactor-produced radioisotopes became rather high, users requested still higher levels. For the investigation of living systems involving human beings by radioisotopes of toxic elements, the requested specific activity was beyond that of the ordinary reactor product. Therefore, the Szilard–Chalmers process found its *raison d'être* during the “nuclear age” in the second half of the twentieth century.

A French radioisotope production group provided radionuclides such as ^{51}Cr , ^{59}Fe , ^{64}Cu , ^{65}Zn , and ^{76}As by the Szilard–Chalmers processes (Henry 1957). At the Japan Atomic Energy Research Institute, this process was applied to obtain pure ^{32}P from neutron-irradiated potassium phosphate. Ordinary ^{32}P products using (n,p) reaction in a nuclear reactor contain an impurity isotope ^{33}P in ^{32}P , but ^{32}P produced by (n,γ) reaction in neutron-irradiated phosphate does not contain ^{33}P . Hot atom chemically obtained ^{32}P by (n,γ) reaction was therefore appropriate for some special experiments in which contamination of ^{33}P with different half-life and β -particle energy had to be excluded (Shibata et al. 1963).

Although the Szilard–Chalmers process using nuclear reactors can normally ensure high concentration of the desired radioisotope, it suffers from radiation decomposition problems of the target compound. At higher neutron flux values, radiation decomposition also increases which sets a limit to the enrichment factor (concentration factor). When the enrichment factor (E) is defined by the ratio of the specific activity (S_1) of the separated part of the Szilard–Chalmers process to that (S_2) before separation,

$$E = \frac{S_1}{S_2} = \frac{\gamma m_2}{100 m_1} \quad (24.21)$$

where γ is a radiochemical yield of the separated radioisotope, m_2 is the total mass of the target element, and m_1 is the mass of the separated element. For intense radiation in a nuclear reactor the separable weight of the element (m_1) increases by decomposition, whereas the radiochemical yield (γ) is almost unchanged, and therefore the enrichment of radioisotopes is only practical for materials, which can withstand radiation decomposition in a nuclear reactor.

Generally, the Szilard–Chalmers process is based on valence change of the element, decomplexation, transformation of organic to inorganic compounds, etc. For example, hot atom chemical reactions, $^{50}\text{CrO}_4^{2-}(n,\gamma)^{51}\text{Cr}^{3+}$, $^{63}\text{CuPc}(n,\gamma)^{64}\text{Cu}^{2+}$, and $\text{C}_2\text{H}_5^{79}\text{Br}(n,\gamma)^{80}\text{Br}^-$, are typical cases. In the first reaction, chromate Cr(VI) changes to chromic Cr(III), in the next one copper phthalocyanine complex to noncomplex Cu, and in the last one ethyl bromide to free bromide tagged with radioactivity. Exchange reaction between the mother substance and the product does not occur in either case. ▶ Table 24.3 shows various radioisotopes separated by the Szilard–Chalmers process (Yoshihara 1984).

Note that in ▶ Table 24.3 phthalocyanines are useful target materials. Fe, Co, Cu, Zn, Ga, Mo, Pd, In, Dy, Os, and Pt radioisotopes can be separated from neutron-irradiated metal phthalocyanines. Metal chelate compounds such as metal oxinates are other examples. Ca, V, Mn, Ni, Cu, In, and W are separated by the Szilard–Chalmers process from their oxinates. Salts of oxyacids

■ Table 24.3

Enrichment of radioisotopes by the Szilard–Chalmers process. (ppt: precipitate)

Nuclide	Target material	Separation procedure
^{36}Cl	$\text{NaClO}_3, \text{NaClO}_4$	ppt as AgCl
^{36}Cl	$\text{MXO}_3, \text{MXO}_4$	ppt as AgX , ion exchange
^{38}Cl	Organic halogen compd.	extraction into aqueous phase shaking with active carbon, alumina, metal powder, electrolysis
$^{80\text{m}}\text{Br}$		
^{80}Br		
^{82}Br		
^{128}I		
^{32}P	$(\text{C}_6\text{H}_5)_3\text{PO}_4$	shaking with water, carbon extraction with water
	$(\text{C}_4\text{H}_9)_3\text{PO}_4$	
^{35}S	CS_2	evaporation residue
^{45}Ca	Ca-oxinate	ion exchange from n-butylamine soln.

²³⁹ U	U(SO ₄)·xH ₂ O	CHCl ₃ extraction
	UO ₂ -benzoylacetate	soln. in acetone, shake with BaCO ₃

M_nXO_m are another group of compounds that are available for the process. Two examples of the Szilard–Chalmers processing will be shown to demonstrate the practical use of radioisotopes at 10^8 – 10^{10} Bq levels.

High specific activity ^{51}Cr demand came from the users of blood flow measurements. This radioisotope could be produced either by irradiation of chromium (enriched ^{50}Cr) metal in a high neutron flux ($10^{15} \text{ n cm}^{-2} \text{ s}^{-1}$) for several days or by the Szilard–Chalmers process using potassium chromate (K_2CrO_4) crystals. However, the use of a high flux reactor was not frequently available for ordinary radioisotope production purposes. On the other hand, the Szilard–Chalmers process was practical in any type of nuclear reactor without severe limitations. The following process (Shibata et al. 1969) is used for ^{51}Cr production by the Szilard–Chalmers method as adopted by the Japan Atomic Energy Research Institute. Neutron-irradiated potassium chromate is dissolved in 0.3 M hydrochloric acid containing a small amount of lanthanum chloride. To the solution 1 M sodium hydroxide is added and the mixture is stirred and the formed precipitate is filtered. The precipitate is washed repeatedly, and is dissolved in 0.15 M hydrochloric acid. The precipitation procedure is repeated using 1 M NaOH. The washed precipitate containing chromic and lanthanum hydroxides is submitted to oxidation leaching. This procedure is performed to convert $^{51}\text{Cr(III)}$ to a chemical form of chromate and to separate it from lanthanum using 0.15 M NaOH and hydrogen peroxide.

The leached chromate solution is heated for 30 min to expel hydrogen peroxide. It is filtered and the filtrate is concentrated in a small volume and neutralized with hydrochloric acid. The formed product is distributed to the users. The specific activity of ^{51}Cr ranges between 2×10^6 Bq/mg and 4×10^6 Bq/mg.

The other radioisotope ^{64}Cu has been produced by the Szilard–Chalmers process at the Japan Atomic Energy Research Institute in the 4×10^6 Bq/mg level. This radioisotope is useful for medical purposes, but the total amount of copper should be limited because of its toxicity to biological systems. Therefore, enrichment procedure by the Szilard–Chalmers process using copper phthalocyanine is recommended.

The procedures adopted are as follows. Neutron-irradiated copper phthalocyanine (α -form) is dissolved in concentrated sulfuric acid. The solution is poured on frozen redistilled water, and the mixture of a diluted solution of sulfuric acid and precipitated copper phthalocyanine is filtered using a glass filter. The filtrate of $^{64}\text{CuSO}_4$ in H_2SO_4 is neutralized with 10 M sodium hydroxide. Formed $^{64}\text{Cu(OH)}_2$ is filtered, and washed with water (50°C) three times, and is dissolved in a small volume of acetic acid. The solution is filtered again, and the final product is distributed to the users. Specific activity of ^{64}Cu ranges 1 – 2×10^6 Bq/mg on shipment.

24.4 Hot Atom Reactions in Gaseous Phase

This section describes reactions of recoil atoms in a gaseous phase. Tritium, halogens, and carbon will be involved.

24.4.1 Tritium

First, decay-induced reactions will be considered in simple compounds combined with tritium, RT. The potential energy curve obtained by an ab initio MO calculation (Ikuta et al. 1977)

Fig. 24.5

RT \rightarrow RHe⁺ decay and potential energy curves

reveals stability of the RHe⁺ ion decayed from the compound RT in the event of β^- decay of tritium ($T \rightarrow {}^3\text{He}^+$).

As shown in Fig. 24.5 there are three cases; there exists a potential well for (I) and (II) and there is no well for (III) indicating that chemical bonding is not possible in this case. The transition from the bottom of the potential energy curve of compound RT to the curve of RHe⁺ determines the excess energy E shown in the figure. If E is not beyond the dissociation limit, R–He bonding will be stable (I), but if E is beyond the limit, then the bonding will be broken (II). Calculation shows that HHe⁺, LiHe⁺, and BeHHe⁺ are stable (I) after the β^- decay of HT, LiT, and BeHT, but OHHe⁺ dissociates (II) after the decay of OHT.

As there is no potential well for CH₃He⁺, fragmentation occurs (III). Similarly, after the β^- decay of C₂H₅T dissociation occurs as follows:

■ Fig. 24.6

O₂ scavenger effect on recoil tritium reaction with *i*-C₄H₁₀

These fragmentation paths were confirmed by Wexler (1961b) by means of mass spectroscopy. Hot tritium reactions in a gaseous phase are most interesting because they are relatively simple.

A part of hot tritium atoms produced in the gas phase can escape from the “hot” energy range and react with organics as thermalized ones. In order to study “hot” reactions, therefore, an oxygen scavenger is mixed to the reaction system to exclude thermal tritium atoms. Figure 24.6 shows the scavenger effect of oxygen in recoil tritium reaction with *i*-C₄H₁₀ (Rosenberg and Wolfgang 1964).

A hot reaction yield is not affected by the introduction of a scavenger, but greatly decreases by mixing with moderators such as He, Ne, Ar, Kr, and Xe. These rare gases do not take part in the hot reaction directly, but can contribute to the slowing down of the hot atom. As a result, the hot reaction yield of recoiling tritium decreases with increasing concentration of moderator rare gases. Figure 24.7 reveals a remarkable moderator effect of helium gas in the recoil tritium reaction with propane C₃H₈, especially at the higher concentration region (Rosenberg and Wolfgang 1964). It is clearly seen that the yields of HT, C₃H₇T, and others vanish at the limit of 100% added helium. Hot tritium reactions may be divided into three main types:

1. Hydrogen abstraction reaction: $T^* + RH \rightarrow HT + R$
2. Substitution reaction: $T^* + RX \rightarrow RT^* + X$ ($X = H, Cl, Br, \text{etc.}$)
3. Addition reaction: $T^* + >C=C< \rightarrow [>CT-C<]^*$

Hydrogen abstraction and substitution reactions usually make up 80–90% of the total reaction yield. The rest (10–20%) is the yield for organic compounds with smaller size. The HT/RT ratio increases with increasing number of carbon atoms in the target organic compound, and as a rule decreases with complexity of branching. Generally, isomerization of the compound does not occur by tritium attack. The yield of substitution of an alkyl radical decreases with an increase of the number of carbon atoms. In the case of recoil tritium reaction with unsaturated organic compounds, addition reaction results in further decomposition leading to the formation of a variety of organic compounds. For example,

■ Fig. 24.7

He moderator effect on recoil tritium reaction with C_3H_8 

Decomposition competes with stabilization (through collision with other molecules), and shows a pressure dependence. The decomposition to stabilization ratio decreases at increased pressure.

It is interesting to see the pressure dependence of hot tritium reaction in cyclobutane C_4H_8 . Recoil tritium attacks this molecule to give tritiated cyclobutane (substitution reaction) in an excited state, which either stabilizes by collision with a third body or decomposes into two molecules of ethylene. This is shown in the following scheme:

where S denotes stabilization and D decomposition. The S/D ratio depends on pressure because the intermediate C_4H_7T molecule de-excites by collision with cyclobutane molecules in the reaction system. An increase of pressure favors stabilization compared with decomposition. Inspection of pressure dependence gives some knowledge on the extent of excitation in the molecule. In this case, average excitation of 5 eV is deduced from the RRK (or RRKM (Rice-Ramsperger-Kassel-Marcus)) theory.

Similar experiments using various organic substances give mean excitation energy in recoil tritium reaction. [▶ Table 24.4](#) lists selected cases for such studies (Tominaga and Tachikawa 1981). Note that the recoil reaction of ^{18}F for fluorine gives the largest values around 10 eV.

In the abstraction reaction of recoil tritium, an important factor is binding energy (Tachikawa and Rowland 1968, 1969). The relation between the H-abstraction yield by recoil tritium (expressed by HT yield per C–H bonding) and the binding energy is shown in [▶ Fig. 24.8](#). It is clear that the higher the binding energy the lower the HT yield. Fluorine substitution of hydrocarbon results in shift of the curve to the higher energy side, but its tendency does not change so much. The same relation is confirmed in the case of Si–H and N–H bonds (Tominaga and Rowland 1969).

For the H substitution reaction of recoil tritium, binding energy also plays an important role. In the $T + CH_3X$ reaction, where $X = SH, NH_2, Cl, OH,$ and F , the yield of substituted CH_2TX increases with binding energy of C–X. This is due to weakening of the C–H bond by introduction of X.

The HT yield linearly correlated (Tang et al. 1971) with proton nuclear magnetic resonance (NMR) chemical shift, indicating the importance of electronic density effect in the reaction.

In the tritium reaction, the following kinds of isotope effects are known:

1. *Moderator isotope effect* due to different moderation efficiency on different molecules
2. *Probability integral isotope effect* due to different reaction probability per collision and different range of reaction
3. *Average energy isotope effect* due to difference of average reaction energy.

■ **Table 24.4**

Average excitation energy of recoil reaction products

Reaction	Molecule	Primary product	Secondary product	Average excitation energy (eV)
T/H	$c\text{-}C_4H_8$	$c\text{-}C_4H_7T$	C_2H_3T	5 ± 1
	CH_4	CH_3T	CH_2T	3.5 ± 1
	CH_3NC	CH_2TNC	CH_2TNC	> 4
	CH_3CF_3	$CH_2T CF_3$	$CHT=CF_2$	4.7 ± 1
T/D	$c\text{-}C_4D_8$	$c\text{-}C_4D_7T$	C_2D_3T	5 ± 1
T/ CH_3	$C_4H_6(CH_3)_2$	$C_4H_5T(CH_3)_2$	$CH_2=CHT$	6–8
T + olefin	$CH_2CHCH_2CH_3$	$CH_2TCH CH_2CH_3$	$CH_2TCH=CH_2$	≤ 0.5
$^{18}F/F$	CF_4	$CF_3^{18}F$		≥ 10
	CH_3CF_3	$CH_3CF_2^{18}F$	$CH_2=CF_2^{18}F$	8.3 ± 1.5
	$c\text{-}C_4F_8$	$c\text{-}C_4F_7^{18}F$	several	10 ± 2
	$c\text{-}C_3F_6$	$c\text{-}C_3F_5^{18}F$	$CF_2=CF^{18}F$	~ 10
$^{18}F/H$	CH_3CF_3	$CH_2^{18}FCF_3$	$CH^{18}F=CF_2$	6.3 ± 1.0

■ Fig. 24.8

C–H binding energy and HT abstraction yield (per bond)

Of these isotope effects, (1) moderator isotope effect and (3) average reaction energy isotope effect can be eliminated when experiments are performed at a high concentration of rare gas moderator. Therefore, use of a large amount of rare gas moderator (e.g., 90% Ar) is recommended to observe (2) the probability integral isotope effect, which is the most interesting one for hot atom chemists.

In [Table 24.5](#) (Wolfgang 1965; Seewald et al. 1968; Smail and Rowland 1968; Chou and Rowland 1971; Tachikawa and Yanai 1972; Saeki and Tachikawa 1973; Numakura et al. 1973; Numakura and Tachikawa 1973) several examples of the isotope effect experimentally obtained are listed. The effect ranges between 1.25 and 1.41 for recoil tritium substitution reaction, but is much larger (3.1–7.2) for photochemically produced tritium (2.8 eV) in hydrocarbon mixture gases.

In recoil tritium reaction with organic gases, kinetic theory analysis proposed by Estrup and Wolfgang (1960) is worth mentioning. They assumed that the recoil atom slows down through elastic collisions, but in many existing gases elastic collision was recognized to be a rather poor approximation. Therefore, the results obtained from this analysis showed deviations from experiments. The essence of this theory is briefly described in the followings.

Table 24.5

Reactive isotope effect of hot atom reaction

Reacting atom	Type of reaction	Compound	Isotope effect
Recoil T	H(D)-abstraction	CH ₂ D ₂	1.32 ± 0.01
		CH ₃ CD ₃	1.34 ± 0.01
		CH ₃ F-CD ₃ F	1.26 ± 0.05
		CH ₄ -CD ₄	1.28 ± 0.02
		H ₂ -D ₂	1.15 ± 0.04
	H(D)-substitution	(CH ₃) ₃ CH-(CD ₃) ₃ CH	1.41
		CH ₃ F-CD ₃ F	1.33 ± 0.04
		CH ₄ -CD ₄	1.31 ± 0.05
		<i>n</i> -C ₄ H ₁₀ , <i>n</i> -C ₄ D ₁₀	1.31 ± 0.05
		(CH ₃) ₃ CH-(CH ₃) ₃ CD	1.25
	F-substitution	CH ₃ F-CD ₃ F	1.40 ± 0.06
Recoil ⁸² Br	H(D)-abstraction	CH ₄ -CD ₄	2.7 ± 0.3
		C ₂ H ₆ -C ₂ D ₆	1.6 ± 0.2
		C ₃ H ₈ -C ₃ H ₂ D ₆	1.5 ± 0.2
		C ₃ H ₈ -C ₃ D ₂ H ₆	1.5 ± 0.2
2.8 eV T (photochemical)	H(D)-substitution	CH ₄ -CD ₄	7.2 ± 0.2
		C ₂ H ₆ -C ₂ D ₆	5.6 ± 0.2
		CH ₂ D ₂ -CD ₄	3.1 ± 0.3
		CH ₂ D ₂	1.06 ± 0.1
		CHD ₃	1.2 ± 0.3

A recoil atom produced by nuclear reaction undergoes many collisions with surrounding molecules, and loses a great part of its kinetic energy, until the latter drops to E_1 , at which the hot atom is slow enough to get a chance to initiate a hot atom reaction with one of the molecules. If the hot atom escapes reaction, it keeps slowing down by further collisions to energy E_2 below which hot atom reaction is no more possible. In a multicomponent system, the total probability of hot atom reactions (considering all possible reactants and products) is expressed as

$$P = \sum_j \int_{E_2}^{E_1} f_j p_j(E) n(E) dE \quad (24.22)$$

where f_j is the relative collision probability of the hot atom with a molecule of component j , $p_j(E)$ is the reaction probability of the hot atom with the molecule of component j per collision, and $n(E)dE$ is the total collision number of hot atoms with energy between E and $E + dE$. The collision density $n(E)$ is expressed as

$$n(E) = -\frac{1}{\alpha E} \exp \left(-\sum_j \int_E^{E_2} \frac{f_j p_j(E)}{\alpha E} dE \right) \quad (24.23)$$

where α is the *mean logarithmic energy loss* per collision while the hot atom is slowing down.

For a mixture of a *single* reactant and a moderator, the subscript j can be omitted and (using some simplifying assumptions) one gets for the production probability of all possible products:

$$P = 1 - \exp\left(-\frac{f}{\alpha}I\right) \quad (24.24)$$

where I is called the *reactivity integral*:

$$I = \int_{E_1}^{E_2} \frac{p(E)}{E} dE. \quad (24.25)$$

The parameter α is a linear combination of two components:

$$\alpha = f\alpha_{\text{reactant}} + (1-f)\alpha_{\text{moderator}}. \quad (24.26)$$

Inserting [Eq. \(24.26\)](#) into [Eq. \(24.24\)](#), the following formula is obtained:

$$-\frac{1}{\ln(1-P)} = \frac{\alpha_{\text{reactant}}}{I} + \frac{\alpha_{\text{moderator}}}{I} \left(\frac{1-f}{f}\right). \quad (24.27)$$

Using the above equation, the parameters can be determined graphically from experimental data. If, for example, $-1/\ln(1-P)$ is plotted against $(1-f)/f$, then the slope will be equal to $\alpha_{\text{moderator}}/I$ and the intercept to $\alpha_{\text{reactant}}/I$.

Staying with binary mixtures of the moderator-plus-reactant type, in the more general case the hot atom can produce several different products with the reactant. Such products and their characteristic parameters will be identified by the new subscript i . The probability $p(E)$ shown by [Eq. \(24.25\)](#) is now given as the sum of the partial probabilities $p_i(E)$ characterizing the individual reactions: $p(E) = \sum p_i(E)$. After substituting the analogue of [Eq. \(24.23\)](#) into the analogue of [Eq. \(24.22\)](#), series expansion yields for the formation probability P_i of the i th product:

$$P_i = \frac{f}{\alpha} I_i - \frac{f^2}{\alpha^2} K_i + \dots \quad (24.28)$$

where I_i is the *reactivity integral* for the i th product:

$$I_i = \int_{E_1}^{E_2} \frac{p_i(E)}{E} dE \quad (24.29)$$

and K_i is the *ith shadowing parameter*:

$$K_i = \int_{E_1}^{E_2} \frac{p_i(E)}{E} \left(\int_E^{E_2} \frac{p(E)}{E} dE \right) dE. \quad (24.30)$$

Note that the second integral in the shadowing-parameter formula contains $p(E) = \sum p_i(E)$ rather than $p_i(E)$.

The parameters α , I_i , and K_i can be determined graphically from experimental data in a similar way as mentioned after [Eq. \(24.27\)](#). Using now [Eq. \(24.28\)](#), $\alpha P_i/f$ is plotted against f/α . This graph gives I_i as an intercept and K_i as a slope. Typical I and K (actually I_i and K_i) values are shown in [Table 24.6](#).

■ Table 24.6

Reactivity integral I and shadowing parameter K in hot tritium reaction with hydrocarbons

Reactant	Product	$I(\text{He})$	$K(\text{He})$	Reactant	Product	$I(\text{He})$	$K(\text{He})$
CH_3	HT	0.35	0.07	$n\text{-C}_4\text{H}_{10}$	HT	2.34	5.10
	CH_3T	0.61	0.35		CH_3T	0.094	0.16
	CH_2T	0.13	0.087		$\text{C}_2\text{H}_3\text{T}$	0.095	0.21

	CH_3T	0.07	0.10		$\text{C}_3\text{H}_7\text{T}$	0.034	0.038
	$\text{C}_2\text{H}_3\text{T}$	0.035	~ 0		$n\text{-C}_4\text{H}_9\text{T}$	0.77	0.25
	$\text{C}_2\text{H}_5\text{T}$	0.57	0.10	$i\text{-C}_4\text{H}_{10}$	HT	3.15	11.3
					$i\text{-C}_4\text{H}_9\text{T}$	1.00	0.25
					others	0.50	0.95

The threshold energy and the excitation function of hot hydrogen reactions are interesting from the physicochemical point of view. Photolysis of DI or DBr gives a hot D atom, which is able to react with hydrogen:

Using this reaction, White and Kuppermann (1966) obtained a threshold energy of 0.33 ± 0.02 eV for the D-abstraction reaction. Similarly, Dubrin and coworkers (Rebick and Dubrin 1970; Gann et al. 1971) studied D-abstraction reaction by photochemically produced H in deuterated butane.

They obtained a threshold energy of 0.35 ± 0.02 eV for the secondary D atom (0.45–0.55 eV for the primary D atom).

Threshold energy for hydrogen substitution reaction is more difficult to measure. Chou and Rowland (1969) used photolysis of TBr to obtain hot tritium atoms for the substitution reaction. They compared the yield of substituted CD_3T in methane to the DT abstraction yield whose threshold energy is known to be smaller. The ratio substitution/abstraction was extrapolated to zero at which the threshold value of energy for substitution was determined to be 1.5 eV.

Wolfgang and his coworker (Menzinger and Wolfgang 1969) studied threshold energy of substitution products in $\text{T}^* + \text{C}_6\text{H}_{12}$ (solid cyclohexane) reaction using a tritium beam accelerator. For simple substitution, the threshold energy is about 0.5 eV. However, for the products (n -hexane-T and hexane-T) for which C–C bond rupture is required, it is about 4.5 eV.

24.4.2 Halogens

In hot atom chemistry of halogens it is known that there exists an interesting case in which electronic charge on the recoil atom plays an important role. Rack and Gordus (1961)

irradiated a mixture of methane and iodine vapor (and moderator gases) with nuclear-reactor neutrons.

The recoil atoms ^{128}I produced by the reaction $^{127}\text{I}(n,\gamma)^{128}\text{I}$ distributed among $\text{CH}_3^{128}\text{I}$ (54.4%), $\text{CH}_2^{128}\text{I}$ (1%), and inorganic species ($\text{H}^{128}\text{I} + \text{I}^{128}\text{I}$, 45%) when no moderator gas was added. Mixing of moderator gases Ne, Ar, or Kr changed the yield of $\text{CH}_3^{128}\text{I}$ to 36% at 100% moderator concentration. On the other hand, mixing of Xe remarkably changed it to the limit of 11% as shown in [Fig. 24.9](#). This specific feature of recoil ^{128}I reaction with methane could be interpreted as follows:

Part A. 18.4% hot reaction affected by moderators.

Part B. 25% thermal reaction of $\text{I}^+(\text{}^1\text{D}_2)$, $^{128}\text{I}^+ + \text{Xe} \rightarrow ^{128}\text{I} + \text{Xe}^+$ (charge transfer reaction)

Part C. 11% thermal reaction of ^{128}I or I^+ ($^3\text{P}_2$, $^3\text{P}_1$, $^3\text{P}_0$).

Importance of ion-molecule reaction in a gas phase was recognized in this recoil atom reaction. A similar study on a bromine-methane mixture was performed, but no contribution of charge was found.

An interesting difference of decayed atom behavior between the decays $^{80\text{m}}\text{Br} \rightarrow ^{80}\text{Br}$ and $^{82\text{m}}\text{Br} \rightarrow ^{82}\text{Br}$ was studied using Br_2 and HBr systems. The decay schemes for $^{80\text{m}}\text{Br}$ and $^{82\text{m}}\text{Br}$ are shown in [Fig. 24.10](#).

In $^{80\text{m}}\text{Br}$ decay there are two steps, one having a large conversion coefficient $e_K/\gamma (= 298)$ and the other a small one $e_K/\gamma (= 1.6)$. The first step of decay results in high charge that is then neutralized during the lifetime 7.4 ns of the intermediate level. The cause of the high charge is the Auger process that follows the emission of conversion electron from the radiobromine atom. In the $^{80\text{m}}\text{Br}-\text{Br}(\text{Br}_2)$ system, a part of the charge will be transferred to the partner atom, and the Br-Br bond will be broken by electric repulsion, and $^*\text{Br}$ will acquire kinetic energy. Most of the electric charge will be neutralized during the lifetime of 7.4 ns at the intermediate level, but the kinetic energy will survive. The second decay to the final ^{80}Br level from the intermediate level with a conversion factor $e_K/\gamma (= 1.6)$ produces both charged ^{80}Br and neutral ^{80}Br with kinetic energy. Therefore, ^{80}Br undergoes hot atom chemical reaction with methane to give $\text{CH}_3^{80}\text{Br}$ and therefore the yield will show moderator effect against Kr concentration

Fig. 24.9

Chemical effects of $^{127}\text{I}(n,\gamma)^{128}\text{I}$ reaction in methane

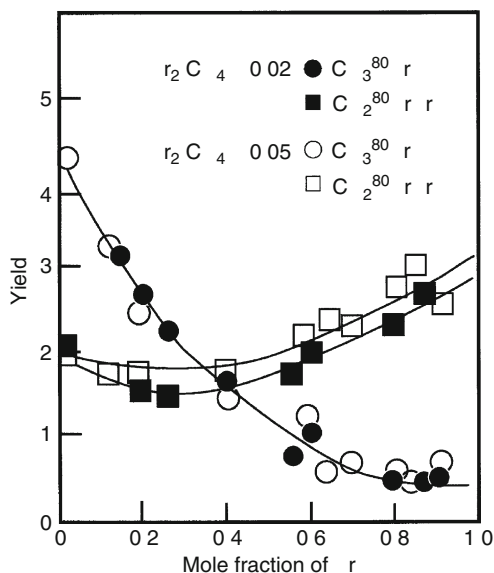

■ Fig. 24.10

Decay schemes for ^{80m}Br and ^{82m}Br . The ratios presented are internal conversion coefficients

■ Fig. 24.11

Kr moderator effect on hot atom chemical reaction products in $^{80m}\text{BrBr}-\text{CH}_4$ mixtures

(► Fig. 24.11). A part of ^{80}Br with electric charge reacts with methane to give $\text{CH}_2\text{Br}^{80}\text{Br}$, but no moderator effect is seen in this case.

On the other hand, in H^{82m}Br the decay has only one step (► Fig. 24.10) and the decayed atom ^{82}Br will acquire high charge. But after charge redistribution between H and ^{82}Br , the ^{82}Br has little kinetic energy because of its larger mass compared to H (see ► Sect. 24.2.1), and the charge remains on the ^{82}Br atom. For this reason, ^{82}Br reaction with CH_4 does not show a moderator effect (► Fig. 24.12) for any of the products, that is, $\text{CH}_2\text{Br}^{82}\text{Br}$ and $\text{CH}_3^{82}\text{Br}$ (Yagi et al. 1973). Note, however, that for higher concentration of the Kr moderator, probable formation of krypton clusters involving charged bromine increases the yield of the $\text{CH}_2\text{Br}^*\text{Br}$ component.

Fig. 24.12

Kr moderator effect on hot atom chemical reaction products in $\text{H}^{82\text{m}}\text{Br-CH}_4$ 

24.4.3 Carbon

Radioactive carbon can be produced through various nuclear reactions (Stöcklin 1969; Tachikawa 1975). Carbon-11 hot atom reactions are relatively known. Wolfgang (1965) postulated that recoil ^{11}C was obtained by neutron abstraction reaction of carbon ^{12}C , and this energetic carbon could be led into a reaction chamber filled with organic gases. The state of ^{11}C in the reaction region is mostly neutral $\text{C}(^3\text{P})$, but its smaller part consists of $\text{C}(^1\text{D})$ and $\text{C}(^1\text{S})$. ^{11}C reacts with alkanes (e.g., with ethane) as follows.

This is known as insertion reaction of a hot carbon atom. The product further changes to alkane and alkyne type compounds.

In the case of insertion of ^{11}C to alkenes, the following reactions take place.

The ^{11}C reaction with cyclopropane gives acetylene and ethylene.

24.5 Hot Atom Reactions in Liquid Phase

Hot atom reaction in a liquid phase may be characterized by the “cage effect,” which increases retention (parent chemical form). The hot atom produced by nuclear reaction interacts with surrounding atoms or molecules that form a cage to confine motion of the recoil atom in a liquid phase.

In ▶ [Table 24.7](#) ^{38}Cl -labeled product distributions of neutron-irradiated propyl chloride ($\text{C}_3\text{H}_7\text{Cl}$) are shown for gaseous and liquid phases. Comparison of the results by gaschromatographic separation showed that the organic yield is considerably larger in the liquid phase than in the gas phase, in particular for the case of retention (Willard 1953).

■ **Table 24.7**

^{38}Cl -labeled compound formation by (n,γ) reaction in isopropyl chloride and normal propyl chloride (%)

	<i>i</i> -C ₃ H ₇ Cl		<i>n</i> -C ₃ H ₇ Cl	
	Gaseous	Liquid	Gaseous	Liquid
Total organic yield	8.9	20.2	10.1	21.6
CH ₃ Cl	1.23	2.79	1.63	2.48
CH ₂ CHCl	1.03	1.09	1.18	1.01
CH ₃ CH ₂ Cl	0.11	0.50	0.35	1.01
CH ₃ CClCH ₂	0.22	0.46	0.04	0.11
CH ₃ CHClCH ₃	<u>2.32</u>	<u>6.75</u>	0.53	1.92
<i>cis</i> -CH ₃ CHCHCl	0.19	0.30	0.1	0.2
CH ₂ Cl ₂	0.52	0.93	1.24	1.66

CH ₃ CH ₂ CH ₂ Cl	0.14	0.73	<u>1.34</u>	<u>5.03</u>
CH ₃ CHCl ₂	0.21	0.93		0.06
CH ₃ CH ₂ CHCl CH ₃			0.21	0.17
CH ₃ CCl ₂ CH ₃	0.42	0.91		
CH ₂ Cl CH ₂ Cl			trace	0.13
CH ₃ CH ₂ CHCl ₂	0.84	3.45	0.51	2.05
CH ₂ Cl CH ₂ CH ₂ Cl			0.68	2.27
Others	1.34	1.39	1.87	1.54

Retention underlined

This is true for isopropyl chloride and normal propyl chloride. The products are complicated, but can be divided into several groups:

- Shortening of carbon chain: CH_3Cl , $\text{CH}_3\text{CH}_2\text{Cl}$
- Elongation of carbon chain: $\text{CH}_3\text{CH}_2\text{CH}_2\text{CH}_2\text{Cl}$
- Double bond formation: $\text{CH}_2=\text{CHCl}$, $\text{CH}_3\text{CH}=\text{CH}_2$
- Doubly chlorinated compounds: CH_2Cl_2 , etc.
- Isomerization

It is concluded from the results that recoil chlorine ^{38}Cl recombines with its original partner or replaces a chlorine atom of the neighboring molecule (formation of retention); ^{38}Cl attacks a C–C bond to give various kinds of radicals; ^{38}Cl replaces an H atom, and HCl or H_2 elimination occurs from the intermediate in the hot atom reaction.

In the presence of a radical scavenger Br_2 , the thermal reaction component in the hot atom reaction is suppressed. By changing the concentration of Br_2 , the hot reaction component can be obtained as an extrapolated intercept in a scavenger curve as shown in [Fig. 24.13](#) (Milman and Shaw 1957).

The hot reaction yield, namely, decreases linearly with the concentration of the scavenger added, causing a decrease of concentration of ethyl bromide. On the other hand, thermal reaction drops rapidly by addition of the scavenger Br_2 . [Figure 24.13](#) indicates a large contribution of thermal reaction in ethyl bromide.

When comparing recoil atom reaction yields of (n,γ) and $(n,2n)$ reactions, there is a distinct difference in the thermal reaction yield, whereas little if any difference can be observed in the hot reaction yield. Note that an $(n,2n)$ reaction provides recoil energy $10^2 - 10^3$ times larger than that an (n,γ) reaction. Probably this result indicates a difference of thermal radical concentration in the cages formed along the track of the recoil atom. As hot reactions occur at the end of the recoil track after slowing down and is not affected by recoil energy so much. This is shown in [Fig. 24.14](#) for the $^{82\text{m}}\text{Br}$ recoils produced by (n,γ) and $(n,2n)$ reactions (Cole et al. 1966).

Other examples of scavenger effect are recognized in benzene solutions of cobalt-acetylacetonate complex $\text{Co}(\text{acac})_3$. Addition of FeCl_3 , AlCl_3 , CuCl_2 , NiCl_2 , CoCl_2 , and MgCl_2

Fig. 24.13

■ Fig. 24.14

Comparison of organic yields of $(n,2n)$ and (n,γ) reactions

as scavenger salts in the complex solutions drastically drop the $^{60}\text{Co}(\text{acac})_3$ yield (retention) (Tominaga 1975).

24.6 Hot Atom Reaction in Solid Phase

Solid systems are more complicated and more specific in many respects than gaseous and liquid systems. Some special features concerning hot atom chemistry in solids are noted as follows.

1. There is a threshold energy (appearance energy) larger than the typical Frenkel pair formation energy (~ 25 eV).
2. Annealing (thermal or radiational) after irradiation alters chemical form distribution of recoil products. This usually increases the yield of the parent chemical form (retention).
3. Some features specific to solid matrices affect the recoil product distribution; crystal structures, defects introduced into crystals, etc., play important roles in determining chemical fates of recoil atoms.

24.6.1 Appearance Energy

The relation between recoil energy and hot atom reaction yield is a question of fundamental importance in a solid system, but no answer had been given until Yoshihara and Kudo (1970) proposed use of (γ,γ') reaction in an indium complex in 1970. Controlling energy of γ -rays from a linear electron accelerator, a separable yield of $^{115\text{m}}\text{In}^{3+}$ from a bulk of irradiated In-EDTA complex was obtained. As shown in Fig. 24.15, the yield of $^{115\text{m}}\text{In}^{3+}$ rises at a threshold of about 60 eV, increases until 200 eV, and stays almost constant (20%) above 200 eV.

Fig. 24.15

Appearance energy of $^{115m}\text{In}^{3+}$ in various In-complexes

This trend was further confirmed in similar indium and lutetium complexes by the (γ, γ') nuclear excitation (Yoshihara et al. 1970, 1977; Yoshihara and Mizusawa 1972). The threshold energy (appearance energy) larger than Frenkel pair formation (~ 25 eV) indicates participation of chemical factors in the moment of recoil reaction in solids. They proposed a hot atom reaction model involving three reaction zones: (1) the region in which recoil energy is under the appearance energy and the recoil atom always recombines with its original partner, (2) the intermediate region in which recoil energy is above the appearance energy and the recoil atom escapes from recombination reaction to give “retention,” and (3) the region in which the recoil atom attacks surrounding molecules to give a fragmentary component with a constant probability. Namely, region (1) may be regarded as a sink for the recoil atom and in region (3) free attacking of the recoil atom to the surroundings is considered. Saturation of the yield suggests that at the end of its track the recoil atom reacts with its partner in the same manner, irrespective of its (initial) recoil energy. Region (2) is an intermediate one before the recoil energy reaches region (3).

24.6.2 Phosphorus Hot Atom Chemistry

Selected topics will be described on solid hot atom chemistry of phosphorus (^{32}P). The recoil atom produced in phosphate by (n, γ) reaction has relatively large energy (max. 1.05×10^3 eV) and is distributed in a variety of compounds.

Lindner and Harbottle (1961) irradiated various phosphates (K, Na, NH_4 , and Li salts of phosphate, both anhydrous and hydrated) with neutrons at low temperature (-78°C) in a nuclear reactor. After the irradiated phosphates were dissolved in water, the solution was submitted to the analysis using paper electrophoresis. As shown in Fig. 24.16, the recoil products contained many components. (A) tripolyphosphate, (B) $\text{P}^5\text{-O-P}^5\text{-O-P}^5$, (B) pyrophosphate, $\text{P}^5\text{-O-P}^5$, (C) unknown, probably two species, (D) isohypo-phosphate, $\text{P}^5\text{-O-P}^5$, (E) hypophosphate, $\text{P}^4\text{-P}^4$, (F) orthophosphate, P^5 , (G) diphosphate, $\text{P}^4\text{-P}^2$ (and possibly another species), (H) phosphite, P^3 , and (I) hypophosphite, P^1 .

The variety of compounds thus obtained appeared to indicate chemical specialties of the reaction zone. “Hot zone” concept was proposed by Seitz and Koehler (1956) in solid-state physics and it was also discussed by Harbottle and Sutin (1958) from the viewpoint of hot atom chemistry. The interesting phenomena of specific labeling of ^{32}P at the P^3 position of

■ Fig. 24.16

Separation of ^{32}P recoil products in neutron-irradiated $\text{Na}_2\text{HPO}_4 \cdot 7\text{H}_2\text{O}$ by paper electrophoresis. See text for the notation

isohypophosphate $\text{P}^5\text{-O-P}^3$ and at the central position of tripolyphosphate $\text{P}^5\text{-O-P}^5\text{-O-P}^5$ (80%) were inconsistent with a uniformly melting domain around the recoil atom, and with simple sequences of ligand loss.

The reaction zone in ^{32}P hot atom reaction includes at least three phosphorus atoms in the above case. Formation of larger polyphosphates (tetra to hexa) was reported by Nakamura et al. (1970) by ion exchange chromatography in neutron-irradiated phosphate.

In the similar systems, annealing (thermal and radiation) processes were studied by Claridge and Maddock (1963a, b). It was revealed that thermal annealing conversion of $\text{P}^5\text{-O-}^{32}\text{P}^3$ into $^{32}\text{P}^3$ took place at low temperature and polymeric $^{32}\text{P}^5$ species changed into $^{32}\text{P}^3$ at higher temperature. Radiation annealing proceeded somewhat differently from thermal annealing. The most prominent processes were the conversion of $^{32}\text{P}^1$ into $^{32}\text{P}^3$ and $\text{P}^5\text{-O-}^{32}\text{P}^3$ into $\text{P}^5\text{-O-}^{32}\text{P}^5$.

24.6.3 Other Oxyanions

There are many examples of hot atom chemical studies on oxyanions. Among them permanganates, chromates, chlorates, bromates, iodates (and related halogenoxy acid salts) are relatively well known.

After the pioneering work by Libby mentioned in ▶ Sect. 24.1 the valence change of the target element and the appearance of separable fractions were noticed. In the case of

neutron-irradiated permanganate, $^{56}\text{Mn}^{2+}$ and $^{56}\text{MnO}_2$ could be separated from $^{56}\text{MnO}_4^-$ (retention) (Apers 1979). Very careful analytical treatment using double tracer technique disproved the presence of MnO_2 at the recoil event (Collins and Collins 1979). This shows that the chemical species formed at the moment of dissolution.

In the case of ^{51}Cr recoils in neutron-irradiated chromates, most prominent chemical species are chromic Cr(III) and chromate Cr(VI). A review (Collins and Collins 1979) described their chemical behavior from various sides. In spite of apparent simplicity of chromium hot atom chemistry, there are many problems that are not easily solved. The search for the presence of Cr(II) was not successful. In some papers chromium species are classified as Cr(VI), Cr(III)-monomer, Cr(III)-dimer, Cr(III)-trimer, and Cr(III)-polymer, but dissolution before analytical procedure made the initial processes of recoil too much complicated.

Hot atom chemistry of salts of halogen oxyanions has been studied by many authors (Owens 1979) since the Roman group led by Fermi (Amaldi et al. 1935) dealt with it. Boyd and Larson (1968) noticed that the BrO_3^- retention is little dependent on its partner cation but the yield of $^{82}\text{BrO}_2^-$ and $^{82}\text{BrO}^-$ are strongly dependent on the cation. It was found in a variety of bromates that the retention of $^{80\text{m}}\text{Br}$, ^{82}Br , and ^{78}Br was in a good correlation with the electron affinity of the cations (Saito et al. 1965).

24.6.4 Complexes of Cobalt

Hot atom chemistry of cobalt complexes was intensively studied (Tominaga and Saito 1979). Chemical varieties of recoil products found in cobalt complexes of cyano, ammine, and ethylenediamine ligands are worth mentioning. For example, neutron irradiation of hexamminecobalt(III) nitrate $[\text{Co}(\text{NH}_3)_6](\text{NO}_3)_3$ produces $[\text{Co}(\text{NH}_3)_6]^{3+}$, $[\text{Co}(\text{NH}_3)_5\text{NO}_2]^{2+}$, *cis*- and *trans*- $[\text{Co}(\text{NH}_3)_4(\text{NO}_2)_2]^+$, $[\text{Co}(\text{NH}_3)_3(\text{NO}_2)_3]$, $[\text{Co}(\text{NH}_3)_2(\text{NO}_2)_4]^-$, and Co^{2+} , which were detected by paper electrophoresis (Saito et al. 1962).

In neutron-irradiated $[\text{Co}(\text{NH}_3)_5\text{X}]\text{Br}_{2,3}$ a ligand displacement product $[\text{Co}(\text{NH}_3)_5\text{Br}]^{2+}$ was formed, and the yield of this $^{*}\text{Br}$ for displacement correlated with the stability of $[\text{Co}(\text{NH}_3)_5\text{X}]\text{Br}_{2,3}$ as indicated by optical absorption spectra (Saito et al. 1961).

Chemical form distribution of ^{57}Co decayed from ^{57}Ni was compared with that of ^{57}Co produced by $^{58}\text{Ni}(\gamma, p)^{57}\text{Co}$ reaction in the same substance of $[\text{Ni}(\text{NH}_3)_6]\text{Cl}_2$ (Yoshihara 1964). Initial distribution and annealing processes were found fairly different for both cases. This fact suggests that the size of fragmentation zone plays a role in recombination processes.

In neutron-irradiated $\text{Co}(\text{acac})_3$, formation of $^{60}\text{Co}(\text{acac})_2$ was confirmed by Sakanoue and his coworker (Amano and Sakanoue 1974) by sublimatography.

24.6.5 Rhenium and Osmium Compounds

An important contribution to solid hot atom chemistry came from H. Müller's laboratory in Freiburg with rhenium (osmium) compounds (Müller 1979). Müller performed his studies on mixed crystal systems involving rhenium, osmium, etc., for many years. An advantage of rhenium (n, γ) recoil reaction is its relatively small recoil energy (E_{max} : 102 eV, average energy may be much lower for ^{186}Re), which results in a reaction zone with a radius of ca. 0.5 nm (one or two unit cells of the crystal lattice).

■ Fig. 24.17

Proportions of the different hexabromochlororhenates resulting from the $^{187}\text{Re}(\gamma, n)^{186}\text{Re}$ reaction as a function of the mixed crystals composition

In the mixed crystal system $\text{K}_2\text{ReBr}_6\text{--K}_2\text{SnCl}_6$, ^{186}Re produced by (γ, n) reaction distributes among various mixed ligand compounds $\text{ReBr}_n\text{Cl}_{6-n}^{2-}$ ($n = 0 \dots 6$) and can be separated by thin layer chromatography. As shown in Fig. 24.17, the distribution is nearly statistical with a slight preponderance of the chloride-containing form. Because of large recoil energy for the (γ, n) reaction (~ 10 keV, recoil range 10 nm) this behavior is not so strange. However, ^{186}Re produced by (n, γ) reaction has a different pattern of the distribution of $\text{ReBr}_n\text{Cl}_{6-n}^{2-}$ ($n = 0 \dots 6$) as seen in Fig. 24.18. It is interesting to see that at the dilution limit (extrapolated to zero) of K_2ReBr_6 with K_2SnCl_6 the $\text{ReBr}_n\text{Cl}_{6-n}^{2-}$ yields are not zero. This fact shows that the reaction zone is very small, and the reaction occurs near the original site where the $^*\text{Re}$ was generated. Müller discussed that this behavior of rhenium recoils could be explained in terms of the disorder model rather than the hot-zone model proposed by Harbottle and Sutin (1958).

Progressively piling up a huge amount of experimental data on these kinds of mixed crystal systems, Müller created the “*little disorder model*” using central Re recoil. As for halogen ligand recoil, the recoil ranges for (n, γ) reactions for bromine and chlorine are larger than that for rhenium, and its reaction zone is also larger.

He verified that there are two kinds of retention; one is primary retention at the original site and the other is billiard ball secondary retention. For the system $\text{K}_2\text{ReBr}_6\text{--K}_2\text{ReCl}_6$, $^{82}\text{Br}^-$ yield was 12%, primary retention 8%, billiard ball secondary retention 74%, and some products of “larger disorder” $[\text{Re}^{82}\text{Br}_n\text{Cl}_{5-n}]^{2-}$ ($n = 0 \dots 4$) were about 6% altogether.

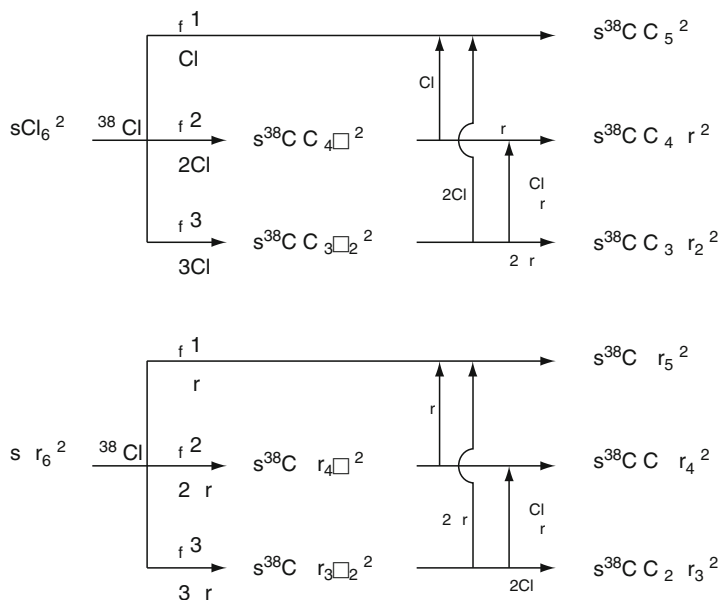

Then he succeeded in interpreting these product yields using a model called “Impact-induced Multiple Ligand Abstraction (IMULA).” Quantitative results were obtained for the system $\text{K}_2\text{OsBr}_6\text{--K}_2\text{SnCl}_6$ (^{82}Br produced by (n, γ) reaction) (Müller et al. 1984) and

■ Fig. 24.18

Yield of mixed hexachlorobromorhenates and perrhenate produced in neutron-irradiated $K_2ReBr_6-K_2SnCl_6$

$K_2OsBr_6-K_2SnCl_6$ (^{36}Cl produced by (n,γ) reaction) (Müller et al. 1986). In the latter case, the production of transient ligand vacancy complexes and their final fates resulting in mixed hexachlorobromometallate species are shown in the following scheme.

Using this scheme the calculated $[\text{Os}^{38}\text{ClCl}_4\text{Br}]^{2-}$ and $[\text{Os}^{38}\text{ClClBr}_4]^{2-}$ yield curves plotted against mixing fraction were in agreement with the experimental ones.

24.7 Implantation Reactions

Implantation reactions are interesting because of their similarity as regards reaction mechanisms to hot atom reactions. (However, some features are specific to recoil implantation reactions.) Ion implantation-induced chemical reactions have such features as well, but difficulty lies in keeping surface temperature as low as possible and in obtaining radioactive beams without contamination by other stable isotopes (which may result in severe damage in the target substance). These demerits restricted usefulness of ion implantation. Recoil implantation can be performed simply in the mixture of a recoil source and a catcher (receptor) material. In some cases, thin films of source and catcher could be combined in order to control recoil energy.

24.7.1 Ion Implantation

Ion implantation reaction using a mass spectrometer was first studied by Italian researchers Croatto and Giacomello. Since then implantation of ^{51}Cr in K_2CrO_4 (Andersen and Sørensen 1966), $^{32}\text{P}^+$, and $^{35}\text{S}^+$ in alkali halides (Freeman et al. 1967; Andersen and Ebbesen 1971; Kasrai et al. 1971), ^{57}Co in *trans*- and *cis*- $[\text{Co}(\text{en})_2\text{Cl}_2]\text{NO}_3$ (Andersen and Ostergaard 1968; Wolf and Fritsch 1969) and ^{64}Cu in copper phthalocyanine (Andersen and Ostergaard 1968) were investigated.

Studying chemical effects of ion implantation of ^{35}S into single crystal NaCl , it was found that the same chemical species S^{2-} , S^0 measured as CNS^- , SO_3^{2-} , and SO_4^{2-} were formed as those in $^{35}\text{Cl}(\text{n,p})^{35}\text{S}$ reaction in NaCl , but their percentages showed a little difference. Implantation angles to the crystal axis affected the chemical fate of $^{32}\text{P}^+$ in NaCl single crystals (Andersen and Ebbesen 1971).

In^+ was implanted into copper phthalocyanine, in which new synthesis of indium phthalocyanine was observed (Yoshihara et al. 1974a). The species thus formed was identical with that produced by β -decay synthesis using cadmium phthalocyanine (Yoshihara and Kudo 1969; Kudo and Yoshihara 1970).

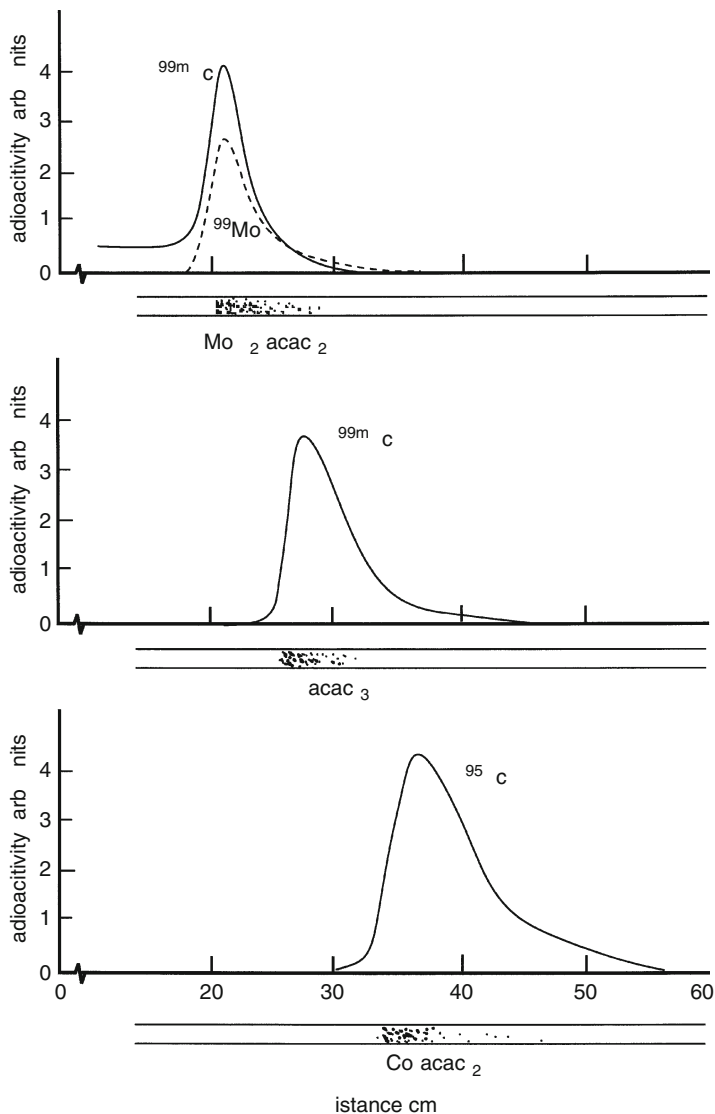

24.7.2 Recoil Implantation

Recoil implantation was first performed by Baumgärtner and Reichold (1961) for fission recoil synthesis of ruthenocene. This technique was applied to the synthesis of new compounds of technetium phthalocyanine (Yoshihara et al. 1974b) and $\text{Tc}(\text{II})(\text{acac})_2$ (Sekine and Yoshihara 1981). In the latter case, sublimatographic separation was effectively employed (► Fig. 24.19).

A “thin film technique” to control implantation energy is introduced in the study of energy dependence of product yield of implantation reaction (Miyakawa et al. 1992). For example, onto a palladium layer deposited on a mylar film, $\text{Rh}(\text{acac})_3$ is evaporated and this set of double layers of $\text{Pd-Rh}(\text{acac})_3$ is irradiated with γ -rays. In the Pd layer, ^{105}Rh is produced by

■ Fig. 24.19

Sublimatograms for (a) $\text{TcO}_2(\text{acac})_2$ produced by (n,γ) reaction in $\text{MoO}_2(\text{acac})_2$, (b) $\text{Tc}(\text{acac})_3$ produced by (γ,p) reaction in $\text{Ru}(\text{acac})_3$, and (c) $\text{Tc}(\text{acac})_2$ produced by recoil implantation of ^{95}Tc into $\text{Co}(\text{acac})_2 \cdot 2\text{H}_2\text{O}$

$^{106}\text{Pd}(\gamma,p) ^{105}\text{Rh}$ reaction, while ^{102}Rh is produced by $^{103}\text{Rh}(\gamma,n) ^{102}\text{Rh}$ in the $\text{Rh}(\text{acac})_3$ layer. Average recoil energy of ^{105}Rh is controlled by the thickness of palladium film and ^{105}Rh from the palladium film is implanted into the $\text{Rh}(\text{acac})_3$ layer with variable mean energy.

As shown in Fig. 24.20, the $^{105}\text{Rh}(\text{acac})_3$ yield increases with increasing mean implantation energy (MIE) up to 80 keV. On the other hand, for the inner recoil atom ^{102}Rh , the complex yield $^{102}\text{Rh}(\text{acac})_3$ is unchanged under the same irradiation conditions. Surprisingly,

■ Fig. 24.20

The substitution yield for Rh+Rh(acac)₃ reaction against the mean implantation energy (MIE)

the yield for implanted ^{105}Rh (2–7%) is one order of magnitude larger than that ($\sim 0.65\%$) for the inner recoil atom ^{102}Rh . This shows that implantation reaction yield is more enhanced compared to ordinary hot atom reaction. The reason for the yield enhancement is not fully understood, but a mathematically fitted curve suggests that a shock-wave-like action connected with collision cascades is exerted on the implanted atom at the top of the reaction site (Miyakawa et al. 1993; Matsue et al. 1995a; Yoshihara et al. 1996).

24.8 Other Topics in Hot Atom Chemistry

There have been so many published papers on hot atom chemistry that it is impossible to cover all of them in this section. Therefore, only the most important topics related to hot atom chemistry will be mentioned.

24.8.1 Hot Atom Chemistry in Space

It was pointed out by Rössler (1992) that hot or suprathermal reactions of H, C, N, O, etc., with frozen H_2O , NH_3 , CH_4 , CO, and other substances in space are important. The reactant may be either radioactive or nonradioactive. Hydrogen abstraction is typical of hot hydrogen, resulting in the formation of H_2 . Hot C, N, O can form CH, NH, and OH, and then CH_2 , CH_3 , and NH_2 successively. Hot oxygen can abstract O from oxygen-containing molecules. Replacement takes place in a nearly billiard ball collision manner. Addition can eventually cause fragmentation of the intermediate. Insertion occurs in O–H, N–H, C–C, N–N bonds to give various interesting products as shown in ▶ Table 24.8.

When the reaction takes place in a mixture matrix such as $\text{H}_2\text{O}-\text{CH}_4$ or $\text{H}_2\text{O}-\text{NH}_3-\text{CH}_4$ the products should have more variety. Thus, formation of more complicated large molecules is expected. The key materials of biomolecules can be formed in this manner. It is known that solar wind consists of 1 keV H^+ (95%), 4 keV He^{2+} (4%), 10 keV C^{6+} (0.19%), 13 keV O^{8+}

Table 24.8

Insertion of hot C, N, and O

Reaction to intermediate	Product formation		
	H-elimination	1,2-H transfer	H-uptake
$C + H_2O \rightarrow [HCOH]^*$	<u>CO</u> , COH, HCO	<u>H₂CO</u>	<u>CH₃OH</u>
$C + NH_3 \rightarrow [HCNH_2]^*$	HCN, <u>CN</u> , HNC	<u>CH₂NH</u>	<u>CH₃NH₂</u>
$C + CH_4 \rightarrow [HCCH_3]^*$	<u>C₂H₂</u> , C ₂	<u>C₂H₄</u>	<u>C₂H₆</u>
$N + H_2O \rightarrow [HNOH]^*$	<u>NO</u> , <u>HNO</u>		<u>NH₂OH</u>
$N + NH_3 \rightarrow [HNNH_2]^*$	<u>N₂</u>		<u>N₂H₄</u>
$N + CH_4 \rightarrow [HNCH_3]^*$	HNC, <u>CN</u> , CH ₂ NH		<u>CH₃NH₂</u>
$O + H_2O \rightarrow [HOOH]^*$	<u>O₂</u> , HO ₂		
$O + NH_3 \rightarrow [HONH_2]^*$	<u>NO</u> , <u>HNO</u>		
$O + CH_4 \rightarrow [HOCH_3]^*$	CO, HCO, HOC		

Underlined: experimentally observed

(0.05%), etc. And comets contain ices of H₂O, NH₃, CH₃, CO, CO₂, etc. Meeting of the two (causing ion implantation in solids) can produce various substances both inorganic and organic. Owing to the radiation effects in space, these substances may change further into biomolecule precursors. Although the origin of life has been sought for many years by a number of researchers, the goal of the study seems to be still far. However, its direction is promising. The knowledge accumulated in hot atom chemistry is no doubt important for such studies.

24.8.2 Hot Atom Chemistry for Radiopharmaceuticals

Hot atom chemical techniques are available in production of radiopharmaceuticals labeled with short-lived positron emitters such as ¹¹C, ¹³N, ¹⁵O, and ¹⁸F (Iwata and Wolf 1992). These radionuclides are used for positron emission tomography (PET). They can be easily produced with a small medical cyclotron using protons, deuterons, etc.

Such positron emitters can be produced right in the hospital using a small cyclotron (there exist “baby” cyclotrons!). The hot atom chemical processes are advantageous because the reaction to produce the aimed simple product labeled with a favorable positron emitter takes no time. Of course, for larger, complicated molecules the above products can only serve as starting materials. Examples of labeled compounds (precursors) involving hot atom reactions are listed in ▶ Table 24.9.

24.8.3 Some New Aspects Related to Hot Atom Chemistry

24.8.3.1 Quantum Mechanical Tunneling Effect

It is well known that at very low temperatures quantum mechanical tunneling effect plays a part in the chemical reaction of hydrogen. Miyazaki and coworkers (Fujitani et al. 1991;

	H_2^{18}O (enriched)	$^{18}\text{O}(\text{p},\text{n})^{18}\text{F}$

Kumagai et al. 1998; Aratono et al. 1998) studied this effect in the reaction of H, D, and T with hydrogen molecule (H_2 or D_2) and with mixtures of neopentane and *i*- C_4H_{10} (*c*- C_5H_{10}).

Recoil tritium produced by $^6\text{Li}(\text{n},\alpha)\text{T}$ reaction in enriched ^6LiF reacted with $\text{H}_2\text{-D}_2$ mixture at 4.2 K giving HT and DT as hydrogen abstraction products. From the isotope effect of the rate constants it was deduced that more than 90% of recoil T atoms react with hydrogen in the hot

energy range before thermalization. However, H atoms produced by the photolysis of HI or the radiolysis of *neo*-C₅H₁₂ in the mixture of *neo*-C₅H₁₂ and *i*-C₄H₁₀ react selectively with *i*-C₄H₁₀ in the thermal energy range, in which tunneling abstraction reaction by H atoms occurs. Less energetic T can be obtained from the ³He(n,p)T reaction. They studied the following abstraction reactions in liquid ³He – ⁴He media at 1.3 K:

and compared the isotope effects experimentally obtained. It was suggested that quantum mechanical tunneling abstraction dominantly occurs through van der Waals complex.

24.8.3.2 Molecular Rocket

Metallocenes are known to be included in cyclodextrin (CD) and these are called “inclusion complexes.” When neutrons or γ quanta irradiate them, recoil energy is given to the central metal atom of metallocene. The molecules become partly broken to give decomplexed metal,

■ Fig. 24.21

Possible processes occurring in the moment of recoil in metallocene β -cyclodextrin inclusion compounds

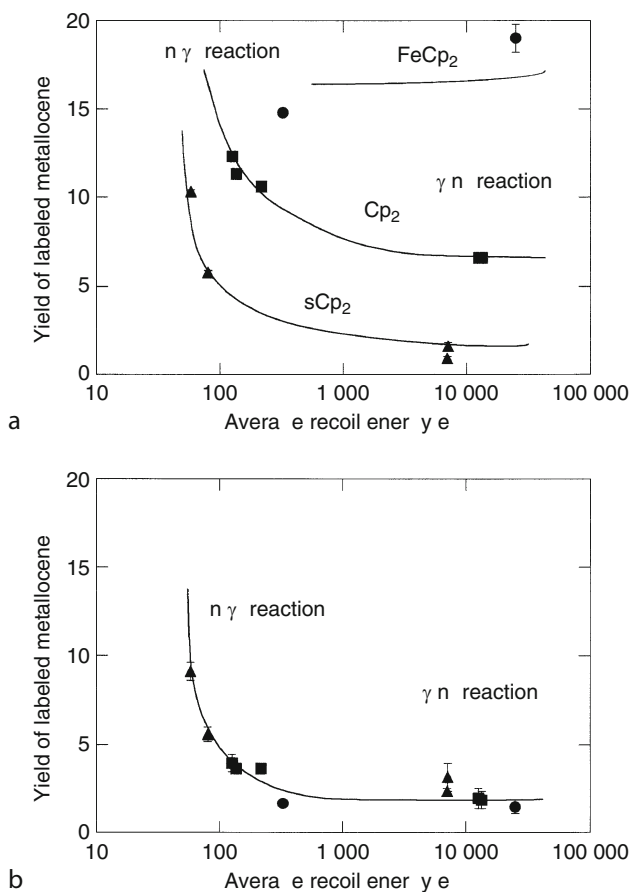

but partly retain their original structure. If excess energy is left in this retained metallocene molecule, it is expected that this molecule dashes out of the cyclodextrin cage just like a rocket.

Matsue et al. (1992, 1993) studied this “*molecular rocket*” phenomenon in metallocene–CD inclusion complex. The yield of unbroken ruthenocene molecules against recoil energy consists of two components of the molecular rocket: one directly ejected outside of the cyclodextrin cage, and the other once broken, but recombined rapidly in the CD cage, and then ejected from the CD cage (► Fig. 24.21). The latter component stays almost energy independent, while the former vanishes at higher energy (Matsue et al. 1995b; Yoshihara and Sekine 1997).

In ► Fig. 24.22a, the retention of metallocene is compared with (► Fig. 24.22b) that of metallocene-CD. Surprisingly, the retention of ferrocene, ruthenocene and osmocene can be plotted on one curve when metallocenes are included in CD (Yoshihara et al. 1994).

■ Fig. 24.22

The relation between retention and recoil energy: (a) metallocenes and (b) their β -cyclodextrin inclusion compounds

24.8.3.3 Fullerenes

The action of recoil atoms on fullerenes (C_{60} , C_{70} , etc.) has been studied recently (Braun and Rausch 2000; Nakahara et al. 2000). Some radionuclides with energy of nuclear recoil easily come to rest inside the fullerene. Braun and Rausch observed the formation of endohedral argon compound of fullerene $^{41}\text{Ar}@C_{60}$ during neutron irradiation of C_{60} in the presence of argon (Braun and Rausch 1995). They attributed their results to endohedral argon compound by implosion of C_{60} in argon nuclear recoil. ▶ Table 24.10 shows endohedral fullerene compounds reported.

Polymer formation of fullerene labeled with radionuclides was also observed. In a multi-tracer study using heavy-ion nuclear reaction of ^{12}C with ^{197}Au formation of new metallofullerenes (Zr, Hf, and Nb included in fullerene) was also reported.

Recently, a great interest was taken to the finding that the half-life of ^7Be in endohedral C_{60} ($^7\text{Be}@C_{60}$) was shortened by about 1% compared to that in Be metal (Ohtsuki et al. 2004).

■ Table 24.10

Labeling of fullerenes by nuclear recoil implosion

Nuclear reaction	Irradiated matrix	Facility	Endohedral fullerene	Reference
(n,γ)	C_{60} + adsorbed Ar	Nuclear reactor	$^{41}\text{Ar}@C_{60}$	Braun and Rausch (1998)
(n,γ)	$\text{Ar}C_{60}$	Nuclear reactor	$^{41}\text{Ar}@C_{60}$	Gadd et al. (1996)
(p,n)	$\text{Li}_2\text{CO}_3 + C_{60}$	Cyclotron	$^7\text{Be}@C_{60}$	Ohtsuki and Masumoto (1996)
(γ,αn)	C_{60}	Linac	$^7\text{Be}@C_{60}$	Ohtsuki and Masumoto (1996)
(n,γ)	Kr_1C_{60} , Xe_1C_{60}	Nuclear reactor	$^{83}\text{Kr}@C_{60}$, $^{125}\text{Xe}@C_{60}$	Gadd et al. (1997)
(n,γ)	Metal oxides + C_{60}	Nuclear reactor	Ho, Pr, La, Zn, $\text{Cu}@C_{60}$	Braun and Rausch (1998)
(d,2n)	$\text{KI} + C_{60}$, C_{70}	Cyclotron	$^{127}\text{Xe}@C_{60}$, $^{127}\text{Xe}@C_{70}$	Ohtsuki et al. (1998)
(d,2n)	$\text{KBr} + C_{60}$, C_{70}	Cyclotron	$^{79}\text{Kr}@C_{60}$, $^{79}\text{Kr}@C_{70}$	Ohtsuki et al. (1998)
(n,γ)	$\text{Xe}_{0.26}C_{60}$	Nuclear reactor	$^{131}\text{Xe}@C_{60}$	Gadd et al. (1998)
(γ,n)	$\text{Sb}_2\text{O}_3 + C_{60}$	Linac	$^{120,122}\text{Sb}@C_{60}$	Ohtsuki et al. (2001)
(d,2n)	"	Cyclotron	$^{121}\text{Te}@C_{60}$	Ohtsuki et al. (2001)
(d,2n)	$\text{As}_2\text{S}_3 + C_{60}$	Cyclotron	$^{75}\text{Se}@C_{60}$	Ohtsuki et al. (2002)
α decay	$^{224}\text{Ra} + C_{60}$	–	$^{212}\text{Pb}@C_{60}$	Diener et al. (2007)
(d,n)	$\text{Bi}_2\text{O}_3 + C_{60}$	Cyclotron	$^{210}\text{Po}@C_{60}$	Ohtsuki and Ohno (2005)
Ion implantation	$^{133}\text{Xe} + C_{76}$, C_{84}	Isotope separator	$^{133}\text{Xe}@C_{76}$, $^{133}\text{Xe}@C_{84}$	Watanabe et al. (2007)

The EC decay rate of ^7Be was further enhanced at 5 K (Ohtsuki et al. 2007). It was explained by the electron density effect at the Be nucleus position inside the C_{60} .

24.8.4 Impact of Hot Atom Chemistry on Other Research Fields

Impact of hot atom chemistry was seen in the study of reaction dynamics in its early days (1970s). See, for example, the international atomic energy agency (IAEA) report written by Y.T. Lee (1975).

Since 1981 (Harris and Kasemo 1981), hot atom reaction concepts have been adopted in the study of adsorption phenomena on surfaces. No radioactivity was used in these studies. Hot atoms of H, D, and O on surfaces have been studied experimentally (Yamanaka et al. 1999) and theoretically (Shalashilin and Jackson 1999).

In muonium chemistry, hot muonium (Mu^*) has been used for its similarity to hot hydrogen. Senba et al. (2000) studied hot atom reaction yield in $\text{Mu}^* + \text{H}_2$, and $\text{T}^* + \text{H}_2$ from quasiclassical trajectory cross sections on the Liu–Siegbahn–Truhler–Horowitz surface. Other examples are described in ► Chap. 28 on “Exotic Atoms and Muonium” in this Volume.

Interaction between energetic deuterium or tritium and wall materials such as graphite has been studied intensively in relation to nuclear fusion technology. For example, Okuno and coworkers (Morimoto and Okuno 2003; Oyaidzu et al. 2003) showed that deuterium implanted in highly oriented pyrolytic graphite revealed two kinds of C–D bonding (in sp^3 and sp^2 hybrid orbitals) as inspected by thermal desorption spectroscopy (TDS) and X-ray photoelectron spectroscopy (XPS).

Abstract: Mössbauer spectroscopy, based on the recoilless resonance emission and absorption of γ photons observed with certain atomic nuclei, is a powerful investigating tool in most disciplines of natural science ranging from physics to chemistry to biology. This nuclear method makes it possible to measure the energy difference between nuclear energy levels to an extremely high resolution (up to 13–15 decimals). This resolution is required to measure the slight variation of nuclear energy levels caused by electric monopole, electric quadrupole, and magnetic dipole interactions between the electrons and the nucleus. Mössbauer nuclides being at different microenvironments act as local probes for the sensitive detection of the hyperfine interactions. Such interactions reflect changes in the electronic, magnetic, geometric, or defect structure as well as in the lattice vibrations, serving as a basis for a variety of applications. In this chapter, the principles and some practical aspects of Mössbauer spectroscopy are described.

25.1 Principles of Mössbauer Spectroscopy

Mössbauer spectroscopy is based on the Mössbauer effect discovered by Rudolf Mössbauer (Mössbauer 1958a, b). The discovery was honored by the Nobel Prize in 1961.

Mössbauer effect is the recoilless (also called: recoil-free) nuclear resonance emission/absorption of γ rays (see Fig. 25.1). In the case of a nuclear transition, the de-excited nucleus is normally recoiled by the momentum of the γ photon emitted, which makes its resonance absorption impossible by another ground-state nucleus of the same type. In solids, however, recoilless photons can be emitted (and reabsorbed by another ground-state nucleus) with some probability.

A number of monographs and articles describe the basic aspects and applications of Mössbauer spectroscopy in detail (see, e.g., Kagan 1962; Goldanskii 1963; Frauenfelder 1962; Wertheim 1964; Abragam 1964; Wegener 1965; Gruverman 1965–1976; Danon 1968; Matthias and Shirley 1968; Goldanskii and Herber 1968; Shpinel 1969; Greenwood and Gibb 1971; Sano 1972; May 1971; Janot 1972; Kaipov 1976; Bancroft 1973; Bhide 1973; Cohen and

■ Fig. 25.1

Schematic representation of nuclear resonance based on the recoilless emission and absorption of a γ photon. The story that goes with the figure is this. A nucleus in excited state emits a γ photon with energy (E_0) equal to the difference between the energies of the excited and ground-state levels, and, subsequently, the same γ photon is absorbed resonantly by another nucleus in the ground state by transforming it to the excited state. This sounds rather trivial but in order to happen both the emission and the absorption of the photon must be a recoilless/recoil-free event (this is called the Mössbauer effect), because recoil of either nucleus would render the energy of the photon insufficient for the resonance to occur

Pasternak 1973; Gruverman and Seidel 1973; Gonser 1975a; Gibb 1976; Cohen 1976; Perlow 1977; Shenoy and Wagner 1978; Gütlich et al. 1978; Vértés et al. 1979; Cohen 1980; Gonser 1981; Mørup 1981; Stevens and Shenoy 1981; Thosar and Iyengar 1983; Long 1984; Herber 1984; Cranshaw et al. 1985; Long 1987, 1989; Vértés and Nagy 1990; Long and Grandjean 1993; Schatz et al. 1996; Long and Grandjean 1996, 1997; Vértés and Homonnay 1997; Fujita 1999). The Mössbauer Effect Reference and Data Index (MERDI) (Muir et al. 1958–1965; Stevens and Stevens 1966–) and Journal (MERDJ) serve as an important data source and contain a compilation of all references in the field.

25.1.1 Isomeric Transition Between Nuclear Levels

With regard to the nuclear resonance effect of γ rays, the (median) energy, E_0 , of the transition and the mean life, τ , of the excited state are very important parameters. The fact that the mean life of the excited state is finite – that the excited state sooner or later “decays” to the ground state according to the exponential law of decay (see [Chap. 7 in Vol. 1](#) on the “Kinetics of Radioactive Decay”) – causes a “blurring” of the supposedly discrete energy of the excited level. The energy of the excited nuclear levels is characterized by a $C(E_0, \Gamma/2)$ Cauchy distribution (see [Chap. 9 in Vol. 1](#) on the “Stochastics and Nuclear Measurements”) whose un-normalized density function is called a *Lorentzian* (or *Breit–Wigner*) curve in physics (Breit and Wigner 1936):

$$L(E) = A \frac{\Gamma}{2\pi} \frac{1}{(E - E_0)^2 + (\frac{\Gamma}{2})^2} = H \left(\frac{\Gamma}{2} \right)^2 \frac{1}{(E - E_0)^2 + (\frac{\Gamma}{2})^2} \quad (25.1)$$

where A is the area under the Lorentzian curve (i.e., for $A = 1$, $L(E)$ is a normalized $C(E_0, \Gamma/2)$ density function), H is the height of the Lorentzian at its maximum (i.e., at $E = E_0$), and $E_0 = E_e - E_g$ is the transition energy, i.e., the median difference between the energies of the excited state and the ground state. (The adjective “median” is used as a technical term here. The reason for avoiding the more usual term “mean” is that the underlying Cauchy distribution does not have a mean in the statistical sense; however, it *does* have a median.) Finally, Γ is the natural line width representing the full width at half maximum (FWHM) of the bell-shaped Lorentzian.

The *natural line width* Γ is also referred to sometimes as the “Heisenberg line width” because it obeys the following equation (see also [Eq. \(2.36\) in Chap. 2, Vol. 1](#), as well as remarks #62–64 in [Chap. 9, Vol. 1](#).):

$$\Gamma \tau = \hbar. \quad (25.2)$$

For the stationary ground state, the mean life is infinite, and [Eq. \(25.2\)](#) shows that such a state is indeed sharp having $\Gamma = 0$. For the excited state, on the other hand, the mean life is finite, so it will result in an energy uncertainty in the range of 10^{-12} to 10^{-5} eV for the states interesting from the point of view of Mössbauer spectroscopy.

Normally, the photons emitted in an isomeric transition will only have the sharp energy distribution of the excited state shown by [Eq. \(25.1\)](#) if the emission is recoilless. In general, however, there will be an energy loss E_R due to the recoil of the body that emits the radiation. (In the case of gases, this body is the nucleus (atom). With solids, the situation is more complex as it will be pointed out later on.)

To calculate E_R , consider an isolated nucleus of mass M that had been at rest before the decay took place and the photon got emitted. It follows from momentum conservation that $p_N = p_\gamma$, where p_N is the magnitude of the momentum of the recoiled nucleus and $p_\gamma = E_\gamma/c$ is that of the photon. The recoil energy can therefore be given as $E_R = (p_N)^2/(2M)$. Since E_R is small compared with E_0 , one can set $E_\gamma = E_0 - E_R \approx E_0$ and thus the *recoil energy* can be expressed as

$$E_R = \frac{E_0^2}{2Mc^2}. \quad (25.3)$$

Considering the excited nuclei of such isolated atoms at rest, the (median) energy of the emitted γ photons (i.e., $E_0 - E_R$) will be less than the transition energy E_0 . For the $\pm 3/2 \rightarrow \pm 1/2$ transition of ^{57}Fe , which is the most frequently used Mössbauer nuclide, one has $E_0 = 14.4 \text{ keV}$, $\Gamma = 4.67 \times 10^{-9} \text{ eV}$, $E_R = 1.92 \times 10^{-3} \text{ eV}$. The energy distribution of the emitted photons – called the emission line that is characterized by a Lorentzian having line width Γ – gets shifted toward the low energies. On the other hand, the energy distribution of the photons, which can be absorbed resonantly by the ground-state nucleus – called the absorption line – is characterized by the same line width, Γ , with a median energy $E_0 + E_R$ due to the recoil of the absorbing nucleus. Resonance absorption can only occur when the absorption and emission lines overlap each other. In other words, the shift between the absorption and emission lines cannot exceed substantially 2Γ . However, in case of recoil, the energy separation between the emission and absorption lines (which is $2E_R$) can be by six orders of magnitude larger than Γ in the case of ^{57}Fe . Thus, there is no overlap between the emission and absorption lines, and, consequently, no resonant absorption occurs in this case.

25.1.2 Thermal Broadening: γ Emission and Absorption in Gases

In the case of gases, one should also consider that the atoms move with relatively large velocities and thus the energy of the emitted γ rays is modified by the Doppler shift. This will cause a smearing out of both the emission and absorption lines and lead to an additional broadening of the spectrum peaks, which is called the *Doppler* or *thermal broadening*.

Let \mathbf{x} refer to the direction of γ emission/observation. The energy of the γ photon emitted by an atom moving at velocity \mathbf{u} is now

$$E_\gamma = (E_0 - E_R) \left(1 + \frac{u}{c} \cos \theta \right) \quad (25.4)$$

where $u = |\mathbf{u}|$ is the speed of the atom, and θ is the angle between \mathbf{u} and the \mathbf{x} -axis as shown in [Fig. 25.2](#).

Since the direction of γ emission is independent of the velocity of the particle, the expected value of the γ energy is easily calculated as

$$\langle E_\gamma \rangle = (E_0 - E_R) \left(1 + \frac{\langle u \rangle}{c} \langle \cos \theta \rangle \right) \quad (25.5)$$

where $\langle u \rangle$ is the mean speed of the atom as calculated from the Boltzmann distribution, and $\langle \cos \theta \rangle$ is calculated with the density function $(\sin \theta)/2$ according to [Fig. 25.2](#).

Due to symmetry, $\langle \cos \theta \rangle = 0$ and therefore

$$\langle E_\gamma \rangle = E_0 - E_R \quad (25.6)$$

that is, thermal motion does not affect the mean energy at all.

■ Fig. 25.2

Representation of the notation used in the calculation of Doppler broadening. The density function that is used for averaging out θ (for all possible values between 0 and π) should be proportional to the circumference $2\pi \sin\theta$ of the shaded disc that is perpendicular to the x -axis at $x = \cos\theta$

The variance of the γ energy (i.e., *Doppler broadening*), on the other hand, *does* depend on temperature as one can easily show

$$D^2(E_\gamma) = \langle (E_\gamma - \langle E_\gamma \rangle)^2 \rangle = (E_0 - E_R)^2 \frac{\langle u^2 \rangle}{c^2} \langle \cos^2 \theta \rangle = (E_0 - E_R)^2 \frac{\langle u^2 \rangle}{3c^2} \quad (25.7)$$

where the same density function was used as before for averaging out θ , and $\langle u^2 \rangle$ is the mean square speed of the atoms.

The temperature dependence can be made explicit by using the kinetic theory of gases according to which

$$\frac{M \langle u^2 \rangle}{2} = \frac{3kT}{2} \quad (25.8)$$

Thus, one observes the following formula for the standard deviation of the γ energy:

$$D(E_\gamma) = (E_0 - E_R) \sqrt{\frac{kT}{Mc^2}} \approx E_0 \sqrt{\frac{kT}{Mc^2}} = \sqrt{2kTE_R} \quad (25.9)$$

where it was made use of the fact that $E_R \ll E$.

For the $\pm 3/2 \rightarrow \pm 1/2$ transition of ^{57}Fe one has $D(E_\gamma) = 1.0 \times 10^{-2}$ eV at 300 K. Since $D(E_\gamma)$ is commensurable with E_R , one can see that Doppler broadening can cause some overlapping between the shifted emission and absorption lines (► Fig. 25.3), and thus a small yield of nuclear resonance absorption is to be expected (and, indeed, achieved; see Malmfors 1953). However, if the overlap occurs due to such thermal motion, the essence of using resonant nuclear absorption to develop a spectroscopic method with an extremely high-energy resolution is lost.

■ Fig. 25.3

Doppler/thermal broadening in gases. Thermal motion causes blurring of the (normalized) emission and absorption profiles. At high-enough temperatures, the profiles will overlap thus bridging the gap of $2E_R$ between the maxima. Without recoil (and thermal broadening), both the emission and the absorption profile would be represented by a Lorentzian at E_0 , with a full width at half maximum (FWHM) so small that the (normalized) peak would be way out of the vertical scale

25.1.3 Recoilless γ Emission and Absorption in Condensed Matter, the Mössbauer Effect

25.1.3.1 Conditions of Nuclear Resonance Absorption

Before the discovery of the Mössbauer effect, many attempts had been made to improve the chances for γ ray resonance absorption. The idea was to make the overlap between the emission and absorption lines larger by setting the emitter/absorber nuclei in motion (in order to compensate for the energy loss due to recoil) either mechanically (Moon 1950) or thermally (Malmfors 1953).

The key problem, i.e., how to avoid recoil and Doppler broadening at the same time, has been solved by Rudolf Mössbauer (Mössbauer 1958a) when he discovered that γ -ray emitting and absorbing nuclei if embedded in the lattice of a solid give rise to a recoilless line (the so-called Mössbauer line) at the energy E_0 .

The cross section for the resonant absorption depends on the energy E of the γ photons. The energy dependence can be expressed by a Lorentzian shown by ▶ Eq. (25.1) (Frauenfelder 1962):

$$\sigma = \sigma_0 \left(\frac{\Gamma}{2} \right)^2 \frac{1}{(E - E_0)^2 + \left(\frac{\Gamma}{2} \right)^2} \quad (25.10)$$

where σ_0 is the maximum of the resonant cross section for which one has

$$\sigma_0 = 2\pi\lambda^2 \frac{2I_e + 1}{2I_g + 1} \frac{1}{1 + \alpha} \quad (25.11)$$

where I_e and I_g are the nuclear spin quantum numbers of the excited and ground state, respectively, $\lambda \equiv \lambda/(2\pi)$ is proportional to the wavelength λ of the γ ray, and α is the internal conversion coefficient (see [Sect. 2.3.2.1 in Chap. 2, Vol. 1](#)).

25.1.3.2 Lattice Vibrations

Mössbauer effect is unique in that it provides a means of eliminating the destructive effect of recoil and thermal energies. In the Mössbauer domain, recoil energy is much less than the chemical binding energy and also less than the energy needed to excite lattice vibrations (phonons). Since the energy of lattice vibrations is quantized, the relatively low recoil energy cannot be transferred to the solid to increase its internal vibrational energy. It can only be transferred to the lattice, if it suffices to induce a vibrational quantum jump. If no quantum jump occurs (as in the case of the Mössbauer effect), then the recoil energy can be considered as being taken by the whole crystal grain as a rigid object in which the Mössbauer nuclide is embedded. The recoiled mass (M) in the denominator of [Eq. \(25.3\)](#) becomes extremely large (in fact, it becomes equal to the mass of the whole grain), and therefore the recoil energy E_R will be negligibly small in comparison with the natural line width Γ .

In order to understand the interactions between the emitting/absorbing nuclei and the lattice, some basics of the Einstein model and the Debye model of solids are needed.

The *Einstein model* (Kittel 1968) assumes that the solid is composed of a large number of independent linear oscillators each vibrating at the same angular frequency ω_E . (Each atom is represented by three oscillators, one for each dimension.) As the temperature increases, the oscillators keep vibrating with the same frequency, however, the amplitude of vibration – and so the mean square displacement of the atoms – becomes larger. The Einstein frequency ω_E is associated with the Einstein temperature θ_E :

$$\hbar\omega_E = k\theta_E \quad (25.12)$$

and the Einstein energy E_E , which is the minimum of vibrational energy that the lattice can emit or absorb:

$$E_E = \hbar\omega_E = \frac{\hbar c_s}{\lambda_s} = \frac{\pi \hbar c_s}{a} \quad (25.13)$$

where a is the lattice constant, c_s is the speed of the sound waves in the solid, and $2\pi\lambda_s$ is the wavelength of the sound associated with the vibration. The wavelength is supposed to satisfy the condition $\lambda_s = 2a$. For the bcc iron lattice (α -Fe), this yields $E_E = 0.04$ eV.

It is interesting to compare the γ emission of different isotopes of iron embedded in the same α -Fe lattice. Consider, e.g., the 14 keV transition of ^{57}Fe and the 800 keV transition of ^{58}Fe . It is found that the recoil energy of ^{57}Fe ($E_R = 0.002$ eV) is small compared with the Einstein energy ($E_E = 0.04$ eV) and, consequently, recoilless emission can occur. For ^{58}Fe , on the other hand, the recoil energy ($E_R = 6$ eV) is large enough to excite the lattice.

The Einstein model gives a good qualitative agreement with the real behavior of solids, but the quantitative agreement is poor (Cranshaw et al. 1985). A more realistic representation of a solid is given by the *Debye model*. The model describes the lattice vibration of solids as a superposition of independent vibrational modes (i.e., collective wave motion of the lattice, associated with “phonons”) with different frequencies. The (normalized) density function $p(\omega)$ of the vibrational frequencies is monotonically increasing up to a characteristic maximum of ω_D , where it abruptly drops to zero (Kittel 1968):

$$p(\omega) = \begin{cases} 3 \frac{\omega^2}{\omega_D^3} & \text{for } 0 \leq \omega \leq \omega_D \\ 0 & \text{elsewhere} \end{cases} \quad (25.14)$$

It is usual to express the cutoff frequency ω_D with the characteristic Debye temperature θ_D :

$$\hbar\omega_D = k\theta_D \quad (25.15)$$

The energy is quantized for each possible frequency ω :

$$\varepsilon_n = \left(n + \frac{1}{2}\right) \hbar\omega \quad (25.16)$$

where n is a quantum number ($n = 0, 1, 2, \dots$).

The mean energy for a given frequency ω at a given temperature T is calculated as

$$\bar{\varepsilon}(\omega, T) = \frac{\sum_{n=0}^{\infty} \varepsilon_n \exp\left(-\frac{\varepsilon_n}{kT}\right)}{\sum_{n=0}^{\infty} \exp\left(-\frac{\varepsilon_n}{kT}\right)} = \left(\bar{n}(\omega, T) + \frac{1}{2}\right) \hbar\omega \quad (25.17)$$

where $\bar{n}(\omega, T)$, representing the mean of the quantum number n , is called the Bose–Einstein distribution function

$$\bar{n}(\omega, T) = \frac{1}{\exp\left(\frac{\hbar\omega}{kT}\right) - 1} \quad (25.18)$$

In quantum theory, the time-average of the square displacement (and that of the square speed) of an atom doing harmonic oscillation along the x -axis with angular frequency ω is given by

$$\langle x^2 \rangle_{\omega, T} = \frac{\langle \dot{x}^2 \rangle_{\omega, T}}{\omega^2} = \left(\bar{n}(\omega, T) + \frac{1}{2}\right) \frac{\hbar}{M\omega} \quad (25.19)$$

where M is the mass of the atom and the subscripts are to indicate that the time-averages depend on both the frequency and the temperature.

The *mean square displacement* at a given temperature is obtained by averaging the time-average of the square displacement over all frequencies:

$$\langle x^2 \rangle_T = \int_0^{\omega_D} \langle x^2 \rangle_{\omega, T} p(\omega) d\omega = \frac{3\hbar^2}{Mk\theta_D} \left[\frac{1}{4} + \left(\frac{T}{\theta_D}\right)^2 \int_0^{\theta_D/T} \frac{x}{e^x - 1} dx \right]. \quad (25.20)$$

For very low and very high temperatures, [Eq. \(25.20\)](#) can be approximated by the following expressions:

$$\langle x^2 \rangle_T \approx \frac{3\hbar^2}{Mk\theta_D} \left[\frac{1}{4} + \left(\frac{T}{\theta_D} \right)^2 \frac{\pi^2}{6} \right], \quad T \ll \theta_D, \quad (25.21)$$

$$\langle x^2 \rangle_T \approx \frac{3\hbar^2}{Mk\theta_D} \frac{T}{\theta_D}, \quad T \gg \theta_D \quad (25.22)$$

Note that [Eqs. \(25.20\)–\(25.22\)](#) justify the intuitive expectation that the mean square displacement of the vibrating atoms should increase with temperature.

The *mean square velocity* of the lattice vibration, $\langle u^2 \rangle$, at a given temperature can be derived similarly to that of mean square displacement, and obtained as

$$\langle u^2 \rangle_T = \int_0^{\omega_D} \langle u^2 \rangle_{\omega,T} P(\omega) d\omega = \frac{9k\theta_D}{M} \left[\frac{1}{8} + \left(\frac{T}{\theta_D} \right)^4 \int_0^{\theta_D/T} \frac{x^3}{e^x - 1} dx \right] \quad (25.23)$$

25.1.3.3 The Probability of the Mössbauer Effect

The probability of the recoilless emission or absorption is given by the *recoilless fraction* f , meaning the fraction of all γ rays of the Mössbauer transition that are emitted (f_s) or absorbed (f_a) without recoil-energy loss. This is also commonly referred to as the Mössbauer fraction, Debye–Waller factor, Mössbauer–Lamb factor or, simply, the f -factor.

The theory of the *Mössbauer–Lamb factor* has been developed by several authors (Lamb 1939; Mössbauer 1958a; Singwi and Sjolander 1960; Lipkin 1960; Shapiro 1960).

In its most general form, the recoilless fraction is given by the following formulas that are completely equivalent to each other:

$$f = \exp(-k^2 \langle x^2 \rangle_T) = \exp\left(-\frac{\langle x^2 \rangle_T}{\lambda^2}\right) = \exp\left(-\frac{E_0^2}{\hbar^2 c^2} \langle x^2 \rangle_T\right) = \exp\left(-\frac{2ME_R}{\hbar^2} \langle x^2 \rangle_T\right) \quad (25.24)$$

where $k/(2\pi)$ is the wave number of the γ ray:

$$k = \frac{2\pi}{\lambda} = \frac{1}{\lambda} = \frac{E_0}{\hbar c} \quad (25.25)$$

[Equation \(25.24\)](#) carries several important messages for the Mössbauer spectroscopist:

1. The recoilless fraction decreases with increasing γ energy (note that in the recoilless case $E_\gamma = E_0$ except for the energy uncertainty expressed by [Eq. \(25.2\)](#)). This means that isomeric transitions with $E_0 \geq 200$ keV are not practical for the purpose of Mössbauer spectroscopy, since the f -factor would be too small. (The Mössbauer effect has been observed with over 100 transitions of near 50 elements shown in [Fig. 25.4](#). The nuclear data for the Mössbauer transitions are summarized in [Sect. 36.1 of the Appendix of this Volume](#).)
2. Since according to [Eq. \(25.21\)](#) the value of $\langle x^2 \rangle_T$ is supposed to decrease on cooling, the recoilless fraction should increase when the temperature is lowered. This was the crucial and unexpected finding of the first recoilless resonance absorption experiment by Rudolf Mössbauer using ^{191}Ir , which lead to the discovery of the Mössbauer effect (Mössbauer 1958a).

The explicit temperature dependence of the Mössbauer–Lamb factor can be estimated from the Debye model by using [Eqs. \(25.20\)–\(25.22\)](#) and [Eq. \(25.24\)](#):

■ Fig. 25.4

The Mössbauer periodic table. Shaded cells contain elements with no known Mössbauer isotope. Unshaded cells also indicate the mass number(s) of the Mössbauer isotope(s) below the chemical symbol. For brevity's sake no more than two (of the most important) isotopes are indicated for each element. An asterisk "*" after the last mass number means that the full list of the Mössbauer isotopes (see [▶ Sect. 36.1 of the Appendix of this Volume](#)) is longer than shown here

[illegible]

$$f(T) = \exp \left\{ -\frac{6E_R}{k\theta_D} \left(\frac{1}{4} + \left(\frac{T}{\theta_D} \right)^2 \int_0^{\theta_D/T} \frac{x}{e^x - 1} dx \right) \right\}. \quad (25.26)$$

Let us emphasize here, however, that the Debye model had been developed for a monatomic cubic lattice, and thus the quantitative results applied to an arbitrary lattice must be taken with more than a grain of suspicion.

25.1.4 The Mössbauer Spectrum

► **Figure 25.5** shows the schematic arrangement of a typical transmission Mössbauer experiment. The assembly consists of a source, an absorber, and a detector.

■ Fig. 25.5

Schematic arrangement of a transmission type Mössbauer measurement. The scanning of the absorption line with the emission line using the Doppler principle is illustrated. The intensity of the resultant spectrum is proportional to the overlap of the emission and absorption lines (marked at four arbitrarily chosen velocities u_1 to u_4)

The *source* is a body containing the excited-state nuclei of a Mössbauer-active nuclide “frozen” in a solid matrix thus providing the conditions for recoilless γ emission.

The *absorber* is another body that contains the ground-state nuclei of the same Mössbauer-active nuclide also “frozen” in a solid matrix so satisfying the conditions for recoilless absorption.

The γ photons transmitted by the absorber are counted by the detector.

The resonance curve of the absorber (absorption line), however, cannot be measured at all by any existing detector, since it would require an energy resolution (Γ/E_0) of about 13–15 orders of magnitude. Therefore, the Mössbauer nuclei themselves are used to measure the resonance curve in the following way. If both the source and the absorber are at rest, and have the same chemical environment for the Mössbauer nuclei, then there is a maximum overlap of the emission and the absorption lines, and a certain intensity is observed by the detector. This ideal condition for the resonance absorption is destroyed by modifying the energy of the emission line according to the Doppler effect by moving the source with velocity u , relative to the absorber. This action results in a decreased overlap of the emission and absorption lines and therefore an increased count rate of the detector (see [Fig. 25.5](#)). A systematic energy modification of the emission line on the basis of the Doppler effect can be used to scan the absorption characteristics of the absorber very sensitively (with the required resolution). The count rate detected as a function of the Doppler velocity results in the Mössbauer spectrum.

The Mössbauer spectrum itself is usually presented as a plot of counts/percentage/fraction of transmission vs. channel/Doppler velocity.

The transmitted intensity vs. Doppler velocity (i.e., the transmission Mössbauer spectrum) will show a resonance “dip” around the Doppler velocity where the overlap is at its maximum (see [Fig. 25.6](#)).

In the *simplest* (thin-source, thin-absorber) *approximation*, a simple transmission Mössbauer spectrum ([Fig. 25.6](#)) consists of one single *Lorentzian peak* the half width of which corresponds to twice of the natural line width $\Gamma = \hbar \ln 2 / T_{1/2}$ (in energy unit). (The natural line width Γ is characteristic of both the recoilless emission in the source and the resonant absorption in the absorber. So doubling is actually the result of “adding up.”) The peak width $W_0 = 2c\Gamma/E_\gamma$ (in speed unit) thus obtained is an asymptotic minimum to which (normally) actual experimental peak widths are compared. For the $3/2 \rightarrow 1/2$ (see [Fig. 25.7](#)) transition of ^{57}Fe , e.g., $W_0 \approx 0.2$ mm/s is the minimum (or natural) peak width.

In the general case, the peak width will be broadened and the peak shape will be different from Lorentzian.

A general evaluation of the integrated absorption intensity is rather difficult, but a useful result can be obtained under the following conditions (Margulies and Ehrman 1961).

Let both the emission and absorption line be centered at E_0 and have the same natural line width $\Gamma_S = \Gamma_A = \Gamma$. The distribution of the ground-state Mössbauer atoms in question (e.g., ^{57}Fe) is taken to be uniform in both the source and the absorber. The distribution of the parent atoms (e.g., ^{57}Co) producing the excited Mössbauer atoms ([Fig. 25.7](#)) (and thus the γ photons) is described by the density function $\rho(x)$ along the x -axis (see [Fig. 25.6](#) for the notation). In the derivation of the peak shape of the Mössbauer spectrum, nonresonant and resonant absorption processes are to be considered in both the source and the absorber as illustrated schematically in [Fig. 25.6](#).

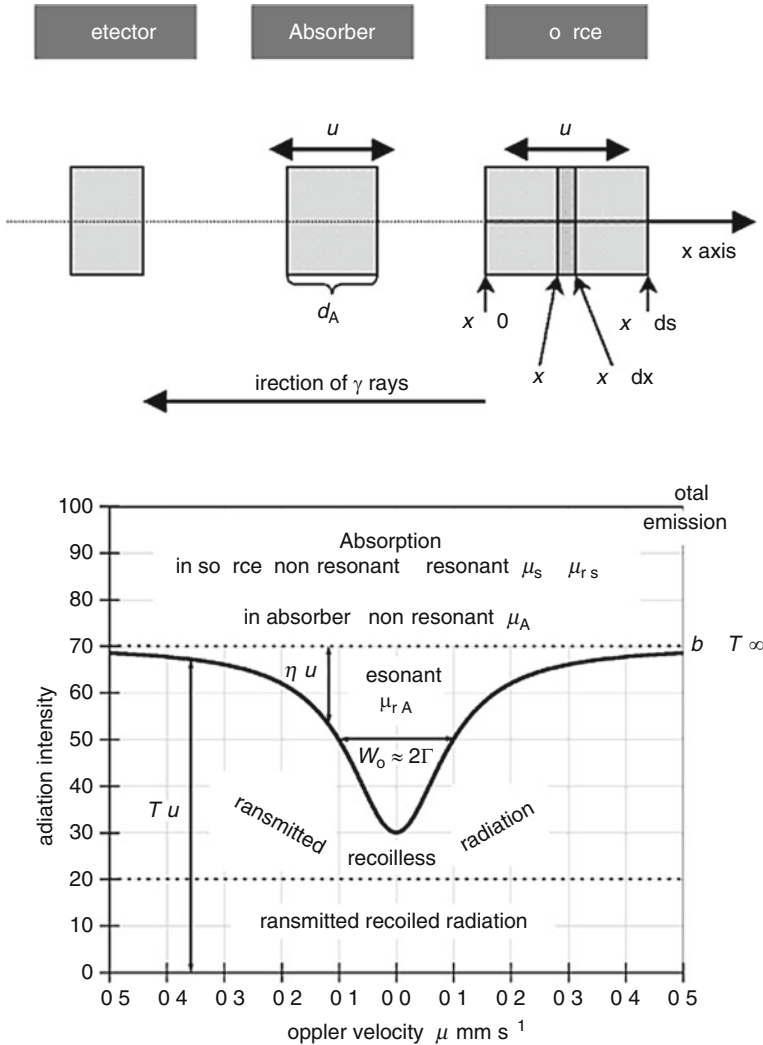

The γ radiation emitted by the excited Mössbauer nuclei will be attenuated by both “electronic” absorption/scattering (mainly due to photoelectric effect) and resonance absorption by ground-state nuclei.

Electronic absorption consumes both the recoiled $(1 - f_S)$ and the recoilless fraction (f_S) of photons. Their attenuation is described by the coefficients μ_S and μ_A for the source and the absorber, respectively. The electronic attenuation coefficients can be considered constant over the whole Doppler-velocity range.

Resonance absorption only concerns the recoilless fraction (f_S) of the radiation. According to [Eq. \(25.1\)](#), the energy distribution of this fraction can be given as

■ Fig. 25.6

Schematic transmission Mössbauer spectrum (*bottom*) with notations for the simplest arrangement (*top*). Either the source or the absorber is vibrated by a transducer. As usual, positive Doppler velocities (u) refer to approaching source and absorber

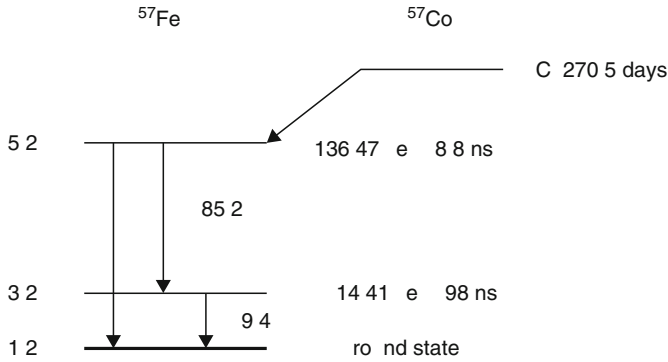

$$L(E) = f_s \frac{\Gamma}{2\pi} \frac{1}{(E - E_0)^2 + \left(\frac{\Gamma}{2}\right)^2}. \quad (25.27)$$

The attenuation coefficients $\mu_{r,s}$ and $\mu_{r,A}$ that characterize the resonance absorption of the recoilless radiation (in the source and in the absorber, respectively) are, however, energy dependent.

Using ➤ Eq. (25.10), for the case when the source is at rest and the absorber is moving with relative velocity u one can write

■ Fig. 25.7

Decay scheme of ^{57}Co to ^{57}Fe . The half-lives of γ transitions are indicated in parentheses

$$\mu_{r,S} = \frac{f_S n_S a_S \sigma_0 (\Gamma/2)^2}{(E - E_0)^2 + (\Gamma/2)^2}, \quad \mu_{r,A} = \frac{f_A n_A a_A \sigma_0 (\Gamma/2)^2}{[E - E_0(1 - u/c)]^2 + (\Gamma/2)^2} \quad (25.28)$$

where f_S and f_A are the Mössbauer–Lamb factors, n_S and n_A are the number densities (unit: number of atoms per volume) of the Mössbauer element (e.g., Fe), a_S and a_A are the fractional abundances of the Mössbauer isotope (e.g., ^{57}Fe in Fe), for the source and absorber, respectively, and σ_0 is the maximum of resonant absorption cross section given by ► Eq. (25.11).

Note that the negative sign before u/c in the second formula means that when the absorber approaches the source, the positive Doppler shift helps lower-energy γ photons to meet the condition of resonance absorption. As a result of this, the absorption line represented by the second formula is shifted to the left by the Doppler term.

The fraction of γ photons reaching the detector (considering only those photons that are emitted in the direction of the detector) can be given as

$$T(u) = \left\{ (1 - f_S) \left[\int_0^{d_S} \rho(x) \exp(-\mu_S x) dx \right] + f_S \left[\int_{-\infty}^{+\infty} \frac{\Gamma}{2\pi} \frac{1}{(E - E_0)^2 + (\Gamma/2)^2} \times \int_0^{d_S} \rho(x) \exp\left(-\frac{f_S n_S a_S \sigma_0 (\Gamma/2)^2}{(E - E_0)^2 + (\Gamma/2)^2} x - \mu_S x\right) dx \times \exp\left(-\frac{\tau_A (\Gamma/2)^2}{[E - E_0(1 - u/c)]^2 + (\Gamma/2)^2} dE \right) \right] \right\} \exp(-\mu_A d_A) \quad (25.29)$$

where d_A is the thickness, and τ_A is the *effective thickness* of the absorber:

$$\tau_A = f_A n_A a_A d_A \sigma_0. \quad (25.30)$$

The first term (line 1) in ► Eq. (25.29) represents the γ radiation emitted with recoil from the source (S) in which it is attenuated by nonresonant absorption via Compton or

photoelectric effect as it proceeds toward the absorber (A). This term is independent of the Doppler shift.

Line 2 contains the $C(E_0, \Gamma/2)$ Cauchy distribution of the γ photons emitted from the source without recoil.

Line 3 describes the resonant and nonresonant (self) absorption within the source for the recoilless γ photons emitted at different depths (x) of the source while they proceed toward the front of the source ($x = 0$) on their way to the absorber.

The first exponential in line 4 expresses the resonant absorption of the recoilless γ photons in the absorber that moves with velocity u toward the source. Finally, the factor $\exp(-\mu_A d_A)$ in the same line accounts for the nonresonant absorption/scattering in the absorber attenuating both the recoiled and the recoilless photons.

In the case of an infinitely thin source – when the radioactive parent forms a monatomic layer on the front of the source at $x = 0$, and therefore $\rho(x) = \delta(x)$, where δ is the Dirac “function” – lines 1 and 3 in [Eq. \(25.29\)](#) are equal to $(1 - f_s)$ and 1, respectively. Therefore, one obtains the following formula, generally called the *transmission integral*:

$$T(u) = \left\{ 1 - f_s + \int_{-\infty}^{+\infty} \frac{\frac{\Gamma f_s}{2\pi}}{(E - E_0)^2 + \left(\frac{\Gamma}{2}\right)^2} \exp\left(-\frac{\tau_A \left(\frac{\Gamma}{2}\right)^2}{[E - E_0(1 - \frac{u}{c})]^2 + \left(\frac{\Gamma}{2}\right)^2}\right) dE \right\} e^{-\mu_A d_A} \quad (25.31)$$

For very large Doppler speeds, there is no resonance absorption at all (note that the exponential part of the integrand is 1 at the limit $|u| \rightarrow \infty$), and therefore, the baseline b can be expressed as

$$b = T(\infty) = e^{-\mu_A d_A}. \quad (25.32)$$

The contour of the transmission peak (see [Fig. 25.6](#)) can be easily determined from the above equations:

$$\eta(u) = \frac{b - T(u)}{b} = f_s \left\{ 1 - \int_{-\infty}^{+\infty} \frac{\frac{\Gamma}{2\pi}}{(E - E_0)^2 + \left(\frac{\Gamma}{2}\right)^2} \exp\left(-\frac{\tau_A \left(\frac{\Gamma}{2}\right)^2}{[E - E_0(1 - \frac{u}{c})]^2 + \left(\frac{\Gamma}{2}\right)^2}\right) dE \right\} \quad (25.33)$$

If the effective thickness of the absorber is very small (i.e., $\tau_A \rightarrow 0$), then the exponential in the integrand of [Eq. \(25.33\)](#) can be replaced by the linear terms of its Taylor series.

As a result, the peak shape can be expressed by the following integral:

$$\eta(u) = f_s \tau_A \int_{-\infty}^{+\infty} \frac{\frac{\Gamma}{2\pi}}{(E - E_0)^2 + \left(\frac{\Gamma}{2}\right)^2} \times \frac{\left(\frac{\Gamma}{2}\right)^2}{[E - E_0(1 - \frac{u}{c})]^2 + \left(\frac{\Gamma}{2}\right)^2} dE. \quad (25.34)$$

Using the residuum theorem, the above formula yields

$$\eta(u) = \frac{f_s \tau_A}{2} \frac{\Gamma^2}{\left(\frac{E_0}{c} u\right)^2 + \Gamma^2} = \frac{f_s \tau_A}{2} \frac{\left(\frac{W_0}{2}\right)^2}{u^2 + \left(\frac{W_0}{2}\right)^2}. \quad (25.35)$$

As it has turned out, the peak shape – in this thin-source, thin-absorber approximation – is indeed Lorentzian, and the FWHM of the peak (W_0), apart from the conversion factor between Doppler speed and energy, is twice the natural line width Γ .

$$W_0 = 2\Gamma \frac{c}{E_0}. \quad (25.36)$$

Note also that the height of the peak is proportional to the effective thickness and, consequently, (through the number density n_A) to the concentration of the Mössbauer species:

$$\eta(0) = \frac{f_S \tau_A}{2} = \frac{f_S f_A n_A a_A d_A \sigma_0}{2}. \quad (25.37)$$

In the general case, one observes a nonlinear formula for the peak height (Mössbauer and Wiedemann 1960):

$$\eta(0) = f_S \left[1 - \exp\left(-\frac{\tau_A}{2}\right) I_0\left(\frac{\tau_A}{2}\right) \right] \quad (25.38)$$

where I_0 is the 0th order modified Bessel function of the first kind (see, e.g., BESSEL 2010). The peak area can be obtained by the integration of [Eq. \(25.33\)](#):

$$A = \int_{-\infty}^{\infty} \eta(u) du = \pi \Gamma f_S \frac{\tau_A}{2} \exp\left(-\frac{\tau_A}{2}\right) \left[I_0\left(\frac{\tau_A}{2}\right) + I_1\left(\frac{\tau_A}{2}\right) \right] \quad (25.39)$$

where I_1 is the first-order modified Bessel function of the first kind.

In the case of a thin absorber ($\tau_A \rightarrow 0$), the Taylor expansion of the exponential and Bessel functions yields a proportional relationship between the peak area and the number of resonant atoms in the absorber:

$$A \approx \frac{\pi \Gamma f_S \tau_A}{2}. \quad (25.40)$$

The latter equation is fundamental in Mössbauer spectroscopy establishing its use as a tool of quantitative analysis.

25.1.5 Hyperfine Interactions

The interaction between the electrons and the nucleus causes a very small perturbation of the nuclear energy levels in comparison with the energy of the nuclear transition. Such interactions are called *hyperfine interactions*. The main hyperfine interactions are the following: electric monopole, electric quadrupole, and magnetic dipole interactions between the nucleus and the electrons (shell electrons, ligands, etc.). Such interactions can be sensitively monitored by Mössbauer spectroscopy. The measurement of hyperfine interactions is the key to the utilization of Mössbauer spectroscopy in a wide range of applications.

Hyperfine interactions shift and/or split the energy levels of the nucleus. The total Hamiltonian can be written as a sum of various contributions:

$$H = H_0 + H_C + H_Q + H_m, \quad (25.41)$$

where H_C , H_Q , and H_m refer to electric monopole (Coulomb) interaction, electric quadrupole interaction, and magnetic dipole interaction, respectively, and H_0 represents all other terms not considered here.

All of the hyperfine interactions may occur together, but only the magnetic and quadrupole interactions are directional thus having a complicated interrelationship.

25.1.5.1 Electric Monopole Interaction

The electric monopole interaction is part of the full electric Coulomb interaction occurring between the nucleus and the surrounding charges. Because of this interaction, the energy levels of the nucleus become shifted. The corresponding energy shift of the ground-state nuclear level may differ from that of the excited state level when the finite size of the nucleus is taken into consideration. (If the nucleus were a point charge, the Coulomb shift due to electrons would be the same for its ground state and its excited state.) Consequently, the electric monopole interaction leads to a change in the energy of the emitted γ ray compared to the case of a bare nucleus that is without any surrounding electric charge (Dunlap and Kalvius 1978).

The full *Coulomb interaction* between the nuclear charge distribution $\rho_N(r_N)$ and the electronic charge distribution $-\rho_e(r_e)$ is given by

$$U = -e^2 \iint \frac{\rho_e(r_e)\rho_N(r_N)}{|r_e - r_N|} dV_e dV_N \quad (25.42)$$

where r_e and r_N are location vectors, and dV_e and dV_N are the volume elements containing the points determined by r_e and r_N , respectively.

The above equation can be rewritten by using the following multipole expansion (Clauser and Mössbauer 1969):

$$\frac{1}{|r_e - r_N|} = \sum_{l=0}^{\infty} \sum_{m=-l}^{+l} \frac{2\pi}{2l+1} \left(\frac{r_{<}^l}{r_{>}^{l+1}} \right) Y_{lm}^*(\theta_N, \phi_N) Y_{lm}(\theta_e, \phi_e) \quad (25.43)$$

where Y_{lm} are the normalized spherical harmonics, $r_{<}$ and $r_{>}$ are the smaller and the larger of $|r_e|$ and $|r_N|$, respectively.

The full Coulomb interaction energy term can be expressed by combining [Eqs. \(25.42\)](#) and [\(25.43\)](#) as the sum of a number of terms with multipole order l . The term for $l=0$ is the electric monopole term. The $l=2$ term gives rise to electric quadrupole interactions and will be discussed later. (All the odd l terms vanish for reasons of symmetry. The very small even terms for $l>2$ can also be ignored.)

For $l=0$, the energy of the interaction is

$$U_0 = -e^2 \iint \frac{\rho_e(r_e)\rho_N(r_N)}{r_{>}} dV_e dV_N. \quad (25.44)$$

In Mössbauer spectroscopy, the only thing that matters is not the energy shift of an individual level, but the energy-shift difference between the ground-state and excited-state levels. Let us consider the energy shifts of the nuclear levels due to the electric monopole interaction and the energy of the γ ray emitted from the source and absorbed by the absorber ([Fig. 25.8](#)).

If the nuclei did not experience any hyperfine interaction, they would have the same energy levels in both the source and the absorber ($E^{S*} = E^{A*}$, $E^S = E^A$, and thus $E^{S*} - E^S = E^{A*} - E^A = E_0$, see [Fig. 25.8](#) for notations). With a finite size nucleus the Coulomb term, U_0 , can be different for the excited state ($U_{0,S}^*$) and the ground state ($U_{0,S}$) in the source, and also for the excited state ($U_{0,A}^*$) and the ground state ($U_{0,A}$) in the absorber.

The energy of the γ ray emitted from the source will be

$$E_{\gamma}^S = (E^{S*} - E^S) + (U_{0,S}^* - U_{0,S}) = E_0 + \Delta E_C^S \quad (25.45)$$

where the notation $\Delta E_C^S = (U_{0,S}^* - U_{0,S})$ has been introduced.

■ Fig. 25.8

The shifts of nuclear energy levels in the source and the absorber due to the electric monopole interaction between the nucleus and the electrons, and the resulted Mössbauer spectrum.

According to ► Eq. (25.80), the chemical isomer shift δ_c is proportional to the energy shift ΔE_{IS}

The energy of the γ ray, which can be absorbed by the absorber will be

$$E_\gamma^A = (E^{A*} - E^A) + (U_{0,A}^* - U_{0,A}) = E_0 + \Delta E_C^A \quad (25.46)$$

with the notation $\Delta E_C^A = (U_{0,A}^* - U_{0,A})$.

The energy difference

$$\Delta E_{IS} = E_\gamma^A - E_\gamma^S = \Delta E_C^A - \Delta E_C^S = (U_{0,A}^* - U_{0,A}) - (U_{0,S}^* - U_{0,S}) \quad (25.47)$$

is the missing (or excess) energy of the γ quantum emitted by the source that needs to be compensated in the Mössbauer experiment in order to achieve maximum resonance absorption, i.e., maximum overlap between the emission and absorption lines (► Fig. 25.5). In the corresponding Mössbauer spectrum, the need for this compensation of energy appears as a line shift (see ► Fig. 25.8) that is called the *chemical isomer shift*.

By substituting the Coulomb shifts $U_{0,A}^*$, $U_{0,A}$, $U_{0,S}^*$, and $U_{0,S}$ in [Eq. \(25.47\)](#) with corresponding expressions according to [Eq. \(25.44\)](#) one obtains

$$\Delta E_{\text{IS}} = -e^2 \iint \frac{\rho_{e,A}^*(r_e) \rho_{N,A}^*(r_N) - \rho_{e,A}(r_e) \rho_{N,A}(r_N) - \rho_{e,S}^*(r_e) \rho_{N,S}^*(r_N) + \rho_{e,S}(r_e) \rho_{N,S}(r_N)}{r_{>}} dV_e dV_N \quad (25.48)$$

where the asterisk (*) refers to the excited state of the nucleus in the source (s) and in the absorber (a).

In order to get a simpler expression for the chemical isomer shift, it will be assumed that the electronic charge density around the nucleus is the same whether or not the nucleus is excited:

$$\rho_{e,S}^*(r_e) = \rho_{e,S}(r_e); \rho_{e,A}^*(r_e) = \rho_{e,A}(r_e). \quad (25.49)$$

It is plausible to assume that for a given energy state of the nucleus the nuclear charge density is the same in the source and in the absorber:

$$\rho_{N,S}^*(r_N) = \rho_{N,A}^*(r_N) \equiv \rho_N^*(r_N); \rho_{N,S}(r_N) = \rho_{N,A}(r_N) \equiv \rho_N(r_N). \quad (25.50)$$

Introducing spherically averaged electronic densities

$$\bar{\rho}_e(r_e) = \frac{1}{4\pi} \iint \rho_e(r_e) \sin \theta d\theta d\phi, \quad (25.51)$$

and assuming that the nuclear charge distribution is spherically symmetric one obtains

$$\Delta E_{\text{IS}} = -4\pi e^2 \int_0^\infty (\rho_N^*(r_N) - \rho_N(r_N)) I(r_N) dr_N. \quad (25.52)$$

with

$$I(r_N) = \int_0^{r_N} (\bar{\rho}_{e,A}(r_e) - \bar{\rho}_{e,S}(r_e)) \left(\frac{1}{r_N} - \frac{1}{r_e} \right) r_e^2 dr_e. \quad (25.53)$$

Thus, ΔE_{IS} will depend on the assumptions made for the radial dependence of the average electronic densities in the source and in the absorber within the nuclear volume.

In light atoms (for which $Z \ll 137 \approx 1/\alpha$, where α is the fine-structure constant) relativistic effects are negligible. In such a case, only s electrons (having spherically symmetric distribution) have nonvanishing charge density at the place of the nucleus. Considering also the small size of the nucleus, the electronic density can be taken to be approximately constant over the nuclear volume, and therefore:

$$\bar{\rho}_e(r_e) = \rho_e(r_e) = \rho_e(0) \equiv |\psi(0)|^2 \quad (25.54)$$

where $\psi(0)$ is the nonrelativistic many-electron wave function at the place of the nucleus. Thus, carrying out the integration in [Eq. \(25.53\)](#) one obtains

$$I(r_N) = -\frac{1}{6} r_N^2 |\psi(0)|^2. \quad (25.55)$$

Substituting this result into [Eq. \(25.52\)](#), for the chemical isomer shift one obtains the expression

$$\Delta E_{\text{IS}} = \frac{2\pi e^2}{3} \Delta |\psi(0)|^2 \int_0^\infty \Delta \rho_N(r_N) r_N^2 dr_N = \frac{2\pi Z e^2}{3} \Delta |\psi(0)|^2 \Delta \langle r_N^2 \rangle. \quad (25.56)$$

Note that on the right-hand side of the equation, the *first* Δ (related to the atomic electrons through Ψ) refers to the *difference between absorber and source*, while the *second* Δ (related to the nucleus through r_N) refers to the *difference between the nuclear states*.

In [Eq. \(25.56\)](#) the following expression was used for the *mth* momentum of the nuclear charge distribution:

$$\langle r^m \rangle = \frac{\int r_N^m \rho_N(r_N) dV_N}{\int \rho_N(r_N) dV_N} = \frac{1}{Z} \int r_N^m \rho_N(r_N) dV_N. \quad (25.57)$$

According to [Eq. \(25.56\)](#), one obtains that the energy shift due to electric monopole interaction is proportional to the product of the s electronic density and the second moment of the nuclear charge distribution also called the *mean square nuclear charge radius* (see also [Sect. 2.2.3.1 in Chap. 2, Vol. 1](#)). When the nucleus is considered to be a homogeneously charged sphere with a radius R (often called charge equivalent nuclear radius), then

$$\rho_N(r_N) = \frac{3Z}{4\pi R^3} \quad (25.58)$$

and therefore

$$\langle r_N^2 \rangle = \frac{3}{5} R^2 \quad (25.59)$$

which yields the following expression for the chemical isomer shift:

$$\Delta E_{\text{IS}} = \frac{2\pi Z e^2}{5} \Delta |\psi(0)|^2 \Delta R^2. \quad (25.60)$$

By considering also relativistic effects, in addition to s electrons relativistic $p_{1/2}$ electrons will also turn out to have finite density at the place of the nucleus. Then, for a uniformly charged spherical nucleus of radius R , single-electron approximation gives the following radial density distribution $\rho_e(r)$:

$$\rho_e(r) = \rho_e(0) \left[1 - \frac{\alpha^2 Z^2}{2} \left(\frac{r}{R} \right)^2 + \frac{\alpha^2 Z^2}{10} \left(1 + \frac{9\alpha^2 Z^2}{8} \right) \left(\frac{r}{R} \right)^4 + \dots \right]. \quad (25.61)$$

Hence, the energy corresponding to the chemical isomer shift can be written as

$$\Delta E_{\text{IS}} = \frac{2\pi}{5} Z e^2 S'(Z) \Delta R^2 \Delta |\psi(0)|^2, \quad (25.62)$$

where the numerical factor $S'(Z)$, the so-called *Shirley factor*, corrects the nonrelativistic electron density for relativistic effects. Its value is 1.29 for ^{57}Fe , 2.31 for ^{119}Sn , and 13.6 for ^{237}Np (Shirley 1964).

In the case of a relativistic multi-electron system, further considerations are necessary. The total electron density can be written as

$$\rho_e(r) = \rho_e(0) [1 - a_2 r^2 + a_4 r^4 - \dots] \quad (25.63)$$

which will introduce higher moments of the nuclear charge distribution into the expression of the energy corresponding to the chemical isomer shift:

$$\Delta E_{\text{IS}} = \frac{2\pi}{3} Z e^2 \Delta \rho_e(0) [\Delta \langle r^2 \rangle - b_4 \Delta \langle r^4 \rangle + b_6 \Delta \langle r^6 \rangle - \dots]. \quad (25.64)$$

25.1.5.2 Electric Quadrupole Interaction

A nucleus with nonzero nuclear quadrupole moment is subject to electric quadrupole interaction if it is experiencing an inhomogeneous electric field. The latter is characterized by the electric field gradient (EFG) tensor defined by $\nabla \circ \mathbf{E} = -\nabla \circ \nabla V$, where “ \circ ” indicates dyadic product (the matrix product of a column vector and a row vector resulting in a square matrix). The V_{ij} element of the EFG tensor is given by

$$V_{ij} = -\frac{\partial^2 V}{\partial x_i \partial x_j}(x_i, x_j = x, y, z) \quad (25.65)$$

where V is the electrostatic potential. (Note that from this point on only those charges are considered that are outside the volume of the nucleus.) The EFG tensor can be transformed into its *principal axis system* (PAS) where it is represented by a diagonal matrix with components V_{xx} , V_{yy} , and V_{zz} . One can show that electric charge distributions with spherical symmetry around the nucleus (like s electrons) do not contribute to the electric quadrupole interaction. According to the Laplace equation $\nabla^2 V = V_{xx} + V_{yy} + V_{zz} = 0$ outside the sources of the electric field. Therefore, the EFG at the place of the nucleus is traceless and two independent parameters are enough to specify it completely. The two parameters used in practice are the principal component V_{zz} and the asymmetry parameter η defined as

$$\eta = \frac{V_{xx} - V_{yy}}{V_{zz}}. \quad (25.66)$$

By convention the PAS is chosen such that $|V_{xx}| \leq |V_{yy}| \leq |V_{zz}|$ is satisfied, which ensures $0 \leq \eta \leq 1$.

In operator form, the nuclear quadrupole moment is given by

$$Q_{ik} = \frac{3Q}{2I(2I-1)} \left[I_i I_k + I_k I_i - \frac{2}{3} I^2 \delta_{ik} \right] \quad (25.67)$$

where \mathbf{I} is the nuclear spin operator and δ_{ik} is the *Kronecker delta*. The energy term for the quadrupole interaction, $\frac{e}{6} \sum_{i,k} V_{ik} Q_{ik}$, can be derived by expanding the electrostatic potential into a series at the center of the nucleus (see, e.g., Gütlich et al. 1978). The Hamiltonian for the quadrupole interaction turns out to be

$$\begin{aligned} H_Q &= \frac{e}{6} \sum_i V_{ii} Q_{ii} = \frac{eQ}{2I(2I-1)} \left[V_{xx} I_x^2 + V_{yy} I_y^2 + V_{zz} I_z^2 \right] \\ &= \frac{eQV_{zz}}{4I(2I-1)} \left[3I_z^2 - I^2 + \eta(I_x^2 - I_y^2) \right] \\ &= \frac{eQV_{zz}}{4I(2I-1)} \left[3m_I^2 - I(I+1) + \frac{\eta}{2}(I_+^2 + I_-^2) \right] \end{aligned} \quad (25.68)$$

where \mathbf{I} , \mathbf{I}_x , \mathbf{I}_y , \mathbf{I}_z , $\mathbf{I}_+ = \mathbf{I}_x + i\mathbf{I}_y$ and $\mathbf{I}_- = \mathbf{I}_x - i\mathbf{I}_y$ are the nuclear spin operators ($i^2 = -1$), I and m_I are the quantum numbers belonging to the nuclear spin and its z component, respectively. (The quantity m_I is also called the *magnetic quantum number*.)

In the presence of the quadrupole interaction, represented by the Hamiltonian in [Eq. \(25.68\)](#), the eigenstates of the nucleus will in general be a linear combination of the original orthogonal set of $|I, m_I\rangle$ nuclear states. As H_Q depends on $|m_I|$, the degeneration of

the energy levels of the nuclear states $|I, -I\rangle, |I, -I + 1\rangle, \dots, |I, I - 1\rangle, |I, I\rangle$ is partly removed by the quadrupole interaction. To find the perturbation of the energy levels of the excited (nuclear spin: I_e) and the ground (nuclear spin: I_g) nuclear states, one has to apply the first-order perturbation theory of degenerate states (see, e.g., Raimes 1961 or textbooks on quantum mechanics). In accordance with this theory, the eigenvalues of the matrices $\langle I_e, m_i | H_Q | I_e, m_j \rangle (m_i, m_j = -I_e \dots I_e)$ and $\langle I_g, m_i | H_Q | I_g, m_j \rangle (m_i, m_j = -I_g \dots I_g)$ will provide the energy perturbations of the individual sublevels of the excited state and the ground state, respectively.

As a simple but important example, the energy perturbations of the $I_e = 3/2$ excited state of ^{57}Fe (► Fig. 25.9) experiencing quadrupole interaction are calculated below.

For the calculation of the matrix $\langle 3/2, m_i | H_Q | 3/2, m_j \rangle$ one has to take into account the effect of the I_+ and I_- operators (see ► Eq. (25.68)) on a $|I, m\rangle$ nuclear state:

$$I_+ |I, m\rangle = \sqrt{I(I+1) - m(m+1)} |I, m+1\rangle, \quad (25.69)$$

$$I_- |I, m\rangle = \sqrt{I(I+1) - m(m-1)} |I, m-1\rangle. \quad (25.70)$$

■ Fig. 25.9

Quadrupole splitting of the $I = 3/2$ nuclear level and the resulted Mössbauer spectrum. According to ► Eq. (25.91), Δ is proportional to ΔE_Q

The matrix $\langle 3/2, m_i | H_Q | 3/2, m_j \rangle (m_i, m_j = -3/2 \dots 3/2)$ will then be equal to

$$\left\langle \frac{3}{2}, m_i \left| H_Q \right| \frac{3}{2}, m_j \right\rangle = \frac{eQV_{zz}}{12} \begin{pmatrix} 3 & 0 & \sqrt{3}\eta & 0 \\ 0 & -3 & 0 & \sqrt{3}\eta \\ \sqrt{3}\eta & 0 & -3 & 0 \\ 0 & \sqrt{3}\eta & 0 & 3 \end{pmatrix} \quad (25.71)$$

where increasing row (i) and column (j) numbers correspond to increasing m_i and m_j values, respectively. It can be shown that this matrix has only two different eigenvalues:

$$\lambda_+ = \frac{eQV_{zz}}{4} \sqrt{1 + \frac{\eta^2}{3}} \text{ and } \lambda_- = -\frac{eQV_{zz}}{4} \sqrt{1 + \frac{\eta^2}{3}}. \quad (25.72)$$

Thus, due to the quadrupole interaction, the $I_e = 3/2$ excited state of ^{57}Fe splits giving rise to two sublevels of different energy.

If the EFG tensor has axial symmetry ($\eta = 0$), then the eigenstates $|I_e, m_e\rangle$ of H_0 (see [Eq. \(25.41\)](#)) will also be eigenstates of H_Q , and the $I_e = 3/2$ state will split in two energy sublevels with $\lambda_+ = +eQV_{zz}/4$ and $\lambda_- = -eQV_{zz}/4$ for $m_e = \pm 3/2$ and $m_e = \pm 1/2$, respectively (see [Fig. 25.9](#), where $\Delta E_Q = |\lambda_+ - \lambda_-|$).

At the same time, the ground state of ^{57}Fe has a nuclear spin characterized by $I_g = 1/2$ for which the quadrupole moment $Q = 0$ (see [Sect. 2.2.2.2 in Chap. 2, Vol. 1](#) as well as [Sect. 36.1 of the Appendix of this volume](#)) and therefore the energy of its $m_g = \pm 1/2$ sublevels is not changed by a perturbation of the form described by [Eq. \(25.68\)](#).

For $\eta = 0$, the perturbation of the energy level of a nucleus in the quantum state $|I, m_I\rangle$ can also be given simply by (cf. [Eq. \(25.68\)](#))

$$E_Q = \frac{eQV_{zz}}{4I(2I-1)} [3m_I^2 - I(I+1)]. \quad (25.73)$$

25.1.5.3 Magnetic Dipole Interaction

The nucleus can interact with a magnetic field via its magnetic moment (see [Sect. 2.2.2.3 in Chap. 2, Vol. 1](#)). A magnetic flux density, \mathbf{B} , at the place of the nucleus may be produced by electrons as well as it may be the result of an externally applied magnetic field. The *magnetic hyperfine interaction* can be described by the Hamiltonian

$$H_m = -\boldsymbol{\mu} \mathbf{B} = -g_I \mu_N I_z B \quad (25.74)$$

where $\boldsymbol{\mu}$ is the magnetic moment of the nucleus, μ_N is the nuclear magneton ($eh/4\pi m_p = 5.04929 \times 10^{-27} \text{ Am}^2$), and g_I is the nuclear giromagnetic factor ($g_I = \mu/(\mu_N I)$) of the nuclear state having a nuclear spin I .

In the presence of magnetic hyperfine interaction, the perturbation of energy levels in the excited and in the ground state of the nucleus can be found similarly to the case of the electric quadrupole interaction (see [Sect. 25.1.5.2](#)). The case of ^{57}Fe is considered below.

For the $I = 1/2$ ground state of ^{57}Fe the matrix $\langle 1/2, m_i | H_m | 1/2, m_j \rangle (m_i, m_j = -1/2, 1/2)$ has the form

$$\left\langle \frac{1}{2}, m_i \left| H_m \right| \frac{1}{2}, m_j \right\rangle = -g_{1/2} \mu_N B \begin{pmatrix} -\frac{1}{2} & 0 \\ 0 & \frac{1}{2} \end{pmatrix}. \quad (25.75)$$

And for the excited state ($I = 3/2$) one obtains ($m_i, m_j = -3/2, -1/2, 1/2, 3/2$)

$$\left\langle \frac{3}{2}, m_i \left| H_m \right| \frac{3}{2}, m_j \right\rangle = -g_{3/2} \mu_N B \begin{pmatrix} -\frac{3}{2} & 0 & 0 & 0 \\ 0 & -\frac{1}{2} & 0 & 0 \\ 0 & 0 & \frac{1}{2} & 0 \\ 0 & 0 & 0 & \frac{3}{2} \end{pmatrix}. \quad (25.76)$$

As both matrices are diagonal, it is clear that the original orthogonal $|I, m_I\rangle$ states are eigenstates of H_m and consequently they are also eigenstates of $H_0 + H_m$ (see [Eq. \(25.41\)](#)). The eigenvalues of the diagonal matrices are simply the elements in the diagonal.

For a nuclear state $|I, m_I\rangle$ the energy perturbation due to magnetic hyperfine interaction is thus given by

$$E_m = -g_I \mu_N B m_I \quad (25.77)$$

where m_I is the magnetic quantum number ($m_I = I, I - 1, \dots, -I$).

As shown also by [Fig. 25.10](#), the magnetic field splits the nuclear level of spin I into $2I + 1$ equidistantly spaced non-degenerate sublevels with a separation of $g_I \mu_N B$ (*nuclear Zeeman effect*).

25.1.5.4 Combined Interactions

In the general case of combined electric quadrupole and magnetic dipole interactions the peak positions can only be calculated numerically.

Fig. 25.10

Magnetic splitting of the $I = 3/2$ and $I = 1/2$ nuclear levels (of ^{57}Fe) and the corresponding Mössbauer spectrum. The internal magnetic field (induction, B) is proportional to the distance between any two lines of the sextet; the largest such separation is marked

If $|eQV_{zz}| \ll |\mu B|$ first-order perturbation theory may be applied. Let ϑ denote the angle between the z -axis and \mathbf{B} . If the EFG has axial symmetry, the eigenvalue of the Hamiltonian of the combined interaction is given by

$$E_{m_Q} = -g\mu_N B m_I + (-1)^{|m_I|+1/2} \frac{eQV_{zz}}{4} \frac{3\cos^2\vartheta - 1}{2}. \quad (25.78)$$

For more complex cases see Matthias et al. (1963).

25.1.5.5 Microenvironment

The term “microenvironment” is of fundamental importance in Mössbauer spectroscopy. It is directly related to the hyperfine interactions sensed by the nucleus. In a solid studied by Mössbauer spectroscopy, there are a large number of nuclei of the Mössbauer isotope. They all sense local hyperfine interactions, which are determined by the product of a nuclear parameter (charge equivalent nuclear radius, R , nuclear quadrupole moment, Q , and nuclear magnetic moment, μ) and a solid-state parameter (electronic density, ρ , electric field gradient represented by V_{zz} and η , and magnetic flux density, \mathbf{B}) (see [Eqs. \(25.60\)](#), [\(25.68\)](#), and [\(25.74\)](#)).

Normally, the nuclear parameters are the same for all nuclei embedded in a species. However, the solid-state parameters vary from phase to phase in a multiphase species, or may vary within the phase from site to site where the environment of the Mössbauer atom is different. Consequently, there may be assemblies of nuclei sensing different hyperfine interactions in a solid, in general. The microenvironment is a convenient term for the classification of local environments surrounding the Mössbauer atoms. The local environments of two Mössbauer atoms represent the same microenvironment if those atoms experience the same hyperfine interactions there. The correspondence between the microenvironment and hyperfine interactions gives a basis for the analytical use of Mössbauer spectroscopy (see [Sect. 25.3](#)).

25.2 Mössbauer Parameters

25.2.1 Isomer Shift

The isomer shift, denoted by δ , is the most often quoted Mössbauer parameter. It is a peak shift that consists of two terms:

$$\delta = \delta_c + \delta_{\text{SOD}} \quad (25.79)$$

where the first term is the chemical isomer shift δ_c (already mentioned in [Sect. 25.1.5.1](#)) and the second term is the second-order Doppler shift (also called temperature shift). The isomer shift, δ , is measured in velocity units for which the suggested decimal submultiple SI unit is mm/s.

25.2.1.1 Chemical Isomer Shift

The chemical isomer shift, δ_c (measured as Doppler velocity in mm/s units), is related to the electric monopole hyperfine interaction between the nucleus and the electrons. The nuclear energy levels will be shifted as a result of this interaction (see [Fig. 25.8](#), [Sect. 25.1.5.1](#)).

To measure this energy shift in the Mössbauer experiment one should modify the energy of the emitted γ ray by moving the source relative to the absorber by an appropriate Doppler velocity in order to bring the energy of the emitted γ ray into coincidence with the absorption energy in the absorber, when one actually measures the chemical isomer shift.

With the notation introduced in [▶ Sect. 25.1.5.1](#), δ_c can be defined as the Doppler velocity corresponding to the energy shift ΔE_{IS} (see [▶ Eq. \(25.60\)](#)):

$$\delta_c = \frac{c}{E_0} \Delta E_{IS}. \quad (25.80)$$

The name *chemical* isomer shift is related to the fact that the electron density at the place of the nucleus is strongly influenced by the valence state and the chemical bonding of the Mössbauer atom.

The expressions for the chemical isomer shift can be derived by substituting ΔE_{IS} (see [▶ Eqs. \(25.60\)](#), [▶ \(25.62\)](#), and [▶ \(25.64\)](#)) into the formula of δ_c ([▶ 25.80](#)).

All expressions presently used for evaluation of isomer shifts neglect the polarization effects (see [▶ Eqs. \(25.49\)](#) and [▶ \(25.50\)](#)). This introduces an error less than 5%.

By treating the electron density relativistically, the isomer shift can be given by combining [▶ Eqs. \(25.64\)](#) and [▶ \(25.80\)](#) to give

$$\delta_c = C \Delta \rho_e(0) [\Delta \langle r^2 \rangle - b_4 \Delta \langle r^4 \rangle + b_6 \Delta \langle r^6 \rangle] \quad (25.81)$$

where $C = (2/3)\pi Ze^2 c/E_0$, $\Delta \rho_e(0) = \rho_e^A(0) - \rho_e^S(0)$, $\Delta \langle r^m \rangle = \langle r^m \rangle_e - \langle r^m \rangle_g$, and b_4 and b_6 are constants that depend on Z .

In most cases, the terms with order higher than $m = 2$ can be neglected. In this way, one obtains the expression for the chemical isomer shift, which is recommended for general use

$$\delta_c = C \Delta \rho_e(0) \Delta \langle r^2 \rangle \quad (25.82)$$

where with the choice $C = 90.42Z/(E_0/\text{keV})$ and measuring $\Delta \langle r^2 \rangle$ in fm^2 and $\Delta \rho(0)$ in 10^{26} cm^{-3} units, δ_c is obtained in units of mm/s .

The error of using this formula instead of the previous one ([▶ Eq. \(25.81\)](#)) is about 1% to 10%. (The error increases with the mass of the atom.)

By introducing the charge equivalent radius R (see [▶ Eq. \(25.59\)](#)) and by expressing the nuclear parameter as the relative change of this radius one obtains

$$\delta_c = C \Delta \rho_e(0) \frac{\Delta R}{R} \quad (25.83)$$

with $C = (4/5)\pi Ze^2 c(1.2A^{1/3})^2/E_0 = 156.24ZA^{2/3}/E_0$.

The additional error is of the order of a few percentage. This expression has found the most widespread application in the solid state and chemical literature.

If only nonrelativistic electron densities are available a correction by a multiplication factor $S'(Z)$ has to be applied ([▶ Eq. \(25.62\)](#)) and the expression for the chemical isomer shift will be

$$\delta_c = C \Delta |\psi(0)|^2 S'(Z) \frac{\Delta R}{R} \quad (25.84)$$

where $|\psi(0)|^2$ denotes the nonrelativistic s electron density at the place of the nucleus. This is the most commonly used formula of the chemical isomer shift for applications in chemistry.

In the case of ^{57}Fe and ^{119}Sn (which are the most frequently used Mössbauer nuclides), the evaluation of the chemical isomer shift is often performed by using a so-called isomer shift

calibration constant, α or α' , especially in the chemical literature. With the help of these calibration constants, the following expressions can be obtained for the chemical isomer shift:

$$\delta_c = \alpha' \Delta\rho(0) \text{ and } \delta_c = \alpha \Delta|\psi(0)|^2. \quad (25.85)$$

In most chemical applications of Mössbauer spectroscopy, [Eq. \(25.84\)](#) is used. Consequently, from the chemical isomer shift, the charge equivalent nuclear radius (R) and the electron density can be determined. Any of the two can be obtained from a Mössbauer measurement if the other one is determined independently. In most chemical applications, the goal is the determination of the shift in electron density.

In practice, the chemical isomer shift is usually given relative to a standard reference material. In ^{57}Fe Mössbauer spectroscopy, $\alpha\text{-Fe}$ has become the most commonly used standard reference material.

25.2.1.2 Second-Order Doppler Shift

The second-order Doppler shift, δ_{SOD} , which is often called *temperature shift*, is a peak shift related to the relativistic Doppler effect originating from the thermal motion of the nuclei. If the Mössbauer atom has a speed u , and moves in a direction making angle α with the direction of the γ ray it emits, then the ν frequency of the emitted γ ray will differ from the ν_0 frequency it had if the atom had been at rest. The ν frequency is related to ν_0 in the following way:

$$\nu = \nu_0 \frac{\sqrt{1 - \frac{u^2}{c^2}}}{1 - \frac{u}{c} \cos \alpha}. \quad (25.86)$$

As atoms in a solid perform an oscillatory motion with a period in the order of around 10^{-13} s, during the lifetime of the excited state of the Mössbauer nucleus (for the case of ^{57}Fe , e.g., $\tau \approx 10^{-7}$ s) the corresponding atom goes through approximately a million of cycles. As a result, only the time-average of the relativistic Doppler effect can be detected in the Mössbauer spectra. Taking into account that $u \ll c$, time averaging the right-hand side of [Eq. \(25.86\)](#) yields the following equation for the mean frequency of the emitted γ photon (Pound and Rebka 1960):

$$\nu \approx \nu_0 \left(1 - \frac{1}{2} \frac{\langle u^2 \rangle}{c^2} \right), \quad (25.87)$$

i.e., the Doppler effect arising because of the oscillatory motion of atoms in a solid influences the frequency of the emitted γ ray only in the second order of the speed of the atoms.

The corresponding energy shift of the γ ray can be calculated as

$$\Delta E_{\text{SOD}} = h(\nu - \nu_0) = -\frac{h\nu_0}{2} \frac{\langle u^2 \rangle}{c^2} = -\frac{1}{2} \frac{\langle u^2 \rangle}{c^2} E_\gamma \quad (25.88)$$

In the Mössbauer spectrum, the *second-order Doppler shift* is measured as a peak shift in velocity units:

$$\delta_{\text{SOD}} = -\frac{1}{2} \frac{\langle u^2 \rangle}{c}. \quad (25.89)$$

From [Eq. \(25.23\)](#) it follows that δ_{SOD} decreases with increasing temperature.

25.2.2 Quadrupole Splitting

The quadrupole splitting, Δ , is the Mössbauer parameter, which is related to the electric quadrupole hyperfine interaction between the nucleus and the electrons (see [Sect. 25.1.5.2](#)).

In the case of ^{57}Fe and ^{119}Sn , e.g., where the Mössbauer transition occurs between nuclear levels with excited state spin $I_e = 3/2$ and ground state spin $I_g = 1/2$, in the presence of hyperfine quadrupole interaction, the excited state will be split into two sublevels (see [Eq. \(25.72\)](#) and [Fig. 25.9](#)). Resonance absorption can occur between the unsplit ground state and both sublevels of the split-excited state. By performing a Mössbauer measurement (see [Fig. 25.5](#)) one can detect both of the corresponding absorption peaks. The distance between the two peaks, measured in Doppler velocity units as usual in Mössbauer spectroscopy, is called the *quadrupole splitting* Δ . Thus, the quadrupole splitting is proportional to the energy separation (also called the quadrupole splitting energy, ΔE_Q) between the two sublevels of the split-excited state:

$$\Delta \propto \Delta E_Q = \lambda_+ - \lambda_- = \frac{eQV_{zz}}{2} \sqrt{1 + \frac{\eta^2}{3}} \quad (25.90)$$

where λ_+ and λ_- have been defined in [Eq. \(25.72\)](#). The proportionality constant connecting Δ with ΔE_Q depends on the energy of the γ ray (E_0 , see [Fig. 25.1](#)) emitted by the source in a recoilless emission event:

$$\Delta = \frac{c}{E_0} \Delta E_Q. \quad (25.91)$$

The two absorption peaks, appearing in the measured Mössbauer spectrum as a consequence of electric quadrupole hyperfine interaction, are called a *doublet*.

As can be seen from [Eq. \(25.90\)](#), in the case of a $3/2 \rightarrow 1/2$ transition, solely from the knowledge of Δ it is not possible to determine V_{zz} and η independently or to find out the sign of the V_{zz} . It is possible, however, to determine these parameters of the electric field gradient from the angular dependence of the intensity of the peaks when a single crystal is measured. The sign of the V_{zz} can be determined if in addition to electric quadrupole interaction the Mössbauer nuclei experience hyperfine magnetic interaction as well (see [Fig. 25.12](#)).

The connection between the quadrupole splitting energy and the separation of the absorption lines is less obvious if in addition to the excited state, the ground nuclear state is also subject to hyperfine quadrupole interaction. This is the case, e.g., for ^{129}I where the Mössbauer transition occurs between the excited state with $I_e = 5/2$ and the ground state with $I_g = 7/2$. The quadrupole splittings of this transition are treated below by assuming that the asymmetry parameter of the EFG is zero ($\eta = 0$, see [Eqs. \(25.68\)](#) and [\(25.73\)](#)).

In this case, altogether five quadrupole splittings ($\Delta_1 \dots \Delta_5$) can be observed (see [Fig. 25.11](#)). In the excited state the ratio between the splittings $\Delta_1/\Delta_2 = 1/2$, while in the ground state $\Delta_3:\Delta_4:\Delta_5 = 1:2:3$, as can be calculated from [Eq. \(25.92\)](#).

The selection rules for a magnetic dipole (M1) electromagnetic (EM) transition ($\Delta m_I = 0, \pm 1$) allow eight transitions, which result in eight Mössbauer peaks in the spectrum. The positions of the individual peaks (relative to the isomer shift) can be given by

$$\delta_{ij} = \frac{ceV_{zz}Q_g}{4E_0} \left[\frac{Q_e}{Q_g} C(I^e, m_I^e) - C(I^g, m_I^g) \right], \quad \text{where } C(I, m_I) = \frac{3m_I^2 - I(I+1)}{I(2I-1)} \quad (25.92)$$

where Q_e and Q_g are the quadrupole moments of the excited state and the ground state, respectively (Hafemeister 1971).

■ Fig. 25.11

Quadrupole splitting of the $I = 5/2$ (excited state) and $I = 7/2$ (ground state) nuclear levels of ^{129}I . The relative intensities of the allowed transitions indicated are (from the left to the right): 1:6:21:3:10:15:18:10 (May 1971). Note that the $I = 7/2$ levels are indeed lower than the $I = 5/2$ levels in this particular case

From the measured quadrupole splitting, either the nuclear quadrupole moment or the electric field gradient can be determined. Any of the two can be obtained from a Mössbauer measurement if the other can be determined independently. In chemical applications, the determination of the electric field gradient is the goal.

In many cases, not V_{zz} but eQV_{zz} is derived from the measured quadrupole splitting either in velocity or in frequency units. ▶ Table 25.1 shows the corresponding conversion factors for some Mössbauer nuclides.

25.2.3 Magnetic Splitting

The magnetic splitting Δ_m is related to the hyperfine magnetic interaction (see ▶ Sect. 25.1.5.3).

As shown by ▶ Eq. (25.77), the energy levels produced by the nuclear Zeeman splitting can be expressed as a product containing the nuclear magnetic moment μ and the *magnetic flux density*, B , existing at the site of the nucleus.

The magnetic splitting energy ΔE_m means the energy difference between the adjacent Zeeman split sublevels of a nuclear level. Its value derived from ▶ Eq. (25.77) is

$$\Delta E_m = -g_I \mu_N B \Delta m_I = -g_I \mu_N B \quad (25.93)$$

Note that the ΔE_m magnetic splitting energy in the excited state is different from that in the ground state.

■ Table 25.1

Numerical factors that can be used to obtain the value of eQV_{zz} in mm s^{-1} or in MHz units from the value of V_{zz} . In the case of $3/2 \rightarrow 1/2$ transitions (^{57}Fe , ^{119}Sn , ^{125}Te) the conversion factors are calculated with Q referring to the quadrupole moment of the excited nuclear state. For the other nuclides, Q refers to the quadrupole moment of the ground state. The precision of the given numerical factors is limited by the uncertainty of the respective Q values

Mössbauer nuclide ($I_e \rightarrow I_g$)	In order to obtain eQV_{zz} in mm s^{-1} units, $V_{zz}/(10^{21} \text{ V/m}^2)$ should be multiplied by	In order to obtain eQV_{zz} in MHz units, $V_{zz}/(10^{21} \text{ V/m}^2)$ should be multiplied by
^{57}Fe ($3/2 \rightarrow 1/2$)	+0.333(2)	+3.87(2)
^{119}Sn ($3/2 \rightarrow 1/2$)	−0.166(1)	−3.19(2)
^{125}Te ($3/2 \rightarrow 1/2$)	−0.262(17)	−7.5(5)
^{151}Eu ($7/2 \rightarrow 5/2$)	+1.257(14)	+21.83(24)
^{121}Sb ($7/2 \rightarrow 5/2$)	−0.438(9)	−13.13(27)
^{141}Pr ($7/2 \rightarrow 5/2$)	−0.0122(8)	−1.43(10)
^{129}I ($5/2 \rightarrow 7/2$)	−0.537(8)	−12.04(17)
^{237}Np ($5/2 \rightarrow 5/2$)	+1.957(3)	+93.96(15)
^{161}Dy ($5/2 \rightarrow 5/2$)	+2.930(23)	+60.62(48)
^{197}Au ($1/2 \rightarrow 3/2$)	+0.212(6)	+13.23(39)

For a transition between nuclear levels with nuclear spin $I_g = 1/2$ and $I_e = 3/2$, due to hyperfine magnetic interaction, the excited state splits into four sublevels with $m_{3/2} = -3/2, -1/2, +1/2$, and $+3/2$, while the ground state splits into two sublevels with $m_{1/2} = +1/2, -1/2$, as illustrated in [Fig. 25.10](#). According to the selection rule that applies to M1 electromagnetic transitions ($\Delta m_I = 0, \pm 1$), there are six allowed transitions in this case. This results in a six-peak pattern called sextet in the Mössbauer spectrum. The magnetic splitting of the excited state can be determined from the peak separation of the first and second or of the second and third peaks as well as from that of the fourth and fifth or of the fifth and sixth peaks (see [Fig. 25.10](#)). The magnetic splitting of the ground state can be obtained from the peak separation of the second and fourth or of the third and fifth peaks. The peak separation and, consequently, the *magnetic splitting* Δ_m is measured as a Doppler velocity, in mm/s unit:

$$\Delta_m = \Delta E_m \frac{c}{E_0}. \quad (25.94)$$

For the chemical application of Mössbauer spectroscopy, it is not necessary to derive the magnetic splitting explicitly from the Mössbauer spectrum in order to determine the magnetic flux density. As the separation of any two of the peaks in a *magnetic sextet* is also proportional to the magnetic flux density sensed by the corresponding nuclei, the basis of the determination of B is usually the separation of the two outermost peaks of the spectrum.

For a transition between nuclear levels with higher nuclear spin values, the magnetic field results in a more complex peak pattern in the Mössbauer spectrum. In the case of ^{151}Eu , e.g., the Mössbauer transition occurs between the $I_g = 5/2$ and $I_e = 7/2$ nuclear levels, and in the presence of magnetic splitting the Mössbauer spectrum consists of 18 peaks (Greenwood and

Gibb 1971). The separation of the peaks will also be proportional to the corresponding magnetic flux density.

In many cases the hyperfine magnetic dipole interaction occurs together with the electric quadrupole interaction. As shown in [Fig. 25.12](#) for the transition $I = 1/2 \rightarrow 3/2$, when $H_Q \ll H_m$, the sublevels of the excited state are no longer equally spaced, but the $m_I = +3/2$ and $m_I = -3/2$ sublevels are raised while the $m_I = +1/2$ and $m_I = -1/2$ sublevels are lowered when $V_{zz} > 0$. (Note that if $V_{zz} > 0$ and $\eta \neq 0$, the eigenstates of $H = H_0 + H_C + H_m$ (i.e., $|I, m_I\rangle$) will no longer be eigenstates of $H' = H_0 + H_C + H_m + H_Q$ – see [Eqs. \(25.41\)](#) and [\(25.68–25.70\)](#) – and therefore the sublevels shifted higher or lower than those belonging to the case $H_Q = 0$ will no longer represent pure $|I, m_I\rangle$ states but linear combinations of several $|I, m_I\rangle$ states as mentioned in [Sect. 25.1.5.2](#).) In the corresponding Mössbauer spectrum, the separation between the centers of the outermost two and of the inner four peaks will be proportional to the quadrupole splitting. From the position of these centers relative to each other, the sign of V_{zz} can be determined. The energies of the individual nuclear sublevels are given by [Eq. \(25.78\)](#) in this case.

Fig. 25.12

Energy shift and magnetic splitting of the $I = 1/2$ and $I = 3/2$ levels in the presence of an electric field gradient with $\eta = 0$, and the corresponding Mössbauer spectrum ($V_{zz} > 0$). Note that due to quadrupole interaction, the symmetry center of the outermost peaks is shifted relative to the inner four peaks in contrast to [Fig. 25.10](#)

25.2.4 Peak Intensity

If no splitting of the nuclear levels occurs, then the Mössbauer peak intensity can be given by [Eq. \(25.31\)](#).

In the case of the electric quadrupole and magnetic dipole interactions, the individual peaks have characteristic intensities relative to each other, which can confirm the assignment of the peaks to the appropriate nuclear transitions, and, in addition to the information provided by δ , Δ , and Δ_m , it helps assigning the various subspectra of the Mössbauer spectrum to lattice sites. The relative intensities can also furnish information on the orientational relationships in the sample/lattice (Schatz et al. 1996).

The relative intensity of a peak is proportional to the *relative* probability of the corresponding nuclear transition. For the *probability of a transition* from a state $|I_e, m_e\rangle$ to the state $|I_g, m_g\rangle$ by electromagnetic (EM) multipole radiation of σl (where $\sigma = E$ for electric and $\sigma = M$ for magnetic multipole character, and 2^l is the multipolarity of the radiation, see [Sect. 2.3.2.2 in Chap. 2, Vol. 1](#)) one can write

$$p(I_g, m_g, M_l^\sigma, I_e, m_e) \propto \left| \langle I_g, m_g | M_{l,m}^\sigma | I_e, m_e \rangle \right|^2 \quad (25.95)$$

where $M_{l,m}^\sigma$ is the multipole operator (for more details see, e.g., Blatt and Weisskopf (1959) or Mayer-Kuckuk (1994)) corresponding to the multipole radiation σl that carries away an angular momentum of $l\hbar$ with a z component of $m\hbar$.

According to the Wigner–Eckart theory (see, e.g., Rotenberg et al. 1959)

$$\langle I_g, m_g | M_{l,m}^\sigma | I_e, m_e \rangle = (-1)^{I_g - m_g} \begin{pmatrix} I_g & l & I_e \\ -m_g & m & m_e \end{pmatrix} \langle I_g | M_l^\sigma | I_e \rangle \quad (25.96)$$

where the term $\langle I_g | M_l^\sigma | I_e \rangle$ (called the *reduced matrix element*) does not depend on m_g , m_e , and m . Consequently, it has the same value for all of the transitions occurring via σl multipole radiation between the excited state and ground state of the nucleus.

As it is only the *relative* value of probabilities of $|I_e, m_e\rangle \rightarrow |I_g, m_g\rangle$ nuclear transitions ($m_e = -I_e, \dots, I_e$, $m_g = -I_g, \dots, I_g$) that can be detected in a Mössbauer measurement, for the probability of a certain $|I_e, m_e\rangle \rightarrow |I_g, m_g\rangle$ transition via σl multipole radiation one can write

$$p(I_g, m_g, M_l^\sigma, I_e, m_e) \propto \left(\begin{pmatrix} I_g & l & I_e \\ -m_g & m & m_e \end{pmatrix} \right)^2 \quad (25.97)$$

where the term on the right side is the so-called “ $3j$ symbol” (see, e.g., Lindner (1984) and Weisstein (2010)). The $3j$ symbols are closely related to the so-called Clebsch–Gordan coefficients. There are numerous Web sites on the Internet where automatic calculators are available for the calculation of $3j$ symbols as a function of I_g , I_e , l , m_g , m_e , and m .

The square of $3j$ symbol values entering the calculations in the case of the Mössbauer transition of ^{57}Fe ($I_e = 3/2$, $I_g = 1/2$, $\sigma l = M1$) are the following:

$$\left(\begin{pmatrix} 1/2 & 1 & 3/2 \\ \pm 1/2 & \pm 1 & \mp 3/2 \end{pmatrix} \right)^2 = \frac{1}{4}, \quad \left(\begin{pmatrix} 1/2 & 1 & 3/2 \\ \pm 1/2 & 0 & \mp 1/2 \end{pmatrix} \right)^2 = \frac{1}{6}, \quad \left(\begin{pmatrix} 1/2 & 1 & 3/2 \\ \pm 1/2 & \mp 1 & \pm 1/2 \end{pmatrix} \right)^2 = \frac{1}{12}. \quad (25.98)$$

To calculate the relative intensities of absorption lines in a Mössbauer spectrum, one also has to take into account that the intensity of the emitted multipole radiation is not isotropic but has a certain angular dependence $F_{lm}(\theta)$ where θ is the polar angle that the direction of observation encloses with the z -axis of the principal axis system (defined, e.g., by the direction

of the hyperfine magnetic field). It follows that the relative intensity of the peak belonging to the transition $|I_e, m_e\rangle \rightarrow |I_g, m_g\rangle$ can be expressed as

$$I(I_e, m_e, I_g, m_g, \sigma lm) \propto \begin{pmatrix} I_g & l & I_e \\ -m_g & m & m_e \end{pmatrix}^2 F_{lm}(\theta). \tag{25.99}$$

For the case of $3/2 \rightarrow 1/2$ magnetic dipole transitions, the angular dependence of the relative peak intensities are tabulated in [Table 25.2](#) together with corresponding values of $3j$ symbol squares.

For an isotropic distribution of \mathbf{B} (e.g., when a powder sample without texture is measured), the term $F_{lm}(\theta)$ describing the angular dependence of the intensity of multipole radiation can be integrated to give a factor of 1 for all the values of m . This means that in the case of powdered samples (and in the absence of additional effects, see [Sect. 25.2.7.5](#)) the relative intensity of the Mössbauer peaks is determined only by the values of $3j$ symbol squares. For $3/2 \rightarrow 1/2$ magnetic dipole transitions, in the case of magnetic splitting this results in a sextet with relative peak intensities of 3:2:1:1:2:3, while in the case of electric quadrupole interaction, assuming an isotropic distribution of the z direction of the EFG's PAS (principal axis system) in this case, a doublet with relative peak intensities of 1:1 is obtained.

The determination of peak intensities becomes a more complicated issue in the case of combined hyperfine magnetic dipole and electric quadrupole interactions (for the case of ^{57}Fe see, e.g., Kündig (1967) and Housley et al. (1969)), or when the Mössbauer transition has a mixed (most often M1 + E2) multipole character (for the case of ^{99}Ru see, e.g., Foyt et al. (1975)). Further factors influencing the relative peak intensities will be discussed in [Sect. 25.2.7.5](#).

25.2.5 The *f*-Factor

The *f*-factor, also called the Mössbauer–Lamb factor, is not only a measure of the probability of recoilless resonance emission/absorption of γ photons as discussed in [Sect. 25.1.3.3](#), but it is

Table 25.2

$3j$ symbols and angular dependent terms determining the relative intensities of peaks in the case of a magnetic dipole transition occurring between nuclear levels with nuclear spins $I = 3/2$ and $I = 1/2$ (which is the case for, e.g., ^{57}Fe and ^{119}Sn)

$m_{3/2}$	$m_{1/2}$	m	Square of corresponding $3j$ symbol	Angular dependence of intensity
			$\begin{pmatrix} 1/2 & 1 & 3/2 \\ -m_{1/2} & m & m_{3/2} \end{pmatrix}^2$	$F_{lm}(\theta)$ ($l = 1$)
3/2	1/2	−1	$\frac{3}{12}$	$\frac{3}{8}(1 + \cos^2\theta)$
1/2	1/2	0	$\frac{2}{12}$	$\frac{3}{4}\sin^2\theta$
−1/2	1/2	1	$\frac{1}{12}$	$\frac{3}{8}(1 + \cos^2\theta)$
−3/2	1/2	2	Not allowed	
3/2	−1/2	−2	Not allowed	
1/2	−1/2	−1	$\frac{1}{12}$	$\frac{3}{8}(1 + \cos^2\theta)$
−1/2	−1/2	0	$\frac{2}{12}$	$\frac{3}{4}\sin^2\theta$
−3/2	−1/2	1	$\frac{3}{12}$	$\frac{3}{8}(1 + \cos^2\theta)$

an important Mössbauer parameter, which can be obtained from the measurement of Mössbauer spectra. The f -factor is defined as the number of recoilless γ events (emission or absorption) divided by the total number of γ events. Since it can be expressed as a function of the mean square displacement, $\langle x^2 \rangle$, of the Mössbauer atom “frozen” in the lattice, (see [Eq. \(25.24\)](#)), it is possible to get important information from the f -factor about the state of lattice vibrations (e.g., to determine the Debye temperature from its temperature dependence).

The Mössbauer–Lamb factors f_S (for the source) and f_A (for the absorber) show up as coefficients to determine the Mössbauer peak intensity (see [Eq. \(25.31\)](#) for the transmission integral). Unfortunately, it is difficult to determine the absolute values of f_S and f_A from the absorption intensity without tedious and difficult experimentation.

The so-called black absorber method may be used for the determination of f_S . This uses the saturation effect of f_S when the effective thickness, τ_A (see [Eq. \(25.30\)](#)), approaches infinity. In this case, the asymptotic form of the spectral peak amplitude can be used to obtain f_S . The measurement of the f -factor of the absorber, f_A , is based on [Eq. \(25.33\)](#) and the corresponding nonlinear dependence of the intensity, amplitude, and width of the Mössbauer spectrum peak on the effective thickness (see later in [Fig. 25.17](#)). This latter is the so-called *blackness effect*. For the determination of f_A , the peak intensity and the peak amplitude should be measured for at least two absorbers of different thicknesses (Vértes and Nagy 1990).

When the Mössbauer nuclides are in different microenvironments, the determination of the relative values of the Mössbauer–Lamb factors belonging to each microenvironment is necessary in order to obtain the correct relative molar quantities.

25.2.6 Peak Width

The Mössbauer peak is characterized by an experimental parameter, the peak width W , which is measured as the full width at half maximum of the peak.

The peak width W for Lorentzian peaks can be derived from [Eq. \(25.31\)](#) (Margulies and Ehrman 1961) as a function of the absorber thickness:

$$W = W_0 \tau \frac{\exp\left(-\frac{\tau}{2}\right) I_0\left(-\frac{\tau}{2}\right) + I_1\left(-\frac{\tau}{2}\right)}{1 - \exp\left(-\frac{\tau}{2}\right) I_0\left(-\frac{\tau}{2}\right)}, \quad (25.100)$$

where $W_0 = 2\Gamma$, and Γ is the natural line width of the given Mössbauer transition. I_0 and I_1 denote the modified Bessel functions (see, e.g., BESSEL 2003) of the first kind (also referred to as having imaginary argument), and τ is the effective thickness of the absorber (which is proportional to the actual surface density d measured in mg/cm^2 , see [Eq. \(25.30\)](#)).

In the case of an ideally thin absorber, the Mössbauer peak width is twice of the natural line width ($W_0 = 2\Gamma$), which gives a possibility to determine the lifetime of the excited states of the Mössbauer nuclei on the basis of [Eq. \(25.2\)](#).

It is possible to observe Mössbauer peak widths narrower than W_0 without violating the uncertainty principle. This can happen, e.g., if γ photons from a nuclear decay are selected in such a way that only those are counted, which are emitted after a certain time of the “birth” of the excited state (*time-dependent Mössbauer spectroscopy*).

Deviations from the expected peak width may arise due to various effects. A number of inherent physical processes cause peak broadening (like diffusion, relaxation processes) and, consequently, a lot of useful information can be obtained from the peak width W .

25.2.7 Mössbauer Parameters and Experimental Parameters

As it was just seen, the main *Mössbauer parameters* that can be derived from a Mössbauer spectrum are as follows: Mössbauer–Lamb factor (f), isomer shift (δ), quadrupole splitting (Δ), magnetic splitting (Δ_m), peak width (W), and the relative area – also called the relative intensity – of the spectrum peaks (A). Sometimes, it is convenient to consider these parameters as the coordinates of the Mössbauer parameter vector \mathbf{P}_M :

$$\mathbf{P}_M = (f, \delta, \Delta, \Delta_m, W, A), \quad (25.101)$$

where the individual symbols between the parentheses may again represent sets of similar parameters (i.e., vectors).

For instance, instead of A one might write \mathbf{A} meaning:

$$\mathbf{A} = (A_1, A_2, \dots), \quad (25.102)$$

where A_1, A_2, \dots represent the spectral areas of different peaks.

The Mössbauer parameters depend on a number of various *experimental parameters* such as temperature (T), pressure (p), external magnetic flux density (\mathbf{B}_{ext}) if any, the polar angles of the sample relative to the direction of the γ rays (θ, ϕ), the frequency (ν) of high-frequency field if any, etc.:

$$\mathbf{P}_M = f(\mathbf{P}_{\text{exp}}), \quad (25.103)$$

where the vector \mathbf{P}_{exp} represents all of the relevant experimental parameters:

$$\mathbf{P}_{\text{exp}} = (T, p, B_{\text{ext}}, \theta, \phi, \nu, c, \dots) \quad (25.104)$$

in which the c concentration of the Mössbauer species in the sample is also included.

Some of the above-listed experimental parameters may have *standard values*. For instance, $T_0 = 293$ K (room temperature, RT), $p_0 = 1$ bar (\sim atmospheric pressure), $\mathbf{B}_{\text{ext},0} = 0$ T (no external magnetic field applied), etc. The measuring conditions specified by such values are called *standard conditions*.

25.2.7.1 Temperature Dependence

The temperature dependence of Mössbauer parameters can be very useful in qualitative analysis. As the temperature dependence of the different spectrum components is usually different, measuring the same sample at different temperatures may help distinguish between species whose “fingerprints” are similar under standard conditions (i.e., at room temperature in the given instance) but different at lower or higher temperatures.

The *temperature dependence of the isomer shift* (see [Fig. 25.13](#)) is mainly determined by that of the second-order Doppler shift and can be obtained by combining [Eqs. \(25.89\)](#) and [\(25.23\)](#):

$$\delta_{\text{SOD}}(T) = -\frac{9k\theta_D}{2cM} \left[\frac{1}{8} + \left(\frac{T}{\theta_D} \right)^4 \int_0^{\theta_D/T} \frac{x^3}{e^x - 1} dx \right]. \quad (25.105)$$

The *temperature dependence of the quadrupole splitting* comes mainly from the temperature-dependent population of the different valence levels of the Mössbauer nuclide, provided that

■ Fig. 25.13

Temperature dependence of the isomer shift of ^{119}Sn in $\text{V}_3\text{Ga}_{0.1}\text{Sn}_{0.9}$, based on the results of Kimball et al. (1974)

the valence contribution to the electric field gradient is not negligible (Ingalls 1964; Eicher and Trautwein 1969; Gütlich et al. 1978).

In the case of ^{57}Fe one has

$$\Delta(T) = \frac{2}{7} e^2 Q \frac{c}{E_\gamma} (1 - R) \langle r^{-3} \rangle \alpha^2 F(E_i, \alpha^2 \lambda_0, T) \quad (25.106)$$

where the temperature sensitive factor F depends on the energy separation of the 3d levels E_p on the isotropic covalency factor α^2 , and on the free-ion spin-orbit coupling constant λ_0 . $\langle r^{-3} \rangle$ means the expectation value of r^{-3} , and R is the antishielding *Sternheimer factor* (Sternheimer 1950, 1951, 1963).

The temperature dependence of quadrupole splitting is illustrated in ► Fig. 25.14 for $\text{Cd}_3[\text{Fe}(\text{CN})_6]_2$.

The temperature dependence of the Mössbauer–Lamb factor (see ► Fig. 25.15) can be calculated in the frame of the Debye model of solids from ► Eq. (25.26). For different temperature regions, the following formulae can be derived (cf. ► Eqs. (25.20)–(25.22) and ► (25.24)):

$$f(T) \approx \exp \left\{ -\frac{6E_R}{k\theta_D} \left(\frac{1}{4} + \left(\frac{T}{\theta_D} \right)^2 \frac{\pi^2}{6} \right) \right\}, \quad \text{if } T \ll \theta_D \quad (25.107)$$

$$f(T) \approx \exp \left\{ -\frac{6E_R}{k\theta_D} \frac{T}{\theta_D} \right\}, \quad \text{if } T \gg \theta_D \quad (25.108)$$

where E_R is the recoil energy and θ_D is the Debye temperature.

The temperature dependence of the magnetic splitting itself depends on the nature of the magnetic interaction in the investigated material.

■ Fig. 25.14

Temperature dependence of the quadrupole splitting of ^{57}Fe in $\text{Cd}_3[\text{Fe}(\text{CN})_6]_2$ (Based on Vértés et al. 1979)

■ Fig. 25.15

Typical shape of the temperature dependence of the Mössbauer–Lamb factor

For simple *ferromagnetic* interaction, e.g., when the Bloch law (Kittel 1968) is valid for the field, one obtains

$$\frac{\Delta E_m(T)}{\Delta E_m(0\text{K})} = 1 - CT^{3/2} \quad (25.109)$$

where C is a constant.

In the case of some *paramagnetic* materials exhibiting magnetically split Mössbauer spectra, the magnetic splitting is due to the paramagnetic spin relaxation time τ_{SR} being relatively high in comparison with the *Larmor precession* time of the nucleus. In this case, temperature dependence is governed by that of the spin-lattice relaxation of the material (Vértés and Nagy 1990).

The temperature dependence of the peak width W caused by the diffusive motion of resonant nuclei can be expressed either by the formula

$$\frac{\Delta W}{W} = \exp\left(-\frac{E^*}{kT}\right) \quad (25.110)$$

or by

$$\Delta W = \frac{2c\hbar}{E_0\tau_0} \left[1 - \int e^{i\mathbf{k}\mathbf{r}} h(\mathbf{r}) d\mathbf{r} \right], \quad (25.111)$$

where E^* is the activation energy, \mathbf{k} is the wave vector of the γ photon, $h(\mathbf{r})$ is the probability density of finding an atom after one jump at point \mathbf{r} relative to the origin of the jump, and τ_0^{-1} is the jump frequency (Singwi and Sjolander 1960).

25.2.7.2 Pressure Dependence

The pressure dependence of Mössbauer parameters follows from that of the physical quantities that determine the values of those parameters. The pressure dependence of the isomer shift (Shenoy and Wagner 1978), e.g., is illustrated in [Fig. 25.16](#).

25.2.7.3 External Magnetic Field Dependence

The external magnetic field dependence of Mössbauer parameters can be very important, because – by choosing an appropriate external magnetic flux density – one often gets a better-resolved spectrum.

Fig. 25.16

Pressure dependence of the isomer shift of ^{57}Fe in $\alpha\text{-Fe}$, based on the results of Williamson et al. (1972)

By applying an external magnetic field, one can produce sources of polarized γ rays. In ^{57}Fe Mössbauer spectroscopy, this can be done by embedding the ^{57}Co parent nuclide in a ferromagnetic host (e.g., in $\alpha\text{-Fe}$) and by magnetically saturating the host material with an appropriate external field. Such a source will emit six lines (instead of just one) which, when overlapping with a simple six-line absorber hyperfine pattern, will lead to 36 (i.e., six times six) possible absorption peaks (Gonser 1975a).

The *effective magnetic flux density* B measured at the nucleus consists of two terms:

$$B = B_{\text{ext}} + B_{\text{int}} \quad (25.112)$$

where B_{ext} is the external magnetic flux density and B_{int} is the *internal magnetic flux density* which, again, consists of a number of components of different origin (Thosar and Iyengar 1983).

The use of external magnetic field makes it possible to determine the sign of the quadrupole splitting from the induced magnetic pattern (Gütlich et al. 1978) in the case of ^{57}Fe and ^{119}Sn spectroscopy of nonmagnetic materials.

The effect of external magnetic field on the magnetic splitting of magnetic materials depends on the nature of magnetic coupling (i.e., whether the material is ferromagnetic, ferrimagnetic, or antiferromagnetic) (Gonser 1975a).

25.2.7.4 Radio-Frequency Electromagnetic Radiation

Radio-frequency electromagnetic radiation can have two kinds of effect on the Mössbauer spectrum (Gonser 1981). It can result in a collapse of the split Mössbauer pattern, but it can also produce side bands in the spectrum on the basis of which a better identification of the atomic species can sometimes be achieved (Kopcewicz 1989).

25.2.7.5 Angular Dependence of Peak Areas/Intensities

The angular dependence of peak areas follows from the angular dependent nature of the intensity of multipole radiations (see [Table 25.2](#) for $F_{lm}(\theta)$ in the case of $l = 1$).

Magnetic sextet. The angular dependence of the relative peak areas of a magnetic sextet (appearing in, e.g., ^{57}Fe and ^{119}Sn Mössbauer spectra, both representing the $I = 3/2 \rightarrow 1/2$ nuclear spin transition), can be calculated by multiplying the $3j$ symbols with the corresponding $F_{lm}(\theta)$ angular dependent terms (both given in [Table 25.2](#)). Apart from a constant factor one obtains

$$A_1(\theta) = A_6(\theta) = 3(1 + \cos^2\theta) \quad (25.113)$$

$$A_2(\theta) = A_5(\theta) = 4\sin^2\theta \quad (25.114)$$

$$A_3(\theta) = A_4(\theta) = \frac{1}{3}A_1(\theta) = \frac{1}{3}A_6(\theta) = (1 + \cos^2\theta) \quad (25.115)$$

where θ is the angle between the respective directions of the γ ray and the effective magnetic flux density, and the area subscripts refer to the peak numbers of the sextet.

In the case of ferromagnetic materials, the direction of the effective magnetic flux density \mathbf{B} can be manipulated by an external field \mathbf{B}_{ext} .

If the direction of the effective magnetic field changes from point to point in a sample so that each direction has the same occurrence, then the relative peak areas (intensities) of the resultant sextet will average out to

$$A_1 : A_2 : A_3 : A_4 : A_5 : A_6 = 3 : 2 : 1 : 1 : 2 : 3, \quad (25.116)$$

which is the typical case for antiferromagnetic powder samples without texture. Bulk ferromagnetic materials (e.g., a not too thin α -iron foil) also have such a tendency, because the magnetic moments of their domains point at random directions.

In the case of magnetic anisotropy, the relative intensity of the second and the fifth lines compared with that of the first and sixth lines depends on θ in the following way:

$$\frac{A_{2,5}}{A_{1,6}} = \frac{4\sin^2\theta}{3(1 + \cos^2\theta)} \quad (25.117)$$

(Note that the intensity ratio of the inner and the outer pairs of lines of a sextet has no angular dependence, it is always equal to 3.)

Quadrupole doublet. In the case of a quadrupole doublet, the relative areas (intensities) of the doublet peaks (one representing the $m_I = \pm 3/2 \rightarrow \pm 1/2$ and the other the $m_I = \pm 1/2 \rightarrow \pm 1/2$ nuclear transitions) apart from a constant factor will have the angular dependences

$$A_{\pm 3/2 \rightarrow \pm 1/2}(\theta) = 1 + \cos^2\theta \quad (25.118)$$

$$A_{\pm 1/2 \rightarrow \pm 1/2}(\theta) = \frac{5}{3} - \cos^2\theta \quad (25.119)$$

where θ is the angle between the respective directions of the γ ray and the main axis of the EFG at the nucleus.

The intensity ratio of the lines of the doublet can also be expressed as (Gütlich et al. 1978)

$$\frac{I_2}{I_1} = \frac{\int_0^\pi (1 + \cos^2\theta) h(\theta) f(\theta) \sin\theta d\theta}{\int_0^\pi (\frac{5}{3} - \cos^2\theta) h(\theta) f(\theta) \sin\theta d\theta} \quad (25.120)$$

where $h(\theta)$ is the probability density of the angle θ , and $f(\theta)$ gives the angular dependence of the Mössbauer–Lamb factor.

In a well-mixed powder sample, where there is a random distribution ($h(\theta) = 1/\pi$) of the electric field gradients, and the Mössbauer–Lamb factor is isotropic, a symmetrical doublet with equal peak areas is expected: $A_{\pm 3/2 \rightarrow \pm 1/2} : A_{\pm 1/2 \rightarrow \pm 1/2} = 1 : 1$

The deviation from the above symmetry in most cases is an indication that the powder sample has some *texture*. If the asymmetry is indeed due to texture, then in accordance with [Eq. \(25.120\)](#) the relative intensity of the peaks should change when the sample is turned around an axis that is perpendicular to the direction of the γ rays. If the preferred orientation of the sample is such that the z -axis of the principal axis system is parallel to the direction of γ rays ($\theta = 0$ in [Eqs. \(25.118\)–\(25.120\)](#)) then a maximum asymmetry of the peaks is observed (relative intensity of the peaks is 3 in this case). If one turns this sample by $\Delta\theta = 54.7^\circ$ (the so-called *magic angle*) then the two peaks in the Mössbauer spectrum will have equal intensity despite the presence of texture.

The other possible reason for the intensity asymmetry ($A_2/A_1 \neq 1$) of the quadrupole split doublet can be the so-called *Goldanskii–Karyagin effect* (Goldanskii et al. 1963), which is caused by the angular dependence of the Mössbauer–Lamb factor due to the anisotropy of lattice vibrations ($f(\theta)$ depends on θ).

For a comparison of the Goldanskii–Karyagin effect with the effect of texture see, e.g., Pfannes and Gonser (1973).

25.2.7.6 Absorber Thickness

The dependence of the experimental peak width (W) on the absorber thickness for Lorentzian peaks is given (Nozik and Kaplan 1967) by the following equations derived from [Eq. \(25.100\)](#):

$$W = W_0(2 + \tau/4 + \tau^2/96 - \tau^3/64) \quad \text{for } \tau < 2, \quad (25.121)$$

and

$$W = 2W_0\tau/(\sqrt{\pi\tau} - 1) \quad \text{for } \tau < 2, \quad (25.122)$$

where W_0 is the peak width corresponding to the natural line width of the given Mössbauer transition and τ is the effective thickness of the absorber. The absorber thickness can also be optimized as regards the time necessary to measure a spectrum with satisfactory statistics (Nagy et al. 1975).

[Figure 25.17](#) shows the peak area, peak height, and peak width as the function of effective thickness.

Fig. 25.17

Dependence of the peak area A , peak height H , and peak width W on the effective thickness of the absorber (τ_A). Γ is the natural line width and f_s is the Mössbauer–Lamb factor of the source

25.2.7.7 Geometric Arrangement

The dependence of Mössbauer parameters on geometric arrangements is mainly due to the cosine smearing of the velocity u . Since the Doppler energy shift ΔE_γ is given by

$$\Delta E_\gamma = E_\gamma \frac{u}{c} \cos \theta, \quad (25.123)$$

(where E_γ is the energy of the emitted γ photon) a smearing effect can always be observed on the experimental peak shape, peak width, and isomer shift (Shenoy and Wagner 1978), even under “ideal” conditions when one uses a point source and a circular absorber placed coaxially as illustrated by  Fig. 25.18. (Above, θ is the angle between the γ ray and the direction of motion of the source or the absorber, whichever is moved.)

25.3 Analytical Information from Mössbauer Spectra

25.3.1 The Fingerprint Method

Patterns and physicochemical entities. In general, the fingerprint method operates with patterns (“fingerprints”) characteristic of different phases, compounds, crystallographic sites etc., which will be referred to as physicochemical entities for brevity. The correspondence between individual patterns and such entities is determined by the nature of interactions serving as a basis for the analytical method. In the case of Mössbauer analysis, the basic interactions are the hyperfine interactions.

Since the hyperfine interactions are determined principally by the electron density and the inhomogeneous electric field as well as by the effective magnetic flux density at the nucleus, the Mössbauer spectrum patterns differ from site to site where these physical quantities are different. Thus, a single-phase material may be characterized by a complex Mössbauer spectrum superimposed from a number of simple Mössbauer patterns belonging to resonant atoms experiencing different hyperfine interactions.

The microenvironment (see  Sect. 25.1.5.5) is of basic importance for analytical purpose. Since there is a one-to-one correspondence between the microenvironment and the hyperfine interactions, a simple Mössbauer pattern is always associated with a microenvironment characteristic of one particular population of Mössbauer nuclei in the studied sample. For brevity, such a population of like Mössbauer nuclei is referred to as a *Mössbauer species*.

 Fig. 25.18

The origin of cosine smearing. u is the velocity of the source relative to the absorber

25.3.2 Pattern Analysis

The basic task of the analysis is to identify the individual Mössbauer species from the corresponding patterns present in the spectrum. Ideally, this can be done if there is an exact correspondence between them.

Unfortunately, such a one-to-one correspondence between Mössbauer species and individual patterns may be nonexistent under the given conditions, i.e., for that particular set of experimental parameters at which the Mössbauer spectrum was recorded. However, when the whole range of the possible conditions is considered, one may find points in the space of experimental parameters at which only one pattern is associated with one species and vice versa and thus one can get round the problem of ambiguity. One can also do simultaneous evaluation of a whole series of Mössbauer spectra taken from the same sample under different conditions. Such a *serial evaluation* is a very effective tool, because the known dependences of the Mössbauer parameters (e.g., isomer shift) on the externally set experimental parameters (e.g., temperature) can be used as constraints for the serial fit.

From the analytical point of view, one can classify *Mössbauer patterns* in the following way (Kuzmann et al. 2003).

According to *experimental conditions* there are *standard patterns* and *induced patterns*.

According to *complexity* there are *elementary patterns* and *superimposed patterns*.

According to *mathematical processing* there are *natural patterns* and *transformed patterns*.

A Mössbauer spectrum can be a simple spectrum (elementary pattern) reflecting only a unique microenvironment/Mössbauer species or a complex spectrum (superimposed pattern), which consists of a number of subspectra.

The *standard pattern* is associated with a Mössbauer spectrum obtained at a standard set of experimental parameters. In most laboratories, e.g., measurements performed at room temperature, under atmospheric pressure and without external magnetic field are considered as standard. The *induced pattern*, however, is obtained under conditions other than standard (e.g., measurements performed in a cryostat or a furnace or in the field of a magnet). In this case, the differences between the induced and standard patterns can give important contribution to the analysis.

The *elementary pattern* is associated with one type of microenvironment/Mössbauer species. The *superimposed pattern* is the superposition of elementary patterns.

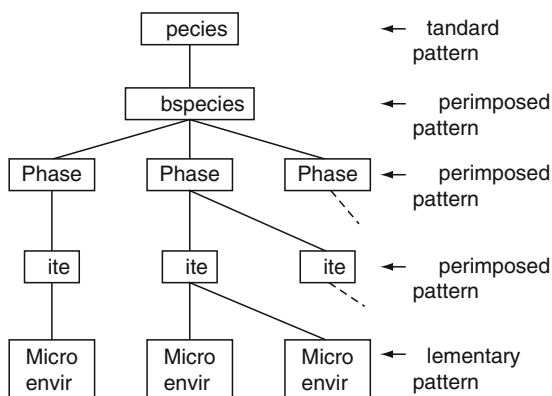

The *transformed pattern* is obtained from the measured Mössbauer spectrum (i.e., from the *natural pattern*) by mathematical transformation (e.g., by Fourier transformation). For instance, the magnetic hyperfine field (i.e., effective magnetic flux density) distribution or the quadrupole splitting distribution are considered transformed patterns. The transformed pattern may give a better resolution for the analysis.

► [Figures 25.19](#) and ► [25.20](#) illustrate the relation between different types of patterns and the object of the analysis as well as the most common strategy followed when doing qualitative analysis in Mössbauer spectroscopy. Generally, the Mössbauer spectrum of a multi-compound/multiphase material is a superposition of superimposed patterns. This is so because each compound/phase can have different crystallographic sites, each site represented by a different pattern. Note that even a single crystallographic site may represent more than one microenvironment due to variations in the hyperfine interactions (e.g., different electronic and spin density and defect arrangement).

In order to give an example, let us consider a steel sample in which ferrite and austenite phases are present. The standard pattern (^{57}Fe Mössbauer spectrum) of the sample is a complex spectrum that is a sum of subspectra (► [Fig. 25.21](#)). The subspectra of the ferromagnetic ferrite

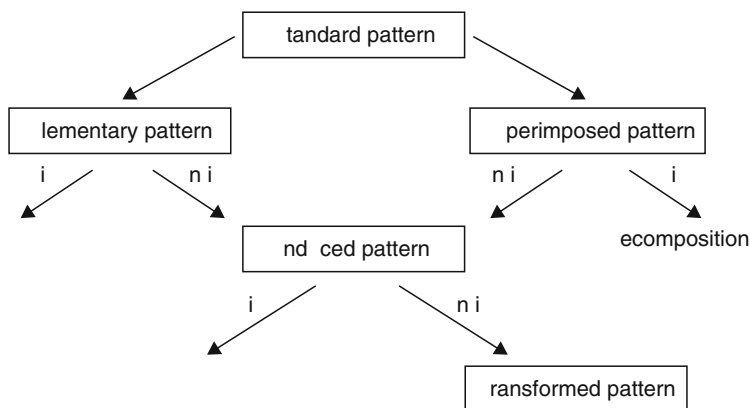

■ Fig. 25.19

Relation between different types of patterns and the object of analysis

■ Fig. 25.20

Simplified strategy of qualitative analysis in Mössbauer spectroscopy (i. and n.i. stand for informative and not informative, respectively)

and the paramagnetic austenite are also superimposed from elementary patterns because of the effect of alloying elements.

Very often, when the characteristic subspectra of components are well distinguishable in the standard spectrum, the qualitative analysis can be performed without the need for measuring further nonstandard spectra (induced patterns). In general, however, the subspectra (elementary patterns) overlap each other in the standard spectrum. When the exact decomposition of the spectrum becomes ambiguous, it is still possible to get further analytical information from an induced pattern (e.g., via serial evaluations).

For example, the standard room-temperature patterns of akageneite (β -FeOOH) and lepidocrocite (γ -FeOOH) are paramagnetic doublets with similar parameters. So they cannot be easily differentiated. However, the induced patterns of β -FeOOH taken below the magnetic

■ Fig. 25.21

The standard pattern of a steel in which ferrite and austenite phases are present. The ^{57}Fe Mössbauer spectrum of the sample is a complex spectrum that is a sum of subspectra. The subspectra of the ferromagnetic ferrite with bcc lattice and the paramagnetic austenite with fcc lattice are also superimposed from elementary patterns because of the effect of alloying elements, although the Fe atoms can only occupy one single crystallographic site in each phase

transition temperature (► Fig. 25.22) reflect magnetically split subspectra (sextets). Now, by the help of the induced pattern, the analytical problem can be solved more easily.

In some cases, the natural pattern consists of hundreds of elementary patterns. This is the typical situation with poorly crystallized and amorphous systems. The transformed pattern (► Fig. 25.23) can help get more information about the short-range ordering (by characterizing some of the most probable arrangements), thus it can enhance the analytical applicability.

25.3.3 Spectrum Evaluation

The Mössbauer parameters are derived from the *peak parameters* (base line parameters, peak position, peak width, and peak area/height) via the fitting process by computer evaluation of spectra in the case of the so-called model-dependent evaluation. In this case, an exact a priori knowledge about the spectrum decomposition (peak-shape function, number, and type of subspectra corresponding to the interactions assumed for each microenvironment in the model) is inevitably necessary. (Incorrectly chosen number of peaks renders the analysis itself incorrect.)

The most precise way of fitting is based on the computation of the transmission integral given by ► Eq. (25.31).

Very often, however, the simple Lorentzian peak shape is considered (see also ► Eqs. (25.1) and (► 25.35)):

■ Fig. 25.22

The induced patterns of akagenite (Kuzmann et al. 1994) carry much more information for the analysis than the standard one

$$L(u) = \frac{1}{\pi} \frac{W}{2} \frac{A}{(u - u_0)^2 + \left(\frac{W}{2}\right)^2} = \left(\frac{W}{2}\right)^2 \frac{H}{(u - u_0)^2 + \left(\frac{W}{2}\right)^2} \quad (25.124)$$

where u_0 is the position (in mm/s), W is the width, A is the area (intensity), and H is the height of the peak. This can be a good approximation, if the absorber is sufficiently thin (the effective thickness τ_A should be less than 1) and if the number of overlapping peaks is not very large.

For the analysis of materials whose spectra consist of a large number of overlapping peaks (e.g., amorphous metals), the product (or rather the convolution) of Lorentzian and Gaussian curves (Voigt function) is used to fit the peaks (Seagusa and Morrish 1982).

The spectrum fitting is done by the least-squares method by using an appropriate model function S , e.g., a linear combination of Lorentzians. (See also [Sect. 9.3.6 on Fitting nuclear spectra in Chap. 9, Vol. 1](#), on “Stochastics and Nuclear Measurements.”) In this procedure, the sum

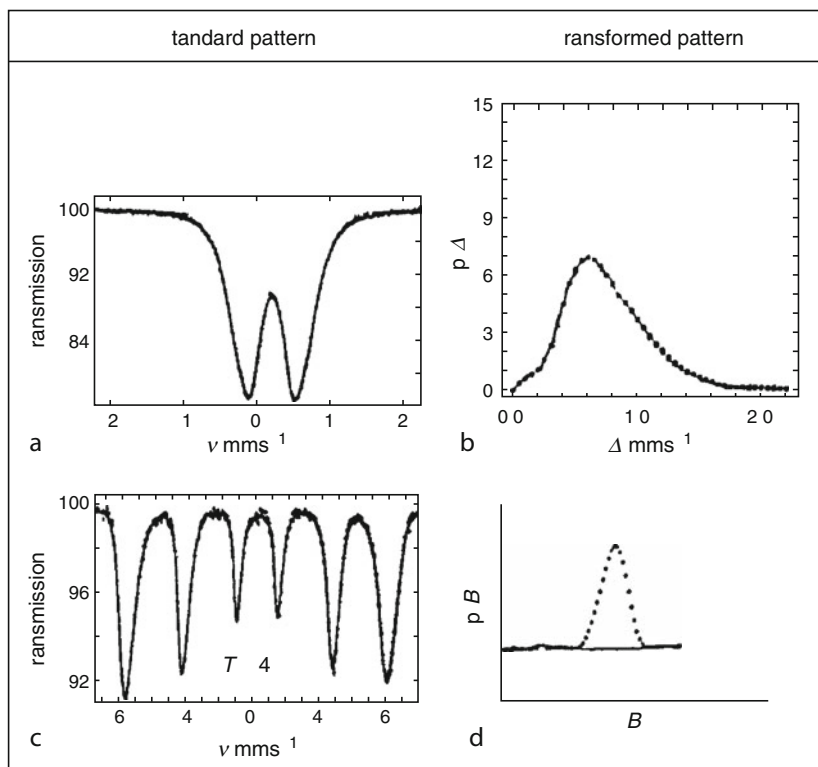

$$\chi^2 = \sum_{i=1}^k \frac{1}{N_i} [N_i - S(i; P_{\text{peak}})]^2 \quad (25.125)$$

is minimized, where N_i is the number of counts stored in the i th channel; k is the total number of channels. The model function S is determined by the vector P_{peak} of the peak parameters that is set up from the individual parameter vectors of the baseline (p_0) and the peaks (p_1, p_2, \dots, p_n):

$$P_{\text{peak}} = (p_0, p_1, p_2, \dots, p_n) \quad (25.126)$$

■ Fig. 25.23

The transformed patterns (graphs on the right side) of poorly crystallized ferrihydrite (Kuzmann et al. 1994). (a) ^{57}Fe Mössbauer spectrum of poorly crystallized ferrihydrite at room temperature, and (b) the corresponding quadrupole splitting distribution. (c) ^{57}Fe Mössbauer spectrum of poorly crystallized ferrihydrite at 4K, and (d) the corresponding hyperfine magnetic field distribution

Each parameter vector \mathbf{p}_j itself represents a set of three parameters characterizing the position, width, and area/height of the j th peak out of n .

In the thin-absorber approximation, an inhomogeneous linear transformation is used to make connection between the vector of the Mössbauer parameters \mathbf{P}_M (set up from isomer shifts, quadrupole splittings, magnetic splittings, etc.) and the vector of the peak parameters \mathbf{P}_{peak} :

$$\mathbf{P}_M^T = \mathbf{T} \mathbf{P}_{\text{peak}}^T + \mathbf{C}^T \quad (25.127)$$

where the constraints are determined by the elements of the transformation matrix \mathbf{T} and the constant vector \mathbf{C} . (The superscript “T” is to indicate that one has column vectors in the formula.)

The a priori knowledge of the matrix \mathbf{T} and the vector \mathbf{C} is normally an essential condition of spectrum evaluation. From the point of view of analytical applications, the a priori determination of the \mathbf{T} matrix is of fundamental importance. Namely, this transformation enables the experimenter to specify a set of peaks as a pattern representing one particular Mössbauer species in the sample.

The assignment of the subspectrum to one particular Mössbauer species is based on the comparison of the derived pattern with a reference spectrum. The *reference spectrum* can be obtained by measuring an etalon material or from the data published in the literature. In some cases, the reference spectrum can be constructed theoretically (computer simulation).

Another, so-called model-independent way of spectrum evaluation is done by obtaining and analyzing transformed patterns. For a thin absorber, the spectrum shape $S(u)$ can be described as the convolution of a density function $f(u)$ with a Lorentzian function $L(u)$:

$$S(u) = \int_{-\infty}^{+\infty} f(v)L(u-v)dv. \quad (25.128)$$

One of the methods for obtaining the distribution of effective magnetic flux density or quadrupole splitting (Campbell and Aubertin 1989; Klencsár et al. 1996) is the *Window method* (Window 1971) that uses a Fourier technique. For instance, the distribution of the effective magnetic flux density (also called *hyperfine field distribution*)

$$p(B) = \sum_i^N a_i \left[\cos \frac{B_i - B_{\min}}{B_{\max} - B_{\min}} - (-1)^i \right] \quad (25.129)$$

can be obtained by fitting the spectrum (B_{\min} and B_{\max} are the minimum and maximum values of the effective magnetic flux density, respectively).

Another way to obtain the distribution of the effective magnetic flux density or the quadrupole splitting is the *Hesse-Rübartsch method* (Hesse and Rübartsch 1974).

25.3.4 Quantitative Analysis

In Mössbauer spectroscopy, as in other spectroscopic methods, quantitative analysis is based upon the determination of peak areas.

In general, the transmission integral (► Eq. (25.31)) can be used to evaluate the peak area that depends nonlinearly on the effective thickness, which, in turn, is proportional to the concentration of the resonant atoms.

In the *thin-absorber approximation* ($\tau_A < 0.1$), the *peak area* is proportional to the Mössbauer atom concentration as shown earlier:

$$A \approx k\tau_A = k\sigma_0 d_A f_A n_A a \quad (25.130)$$

where a is the fractional abundance of the Mössbauer isotope (e.g., that of ^{57}Fe in natural iron) and n_A is the number of atoms of the studied Mössbauer element (e.g., iron) per unit volume of the absorber. The constant k includes other constants and parameters involving the background and matrix effects.

For the determination of concentration n_A all the parameters in the above equation have to be known. However, in most cases, the exact values of the Mössbauer–Lamb factor f_A and the constant k are unknown. In such cases, calibration graphs obtained with etalons are needed. However, the relative f -factors belonging to different microenvironments are usually known. Consequently, Mössbauer spectroscopy has a unique ability for the determination of the relative concentration of individual Mössbauer species in the same sample. The absolute concentration can be determined more accurately using other techniques.

25.4 Measurement Techniques in Mössbauer Spectroscopy

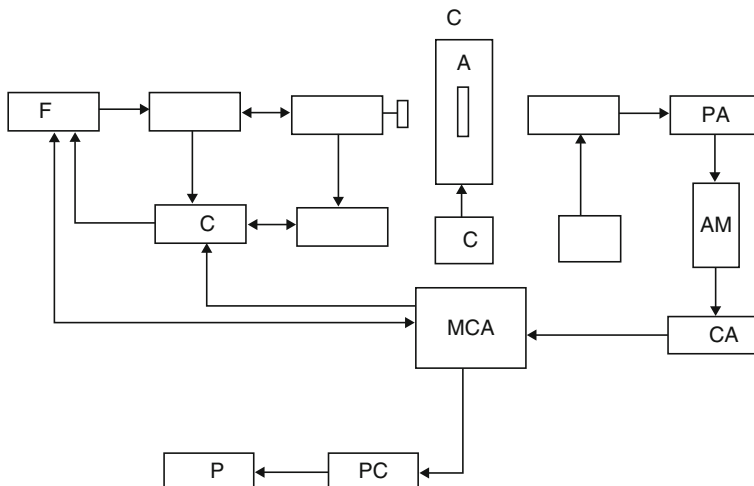

25.4.1 Mössbauer Spectrometers

In order to measure a Mössbauer spectrum one has to detect recoilless absorption or emission of a selected γ radiation as a function of the Doppler velocity of the sample and a reference material relative to each other. In the most common case of transmission geometry, absorption of the γ rays is measured, and the reference material is a standard source, which is moved. Thus, the most important components of a Mössbauer spectrometer are a Doppler velocity drive system and an energy selective γ detection chain with appropriate recording system.

The Mössbauer measurement requires the generation of a precise, controllable relative motion between the source and the absorber. A large variety of drive systems has been developed. The majority of drives work on electromechanical, mechanical, hydraulic, and piezoelectric principle. The spectrometers can be classified into constant-velocity spectrometers and velocity-sweep spectrometers. The mechanical drives, like a lead screw or a cam, move with constant velocity. They have advantages for the thermal scan method and because their absolute velocity calibration is straightforward. The velocity-sweep spectrometers are usually of electromechanical nature (like loudspeaker-type transducers) and normally used in conjunction with a multichannel analyzer. The most commonly used $u(t)$ functions are rectangular (constant velocity), triangular (constant acceleration), trapezoidal, and sinusoidal. A typical Mössbauer spectrometer is shown schematically in [Fig. 25.24](#).

Fig. 25.24

The block scheme of a Mössbauer spectrometer. A, absorber; CR, cryostat with temperature controller TC (optional, for low-temperature measurements); S, source moved by velocity transducer VT of driving unit DR; FG, function generator; VC, velocity calibrator (optional); LI, laser interferometer (optional); DET, detector; HV, high-voltage power supply; PA, preamplifier; AM, amplifier; SCA, single channel analyzer; MCA, multichannel analyzer; and PC, computer, OP, output

The transmitted or scattered radiation is usually detected by scintillation or proportional counters since high resolution is not required. The signals coming from the detector are amplified and gated by a single-channel analyzer set to transmit the Mössbauer transition energy range. These signals are introduced to a multichannel analyzer working in multiscaler regime (multichannel scaling, MCS). The switching (scaling) of channels is synchronized with the moving system so that in every cycle the same velocity is assigned to the same channel. The electromechanical drives move the source relative to the absorber periodically (with 10–100 Hz frequency) according to the given wave form. In the most typical case, a triangular wave form is used (constant acceleration). In modern Mössbauer spectrometers the velocity step signal is produced by a digital reference generator. While evaluating, the triangular waveform of velocity (with a maximum velocity in the orders of several mm/s) is approximated by a stepwise function of time, at each step of which (50–100 μ s) the velocity is considered to be constant. The Mössbauer spectra are usually recorded in 512 or 1,024 channels in each of which 10^5 – 10^7 counts are collected over several hours or days. Nowadays a major part of the Mössbauer equipment is a personal computer including an analyzer card (PCA card). This setup can be used for the pulse height analysis (PHA) that is needed to select the Mössbauer γ ray (or other secondary radiation), for the recording of the spectrum in MCS mode as well as for the evaluation of the recorded spectra with an appropriate software.

The Mössbauer spectrum is usually obtained as the transmitted or scattered intensity (in counts) vs. the Doppler velocity (in mm/s). However, the data provided by the analyzer are normally given in the form of counts vs. channel number. The correspondence between channel numbers and velocity is established by velocity calibration.

The *velocity calibration* of the Mössbauer spectrometer is performed either by measuring the Mössbauer spectrum of standard materials or by a calibrator instrument measuring the absolute velocity of the source relative to the absorber. The latter can be achieved by counting the fringes from a Michelson interferometer with a laser source connected to the multichannel analyzer, and thus the velocity for each channel can be obtained.

25.4.2 Transmission Geometry

Mössbauer spectra can be recorded in different ways. In the most frequently used *transmission technique* (➤ [Fig. 25.5](#)) the γ photons are counted after passing through the sample used as an absorber.

In most cases, the commercial source is moved and the absorber (which is the material to be studied) is at rest. In emission experiments, however, where the source is the material to be studied, the reference absorber is usually moved (see ➤ [Fig. 25.6](#) and ➤ [Sect. 25.4.4](#)).

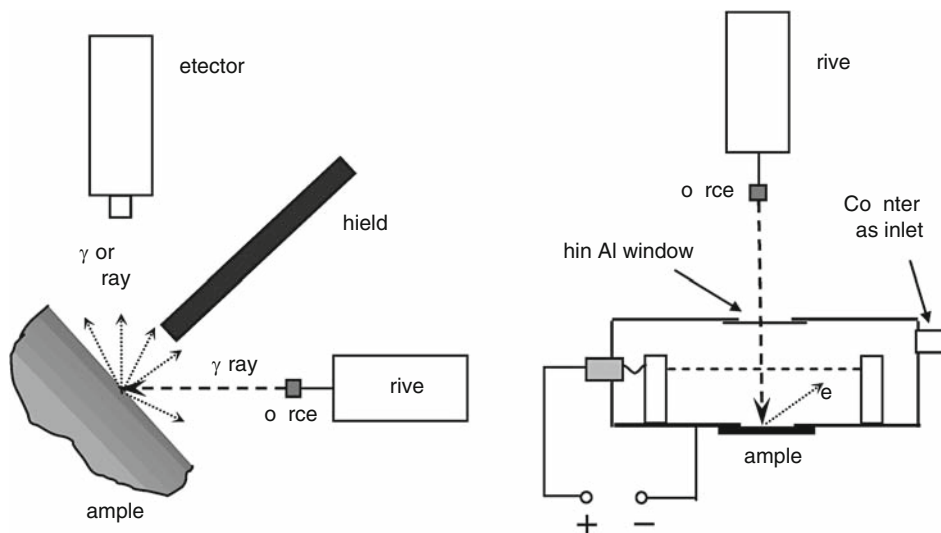

Scintillation detectors with a thin NaI(Tl) crystal are frequently applied for the detection of γ rays for many Mössbauer nuclides depending on the transition energy and the count rate. Various types of proportional counters are also used especially if the count rate is not very high. Semiconductor detectors are also applied occasionally. (For more about γ detectors see ➤ [Chap. 48 in Vol. 5](#).)

25.4.3 Reflection Geometry

In the scattering technique (➤ [Fig. 25.25](#)) the various radiations produced through the de-excitation of the irradiated sample (resonance scatterer) are detected.

■ Fig. 25.25

Scattering techniques. Reflection arrangements for Mössbauer measurements for γ ray or characteristic X-ray detection (*on the left*) and for conversion electron detection, CEMS (*on the right*)

With the *scattering technique*, it is possible to detect γ rays (back-scattering γ -ray Mössbauer spectroscopy), X-rays (X-ray Mössbauer spectroscopy), or conversion electrons (conversion electron Mössbauer spectroscopy, CEMS), which are characterized by different escape depths. Consequently, by the detection of different forms of back-scattered radiation, the surface of the samples can be investigated at different depths. An important advantage of the scattering Mössbauer technique is that it provides a nondestructive way of material testing.

25.4.3.1 Conversion Electron Mössbauer Spectroscopy

Among scattering Mössbauer measurements, the conversion electron Mössbauer spectroscopy (CEMS) is most developed because CEMS provides a unique surface characterization of solid materials. Since in Mössbauer spectroscopy the high Mössbauer–Lamb factor requires low γ energy, it inevitably results in very high electron conversion coefficients (see [▶ Table of Mössbauer Nuclides in Appendix of this volume](#)) and therefore the γ sources work at very high losses. This severe setback is turned to an advantage in CEMS. In this method, the γ rays emitted from the source undergo recoilless absorption in the “CEMS-sample.” The excited Mössbauer nuclei will then de-excite according to a characteristic lifetime and generate the conversion electrons to be detected.

The penetration range of conversion electrons of a few kilo electron volt is limited to a few 100 nm. The depth information of solid surface layers obtained by CEMS depends on the energy of electrons detected. The emitted electron energy corresponds to the photon energy minus the binding energy of the electron. The *conversion coefficient* $\alpha = N_e/N_\gamma$ (where N_e and N_γ are the

numbers of the emitted electrons and photons, respectively) is 8.21 for ^{57}Fe , and 5.1 for ^{119}Sn . The larger the α , the more effective the electron emission. However, not only conversion electrons are emitted, but a large number of Auger electrons can also be expected with substantially lower energies. The emission probability of electrons and photons in the relaxation process following the nuclear absorption in the ^{57}Fe nucleus is 7.3 keV K conversion electrons (80%), 5.6 keV KLL Auger electrons (53%), reemitted 14.4 keV γ rays (10%), and 6.4 keV characteristic $K\alpha$ X-rays (27%). The total number of electrons emitted is 133% of the number of photons absorbed. In the case of ^{119}Sn nuclei, 19.8 keV L conversion electrons (84%), 23.0 keV M conversion electron (13%), 2.8 keV Auger electrons (75%), 23.8 keV γ ray (16%), and 3.6 keV X-ray (9%) are emitted after Mössbauer absorption. The total percent of electrons emitted is 172%. It is clear from the total emission probability of conversion and Auger electrons that the detection of electrons is advantageous for thin films and solid surface studies (Bonchev et al. 1969).

Detectors for CEMS

Gas counter. A simple proportional gas counter is shown in  Fig. 25.25. A backscatter 2π proportional He gas-flow counter has high detection efficiency for low-energy electrons of about 10 keV, because He gas is insensitive to incident X-ray and γ ray (Terrell and Spijckerman 1968). CEMS spectra can be easily recorded by flowing He gas mixed with several % methane or isobutane as a quencher. XM spectra (i.e., when the characteristic X-ray is detected) can also be obtained by using flowing Ar/CH_4 gas mixture and by setting a Lucite plate (3 mm thick) in front of the incident window of the counter in order to filter off the X-rays emitted from the source. Argon, being a relatively light element, can detect 6.3 keV Fe X-rays more efficiently than 14.4 keV incident γ rays. The penetration range of 7.3 keV electrons in He gas at atmospheric pressure is at most 5 mm. The mean energy of electrons emitted is less than 7.3 keV, and the desirable distance between the anode wire and the sample surface is about 2 mm for ^{57}Fe CEMS. The detection efficiency of electrons and good signal-to-noise ratio are crucial to improve the count rate, and they sensitively depend on the actual design of the detector. A good electric contact between the sample (for which it is advisable to be a good conductor) and the body of the detector is very important.

The parallel-plate avalanche counter (PPAC) (Weyer 1976), which consists of flat-plate electrodes of graphite and sample, is advantageous for insulating materials. Any organic polyatomic gas can be used as *counting gas*. Usually acetone vapor is preferred. Depth selective CEMS (DCEMS, see later on) using PPAC is also possible by discriminating electron energy and controlling gas pressure (Weyer 1990). However, the mounting of a sample and the control of pressure in PPAC are rather difficult.

When a proportional counter is operated at low temperature, the gas multiplication decreases, and some quenchers mixed in the He gas get condensed on the cold surface of the sample. A gas counter filled with He + 5% CO at atmospheric pressure showed good performance at 77 K (Isozumi et al. 1983; Cook and Agyekum 1985; Nomura and Ujihira 1985; Meisel 1994). Purified He, H_2 , Ne, and mixtures of two gases such as He + 5% N_2 or He + several % CO may be used from temperatures as low as 15–300 K (Fukumura et al. 1991).

For high-temperature CEMS measurements, a gas-flow counter was installed in a furnace by Isozumi et al. (1979). Another type of gas counter was developed to heat only the sample; it was tested up to 740 K (Inaba et al. 1981). At even higher temperatures, low recoilless fraction, reaction of the quenching gas with the sample surface, and intense thermal electron emission made the measurement impossible. However, the gas reactivity can be utilized to monitor in

situ gas sensing of sensor materials because various gases can be mixed into He gas as a quenching gas (Nomura et al. 1993).

Electron multipliers and other counters. Channeltrons and channelplates have relatively large efficiency for low-energy electrons (below a few kilo electron volt). These types of counters have inherently no energy resolution, and need to work in a vacuum chamber. Both the sample and the channel electron multiplier installed are directly cooled in a conventional vessel by liquid He or liquid N₂ for CEMS (Sawicki et al. 1981).

The avalanche photodiode detector (APD), which is able to detect conversion electrons with very high intensity can also be useful in special applications (Weyer 1976; Gruverman 1976).

Depth Selective CEMS

Since the conversion electrons emitted from the sample surface have different energies depending on the depth they were generated in, it is theoretically possible to record Mössbauer spectra characteristic of selected surface layers of the sample at different depths. Geometric effects and the relatively wide energy spectrum of the various kinds of emitted electrons (K- and L-conversion, Auger, etc.) result in rather poor depth resolution.

To achieve depth selectivity, the Mössbauer setup should be combined with an electron spectrometer. A magnetic wedge spectrometer was first used for the detection of 30.5 keV K shell conversion electrons produced by the 100.1 keV γ transition in ¹⁸²W (Kankeleit 1961). DCEMS was proposed by Baverstam et al. (1973); DCEMS spectra were first measured with ¹¹⁹Sn (Bonchev et al. 1977) and ⁵⁷Fe (Shigematsu et al. 1980) by selecting electrons with a specific energy range.

Practice and theory of DCEMS were further developed by several authors (Liljequist 1981; Kajcsos et al. 1988; Klingelhofer and Kankeleit 1990; Klingelhofer and Meisel 1990; Belozerskii 1993).

Depth selectivity may also be achieved by using normal CEMS (for better distinction sometimes referred to as *ICEMS*, i.e., Integral CEMS) if the sample surface layers are removed stepwise with an appropriate technique like, e.g., noble gas ion sputtering or etching (Smit and van Staple 1982). However, this is already a destructive analytical method.

A pronounced depth selectivity of CEMS spectra is achieved by selecting the angle of the incident γ ray in addition to selection of the energy of the emitted electrons. On the other hand, depth information changes depending on the applied voltage (Kuprin and Novakova 1992). The layer-by-layer analysis of rough structures is possible by selecting the energy of detected electrons and by changing the voltage supplied using a He gas-flow counter.

Glancing angle CEMS (*GACEMS*) is useful to analyze the orientation of thin films. The influence of surface roughness on the surface selectivity in ⁵⁷Fe *GACEMS* is small provided that the electron-emission angle relative to the surface is larger than the average surface inclination angle associated with the surface roughness (Ismail and Liljequist 1986). According to the theory of CEMS at total external reflection (Andreeva and Kuzmin 1984; Topalov and Proikova 1985), the selective observation of a surface layer with a mean depth <10 nm is possible at glancing angles of less than 10 mrad ($\sim 0.6^\circ$).

Grazing incident ⁵⁷Fe CEMS (*GICEMS*) spectra were first observed by Frost et al. (1985), and *GICEMS* equipments were improved to have higher precision (Irakaev et al. 1993).

These techniques are rather time consuming, and the application of monochromatic photon beams of synchrotron sources may reduce the necessary measuring time in the future.

25.4.4 Resonance Counters

The most specific type of detectors used in Mössbauer spectroscopy is the so-called resonance detector. In this type of detectors, mainly conversion electrons are detected in a gas-filled chamber in which an ^{57}Fe -enriched standard target is placed. As conversion electrons can only form after the recoilless absorption of the γ rays in the standard target, the nonresonant radiation is very effectively filtered off, and the resultant Mössbauer spectrum has hardly any background (baseline). Therefore, the signal-to-noise ratio becomes excellent and the required measuring time (or the source activity that is needed) drastically decreases.

Since in this simple case, the detector itself contains a Mössbauer standard, the investigated material is in the source, i.e., one has to perform an emission experiment (see [Sect. 25.4.5](#)).

A “regular” transmission (absorption) experiment can also be carried out using a resonance detector, if the detector and the source are mounted on the same rigid frame and the standard matrix for the source and the target matrix containing the enriched ^{57}Fe (or other Mössbauer nuclide) are the same. The investigated sample should be placed in between. Either the detector + source system or the sample should be moved, which is not simple to realize technically.

A gas-filled resonance counter had been set up, e.g., by installing enriched ^{57}Fe stainless steel foils in a He gas chamber or parallel plate avalanche gas counter by Mullen and Stevenson (1978). An extremely light detector ($\text{K}_2\text{Mg}^{57}\text{Fe}(\text{CN})_6$ in Poly-Vinyl-Xylene scintillator) has also been developed for a movable resonance counter (Budakovski et al. 1999) to replace heavy gas-filled detectors.

Resonance detectors are also useful for Coulomb-excited nuclear experiments and for in situ implantation experiments using short-lived ^{57}Mn as parent nuclide to produce ^{57}Fe (Kobayashi et al. 2000).

25.4.5 Emission Mössbauer Spectroscopy

In an *emission experiment*, the radioactive excited-state Mössbauer nuclide is introduced into the sample to be investigated. In a Mössbauer experiment only the relative velocity of the source and the sample matters. Therefore, the emission experiment may be considered as a simple mirror image of the transmission experiment. This is well reflected by the upper panel of [Fig. 25.6](#), where the “ u ” axes for the (moving) source and absorber point in opposite directions. Instead of a standard source, one can use, in this case, a standard absorber, which consists of a single-peak compound (i.e., no quadrupole splitting and no magnetic splitting is allowed in the absorber). The most commonly used reference material is potassium hexacyanoferrate(II), $\text{K}_4[\text{Fe}(\text{CN})_6] \cdot 3\text{H}_2\text{O}$.

However, the source, which is supposed to be a material doped with a Mössbauer nuclide in its excited state cannot be prepared because the half-life is so short that the source would completely decay before one would start the experiment (for ^{57}Fe , $\tau_{1/2} \approx 10^{-7}$ s). Thus, one has to find a parent nuclide with a reasonably long half-life, which produces the excited Mössbauer level by nuclear decay. This has the consequence that in an emission experiment the dopant element may be different from the Mössbauer active one. In ^{57}Fe Mössbauer spectroscopy, this parent nuclide is ^{57}Co , which decays by electron capture, $^{57}\text{Co}(\text{EC})^{57}\text{Fe}$, with a half-life of ~ 9 months.

The doping with a parent element different from the Mössbauer one needs further considerations. The microenvironment of the parent nuclide in the doped sample may be different from that of its daughter element, the Mössbauer nuclide. (That is, the lattice site occupied and the coordination number or the valence state can all be different.) More importantly, the radioactive decay of the parent nuclide can trigger a relaxation process that alters the microenvironment of the Mössbauer dopant, which, in turn, affects the Mössbauer spectrum. These effects are called “aftereffects” (see [Sect. 25.4.5.1](#)), and in many cases these are the primary targets of this kind of Mössbauer studies in order to explore the hot-atom reactions triggered by the radioactive decay.

A substantial advantage of emission Mössbauer spectroscopy in comparison with the transmission technique is that if the material to be investigated contains heavy elements, then the required dopant concentration (e.g., ^{57}Co) may be 1–2 orders of magnitude lower in the emission experiment than the ^{57}Fe concentration in an analogous transmission experiment. This is in connection with the intensity loss of the Mössbauer radiation due to electronic absorption, which is always *self absorption* in the source and *regular absorption* in the absorber (Vértés and Homonnay 1997). Low dopant concentration is very important in *impurity Mössbauer spectroscopy*, where the investigated material does not contain a Mössbauer element; thus, a conveniently measurable Mössbauer nuclide is introduced artificially as an impurity with a potential risk of perturbing the physicochemical properties of the host phase.

25.4.5.1 Aftereffects

Aftereffects (Spiering et al. 1990; Nagy 1994) show up in the Mössbauer spectra if the relaxation process, which might have been triggered by the nuclear decay of the parent nuclide, is not finished by the time of the decay of the Mössbauer level, or, if it has caused an irreversible change in the microenvironment of the Mössbauer nuclide.

In the case of ^{57}Co , the electron capture triggers an Auger cascade with high probability, in which electrons, mostly in the energy range 0.6–6 keV, will be produced. The resultant highly charged iron ion (up to Fe^{7+}) starts then to recapture electrons and may reach the original oxidation state of the parent nuclide. This neutralization is accompanied by deposition of large excitation energy that has to dissipate fast and smoothly in order to save the microenvironment of the Mössbauer nuclide. If all these processes are completed in $\sim 10^{-9}$ s, then they will be invisible in the Mössbauer spectrum. The probability of this fast relaxation depends most of all on the electronic conduction properties of the host material.

In metals, electronic relaxation is fast and no aftereffects can be detected by Mössbauer spectroscopy. (This is why ^{57}Co can be built in metallic matrices in commercial sources for ^{57}Fe Mössbauer spectroscopy.)

In insulators and semiconductors, aftereffects show up in most cases in the form of *aliovalent charge states* (when the charge state of the nucleogenic ^{57}Fe is different from the equilibrium charge state of iron in that particular host material). The aliovalent charge states are typically higher than the equilibrium charge state (e.g., observation of Fe^{3+} in ^{57}Co -doped CoO , see Harami et al. 1984), but they can also be lower (e.g., Fe^+ in Co^{2+} -doped ZnS , see Garcin et al. 1980). In these ionic or ionic/covalent lattices, the formation of aliovalent charge states is explained mostly by the *competing acceptors model* (Helms and Mullen 1971; Perfiliev et al. 1976).

Aliovalent Fe^{3+} charge states can be observed in frozen aqueous solution of Co(II) -salts, where the formation of Fe^{3+} can be explained by the *radiolysis model*. In this model, oxidation of the nucleogenic Fe^{2+} to Fe^{3+} is assumed by OH radicals, which form during the radiolysis of water molecules coordinated to the parent Co^{2+} ion, by Auger electrons (Friedt and Danon 1980).

Excited electronic states due to aftereffects have been found and verified in only a few cases but in various compounds like in ^{57}Co -doped LiNbO_3 (Doerfler et al. 1984) and $^{57}\text{Co}/\text{Co}(\text{phen})_3(\text{ClO}_3)_2 \cdot 2\text{H}_2\text{O}$ (Ensling et al. 1970).

Bond rupture and complete *fragmentation* of the host molecule due to the deposited large excitation energy during the neutralization of the Auger-ionized Fe^{n+} ion has also been suggested in certain coordination compounds. It was observed that the higher the degree of delocalization in the ligands coordinated to the ^{57}Co center, the higher is the chance to avoid the (supposed) fragmentation (Srivastava and Nath 1976).

Time-differential Mössbauer emission spectroscopy (see Alflen et al. 1989) has also been applied to explore aftereffects.

25.4.6 Thermal Scan Method

In the case of the *Mössbauer thermal scan method*, the spectrum point belonging to zero (or a given constant) velocity is only measured at different temperatures (in the case of zero velocity without Doppler moving). By this simple technique, phase transition temperatures can be detected.

25.4.7 Mössbauer Polarimetry

The principle of *Mössbauer polarimetry* is similar to that of optical polarimetry. In this case, the polarization and the analysis can be performed by appropriately oriented external magnetic fields. Using ^{57}Fe polarization spectroscopy 36 lines, rather than six, are observed with magnetic materials (Gonser and Fisher 1981).

25.4.8 Capillary Mössbauer Spectroscopy

Normally, in liquid state, the recoil of the nucleus at the γ -ray emission hampers the nuclear resonance absorption. However, Mössbauer spectra of liquids can be observed even at room temperature if the molecules of liquids are trapped in the cavities of a special porous silicate glass of a mean pore diameter of ~ 4 nm. This type of Mössbauer spectroscopy is called capillary Mössbauer spectroscopy (Burger and Vértés 1983).

Three different types of behavior were experienced in various systems. It was concluded from the comparison of the Mössbauer parameters of samples obtained in liquid phase and in frozen solution that, in the case of aqueous solution of the Mössbauer active salts, only the solvent molecules were in chemical interaction with the wall of the capillaries in the glass. The microenvironments of the Mössbauer active species were the same both in liquid state and in the frozen solution.

In another case, when the Mössbauer parameters observed for the liquid state were different from those in frozen solution (e.g., SnI_4 in carbon tetrachloride) the Mössbauer atoms were in direct chemical interaction with the wall of the pores of the carrier.

In the third case, when two Mössbauer subspectra were observed in the liquid state and only one of them corresponded to the frozen solution, a fraction of the Mössbauer species was bound to the wall of pores, and the other part exhibited parameters characteristic of the free species.

It was found that high donicity of the solvent is required to keep the Mössbauer solute off the wall of the cavities, which enables one to study the bulk structure of solutions with Mössbauer spectroscopy in liquid phase.

25.4.9 Time-Dependent Measurements

Time-differential Mössbauer spectroscopy (Kajcsos et al. 1986; Alflen et al. 1989; Kobayashi 1989; Nakada et al. 1994) presents a unique tool for the study of chemical aftereffects and relaxation processes following the electron capture of ^{57}Co incorporated into various matrices. The principle of this method is as follows.

Using two detectors simultaneously, one has to detect the 122 keV γ quanta coming from the Mössbauer source as a start signal. This actually marks the birth of the 14.4 keV Mössbauer excited level (see the decay scheme in ► Fig. 25.7). Then, with the other detector, the 14.4 keV γ quantum is detected, and the elapsed time measured (stop signal). With this method, Mössbauer spectra can be recorded in any time interval after the nuclear decay of ^{57}Co . Recording characteristic X-rays following the electron capture, part of the aftereffect events can be filtered off. Due to the coincidence technique, very low activities can only be used, and therefore these measurements are rather time consuming (several weeks or months).

25.4.10 Combined Methods

A number of techniques also use Mössbauer spectroscopy combined with other methods like X-ray diffractometry (Parak et al. 1976; Faigel and Tegze 1994; Kriplani et al. 2002) and electron spectroscopy (Hisatake et al. 1974; Klingelhofer and Meisel 1990).

25.4.11 Measurements Using Synchrotron Radiation

Synchrotron radiation can also be used instead of radioactive sources for the nuclear resonance scattering (Ruby 1974; Gerdau et al. 1985). Since the already achieved results and the future perspectives of this method are very promising, a separate Chapter (see ► Chap. 26 in this Volume) is devoted to this topic.

25.4.12 Sources and Absorbers

The *Mössbauer source* is a solid material containing (or rather continuously generating) the excited-state nuclei of the studied nuclide and thus emitting the γ radiation characteristic of

the nuclear transition in question. Although Mössbauer transition has been observed with more than 48 nuclides (► Fig. 25.4), only a few of them are widely used – those having a relatively long-lived parent nuclide making it possible to produce a source lasting for at least a couple of months. The most common Mössbauer nuclides (and their share from the Mössbauer literature) are as follows: ^{57}Fe (82%), ^{119}Sn (6%), and ^{151}Eu (3%). The remaining 9% is divided among 45 nuclides. The commercial source for the 14.4 keV transition of ^{57}Fe is ^{57}Co diffused into a thin metallic matrix (e.g., Pd, Pt, and Rh) in which the emitted Mössbauer line is sufficiently narrow (to make it possible to produce experimental spectrum peaks as narrow as $W = 0.21$ mm/s). The activity of such sources is typically about 200 MBq to 10 GBq.

The isomer shifts are usually given relative to $\alpha\text{-Fe}$. If the isomer shift is given relative to a particular source matrix, conversion is possible with the help of ► Table 25.3.

If a proper parent nuclide cannot be found for an otherwise promising (e.g., low-energy) isomeric transition for source preparation, the Mössbauer nuclide may be generated continuously by (n, γ) reaction. In such a situation, prompt or slightly delayed γ quanta are used for Mössbauer purpose. The basic requirement is that, for the potential $^A_{Z+1}\text{N}$ Mössbauer nuclide, there should exist an $^A_Z\text{N}(n, \gamma)^{A+1}_Z\text{N}$ reaction with high cross section, and one should have access to a nuclear reactor with high neutron flux capability. A few tens more possible Mössbauer transitions become available with this method; however, the technical background is rather complex.

Normally, the studied sample is used either as an absorber or a scatterer. The *absorber* has to contain the ground-state nuclei of the nuclide responsible for the Mössbauer radiation of the source. Mössbauer absorbers used for transmission experiments can be sheets or powders of solids. Frozen solutions can also be measured.

The ideal sample has uniform thickness, circular shape, texture-free homogeneous distribution of material, and optimum surface density of the Mössbauer nuclide as well as an optimum thickness (Nagy et al. 1975).

For example, in the case of a natural α -iron foil 7 mg/cm² natural iron content (i.e., a linear thickness of 9 μm) is the optimum; however, 0.2 mg/cm² samples can also be measured with some difficulty. From the point of view of the Mössbauer resonant transition, only the ^{57}Fe

■ Table 25.3

^{57}Fe isomer shift conversion for some frequently used standard matrices. To obtain isomer shift values relative to $\alpha\text{-Fe}$, one has to add the corresponding value in column 2 to the isomer shift measured relative to the standard material in column 1

Source matrix/standard material relative to which the isomer shift δ is given	Correction (in mm s ⁻¹) to be added to δ to get the isomer shift relative to $\alpha\text{-Fe}$
Sodium nitroprusside (SNP)	−0.257
Chromium (Cr)	−0.147
Stainless steel (SS)	−0.092
α -Iron (reference)	0.000
Rhodium (Rh)	+0.109
Palladium (Pd)	+0.170
Copper (Cu)	+0.227
Platinum (Pt)	+0.344

content is important (which has a 2.14% abundance in natural iron), and therefore, a significant lowering of the minimum iron content (down to a factor of 1/45) can be achieved by enrichment with that isotope. Thus, e.g., the spectrum of an aluminum sample containing 20 ppm of ^{57}Fe can be easily measured by a conventional modern spectrometer.

Powders to be measured are usually spread out with uniform thickness between thin foils of Mylar or aluminum. Sometimes, in order to avoid vibrational effects, the powder is embedded in a matrix with low atomic absorption (e.g., paraffin, granulated organic, and polymer). It is important that neither the matrix nor the foil should contain any traces of the resonant nuclide (which can happen with aluminum in the case of ^{57}Fe measurements).

For samples used in *scattering experiments*, there is no essential demand other than the available surface density of the Mössbauer nuclide.

25.4.13 Cryostates, Furnaces, Magnets, and Pressure Cells

Different kinds of *cryostats* and *furnaces* are used to determine the temperature dependence of Mössbauer spectra. A simple *cold-finger* cryostat can be designed to measure at the temperature of solid CO_2 or liquid nitrogen. In this case, the precooled sample can be immediately put into the cryostat. This is important, e.g., with frozen solution samples. Temperature-controlled evacuated cryostats are generally applied between the millikelvin and a few hundred kelvin temperature range. They have to be supplied with special coolants (e.g., liquid helium or nitrogen). Nowadays closed circuit *refrigerator* cryostats operating between 12 to 400 K are also used frequently because they do not require liquid helium.

Temperature-controlled *furnaces* operate between room temperature and 1,500 K. *Cryofurnaces* can operate both below and above room temperature.

External magnetic fields are generated by *magnets* producing a field from 1 mT or so to 15 T. High fields are obtained by superconducting magnets. The magnet is usually placed around the cryostat or the furnace.

Cryostats are sometimes combined with *pressure chambers*, which can produce the required pressure on the sample. The high-pressure chambers are capable of pressures up to 200 kbar without disturbing the Mössbauer measurements.

25.5 Applications

Mössbauer spectroscopy has been used to solve problems in a variety of fields. Here is a list of a few examples: archeology (Kostikas et al. 1976), art (Keisch 1976), biochemistry and biology (Moshkovskii 1968; May 1971; Kuzmann 1979; Mössbauer et al. 1981), chemistry (Goldanskii and Herber 1968; Greenwood and Gibb 1971; Gütlich et al. 1978; Vértés et al. 1979; Long 1984; Long 1987; Vértés and Nagy 1990), electronics (Langouche 1989), magnetism (Grant 1975; Long and Grandjean 1993, 1996, 1997), materials sciences, solid-state physics and engineering (Gonser 1971, 1975b; Zemcik 1971), mineralogy and geology (Bancroft 1973; Mitra 1992; Kuzmann et al. 1998), nuclear physics and nuclear chemistry (Hafemeister 1971), physical metallurgy (Fujita 1975), and relativity (Pound 1981).

Shortly after the discovery of recoilless nuclear resonance emission/absorption on ^{193}Ir by Rudolf Mössbauer (Mössbauer 1958a) the Mössbauer effect was shown with ^{57}Fe (Shiffer and Marshall 1959; Pound and Rebka 1959; Hanna et al. 1960; de Pasquali et al. 1960) and

somewhat later with ^{119}Sn (Bartaloud et al. 1960; Deljagin et al. 1960), which nuclides are till now the most frequently used Mössbauer isotopes. The verification of the gravitational red shift of electromagnetic radiation (Pound and Rebka 1960) draws widespread scientific attention to Mössbauer spectroscopy.

More than 40,000 publications are available on various applications. The yearly number of publications is still growing. Bibliographic and other information about all these applications can be found in the Mössbauer Effect Reference Data Index (MERDI) and Mössbauer Effect Reference Data Journal (MERDJ). Many applications are discussed in monographs and in the proceedings of Mössbauer conferences (ICAME, ISIAE, LACAME, and other meetings of Mössbauer spectroscopists).

Accurate knowledge of the physical properties of the nuclei to be used for Mössbauer purpose opens the way for Mössbauer spectroscopy to become a really powerful tool in various research fields. In the followings, a few applications from the field of nuclear sciences are presented along with a list about the important chemical and analytical application areas.

25.5.1 Applications in Nuclear Sciences

Nuclear parameters can be determined and decay aftereffects can be studied with the help of Mössbauer spectroscopy (Hafemeister 1971; Burgov and Davidov 1968; Speth et al. 1978).

Nuclear parameters especially those of the excited state can be obtained from the hyperfine split Mössbauer spectrum.

The *nuclear spin* quantum number of excited state can be derived from the hyperfine spectra, but this is usually known before the Mössbauer experiment.

The fractional *change in the nuclear radius* $\Delta R/R$ can be obtained from the expression of isomer shift (Eq. (25.83)). For this reason, the accurate knowledge of the difference in the electronic density at the site of nucleus of source and absorber is necessary. Because of the difficulties in the estimation of electronic densities at the nucleus, the values of $\Delta R/R$ have considerable uncertainty (Shenoy and Wagner 1978).

The *nuclear magnetic moment* or the *g-factor* of the excited state can be determined with high accuracy from the magnetic splitting (Eq. (25.93)) since the ground-state values are previously known. In certain cases, large external magnetic field is needed to resolve the magnetically split lines (deWaard and Heberle 1964).

For a nucleus with ground-state nuclear spin higher than 1/2, the energy differences between the states in the quadrupole splitting will contain the ratio of the *quadrupole moments* of the excited state and the ground state. If the value of the quadrupole moment of the ground state is known from an independent experiment, then the quadrupole moment of the excited state is obtained from the corresponding ratio (Hafemeister et al. 1964).

For nuclei with ground-state spin $I_g = 1/2$, the determination of quadrupole moment from the expression of quadrupole splitting energy (Eq. (25.90)) can be performed with a relatively large error (Ingalls 1964; Artman et al. 1968; Chappert et al. 1969).

The *internal conversion coefficient* for ^{57}Fe has been accurately determined from the transmission integral (see Eqs. (25.11), (25.30), and (25.31)) by using a series of iron absorbers all having the same thickness of iron atoms but the enrichment in ^{57}Fe varied by a factor of as much as 37 (Hanna and Preston 1965).

Basically, the *lifetime of the excited state* can be determined from the line width (Eq. (25.2)). However, several broadening effects influence the exact determination of the

nuclear lifetime (Hafemeister and Shera 1966), which can be obtained within the range of 10^{-7} and 10^{-10} s. Mössbauer spectroscopy is a unique tool for this application.

A Mössbauer experiment was successfully performed to confirm the *parity nonconservation* in β decay. The Mössbauer spectrum was recorded in a β – γ coincidence experiment and an unequal population of the excited state sublevels was observed when the nuclei in the source were polarized by a large magnetic field in the direction of the β radiation (DeWaard et al. 1968).

The *multipole mixing ratio* δ of mixed M1+E2 radiation ($\delta = |E2/M1|$) as well as the phase angle between E2 and M1 components can be obtained from the relative areas of the corresponding peaks (Kistner 1968; Wagner et al. 1968; Atac et al. 1968). The value of the phase angle has a relevance in testing the time reversal in electromagnetic interaction. No violation of time reversal was found in Mössbauer experiments (Kalvius et al. 1968; Mullen 1986).

25.5.2 Chemical and Analytical Applications

The application of Mössbauer spectroscopy in chemistry is based on the utilization of information obtained mainly from the isomer shift, quadrupole splitting, and magnetic splitting.

The chemical isomer shift is a direct function of the s-electron density at the nucleus (see [Eqs. \(25.83\)–\(25.85\)](#), Shenoy and Wagner 1978), but shows secondary induced effects due to changes in shielding (i.e., electron–electron repulsion) of the s-electrons by p-, d-, or f-electrons. It is therefore sensitive to most changes of orbital occupation in the valence shell of the atom. Since there are well-established monotonous correlations between the electronic density and the oxidation and spin state of the Mössbauer atom, the isomer shift can be used for the *determination of the oxidation and spin state* of Mössbauer nuclides. Isomer shift scales as a function of the oxidation state are now available for a large number of Mössbauer nuclides, and they are helpful in characterizing unknown materials and identifying different species of a certain Mössbauer nuclide in a mixture in wide areas of inorganic chemistry, organic chemistry, biochemistry, and geochemistry.

The quadrupole splitting ([Eqs. \(25.90\)–\(25.91\)](#), see, e.g., Travis (1971), Gütlisch et al. (1978)) is caused by the asymmetric occupation of the nonspherical p-, d-, or f-electron orbitals, and its magnitude and sign can also be used to *determine the asymmetry of the charge distribution with respect to chemical bond*.

The variation of the coordination number in compounds results primarily in a change in the symmetry of the coordination sphere; therefore, the quadrupole splitting can serve as an indicator of such a change. At the same time, the contraction or expansion of the coordination sphere also affects the bond strength between the ligands and the central Mössbauer atom, which will be reflected in the isomer shift values.

One can obtain information about the molecular geometry mainly from the *electric field gradient* data derived from the quadrupole splittings. The principal component of electric field gradient can be written as (Gütlisch et al. 1978)

$$V_{zz} = (1 - \gamma_{\infty})(V_{zz})_L + (1 - R)(V_{zz})_{VAL} = (1 - \gamma_{\infty})(V_{zz})_L + (1 - R)[(V_{zz})_{CF} + (V_{zz})_{MO}] \quad (25.131)$$

where $(V_{zz})_L$ is the *ligand contribution* arising from the aspherical charge distribution in the ligand sphere and/or lattice surroundings with a symmetry lower than cubic, $(V_{zz})_{VAL}$ is

the *valence electron contribution* due to the aspherical distribution of electrons in the valence orbitals. $(V_{zz})_{\text{VAL}}$ can be divided into two parts due to nonspherical population of the *d*-orbitals according to crystal field splitting $(V_{zz})_{\text{CF}}$ and due to anisotropic population of molecular orbitals $(V_{zz})_{\text{MO}}$. The parameters γ_{∞} and R are the Sternheimer factors (Sternheimer 1963).

In the case of compounds where the ligand contribution determines the V_{zz} , the *point-charge model* can be applied to calculate the electric field gradient as the sum of independent contributions of each ligand. Based on the point-charge model, the calculation of V_{zz} for trans and cis isomers of mixed octahedral complexes (Travis 1971) results $(V_{zz})_{\text{trans}} = -2(V_{zz})_{\text{cis}}$. This makes Mössbauer spectroscopy very sensitive to distinguish between *cis* and *trans* isomers by measuring the corresponding quadrupole splitting values.

When the *valence contribution* determines the V_{zz} , the *crystal fields* in the complex compounds (e.g., in the case of high-spin iron(II) or low-spin iron(III) compounds with D_{4h} symmetry) can be determined (Gütlich et al. 1978) by measuring the temperature dependence of the quadrupole splitting (► Eq. (25.106)). In these cases, the change in the thermal

■ Table 25.4

Characteristic applications of Mössbauer spectroscopy considered as fundamental studies of compounds

Fundamental studies of compounds
<i>Electronic structure</i> Determination of oxidation and spin states of the Mössbauer atom, spin transitions (spin crossover)
<i>Bond properties</i> σ and π interactions between the Mössbauer atom and ligands, influence of electronegativity of ligands
<i>Structural properties</i> Molecular geometry, determination of cis- and trans isomers, distortion from cubic symmetry (Jahn–Teller effect), effect of polymerization, finding the right structure of polynuclear complexes, identification of possible structural position occupied by the Mössbauer atom, determination of distribution of Mössbauer atoms among the sites, determination of site preference, determination of coordination number, effect of neighbors
<i>Crystal structure</i> Determination of crystalline and amorphous states, determination of crystal anisotropy, defects and defect structures, characterization of quasicrystalline, microcrystalline, nanocrystalline and amorphous materials
<i>Magnetic properties</i> Diamagnetism, paramagnetism, temperature-dependent spin-changes, spin relaxations, cooperative phenomena, ferromagnetism, ferrimagnetism, antiferromagnetism, determination of transition temperature, determination of magnetic structure
<i>Dynamic processes</i> Phonon mode changes, determination of Debye temperature, determination of effective mass, determination of anisotropy of lattice vibration, electron hopping in spinels, diffusion, determination of jump frequency and diffusion coefficient, paramagnetic spin relaxation, spin–spin relaxation, spin–lattice relaxation, superparamagnetism, determination of grain size

electronic population of the low-lying orbitals is taken into consideration in the temperature dependence of $(V_{zz})_{CF}$.

Bonding properties of complex compounds can be obtained by using data both from isomer shift and quadrupole splitting together, since the electronic density and the electric field gradient at the Mössbauer nucleus are influenced differently by σ donor and π acceptor strengths of surrounding ligands, covalency effects, oxidation/reduction processes, difference in electronegativity of ligands coordinated to the Mössbauer atom, etc.

Magnetically split Mössbauer spectra can be obtained not only with ferro-, ferri-, and antiferromagnetic materials but with paramagnetic compounds, too, when the electronic spin orientation changes slowly as compared to the Larmor precession of the Mössbauer nucleus (paramagnetic spin relaxation, see Wickman et al. 1966). In these cases the internal magnetic flux density at the site of nucleus, B_{int} , is determined from the magnetic splitting (see [Eqs. \(25.93\)](#) and [\(25.94\)](#)). The internal magnetic flux density originates from several terms. In the absence of an external field, $B_{int} = B_c + B_{orb} + B_{dip}$, (Watson and Freeman 1961). The Fermi-contact term B_c arises from the unbalanced spin density of s electrons at the nucleus, the orbital term B_{orb} is from the orbital angular momentum of the ion, while the dipolar term B_{dip} is the field produced at the nucleus by the arrangement of atomic moments through the crystal. By measuring the dependences of the magnetic splitting either on temperature or on concentration of Mössbauer atoms, the *spin-lattice* and *spin-spin relaxation* can also be studied.

As a conclusion, one can distinguish between two main characteristic kinds of applications of Mössbauer spectroscopy in chemistry. It can be applied to study *fundamental properties* of compounds as well as it serves as an *analytical tool* for identifying chemical species. In the latter case it is usually used as a fingerprint method (see [Sect. 25.3.3](#)). In [Tables 25.4](#) and [25.5](#) characteristic applications of Mössbauer spectroscopy in various fields of chemistry are collected.

■ **Table 25.5**

Characteristic applications of Mössbauer spectroscopy considered as analytical studies

Analytical studies
<i>Phase and chemical analysis in compounds and alloys</i>
<i>Surface studies</i> Corrosion, determination of corrosion products on iron and steel surfaces, adsorption properties of ion exchangers, catalysis, surface reactions on catalysts, coatings, effect of the preparation parameters on the phase composition and the short-range order
<i>Solid-state reactions</i> Ligand exchange in transition metal complexes, thermal and radiation-induced decomposition, pressure-induced reactions, electron exchange reactions, substitutional effects in sophisticated oxides
<i>Frozen solution studies</i> Hydration and solvation effects, electron exchange reactions, polymerization
<i>Phase transformation</i> Change in crystal structure, crystallization of amorphous materials, magnetic ordering

26 Mössbauer Excitation by Synchrotron Radiation

M. Seto

Kyoto University, Osaka, Japan

<i>26.1 Isomeric Mössbauer Excitation By Synchrotron Radiation</i>	<i>1448</i>
<i>26.2 Nuclear Resonant Elastic Scattering</i>	<i>1449</i>
<i>26.3 Nuclear Resonant Inelastic and Quasi-Elastic Scattering</i>	<i>1454</i>

Abstract: The use of synchrotron radiation has opened up new areas in nuclear resonant scattering studies. It has permitted measurements that are difficult with conventional radioactive sources, such as the measurement of element-specific dynamics. Recent progress in studies using nuclear resonant scattering of synchrotron radiation is reviewed in this chapter.

26.1 Isomeric Mössbauer Excitation By Synchrotron Radiation

Synchrotron radiation has many distinct properties, such as high brilliance, energy tunability, and pulse structure (For more details on synchrotrons, see [Sect. 50.3.2.4](#) of [Chap. 50](#), Vol. 5, on “Particle Accelerators”). Because of these properties, synchrotron radiation has enabled new types of nuclear resonant excitation experiments. One straightforward use is as an alternative excitation source, which is particularly important for parentless Mössbauer nuclides. The use of synchrotron radiation as a Mössbauer source was first proposed by Ruby (1974). Cohen et al. (1978) reported the first attempt to observe nuclear resonant excitation with synchrotron radiation. Following these pioneering experiments, Gerdau et al. (1985) reported clear observation of nuclear Bragg scattering of synchrotron radiation by ^{57}Fe in a single crystal. In 1991, Hastings et al. (1991) observed nuclear resonant forward scattering by ^{57}Fe in iron foil in the time domain. This experiment showed that examining polycrystalline samples with this method is meaningful and led to an extension of traditional Mössbauer spectroscopy. In addition, other spectroscopic methods using nuclear resonant forward scattering have been developed. One method is the heterodyne (stroboscopic) detection method (Coussement et al. 1996, 1999; Callens et al. 2003); spectra are obtained in the energy domain using this method. A spectroscopic method using the “nuclear lighthouse effect” was developed by Röhlberger et al. (2000); the time evolution of decaying nuclei in a rotating sample is translated into an angular deviation through this method. By contrast, Mössbauer spectra can be obtained in a straightforward manner from synchrotron Mössbauer sources obtained through pure nuclear Bragg scattering (Smirnov et al. 1969; 1997; Smirnov 1999; Mitsui et al. 2005; 2007), although ^{57}Fe is the only available nuclide so far. Recently, another method that yields Mössbauer absorption-type spectra was developed, and this method is applicable to many Mössbauer nuclides (Seto et al. 2009).

Unlike traditional Mössbauer spectroscopy, which is based on recoilless nuclear resonance absorption, the use of synchrotron radiation allows information to be gained from nuclear scattering events that involve the creation or annihilation of quanta of lattice vibrations, i.e., phonons. This was shown in 1994, when the phonon energy spectrum of ^{57}Fe in iron foil was measured (Seto et al. 1995). Following this result, the method of using nuclear resonant inelastic scattering experiments to gain information on phonon spectra found widespread applications. An important feature of this method is that the element-specific phonon density of states can be obtained. Furthermore, the combination of electronic- and phonon-state measurements makes possible to measure site-specific phonons (Seto et al. 2003). Note that this method allows studying diffusion dynamics (Zhang et al. 1995).

At present, *nuclear resonant excitation spectroscopy* performed by synchrotron radiation has two major aspects: (1) it serves as an extended or alternative method of Mössbauer spectroscopy by providing information on hyperfine interactions, and (2) it is used for element-specific local vibration and diffusion studies. These aspects are introduced in the following [Sects. 26.2](#) and [26.3](#). Other applications in fundamental physics and nuclear physics,

such as nuclear excitation by electronic transfer (NEET; see Kishimoto et al. 2000), have also been explored and promising results have been obtained.

Although synchrotron radiation has distinct features, the accessible photon energy range depends on the storage ring and insertion devices installed; it is usually limited to values on the order of 10^5 eV. Moreover, observation of resonant excitation of nuclei using synchrotron radiation is limited by several factors such as the intensity of the radiation, the time resolution of the detector, and the detection efficiency without loss of time resolution. ➤ Table 26.1 shows nuclides with the appropriate properties (excited-state half-life >0.5 ns, energy <100 keV, and ground-state half-life >10 years) for excitation at the nuclear resonant scattering beamline BL09XU at SPring-8, which is a third-generation synchrotron radiation facility.

26.2 Nuclear Resonant Elastic Scattering

One of the main purposes of Mössbauer spectroscopy is the investigation of hyperfine interactions that reflect the electronic state of the resonant nuclei. Compared with traditional Mössbauer spectroscopy, the use of synchrotron radiation for studying hyperfine interactions is advantageous as it is also applicable to nuclides with no appropriate mother nuclide, such as ^{40}K (Seto et al. 2000a, 2002). However, when synchrotron radiation is used as an excitation source (excluding one method discussed later), the energy width is much broader (>0.1 meV) than that of conventional Mössbauer sources. Therefore, special measuring techniques are needed to obtain information on the hyperfine interactions when using synchrotron radiation.

One possibility is to make use of the pulsed structure of synchrotron radiation by measuring the hyperfine interactions in the *time domain* (Trammell and Hannon 1978, 1979). If the nuclear energy levels of the resonant nuclei are split due to hyperfine fields and the energy width of the synchrotron radiation is much broader than the splitting, a coherent superposition of the nuclear sublevels is formed by pulsed excitation of the nucleus. X-rays are then scattered from an excited nucleus decaying with a certain lifetime, and *quantum beats*, whose oscillating cycles reflect the energies of splitting, are measured as the time evolution of the (delayed) scattering, which is called a *time spectrum*. An example of a time spectrum with quantum beats is shown in ➤ Fig. 26.1. Nuclear resonant Bragg scattering can be observed by using a single crystal containing a certain amount of resonant nuclei. Even if the sample is polycrystalline (not a single crystal), scattering can be observed in the forward direction (Hastings et al. 1991). This kind of measurement requires a special timing mode for the pulse bunch structure of the storage ring; the interval between pulse bunches should be longer than the lifetime of the excitation state. In most nuclear resonant scattering measurements, Si avalanche photodiode (APD) detectors (Kishimoto 1991) are used, which have the typical time resolution of 100–1000 ps.

There are also suitable measuring methods applicable in the energy domain, one of which is the *heterodyne* (stroboscopic) *detection method* (Coussement et al. 1996, 1999; Callens et al. 2003). This method uses the interference effect between a sample and a reference moved with respect to the sample. Coherent forward scattering is detected, and the spectrum is obtained as a function of the velocity of the reference. This method is especially useful for the measurement of nuclides with longer excited-state lifetimes compared with measurements in the time domain; this is because the time domain measurement is restricted by the pulse interval of the storage ring, although it is simple and has better efficiency for simple hyperfine interaction measurements. Therefore, measurements of nuclides with longer excited-state lifetimes under

■ Table 26.1

Nuclides for which resonant excitation is expected to be observed at the nuclear resonant scattering beamline (BL09XU) of SPring-8 (Firestone and Shirley 1996; Dunford and Kinsey 1998)

Nuclide	$a(\%)$ [$T_{1/2}$ (years)]	E_γ (keV)	$T_{1/2}$ (ns)	I_g	I_e	α

Fig. 26.1
Nuclear resonant scattering measured in the time domain

extreme conditions that require synchrotron radiation are promising candidates for the heterodyne detection method, although the excitation of a longer excited-state is difficult in general.

Another method with nuclear resonant forward scattering adopts the *nuclear lighthouse effect* (Röhlsberger et al. 2000). When nuclei in a rotating sample are coherently excited, the radiative decay of the excited states proceeds in the tangential direction. The time spectrum of nuclear decay is mapped onto an angular scale, and the delayed signals can be detected with a position-sensitive detector without time resolution in the ideal case. By rotating the sample at an appropriately high frequency (on the order of 1 kHz), this method makes it possible to

detect time spectra of nuclides whose excited states have very short lifetimes and high energies (Röhlsberger et al. 2001b; Roth et al. 2005).

Mössbauer spectroscopy with synchrotron radiation can be used in a straightforward manner with single-line ^{57}Fe Mössbauer sources obtained using iron borate (FeBO_3) single crystals set under diffraction conditions at the Néel temperature (75.3°C) (Smirnov et al. 1969, 1997; Smirnov 1999; Mitsui et al. 2005, 2007). In this method, the spectrum obtained using synchrotron Mössbauer sources is basically identical to that obtained using conventional radioactive sources. This approach, therefore, is easily applicable and beneficial for a wide range of Mössbauer research. However, ^{57}Fe is the only available nuclide so far.

Recently, a new method has been developed that yields Mössbauer absorption type spectra using synchrotron radiation and is applicable to almost all Mössbauer nuclides (Seto et al. 2009). In this method, two samples containing the same resonant Mössbauer nuclide are used: one is used as a transmitter, and the other as a scatterer, which is placed behind the transmitter in the path of the synchrotron radiation. To obtain the Mössbauer spectra in the energy domain, the transmitter or scatterer is moved by a conventional velocity transducer, i.e., a relative energy scan is performed. When the relative resonance energies of the scatterer and transmitter are equal, the nuclear resonant scattering from the scatterer is suppressed compared with that when the relative resonance energies are different. This suppression is due to nuclear resonance absorption in the transmitter. If the resonance energies are different, photons with the resonance energy of the scatterer are not absorbed in the transmitter except for electronic processes such as a photoelectric effect; suppression of the scattering in the scatterer does not occur in this case. Therefore, one can observe a local minimum in the intensity spectrum of the scattering from the scatterer when the relative energy is zero. This velocity-dependent scattering intensity yields a Mössbauer absorption type spectrum in the energy domain. In this method, one of the two samples (the transmitter and the scatterer) is usually the sample under investigation, while the other is a reference sample whose properties are well known. The sample under investigation can be measured as a transmitter or scatterer depending on the sample condition. Note that this method detects not only γ -rays but also fluorescent X-rays and internal conversion electrons, which are emitted at de-excitation. The detection of fluorescent X-rays is easier than γ -rays with a silicon APD detector because the energies of fluorescent X-rays are lower than the energies of γ -rays. Moreover, electron detection is not difficult with APD detectors. Therefore, this method is relatively favorable for high-energy excited state nuclides compared with the method that detects only γ -rays with Si-APD. In fact, the Mössbauer spectrum of the third excited state of ^{73}Ge , which is difficult to measure with RI sources, was obtained by using synchrotron radiation (Seto et al. 2009) as shown in ► Fig. 26.2.

Until now, a considerable number of hyperfine interaction studies using nuclear resonant scattering of synchrotron radiation have already been carried out. Examples to be mentioned here include the use of synchrotron radiation in studying the spin structures of thin films, interfaces, and surfaces (Johnson et al. 1995; Röhlsberger 1999a; Röhlsberger et al. 2001a; Couet et al. 2009) in a superconductor (Kamihara et al. 2008) and in high-pressure experiments (Nasu 1994; Lubbers et al. 1999; Barla et al. 2004). The application of external perturbation synchronized to the pulse timing of synchrotron radiation is a unique method (Shvyd'ko et al. 1995, 1996; Mitsui et al. 1997) and seems to be useful for studying the time evolution of hyperfine interactions caused by light or magnetic fields synchronized to the incident pulse. This kind of experiment is rather difficult to handle using conventional Mössbauer methods.

■ Fig. 26.2

Mössbauer spectrum of ^{73}Ge measured by nuclear resonant scattering of synchrotron radiation. A powder sample of Li_2GeO_3 was used as the transmitter, and a powder sample of $^{73}\text{GeO}_2$ was used as the scatterer (Seto et al. 2009)

Studies on slow dynamics have been performed so far with the conventional method known as *quasi-elastic Mössbauer spectroscopy*. Using synchrotron radiation, the dynamics of glasses (Franz et al. 1999) and the diffusion of atoms in solids (Vogl and Sepiol 1999) can also be studied.

Although hyperfine interaction studies with both radioactive sources and synchrotron radiation have their respective advantages, new techniques based on synchrotron radiation widen the possibilities for studying hyperfine interactions and open up new prospects to perform studies that are out of the reach of conventional Mössbauer spectroscopy.

26.3 Nuclear Resonant Inelastic and Quasi-Elastic Scattering

The nuclear resonant inelastic and quasi-elastic scattering method has distinct features favorable for studies concerning the microscopic dynamics (i.e., lattice vibration, diffusion, and molecular rotation) of materials. One advantageous feature is the ability to measure the *element-specific* dynamics of condensed matter. For example, in solids the *partial phonon density of states* can be measured. Furthermore, measurements under exotic conditions – such as high pressure, small samples, and thin films – are possible because of the high brilliance of synchrotron radiation. (For the definition of brilliance, see 🔗 Sect. 50.3.4.5 of Chap. 50, Vol. 5, on “Particle Accelerators.”) This method is applicable not only to solids but also to liquids and gases, and there is no limitation concerning the sample temperature.

Nuclear resonant excitation accompanied by phonon excitation (🔗 Fig. 26.3) can occur when the nucleus is hit by a gamma photon whose energy is equal to the sum of the energy required for recoilless nuclear resonant excitation and the energy of the phonon. If nuclear resonant excitation occurs, delayed photon(s) (e.g., fluorescence X-ray) or electron(s) (e.g., conversion electron) are emitted at de-excitation. The intensity of the delayed emission as

■ Fig. 26.3

■ Fig. 26.4

Schematic for measurement of the nuclear resonance excitation accompanied by phonon excitation. The avalanche photodiode (APD) detector placed below the sample detects inelastic scattering, and another APD detector in the forward direction detects forward scattering for the energy reference

a function of the energy of the incident radiation gives the *phonon energy spectrum*. Therefore, the nuclear resonant *inelastic scattering* spectrum is measured by scanning the incident radiation energy; this is usually done by changing the Bragg angle of the monochromator. The energy resolution attained with a Si high-resolution monochromator is typically 1–10 meV (in special cases, about 0.1 meV can be achieved; see Yabashi et al. 2001). As material for the monochromator, in addition to Si, sapphire ($\alpha\text{-Al}_2\text{O}_3$) has begun to be used, particularly for high-energy nuclides (Shvyd'ko 2004; Wille et al. 2007). A schematic of the nuclear resonant excitation accompanied by phonon excitation and the detection of delayed emission is shown in ▶ Fig. 26.4. The nuclear resonant inelastic scattering spectra of ^{57}Fe at 150 and 300 K are shown in ▶ Fig. 26.5.

A phonon density of states can be obtained from the measured phonon energy spectrum; for compounds, the partial phonon density of states for the specific element can be obtained. It should be noted that since the direction of the conversion electron and the direction of the

■ Fig. 26.5

Nuclear resonant inelastic scattering spectra of ^{57}Fe at 150 K (open squares) and 300 K (closed circles) (Seto et al. 1996). Lines correspond to spectra calculated from results of neutron inelastic scattering measurements (Minkiewicz et al. 1967)

corresponding characteristic X-ray emitted are independent of each other, the position and solid angle of the APD detector do not affect the shape of the phonon energy spectrum.

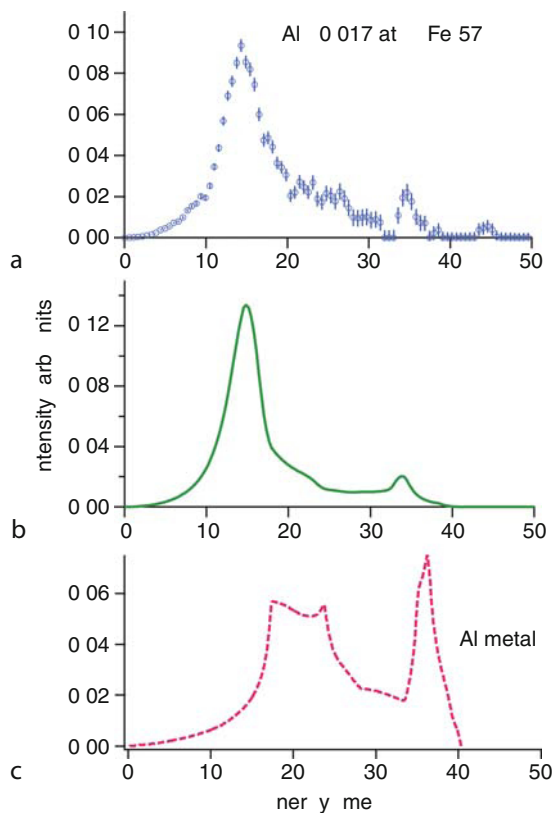

The high brilliance of synchrotron radiation makes possible the phonon density of states to be measured even for small samples. The measurement of the phonon density of states under high pressures using a diamond anvil cell (DAC), where the sample size is usually below 1 mm^2 , is effective for studying the core of earth and has been performed by Lübbbers et al. (2000), Mao et al. (2001), and Lin et al. (2005).

Phonons are quasiparticles, which are quantized lattice vibrations of all atoms in a solid material. Oscillating properties of the individual atoms in nonequivalent positions in a compound, however, are not necessarily equivalent. The dynamics of certain atoms in a compound influence characteristics such as the vibration of the impurity or doped atoms in metals and the rare-earth atom oscillations in filled skutterudite antimonides. Therefore, the ability to measure the *element-specific phonon density of states* is an advantageous feature of the method based on nuclear resonant inelastic scattering. Element-specific studies on the atomic motions in filled skutterudites have been performed (Long et al. 2005; Wille et al. 2007; Tsutsui et al. 2008).

Moreover, it is possible to study the dynamics of specific impurity or doped atoms in metals and semiconductors. The local vibrational density of states of highly dilute Fe (0.017 at%) in Al metal measured by nuclear resonant inelastic scattering of synchrotron radiation is shown in ► Fig. 26.6a (Seto et al. 2000b). The phonon density of states of Al metal, obtained from a neutron inelastic scattering experiment, is also shown in ► Fig. 26.6c for comparison (Gila and Nicklow 1966). The partial phonon density of states of ^{57}Fe in Al clearly differs from the phonon density of states of the Al metal host (compare ► Fig. 26.6a and c). Given the phonon density of states of the host metal, the partial phonon density of states of Fe can be calculated by using the Green function method (Mannheim 1968) along with information on the coupling between Fe and Al. The phonon spectrum calculated this way is shown in ► Fig. 26.6b.

■ Fig. 26.6

(a) Vibrational density of states of ^{57}Fe in Al-0.017 at.% Fe. (b) Response function of the impurity Fe atom to the phonon density of states of Al metal calculated on the basis of Mannheim's impurity theory. (c) Unperturbed phonon density of states of Al (Seto et al. 2000a)

The calculation reproduces the measured (▶ Fig. 26.6a) partial phonon density of states of Fe remarkably well. The characteristic vibrational modes of Fe in Al were found to be modes that vibrate resonantly with the host Al phonons.

The *element-specific dynamics of ions in solutions* can be investigated by nuclear resonant *quasi-elastic scattering* spectroscopy (Zhang et al. 1995). In this case, element-specific diffusion constants of ions can be obtained even in a complex solution. The dynamics of Fe ions in Nafion membranes, which are used as ion-exchange membranes, was studied using this method (Haruki et al. 2000, 2001). In addition, many important studies using the features of nuclear resonant inelastic scattering spectroscopy have been performed, e.g., on nanoparticles (Fultz et al. 1997; Pasquini et al. 2002), very thin films (Keune and Sturhahn 1999; Röhlberger et al. 1999b; Sturhahn et al. 1999; Ruckert et al. 2000; Cuenya et al. 2001), quasi crystals (Brand et al. 1999), low-dimensional material (Kitao et al. 1998), clathrates (Hermann et al. 2005; Tse et al. 2005), superconductors (Higashitaniguchi et al. 2008), macromolecules (Rüffer and Chumakov 1996; Chumakov and Rüffer 1998; Grünsteudel et al. 1998; Keppler et al. 1997; Harami et al. 1998; Parak and Achterhold 1999; Sage et al. 2001; George et al. 2008).

■ Fig. 26.7

Phonon densities of states of ^{57}Fe in the Fe_3O_4 . The phonon density of states of all Fe is shown by closed circles and the partial phonon densities of states of the A and B sites are shown as downward and upward triangles, respectively. Lines are guides for the eye (Seto et al. 2003)

The nuclear resonant inelastic scattering method surely offers element-specific phonon energy spectra. However, for compounds with two or more different atomic states for the same element – such as magnetite, which is a mixed valent Fe compound – even this element-specific method cannot distinguish the “site-specific” vibrational properties. Moreover, no general method is known that could provide the site-specific phonon densities of states (PDOS). However, hyperfine interactions between the nuclei and surrounding electronic states make such measurements possible (Seto et al. 2003). If there are some different electronic states for a certain element in a compound, their hyperfine interactions are different. Therefore, by extracting the information for hyperfine interactions from the time evolution of delayed inelastic scattering by observing the quantum beat pattern, one can get the contributions of the respective sites in the inelastic scattering. Carrying out this procedure at different phonon energies permits the observation of the partial PDOS as distinguished by electronic states. As a mixed valent compound, magnetite (Fe_3O_4) was measured using the site-specific nuclear resonant inelastic scattering method. Magnetite forms a cubic spinel structure at room temperature, and the Fe atoms are located in two nonequivalent positions in the unit cell; one third of the Fe ions (Fe^{3+}) occupy the A sites tetrahedrally coordinated by four oxygen ions, and the remaining two-thirds of the Fe ions ($\text{Fe}^{2.5+}$) occupy the B sites octahedrally surrounded by six oxygen ions. Below $T_N = 858\text{ K}$, magnetite is ferrimagnetic with A sites moments aligned antiparallel to the B sites moments. The measured spectra of partial PDOS for all Fe sites and the site-specific PDOSs of the A and B sites are shown in ► Fig. 26.7.

Although element- and site-specific measurement is one of the advantages of nuclear resonant inelastic and quasi-elastic scattering, available nuclides on which nuclear resonant inelastic scattering has been measured is limited to those whose excitation energy is below about 30 keV. However, the development of a back-scattering type monochromator using high-quality sapphire single crystals has made it possible to extend the available energy range higher; studies using the advantages of this method will be performed widely and will extend the possibility of phonon studies.

Abstract: This chapter demonstrates the applicability of positrons in nuclear chemistry and material sciences. From the very basics to highly developed spectroscopic methods, a brief outline of positron annihilation spectroscopies is given. The possibilities of these methods are emphasized, and the characteristic applications are outlined for every one of them.

27.1 Introduction

As positron annihilation spectroscopies are not conventional methods in studying materials, this chapter might need a more basic introduction than others. Consequently, the very basics of positron annihilation spectroscopies, along with most variations of spectroscopies applying positrons as probes for material properties, are explained below.

27.1.1 What Is a Positron?

The positron is the antiparticle of the electron. It was theoretically deduced by Dirac (1930) and later observed by Anderson (1932) in cosmic rays. As any other antiparticle, the positron reflects its particle counterpart in every respect, their physical properties are equivalent. The masses of the two particles are identical and so are the absolute values of electric charges, spins, and magnetic moments. However, the electric charge of the positron is positive causing its magnetic moment to point in the direction of its spin.

In a vacuum, the positron is a stable particle, but in materials, it annihilates with an electron rapidly. The particle/antiparticle pair disappears in the annihilation process producing gamma photons. The number of photons and their energies are determined by the most basic laws of physics. The conservation of energy guarantees that the summed energy of all the photons must be 1.022 MeV, the rest energy ($2m_e c^2$) of the electron and positron together, while the spin conservation law (and the conservation of momentum) determines the number of photons. If the overall spin of the annihilating particle/antiparticle pair is zero, the number of photons is even. On the other hand, if the summed spin of the pair is equal to one, odd numbers of photons are formed. There is another important rule governing the photon production. Every excess photon, even if other probabilistic factors are ignored, decreases the annihilation probability by a factor of $1/137$, that is, by the fine structure constant. Consequently, combining the spin conservation law and this rule, the most probable way of annihilation is the formation of two gamma photons from an $S = 0$ state. Although the smallest odd number is one, the one-photon annihilation is usually hindered by the law of momentum conservation. (As the proposed single annihilation photon possesses a non-zero momentum, a third “inert” particle is required besides the annihilating pair to compensate the photon’s momentum by recoil. The case is similar for zero photon annihilation from the $S = 0$ state, but two “inert” particles are required for this rare process.) So, from an $S = 1$ state, the annihilation of a positron–electron pair most likely produces three gamma photons. (For a more detailed description of annihilation probabilities, see, for example, Schrader and Jean (1988) and the references therein.)

The momentum conservation law rules the direction of photons, as well. In the case of two-photon annihilation, photons must depart collinearly and the three-photon annihilation determines a plane in which photons should stay. This strict rule is usually altered slightly by

the momentum of the annihilating electron, thus providing a great opportunity to construct a momentum-sensitive spectroscopy.

In the case of two-photon annihilation, the energy conservation law has one more serious consequence on photons. Both should have an energy of 0.511 MeV. This energy is so uniquely characteristic to electron–positron annihilation that Anderson (1932) proved the existence of positrons by the detection of this annihilation radiation. Although the above rule is rather strict, it is altered, again, a little by the momentum of the electrons.

27.1.2 Where to Find It?

Positrons are not normally present in our world, they are not building blocks of ordinary matter. Even so, one can find annihilation radiation here and there indicating the former presence of positrons. The 0.511 MeV radiation was found in hot galactic cores and even among everyday cosmic rays. These positron sources, however strange and rare, serve as models for the production of antiparticles in a world of particles. The common physical process behind all the observed annihilation radiation sources is the well-known pair production.¹

In gamma ray spectroscopy, positron–electron pair production is a frequent, although unwelcome, side effect. On the other hand, under well-designed conditions, pair production might serve as a positron source. Usually, synchrotron radiation or high-energy **Bremsstrahlung** from accelerated electrons stopping in a heavy metal target (Howell et al. 1985) is used to produce positron–electron pairs in “industrial” quantities by pair production. This is how positrons are “made” for large accelerators and positron–electron colliders.

Under laboratory conditions, the most convenient way of producing positrons is the use of positron emitting radionuclides. Some useful nuclides undergoing positive beta decay are listed in ▶ Table 27.1. Although PET, that is, positron emission tomography, is an important field applying positron sources, it is rather a diagnostic method than a spectroscopy, and therefore it will not be discussed further here. For those interested in it, a vivid description is given by McCarthy et al. (1994).²

For spectroscopic purposes ²²Na is the most popular radionuclide. Its decay scheme is given in ▶ Fig. 27.1. It has several advantages: its half-life is convenient, the positron energy is not too high and after the emission of the positron it emits a gamma photon within 10^{−11} s.

■ Table 27.1
Some positron emitting radionuclides

Nuclide	Half-life	Positron energy (E_{\max} in MeV)	Probability of positive beta decay (%)	Application
¹¹ C	20.3 min	0.87	>99	PET
¹⁵ O	2.03 min	1.7	>99	PET
¹⁸ F	109.7 min	0.64	97	PET
²² Na	2.6 years	1.83	0.06	Spectroscopy
		0.54	89	
⁶⁴ Cu	12.7 h	0.66	19	Spectroscopy

■ Fig. 27.1

The decay scheme of ^{22}Na

This “prompt gamma” photon marks the moment of positron formation, making positron lifetime measurements possible.

In some special cases also the short-lived ^{64}Cu is used as a positron source, particularly if high specific activity is needed. Sometimes the short half-life of the applied positron source requires an intricate design. In some particular cases, due to the short half-life, the positron source is produced *in situ* using a nuclear reactor (Kaufmann et al. 1997).

27.1.3 Positrons in Materials

Although stable in a vacuum, any positron will eventually annihilate in normal matter with an electron. Thus its effective lifetime is very short ($\tau = 10^{-12} - 10^{-7} \text{ s}$), however, this incredibly short period is still enough for the positron to react with matter in several ways. These physical (and sometimes even chemical) reactions alter from material to material providing a number of unique possibilities to study materials through their annihilation characteristics.

27.1.3.1 Thermalization of Positrons

Positrons, no matter how they have been produced, usually have considerable kinetic energies initially. If these energetic positrons are injected into a material, the probability of their annihilation is much smaller than that of collisions with the atoms and molecules of the substance (Dirac 1930). The continual collisions decrease the kinetic energy of the positron and slow it down to thermal energies ($\sim 0.1 \text{ eV}$). Obviously, the thermalization takes place differently in different materials, but some common features can be easily identified even in so entirely distinct materials as gasses and metals (➤ Table 27.2).

At the beginning of the thermalization process, inelastic collisions dominate almost totally. At this stage, positrons slow down to about 100 eV very rapidly. It takes only $\sim 1 \text{ ps}$ (10^{-12} s) in metals (Brandt 1983), but $\sim 10 \text{ ns}$ (10^{-9} s) in gasses at atmospheric pressure (Green 1966). In the second stage, both elastic and inelastic collisions take place, together with some negligible

■ Table 27.2

A rough outline of the thermalization of positrons (Green 1966; Brandt 1983). The time is measured from the “birth” of positron till the end of the stage

Stage	Final energy of the positron / eV	Slowing down mechanism	Duration time		The fate of positron
			in Lead	in Argon	
I	~100	Bremsstrahlung, electromagnetic ionization, inelastic collisions	1 ps	7 ns	Slowing down
II	~10	Elastic and inelastic collisions			Slowing down, negligible free annihilation
		Plasmon and phonon excitation			
III	~0.1	Elastic collisions, phonons			Slowing down, free annihilation, reactions
IV	Thermal equilibrium is reached	Elastic collisions	45 ps	110 ns	Free annihilation, reactions

free (or direct) annihilation. In the third stage, when the kinetic energy of the positron decreases below the lowest electronic excitation level (~ 10 eV), elastic scattering becomes dominant. From then on, free annihilation becomes more and more significant. At the end, positrons get to thermal equilibrium with their surroundings, and their further fate depends very much on the material. The whole process takes place in only 45 ps in lead (Brandt 1983), but it takes more than 100 ns in argon at 1 bar (Green 1966).

From a material-centered point of view, the thermalization of positrons is a process very similar to that of electrons. The initial stage of inelastic collisions and the electromagnetic slowing down process form the usual radiation products. In fluids and molecular or atomic solids, these are excited and ionized molecules, free radicals, and electrons. In metals, however, plasmon and phonon excitation also play significant roles in the thermalization of positrons.

27.1.3.2 Positron States

Free annihilation is only one of the possibilities for thermalized positrons to stop existing. In some substances it does not happen at all. In most materials, some or all of the originally free positrons “react” somehow with their surroundings. The consequence of the “reaction” is the formation of new positron states. Such positron states differ from each other and from free positrons in their annihilation characteristics. Moreover, although the possible states are the same for similar materials, their exact annihilation properties depend on local conditions. Consequently, these states make positrons a valuable tool in studying the structure of materials.

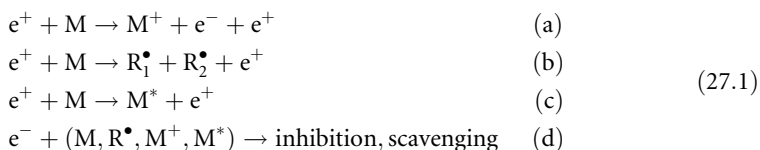

It is the easiest to understand positron states in the case of metals. In a perfect, defectless single crystal, thermalized positrons are in Bloch-states similar to those of electrons (Kittel 1979; Mijnenrends 1983). They are called free positrons. Before their annihilation, these

positrons scan expanded regions of the crystal and have a chance to meet both the electrons of ionic cores and the Bloch-state conducting electrons.

Another positron state is formed when free volume-type crystal defects are present in the metal crystal. The positively charged ionic cores are missing from these defects, so, usually they are effective traps for any positive particle, including the positron in our case. Thus, in most metals, vacancies, vacancy clusters, dislocations, and grain boundaries localize some or all of the free positrons and produce another positron state, the trapped positron. These localized positrons still can meet conducting electrons, but ionic cores are out of their reach. Accordingly, their annihilation characteristics differ from those of free positrons significantly. Different kinds of traps all have their own characteristic annihilation parameters but these parameters are very close to each other.

A positron state of lesser importance is also formed in the case of some metals. The existence of this state is connected with the fact that the work function of positrons is positive in several metals (Lynn 1980). In that particular case, a potential well is formed on the surface of the metal, which can localize positrons reaching the surface eventually during or after their thermalization.

The formation of positron states takes place in a much more complicated way in molecular solids and fluids. The structures of these materials are more complex than those of metals, and diverse radiation products are formed in the thermalization process. Consequently, any theory explaining the behavior of positrons in these materials needs the use of radiation chemistry. The so-called spur model (Mogenssen 1974) does exactly this and states that the thermalized positron reacts with the particles of its own radiation track. The spur contains ground-state (M) and excited molecules (M^*), ions (M^+), free radicals (R^\bullet), and electrons (e^-). These species react with the positron and, parallel, with each other. Some possible reactions are given in ► Eq. (27.1):

Positrons, being antiparticles, ignite some special spur reactions, first of all annihilation. However, positrons are positive particles and, thus, they can replace protons under certain conditions. A positron and an electron are able to form the most specific positron state, a hydrogen-like system called positronium (Ps). Some of the special spur reactions are given in ► Eq. (27.2):

The statistical weights of the above reactions vary in a wide range in different materials. Positronium formation can be as significant as 30%. A positronium atom, being similar to hydrogen atoms, is a reactant particle. Thus, the list of spur reactions should be elongated by its reactions. On the other hand, most of the chemical applications of positrons are based on the use of positronium atoms, consequently these reactions are treated separately in ► Sect. 27.2.3.

27.2 The Positronium

The possibility of a positron–electron bound system was suggested by Mohorovicic (1934) on the basis of theoretical considerations. Several years later, it was given its present name (Ruark 1945), but its actual existence was proved by delayed coincidence measurements only in 1954 (Deutsch 1954). The symbol Ps was introduced by McGervey and De Benedetti (1959) to denote positronium as a chemical element. In a certain sense, Ps is definitely an atom; it can be regarded as an isotope of hydrogen.

27.2.1 Physical Properties of the Positronium Atom

Positronium is a system very similar to a hydrogen atom but its mass is 920 times smaller, because the proton is substituted by the much lighter positron. Because of its lightness, the positronium atom has a smaller binding energy than a hydrogen atom, that is, 6.8 eV instead of 13.6 eV. The smaller binding energy generates a two times larger distance between the positron and the electron in positronium than the ground-state proton–electron distance in a hydrogen atom. However, this does not mean that the Ps atom is larger than a hydrogen atom. Strangely enough, they have the same size. This seeming contradiction can be easily resolved by considering that the proton is located in the center of the hydrogen atom, while the positronium is a totally symmetric entity. In the Ps, the positron and the electron wave functions are identical, at least their spatial part. Metaphorically speaking, the hydrogen atom is a planetary system with a heavy sun at its center (the proton) and a light planet around it (the electron). On the other hand, the positronium is a binary system of two stars of the same mass circling around their center of mass.

The size paradox is only one of the unusual properties of the positronium atom caused by the fact that it is constructed of a particle–antiparticle pair. Some physical properties, not too significant in the case of hydrogen atoms, gain unusual importance in the case of Ps atoms. Most books do not even mention that two kinds of ground-state hydrogen atoms exist that are distinguished by their spins. This seeming ignorance is understandable considering the fact that one should perform very sophisticated measurements to find the differences between *ortho*-H and *para*-H (the effect is well known in, e.g., high-resolution NMR spectroscopy).

In the case of positronium atoms the spin plays a more significant role and distinguishes ground states much more significantly. Determined by the relative orientation of the spins of the constructing electron and positron, the spin of a Ps atom is either 0 or 1 \hbar . The former is called singlet or *para*-Ps (1S_0 , 1Ps), while the latter is the triplet or *ortho*-Ps (3S_1 , 3Ps). According to the magnetic quantum number m , *para*-Ps exists only in one state ($m = 0$), while *ortho*-Ps occurs in three states ($m = +1, 0, -1$). Therefore, the statistical weight of the triplet state is three times larger than that of the singlet. Although both states should be considered ground states, the energy of *para*-Ps is significantly lower. The detailed comparison of the energy levels of hydrogen and positronium was given, for example, by Berko and Pendleton (1980) and Rich (1981).

Beside their energy, the lifetimes of the two states differ significantly as well. Although the expression is similar for the two states, it gives quite distinct lifetimes for *ortho*- and *para*-positronium:

$$\lambda_i^0 = \frac{1}{\tau_i^0} \propto \sigma_i |\psi(0)|^2 \quad (27.3)$$

where i stands for singlet or triplet states, λ is the corresponding decay constant, τ is the mean lifetime, and $\psi(\mathbf{r})$ is the wave function of the positronium. The symbol σ_i denotes the “cross section” of the annihilation from the corresponding spin state. It is determined by fundamental constants of quantum electrodynamics (Schrader and Jean 1988). ➤ Equation (27.3) yields $\tau_S = 1.25 \cdot 10^{-10}$ s for the mean lifetime of free *para*-Ps in a vacuum and $\tau_T = 1.42 \times 10^{-7}$ s for *ortho*-Ps (Asai et al. 1995).

These lifetime values are, seemingly, very short. However, in comparison with the vibration period of atoms in a molecule (10^{-14} s) they are long enough to enable the positronium to take part in interactions with the substance.

27.2.2 The Formation of the Positronium Atom

The formation of positronium atoms is affected by many factors but first of all, as ➤ Eqs. (27.1) and ➤ (27.2) suggest, by the material itself. According to the mentioned spur model (Mogenssen 1974), thermalized positrons compete with molecules of the material and with radiation products for available electrons. Sometimes, these species are such effective inhibitors or scavengers that they prevent positronium formation totally. Even if the inhibition is negligible, not all of the positrons can form Ps. Positronium formation reactions given by ➤ Eqs. (27.2b) and ➤ (27.2c) require positrons of some particular energies.

The energy range most favorable for positronium formation is called Ore gap after its Norwegian discoverer (Ore 1949). The theory was developed for gasses, but, with some restrictions, it applies to liquids and solids as well. Ore has shown that there is a minimum energy, E_{\min} , at which positronium formation is still possible:

$$E_{\min} = V - 6.8 \text{ eV} \quad (27.4)$$

where V is the ionization potential of the gas and the value 6.8 eV is the binding energy of the positronium. This is the minimum energy that still enables the positron to pick up an electron from a gas molecule to form a bound system with it according to ➤ Eq. (27.2c).

The higher energy limit for positronium formation is provided by the requirement that the kinetic energy of Ps cannot be higher than its binding energy; otherwise, it should decompose in a very short time. Kinetic conditions lower this limit. Usually, the positron energy should not exceed the ionization potential of the gas ($V = 15.8$ eV in argon) because, in that case, ionization is a more probable process than Ps formation. Even at this decreased energy limit, the probability of positronium formation is small. It reaches considerable values only if the positron energy is lower than the lowest excitation energy of gas atoms (E_e , which is 11.6 eV for argon). Above this limit, positrons are likelier to excite the atoms of the substance than to form positronium. Thus the width of the **Ore gap** becomes:

$$\Delta = E_e - (V - 6.8 \text{ eV}). \quad (27.5)$$

According to Ore, the **probability of positronium formation** (P_{Ps}) can be estimated as follows:

$$\frac{E_e - (V - 6.8 \text{ eV})}{E_e} < P_{Ps} < \frac{6.8 \text{ eV}}{V}. \quad (27.6)$$

For the special case of argon, the inequality becomes $0.22 < P_{Ps} < 0.43$ and the experimental values measured by different authors are between 0.27 and 0.36 (Green 1966).

Although the Ore model is more quantitative than the spur model, it works without serious errors only for gasses. In a condensed phase, conditions determining Ps formation are much more complicated. Usually, even some crucial parameters (e.g., ionization potential, solvating effect, etc.) are known with insufficient accuracy. Consequently, for condensed phases, one should use the spur model instead. Usually, it does not supply quantitative data, and its list of equations changes from material to material, but, even so, its results are impressive.

Independently of what one thinks of their formation mechanism, Ps atoms need space to be formed. In gasses, there is an enormous empty space between gas molecules, so space (or the shortage of it) is not a limiting factor of Ps formation. In fluids, however, Ps creates a small empty space, a bubble around itself. The **bubble model** was developed a long time ago (Ferrel 1957) and has been modified continually. Its present form tries to synthesize the results of the spur model and modern physical chemistry (Stepanov et al. 2000). In solids, structural free volumes might serve the empty space needed for positronium formation.

In metals and semiconductors Ps formation is negligible. The low excitation energy of electrons, as [Eq. \(27.5\)](#) shows, hinders this process. However, a special kind of positronium might form even in these cases. This is the so-called surface positronium. As mentioned above, some positrons can reach the surface during their thermalization. These antiparticles are reemitted into the vacuum or get trapped on the surface. Some of them form Ps at the solid–vacuum interface.

27.2.3 Reactions of the Positronium Atom

In a material with a random orientation of spins, three quarters of positronium atoms are formed in triplet state (*o*-Ps) and the remaining $\frac{1}{4}$ is *para*-positronium. Usually, the mathematical handling of the annihilation of *p*-Ps is so inconvenient that it is ignored during the interpretation of annihilation data. Ignoring 25% of available signals seems to be too much waste but the separability of *o*-Ps signals compensates for this seeming disadvantage. Consequently, only the reactions of *o*-Ps are discussed below. A more detailed description of the reactions of *o*-Ps was given by Vértés and Kiss (1987). The monograph also gives the radiation chemistry background needed to understand *o*-Ps reactions.

The interaction-free annihilation of an *o*-Ps atom produces three γ photons. According to quantum electrodynamics, the probability of 3γ -annihilation is much smaller than that of 2γ -annihilation, but the spin conservation rule prevents 2γ -annihilation from an $S = 1$ state. Thus, the self-annihilation of *o*-Ps is a relatively slow process, and *ortho*-positronium atoms have enough time to take part in different interactions with the particles of the substance. As a result, *o*-Ps usually escapes self-annihilation because it is forced by its surroundings to undergo quick 2γ -annihilation.

27.2.3.1 The Pick-Off Annihilation

The most general interaction between Ps and materials is the so-called “pick-off” annihilation. It occurs in every material, although sometimes together with other *o*-Ps interactions. This interaction is based on the fact that the positron of the triplet positronium atom can undergo 2γ -annihilation with an opposite-spin electron of a colliding molecule. Thus, the positron–electron pair, which annihilates at the end, is in singlet state ($S = 0$) instead of the original $S = 1$

state. As a result of this interaction, the lifetime of *ortho*-positronium shortens considerably, but, owing to the shielding effect of the Ps-electron, it is still longer than it would be in the case of free annihilation. Pick-off annihilation is especially common in condensed phases.

The pick-off annihilation rate constant λ_p can be described (Hyodo 1985) by the overlap between the wave function of *o*-Ps $\varphi(r_-, r_+)$ and that of surrounding “alien” electrons $\psi_v(r)$:

$$\lambda_p = \frac{r_0^2 c \pi}{4V} \sum_i \sum_v n_i n_v \int \int |\varphi_i(r_-, r) \psi_v(r)|^2 dr dr_- \quad (27.7)$$

where r_0 is the classical electron radius, V is the volume of the sample and n_p , n_v are the occupation probabilities of the Ps and electron states, respectively. (The symbols r_- and r_+ indicate that the wave function is dependent on the positions of both the electron and the positron. Note that in the overlap integral, r_+ is replaced by r since the “alien” electron and the positron should be at the same place at the moment of the annihilation.)

27.2.3.2 The Ortho-Para Conversion

Another important interaction of positronium is the *ortho-para* conversion. It occurs when the substance contains paramagnetic particles with unpaired electrons. When colliding with such a particle, the orientation of one of the parallel spins of *ortho*-positronium may be reversed, simultaneously with the reversion of the spin of the unpaired electron of the colliding molecule. This interaction takes place via electron exchange between the molecule and *o*-Ps. The *para*-positronium formed by this process annihilates very rapidly, according to its short mean lifetime. Consequently, this effect also leads to the decrease of the lifetime of positronium. *Ortho-para* conversion can be demonstrated by the following reaction scheme (vertical arrows show the directions of the spins):

Converters are usually free radicals and transition metal ions having unpaired electrons. However, there is no close relation between the number of unpaired electrons and the “strength” of the converter.

27.2.3.3 Chemical Reactions

The chemical reactions of positronium constitute the third and, with respect to chemistry, the most important group of interactions. (It should be noted that certain types of *ortho-para* conversion reactions, e.g., the interaction with radicals, are also of chemical character.) The most important types of positronium reactions are demonstrated by the following examples:

(a) Addition reactions:

(b) Exchange reactions:

(c) Oxidation reactions:

(d) Reduction reactions:

The common result of such reactions is that Ps senses a more electron-rich environment. Thus, its annihilation resembles the pick-off annihilation. The outcome is a shortened lifetime and an annihilation into two γ -quanta, as denoted.

27.2.3.4 Localization of Ps

The next interaction of Ps is a reaction in a wider sense only, however, it modifies the lifetime of Ps considerably. It is the localization (or trapping) of Ps atoms in free volumes of the material. Consequently, this reaction is characteristic of solids, where structural free volumes are stable. If the free volume behaves as a potential well for Ps atoms, *o*-Ps can be localized in it. From then on, the annihilation is determined by local physical properties of the free volume. The size and the electron density of the free-volume affect the Ps lifetime through the pick-off process.

On the other hand, without this trapping, Ps “diffuses” from one free-volume site to another in amorphous materials (Brandt et al. 1960) or gets into Bloch-state in crystalline materials (Brandt et al. 1969). In these cases the annihilation parameters are determined by a larger volume of the substance.

27.3 Experimental Methods

27.3.1 Construction of Positron Sources

Most popular positron sources are based on the use of ^{22}Na . This nuclide has a lot of advantageous properties; for example, the prompt gamma provides an easy way to solve the timing problem of lifetime measurements. On the other hand, handling of sodium is rather complicated; therefore, sources are prepared from sodium compounds, mainly from sodium chloride.

Sodium chloride is soluble in water, which suggests its *in situ* application in aqueous solutions. However, *in situ* measurements raise serious problems. A large fraction of positrons annihilates in the walls of the sample holder modifying annihilation spectra. Moreover, Na^+ ions get easily adsorbed on different surfaces contaminating the equipment with radioactivity. Consequently, the positron source ^{22}Na should be separated from the sample and the sample holder, but in a way allowing positrons to penetrate the sample.

Usually, the positron source $^{22}\text{NaCl}$ is sealed between very thin metal (Ni, Ti) or polymer (kapton, Mylar) foils. The thickness (i.e., surface density) of these foils is around 1–2 mg/cm², but several percents of positrons annihilate in this wrapping even in the case of the thinnest foil. During spectrum evaluation, positrons annihilated in the source foil should be taken into account.

In the study of liquids, the application of thin foils to wrap the active material is, at least, dubious. The foil and its sealing should be absolutely free of leaks and, in the case of polymers the foil must not swell considerably in the studied liquid. Therefore, in the case of liquid samples, special sources are prepared from ^{22}Na diffused into thin (1.2–2 mg/cm²) sodium

glass foil by thermal ion exchange. The foil is then placed in a platinum or glass frame to gain a handy source.

Some applications use more complex sources in which positrons of a well-defined energy are created in more than one step. As these methods bear only particular interest from a chemical point of view, only an outline of them is given below in ▶ Sects. 27.3.3.4 and ▶ 27.3.3.5.

27.3.2 Measurable Quantities

The parameter of a positron experiment that most obviously carries information on the chemistry of the substance is the positronium formation intensity. This value informs about the relative fraction of positrons forming Ps. For example, by completing the list of reactions in ▶ Eqs. (27.1) and ▶ (27.2) with equations containing solute molecules, a system is gained in which positronium formation sensitively depends on the solute concentration. Moreover, the rate constants connected with this equation system depend on the changes of the electron structure of the molecules very sensitively. Thus, also the Ps formation intensity reflects these changes.

As discussed in the previous section, all the possible interactions of *o*-Ps decrease its lifetime. The degree of this lifetime decrease is another parameter that can be related to physical and chemical properties of a system. The connection is quite obvious in the case of chemical reactions and *ortho-para* conversion. In the case of pick-off annihilation, the effects of the substance on positronium lifetime are expressed indirectly through the overlap integral in ▶ Eq. (27.7). Any change in ψ_v (e.g., changes of electron orbits) or in the overlap integral (e.g., free-volume changes) is reflected in the lifetime of *o*-Ps.

The overlap integral (or rather the physical overlap behind it) supplies another measurable quantity besides *o*-Ps lifetime and intensity. This quantity is the momentum distribution of annihilation gamma rays. Due to the momentum conservation law, annihilation gammas should carry the momentum of the annihilating positron–electron pair. In the case of pick-off annihilation, the conserving momentum, where $\hat{\mathbf{P}}$ is the momentum operator, is the combined momentum of e^+ and the electron of the surrounding material:

$$\mathbf{p} = C_1 \int_V \psi_+^* \psi_v^* \hat{\mathbf{P}} \psi_+ \psi_v dV \quad (27.13)$$

where C_1 is a constant and ψ_v indicates electrons in a given state around the positron. The symbol ψ_+ refers to positrons or positronium atoms depending on the previous history of the positron.

So, any change in the electron structure of the studied material is reflected by the momentum distribution of annihilation γ photons.

Beside momentum distribution, one can also measure the energy distribution of annihilation γ photons. This parameter is also connected with the momentum distribution of electrons of the substance through the Doppler effect. As the resultant velocity of the annihilating positron–electron pair is usually larger than zero, the frequency of annihilation γ photons is shifted. This so-called Doppler shift of the frequency is reflected in the energy distribution. Consequently, although one measures energy distribution in this case, the measured physical quantity is momentum. Note that measuring energy distributions is a rather convenient method

(its required equipment is only a standard gamma spectrometer). Therefore, this method is applied more widely than direct momentum distribution measurements.

Usually not just positronium atoms but also positrons are sensitive to changes in the composition or the structure of materials. If the wave function of positronium is replaced with that of the positron in [Eqs. \(27.7\)](#) and [\(27.13\)](#), one obtains the theoretical foundation of the above statement. Positrons even participate in spur reactions. Consequently, positrons are sensitive to the changes of free volume, structural changes of materials, and chemical composition. Thus, there are usually several distinct positron states in a material, all of them being sensitive to any change in electron density. The pieces of information provided by the annihilation characteristics of these states complete each other.

27.3.3 Methods of Measurements

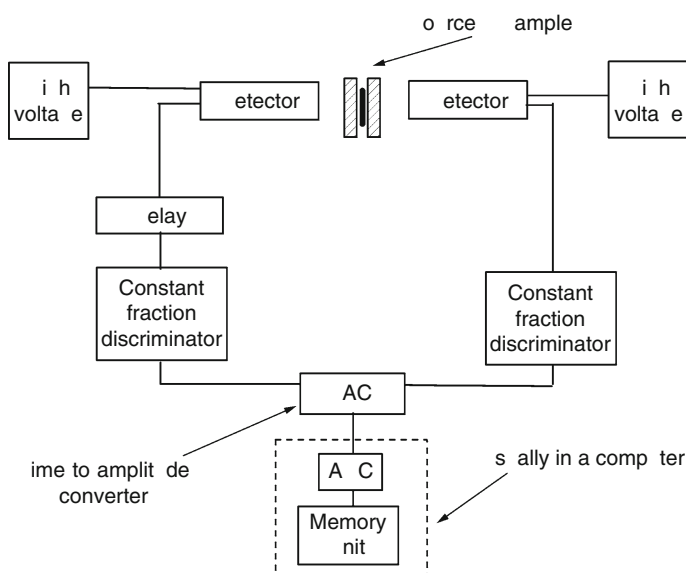

27.3.3.1 Positron Lifetime Spectroscopy

Nowadays positron lifetime spectra are almost exclusively measured by fast-fast coincidence systems ([Fig. 27.2](#)).

[Figure 27.2](#) outlines a general scheme of fast-fast coincidence systems. For positron lifetime measurements, several special requirements should be fulfilled. In positron lifetime spectroscopy, the whole system should be very fast because of the expected very short lifetimes (from ~ 100 ps to ~ 100 ns). Thus, the response of detectors ([Leo 1987a](#)) should be as fast as possible (rise time ~ 2 ns). To ensure the sharp response signal, fast plastic scintillators

Fig. 27.2

The scheme of a fast-fast coincidence system. TAC indicates the “clock”, that is, a time-to-amplitude converter. ADC is an analog–digital converter which is sometimes built into a computer-based multichannel analyzer card

(Ne102, Ne111) or BaF₂ are applied instead of the conventional NaI(Tl), and photomultiplier tubes are chosen accordingly.

The strict timing conditions call for constant fraction discriminators instead of normal leading-edge systems. (A leading-edge discriminator produces its output signal when the incoming signal reaches certain amplitude. The rise times of these input signals vary with their amplitude and the delay of output signals varies accordingly. Even differential discriminators accept a range of incoming amplitudes, so, the output signals are scattered in time. Constant fraction discriminators eliminate this problem by making the delay of output signals to be independent of the rise time input signals.) The time-to-amplitude converter should be linear almost totally and the A/D converter fast (1 MHz) and stable (McKenzie 1983). (The time-to-amplitude converter measures the time elapsed between the detection of a start and a stop signal and produces a proportional electric signal as an output. In the case of positron lifetime spectroscopy, the start signal is provided by the prompt gammas of the decay of ²²Na and the stop signals by the annihilation γ rays.) Fortunately, several firms provide standard electronic units, the properties of which meet these requirements. Even with the best available configuration, the time resolution of a fast-fast coincidence system is about 190 ps for ²²Na. This value is comparable with the shortest lifetimes to be measured, and therefore the resolution curve of the equipment plays a serious role in positron lifetime spectroscopy. The measured spectrum (P) is a convolution of the resolution curve (G) and the actual lifetime spectrum (S):

$$P(t) = G(t) * S(t) = \int_{-\infty}^{+\infty} G(\tau)S(t - \tau)d\tau. \quad (27.14)$$

$G(t)$ is usually approximated by a Gaussian function. $S(t)$ is the “decay curve” of positrons. In most of the materials, several positron states coexist (e.g., free annihilation, p -Ps, o -Ps), so the combined decay curve is formed by a sum of exponentials:

$$S(t) = \sum_{i=1}^n \lambda_i A_i \exp(-\lambda_i t) \quad (27.15)$$

where A_i denotes the relative weight of the i th positron state. Theoretically, n is the number of coexisting states, but in practice, it is not considered larger than four. This restriction is needed because exponential functions are not orthogonal. Consequently, a sum of exponentials cannot be evaluated into more than four components reasonably (Lánczos 1957). A characteristic positron lifetime spectrum is given in [Fig. 27.3](#).

In special cases, instead of the above sum, the lifetime spectrum is approximated by a continuous distribution of exponentials:

$$S(t) = \int_{\lambda} h(\lambda) \exp(-\lambda t) d\lambda \quad (27.16)$$

where $h(\lambda)$ is the density function of states over λ .

The most characteristic example of continuous distribution of states is supplied by polymers. In an amorphous polymer, the size of the structural free volume (the “hole” between chains) varies randomly and so does the electron density in these free volumes. If Ps atoms are trapped by the “holes,” their lifetimes reflect the size distribution of free volumes (Tao 1974; Eldrup et al. 1981).

■ Fig. 27.3

Semilogarithmic presentation of a characteristic positron lifetime spectrum. The left side of the peak characterizes the equipment resolution and the right side is the “decay” curve of positrons

The evaluation of positron lifetime spectra is usually performed by commercial computer codes. POSITRONFIT and RESOLUTION programs (Kirkegaard et al. 1981) work on the basis of Eqs. (27.14) and (27.15) supplying the lifetimes and relative intensities of the assumed states as final results. Positronium lifetime distributions are obtained applying the CONTIN (Gregory and Zhu 1990) algorithm or the MELT (Shukla et al. 1993) code for lifetime spectra.

27.3.3.2 Angular Correlation of Annihilation Radiation

The momentum distribution of annihilation γ photons are measured by one- or two-dimensional angular correlation spectrometers. The angular correlation of annihilation radiation (ACAR) spectrum is determined by the momentum conservation law; that is, the initial momentum of the annihilating positron–electron pair should be reflected in the angular distribution of γ photons. For a zero-momentum pair, in the case of 2γ -annihilation, the angle between the directions of photons is 2π radians (i.e., 180°). For realistic electron energies, this angle is modified by several milliradians. This modification is approximately:

$$\Theta \approx \frac{p_{\perp}}{m_e c} \quad (27.17)$$

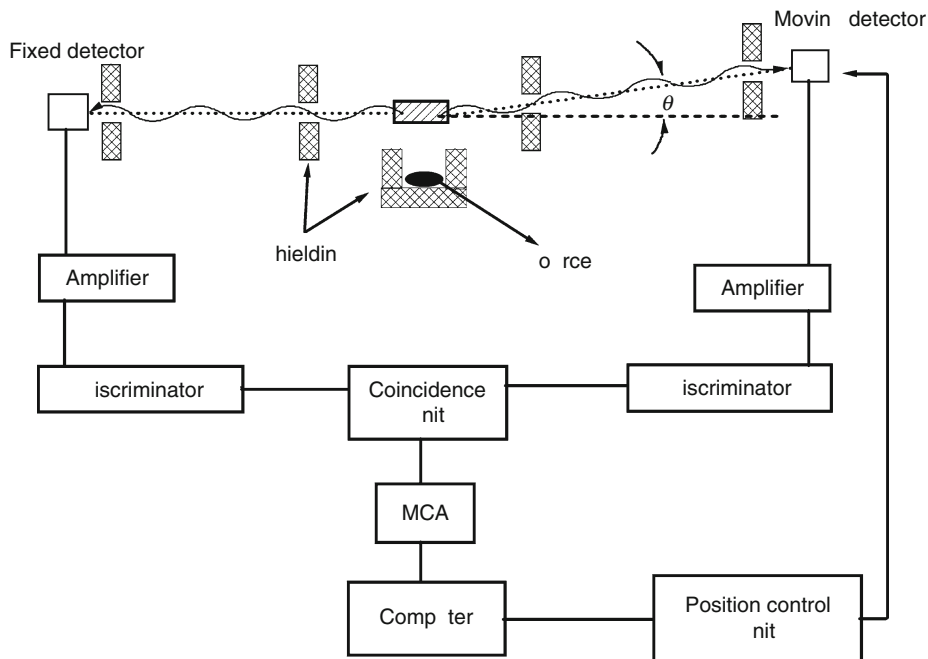

where p_{\perp} indicates the momentum component perpendicular to the axis of the spectrometer, m_e is the electron mass, and c is the speed of light.

The one-dimensional angular correlation “spectrometer” is a relatively simple equipment (Fig. 27.4). It is constructed from two scintillation detectors, several slits, a coincidence unit, and a storage unit.

Although the scheme of an angular correlation spectrometer is simple, due to the very small angles measured, its actual construction is intricate. Very narrow slits, long source/detector distances (several meters), precise positioning of the mobile detector, and an intense source

■ Fig. 27.4

The scheme of a one-dimensional angular correlation equipment. In two-dimensional spectrometers, the mobile detector is moved in two perpendicular directions to map photon distribution. Sometimes the mobile detector is replaced by a position-sensitive gamma camera

(10–20 mCi) should be used to obtain optimum performance. Usually NaI(Tl) or BGO scintillators are applied to optimize detection efficiency (Leo 1987b). However, the complex design and the required preciseness of construction have their advantages; that is, ACAR spectra provide precise and detailed information on the momentum distribution of electrons. In crystals, complete Fermi surfaces are mapped by this method regularly (e.g., Alam et al. 1997).

The measured angular correlation spectrum is a projection of the momentum density function of the sample. In the case of one-dimensional spectra, for example, the density function is integrated over two coordinates:

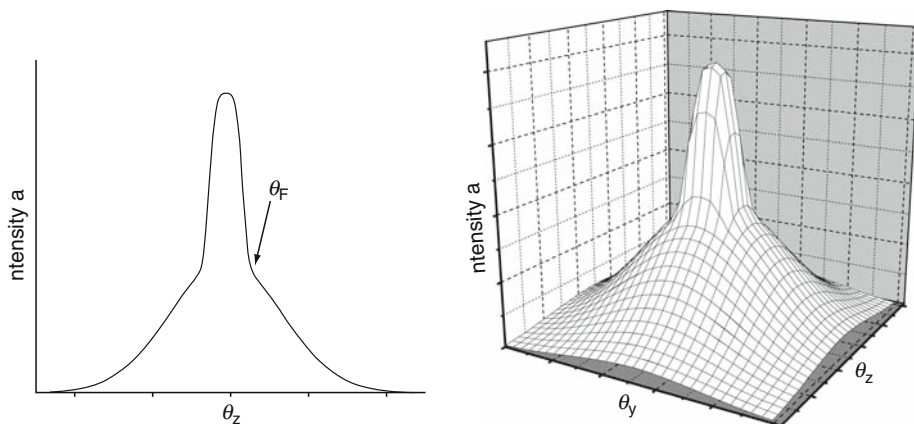

$$N(p_z) = A \int \int \lambda(\mathbf{p}) dp_x dp_y \quad (27.18)$$

where $\lambda(\mathbf{p})$ is the momentum density function and $N(p_z)$ is the transformed angular correlation function. Obviously, two-dimensional mapping decreases the integration coordinates to one. Two characteristic spectra are shown in Fig. 27.5.

There are commercially available computer programs for the evaluation of ACAR spectra (Kirkegaard et al. 1981). Even complicated calculations supplying Fermi surfaces (Dobrzynsky and Holas 1996) or positron distributions (Lock et al. 1973) are well documented in the literature.

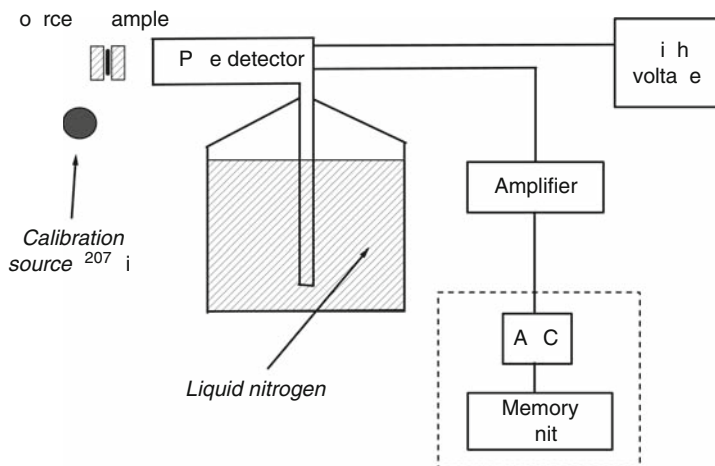

■ Fig. 27.5

One- and two-dimensional ACAR spectra. Note the indication of Fermi energy

■ Fig. 27.6

The scheme of a Doppler-broadening spectrometer. It is a normal gamma spectrometer with some twists. The calibration source is usually applied during measurements to stabilize amplification. Due to large count rates, the amplifier should contain a pile-up rejector unit

27.3.3.3 Doppler-Broadening Spectroscopy

The energy distribution of annihilation photons is studied with standard gamma spectrometers (➡ Fig. 27.6).

The basics of this method are very similar to that of ACAR spectroscopy. For an electron-positron pair of zero kinetic energy, 2γ -annihilation results in two identical photons of

0.511 MeV propagating into opposite directions. If the pair has a momentum component parallel with the direction of photons, the 0.511 MeV energy of photons deviates a little up or down. The phenomenon is called **Doppler-broadening of annihilation radiation**.

The energy deviation is proportional to the momentum component $p_{||}$ of the annihilating electron, which is parallel to the propagation direction of photons:

$$\Delta E \approx mc^2 \frac{v_{||}}{c} = p_{||}c \quad (27.19)$$

ΔE is on the order of a kiloelectronvolt, that is, comparable with the energy resolution of the best gamma spectrometers. Therefore one cannot expect such detailed information on the electron structure as in the case of ACAR spectra.

The evaluation of Doppler-broadening spectra is a crude method. Usually, only the central region of the annihilation peak is compared with the total area of the peak. Their quotient is called *S*-parameter, and it indicates the low-kinetic-energy part of electrons (► Fig. 27.7). Sometimes, another parameter (*w*) is also determined to describe the high-momentum regions of the spectrum (i.e., high- and low-energy tails of the energy spectrum).

Another possibility suggested several years ago was the use of high-energy part of Doppler-broadening spectra (Lynn et al. 1977). Two detectors were placed in 180° geometry, and coincidence measurements were performed together with the Doppler-broadening measurement. The spectral background was decreased by this method considerably. Under these conditions, the high-energy region could be described by the elemental contributions of the studied mixture (Asoka-Kumar et al. 1996).

■ Fig. 27.7

The definition of *S*- and *w*-parameters used to evaluate Doppler-broadening spectra. The symbols I_1 , I_{total} , w_1 , and w_2 denote areas (intensities) under specific sections of the Gaussian peak

27.3.3.4 Variable-Energy Positron Beams

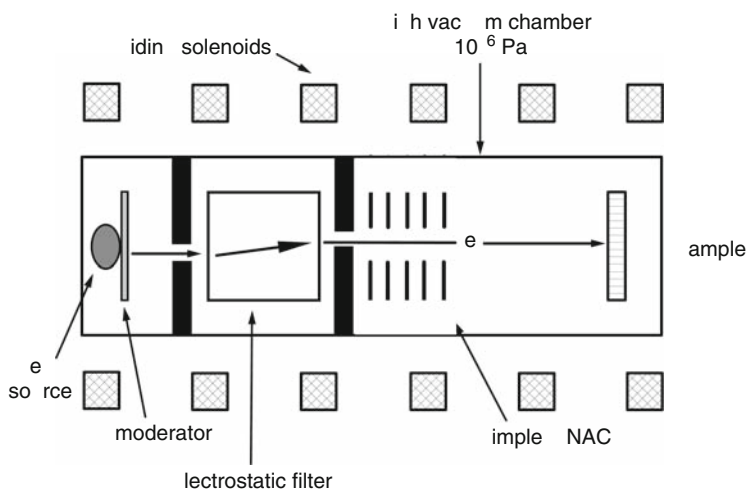

Positrons usually have considerable kinetic energy and, therefore, penetrate materials deeply. The implantation profile is exponential and, using a ^{22}Na source, relatively thick samples are required to stop all the positrons. To be exact, at least a thickness of 100 μm is needed in the case of polymers of $\rho \approx 1 \text{ g/cm}^3$ (Süvegh 1987), but the application of 30 μm of chromium ($\rho = 5.6 \text{ g/cm}^3$) can achieve the same goal (Süvegh et al. 1998). Because of this high penetration depth, positron annihilation spectroscopies provide information on the bulk of materials. To make positrons useful in surface studies and depth-dependent measurements, variable-energy positron beams have been developed.

Any equipment producing monoenergetic positron beams contains a simple linear accelerator (LINAC) in which the polarity is the opposite compared with those accelerating electrons. This is not surprising because, in this respect, positrons are just positively charged electrons. If, for a start, one has a bunch of low-energy positrons, one can do the same things with them as with electrons. They can be accelerated to a certain energy, and the beam can be focused or bent by electrostatic and magnetic fields. The most serious problem is to have low-energy positrons with a narrow-energy distribution and, at the same time, with a high efficiency (Schultz and Lynn 1988).

To obtain low-energy monoenergetic beams, positrons of a continuous energy distribution are injected into a moderator. Most of the injected positrons annihilate in the moderator, but some of them are reemitted into the vacuum. The moderator is usually made of tungsten (W), but sometimes, such exotic materials as solid Ne are used (Schultz and Lynn 1988). Most of the positrons leaving the moderator have low-kinetic energies spread over a narrow range, now useful to make a beam. Moreover, a simple electrostatic filter with an additional shielding is able to produce a very narrow-energy distribution. After the energy filter, everything works as in a LINAC. The beam is accelerated by an electrostatic field and focused by magnets. The outline of a positron beam is given in [Fig. 27.8](#).

■ Fig. 27.8

The outline of a variable-energy positron beam

The energy of positrons is usually varied between 0 and 30 keV, sometimes in a 0–60 keV range. The positrons of such beams penetrate materials only up to several nanometers. Consequently, positron beams are ideal for studying surfaces and near-surface states. However, they are rarely used to solve chemical problems. Their usual application is the investigation of semiconductor surfaces (Schultz and Lynn 1988). Defect structures, oxide layers, interfaces, and absorption processes are frequently studied by variable-energy positron beams. Some of the rare chemical applications of these beams are represented by measurements demonstrating the decomposition of a molecular crystal (Marek et al. 2000), studying Langmuir–Blodgett films (Marek et al. 1999; Koshimizu et al. 2000), and investigating alumina formation on an aluminum substrate (Mills et al. 1983).

The limited application of positron beams is explained by the fact that Doppler-broadening spectroscopy is the only detection method that works with beams without any difficulty. Although angular correlation measurements are possible with positron beams, it requires a very high efficiency beamline. Only very few beams fulfill the requirements of ACAR measurements, but their results are very impressive. The combination of low-energy positron beams and 2D-ACAR measurements is the only possibility to gain direct information on the momentum distribution of electrons at the surface of metals and semiconductors (Chen et al. 1987).

The case is even worse with lifetime spectroscopy. The moderation process erases the information on the “birth” of positrons; thus, performing lifetime spectroscopy is almost impossible. Although this problem was resolved by the construction of pulsed beams (Mills 1980), the time resolution of these systems has only reached that of a normal lifetime spectrometer recently (Hamada et al. 2000; Bauer-Kugelmann et al. 2001).

27.3.3.5 AMOC

The 2γ -annihilation of positrons produces two correlated photons. On the other hand, both lifetime spectroscopy and Doppler-broadening measurements need only one of them. This suggests an evident possibility, that is, the combination of the two measurements. To achieve this goal, a three-photon coincidence system is required. In the system, one of the detectors measures the energy of an annihilation photon, and the other two determine the lifetime of the corresponding positron.

The first age-momentum correlation (AMOC) measurements were performed more than 20 years ago (McKenzie and McKee 1976; Kishimoto et al. 1982a, b). Those measurements applied ^{22}Na sources and measured, in fact, the energy dependence of lifetime spectra. The electronics of those days resulted in a much worse resolution of these age-momentum correlation spectrometers than that of individual lifetime and Doppler-broadening spectrometers. In spite of the bad resolution, these measurements provided valuable information about, for example, the structure of certain solutions (Kishimoto et al. 1982b).

The idea of age-momentum correlation measurements have been raised again recently (Stoll et al. 1992). The system is more complicated now but modern electronics and computer technique improved its resolution significantly. Nowadays, usual AMOC equipment applies high-energy positron beam (above 1 MeV) instead of ^{22}Na . The beam usually passes through a thin plastic scintillator before it reaches the sample. The signal of this plastic scintillator serves as the starting point for the lifetime measurement. The stop signal is measured with a fast scintillation detector, while the energy spectrum is usually provided by an HPGe detector. The evaluation method has also changed. In modern AMOC measurements, the momentum

■ Fig. 27.9

A simulated AMOC spectrum

distribution is calculated as a function of time, just oppositely as before. Sometimes, the entire two-dimensional function (● Fig. 27.9) is handled as a whole to gain more detailed information (Seeger 2000).

27.4 Recent Trends

Today, the field of positron annihilation spectroscopies is so vast that one can only try to give some hints to help the interested reader. The recent trends are briefly scanned below on the basis of the conference proceedings of Ito et al. (1999) and Triftshäuser et al. (2001). The examples are chosen arbitrarily from the two proceedings and other sources, and they do not cover the whole field.

27.4.1 Crystal Defects and Surfaces

The study of defects in metals and semiconductors is still the largest subsection of the applications of positron annihilation spectroscopies demonstrating the use of these methods in metal and semiconductor physics. Both bulk measurements with ^{22}Na sources and surface studies with low-energy beams are frequent.

Pure metals and dilute alloys have been studied in the past 30 years, thoroughly. Positron states have been described theoretically in these materials by the help of the so-called trapping model (West 1973) and even positron distributions have been determined in numerous cases by *ab initio* calculations (e.g., Gupta and Siegel 1980). Moreover, a vast number of experimental data proved the calculations experimentally during the years of extensive studies.

Nowadays, the interest turns more and more toward three-component alloys and inter-metallic compounds. Studies of vacancy formation in an AlPdMn single crystal (Baier et al. 2001), aging of AlCuMg alloys (Reich et al. 2001), and lattice relaxation in polycrystalline Ni₃Al represent this trend.

Very similar tendencies can be observed in the case of surface studies. Now, the basics are well-known, which provides the possibility to investigate complicated systems. Defects near the surface are studied in ion implanted MgO (van Huis et al. 2001), in BF₂ implanted Si (Akahane et al. 2001), and in bioactive ceramic coatings (Härting et al. 2001). As regards beams, both their efficiency and their electronic background have been improved greatly in recent years. Due to this development, “new” methods become available for everyday practice. Although most of these methods were worked out and some kinds of equipment built more than 20 years ago, they are new in the sense that now they are not exotic possibilities but useful spectroscopic methods.

27.4.2 Polymers

Among chemistry-related applications, the study of polymers is undoubtedly the most frequent. Free volume, glass transition, swelling, radiation damage, and aging are just a few examples of phenomena studied by positrons in polymers. However, radiation effects on Ps formation at low temperature have attracted notable attention in the last few years (e.g., Hirade et al. 2000; Suzuki et al. 2000).

This interest in polymers is due to a simple model connecting *o*-Ps lifetime with the size of free-volume holes in the material. The so-called free-volume model (Brandt et al. 1960; Tao 1972; Eldrup et al. 1981) works very well for polymers making *o*-Ps a unique tool in studying free volume. The model provides, at the end, a simple equation to calculate free-volume size from *o*-Ps lifetime:

$$\tau = \frac{1}{2} \left[1 - \frac{R}{R_0} + \frac{1}{2\pi} \sin \left(\frac{2\pi R}{R_0} \right) \right]^{-1} \quad (27.20)$$

where τ is the *o*-Ps lifetime and R is the radius of the hole that trapped Ps before the annihilation. $R - R_0$ is the depth the Ps penetrates the bulk, its value is assumed to be 1.66 Å for solids.

In recent years the field of studies has shifted towards complicated systems and phenomena in the case of polymers as well. Composites (Debowska et al. 2000), doped polymers (Huang et al. 2000), and membranes (Bi et al. 2000) were studied and self-irradiation effects caused by positrons (Balcaen et al. 2000) were observed.

With more and more data/experiments having been collected, positron lifetime spectroscopy might become a unique characterization method for polymers, that can even give qualitative results on the free-volume hole distribution of polymers.

27.4.3 Fluids and Molecular Solids

Fluids, molecular solids, and porous materials received more and more attention in the last few years. This is due to the continuous development of models and calculation methods (Stepanov et al. 2000; Paiziev 2000) supplying the possibility of a more accurate interpretation

of annihilation data in these complicated materials. The determination of such fundamental parameters as positronium mobilities in fluids (Wang et al. 2000) might also benefit structural studies in fluids.

Materials investigated by annihilation methods were chemically varied. Porous Y-zeolite (Kajcsos et al. 2000), organo-metallic compounds (Ito and Suzuki 2000), and cement-based materials (Consolati et al. 2000) were all studied in the last few years.

Abstract: In exotic atoms, one of the atomic electrons is replaced by a negatively charged particle, whereas muonium consists of a positive muon and an electron. After a general review of the theoretical and experimental aspects, the present knowledge of this field is summarized. These include muonium and the application of the muon spin resonance method in solid-state physics and chemistry, muonic hydrogen atoms, muonic molecules and muon-catalyzed fusion, pionic hydrogen atoms and their use in chemistry, testing quantum electrodynamics on heavy muonic atoms, measuring particle and nuclear properties using hadronic atoms, and testing basic symmetry principles with antiprotonic helium atoms and antihydrogen.

28.1 Introduction

When a particle with a negative charge and long-enough lifetime slows down and stops in matter, it “replaces” an atomic electron and gets bound on an atomic orbit. The *exotic atoms* formed this way are named after the constituent particle: the most common ones are presented in [Table 28.1](#). According to the particle, one speaks about *muonic*, *pionic*, *kaonic*, *antiprotonic*, or sometimes *mesonic* or *hadronic* atoms.

The atoms formed by a positive particle and an electron (such as positronium, $\text{Ps} = e^-e^+$ or muonium, $\text{Mu} = \mu^+e^-$) also belong to the family of exotic atoms, and owing to the wide applications of positron annihilation and muon spin research in solid-state physics and chemistry, their study is much more intensive than that of the exotic atoms with negative particles. Also, the physical processes are quite different for exotic atoms with negative and positive particles. As positron annihilation and spectroscopy are treated separately in [Chap. 27](#), this chapter is restricted to exotic atoms with negative particles and with the positive muon.

The research of exotic atoms is or has been pursued at all major, intermediate energy accelerators where low-energy charged particles are or were produced.

The “www” pages of the laboratories (in parentheses) give a lot of useful information on the experiments conducted therein, including those on exotic atoms:

Table 28.1

Properties of *exotic* particles as compared to those of electrons. The particle mass m is rest mass. The strongly interacting particles, the integer spin *mesons* and the half-integer spin *baryons*, are together called *hadrons*. The data are taken from Amsler et al. (2008)

Particle	Spin (\hbar)	Lifetime (s)	m/m_e	mc^2/MeV	Class
e^-	1/2	∞	1	0.511	Lepton
μ^-	1/2	2.197×10^{-6}	207	105.7	Lepton
π^-	0	2.603×10^{-8}	273	139.6	Meson
K^-	0	1.237×10^{-8}	966	493.6	Meson
\bar{p}	1/2	∞	1,836	938.3	Baryon

This field has an extensive literature. The older papers published prior to 1983 are all collected by Horváth and Lambrecht (1984). Later developments are well presented in the proceedings of the conferences and schools on the various fields of exotic atoms (Simons et al. 1989; Benedek and Schneuwly 1992; Froelich 1993; Petitjean et al. 1999) and also in reviews on specific topics (Ponomarev 1975; Brewer and Crowe 1978; Horváth 1981; Hughes 1988; Roduner 1988; Charlton et al. 1994; zu Putlitz 1996; Batty et al. 1997; Eades and Hartmann 1999; Eides et al. 2001; Yamazaki et al. 2002).

The present review first discusses the studies with positive muons and then the research of exotic atoms with negative particles.

28.2 Experimental Methods

All the particles in [Table 28.1](#) are produced in collisions of high-energy protons with nuclei. The protons must have a kinetic energy much higher than the mass of the particle. The *meson factories* (Paul Scherrer Institute, TRIUMF) use proton energies of 500–1,000 MeV to produce charged pions ($m_{\pi^\pm} = 139.9\text{ MeV}$). The pions are then directly used for studies, or they are allowed to decay to muons via reaction:

$$\pi^+ \rightarrow \mu^+ + \nu_\mu. \quad (28.1)$$

Proton–nucleus collisions at high energies (5–20 GeV) create particle–antiparticle pairs, which then can be separated by charge in a magnetic field. (In particle physics, the usual units are $\text{GeV} = 10^9 \text{ eV}$ for energy E , GeV/c for momentum p , and GeV/c^2 for mass m . When expressed in natural units with $\hbar = 1$ and $c = 1$, one gets for the total energy $E^2 = p^2 + m^2$.) Antiproton is the only stable heavy negative particle, and so it has a special treatment. At CERN’s Antiproton Decelerator (AD) antiprotons are produced with a momentum of 3.5 GeV/c when the 26 GeV proton beam of the Proton Synchrotron hits an iridium target.

In order to form exotic atoms the particles have to be stopped in the target material. In principle, a sufficiently thick target can do the trick alone. However, a thick target will also

swallow some of the information to be gained (e.g., X-rays or Auger electrons); thus, it is better to decelerate the particle beam first while keeping it as monochromatic as possible. There are several methods proposed and used to do that, the most successful ones being the radiofrequency quadrupole decelerator (Lombardi et al. 2001) and the cyclotron trap or anticyclotron (Simons 1988).

Once exotic atoms are formed, one can use various methods to gain experimental information:

- Measure transition energies and level populations via detecting X-rays from atomic transitions with semiconductor, *charge-coupled device* (CCD) detectors or bent crystal spectrometers (spherically bent single crystals (e.g., Si and SiO₂) can be used to analyze the energy of X-rays by making use of the fact that X-rays of wave length λ (i.e., of energy $E = hc/\lambda$) are reflected from lattice planes with a spacing of d into a direction given by the reflection angle θ in accordance with the Bragg reflection condition $n\lambda = 2d\sin\theta$, where the integer n is called the order of reflection) or via laser spectroscopy.
- Measure the lifetime of the exotic atom by detecting the incoming particle and the decay products with scintillators, Cherenkov detectors, gas chambers, etc.
- Detect and analyze the products of the reactions after nuclear capture.

28.3 Studies with Polarized Muons

28.3.1 Muonium

Muonium is the atomic bound state of a positive muon and an electron, and thus it can be considered as a light “hydrogen isotope,” with a mass 1/9 of that of hydrogen. It has a wide interest for both physics and chemistry. In particle physics, it is treated as a “laboratory animal” to test the basic symmetries of matter (zu Putlitz 1996), and in solid-state physics, as a probe to measure local magnetic fields (Brewer and Crowe 1978), and in chemistry as a well-traceable light hydrogen atom (Roduner 1988). The laws governing the formation of muonium in gases and condensed systems are similar to those of positronium, the e^+e^- bound state. In gases, muonium is formed mostly in ionization processes, whereas in condensed systems, the spur mechanism, i.e., muonium formation in the ionization track of the muon, can also be significant (Brewer and Crowe 1978).

From the point of view of field theory, muonium is the bound state of two point-like leptons, so it is an ideal system to study quantum mechanical effects. Several such experiments are described by Jungmann (2000): search for muonium–antimuonium conversion, which should be a violation of lepton number conservation; precise measurement of spectroscopic transitions, which can be very well calculated and so provide a sensitive test of theories; and direct tests of symmetry principles of field theory such as CPT invariance, which predicts the equivalent properties of particles and antiparticles.

28.3.2 Muon Polarization, Surface Muons

The use of positive muons in solid-state physics and chemistry is based on the fact that due to the parity violation of the weak interaction (see ➤ Chap. 10 in Vol. 1 on “Standard Model of

Elementary Particles”), in decay (➔ 28.1) of positive pions, the outgoing muons are polarized against the direction of their momentum and in the muon decay reaction,

$$\mu^+ \rightarrow e^+ + \bar{\nu}_\mu + \nu_e \quad (28.2)$$

the positron is preferentially emitted in the direction of the muon spin (i.e., of the polarization of the muon). Thus, when muons are stopped in matter, their polarization at the time of decay can be measured by detecting the momentum direction of the positrons.

Muons are produced at proton accelerators. Protons of 0.5–1 GeV energy are scattered on a target. Depending on where they are produced, one calls them *surface*, *subsurface*, and *cloud* muons. Surface muons originate from pions stopped close to the surface of the target; they have kinetic energies around 4.1 MeV (momenta about 28 MeV/c). Subsurface muons originate from pions stopped in the bulk of the target, thus losing some energy on their way to the surface (momentum range 5–28 MeV/c). Cloud muons originate from pions decaying outside the target (momentum 10–280 MeV/c). For cloud muons, the pion beam line is frequently equipped with a superconducting solenoid to make sure that all pions travel long enough to decay (the pion’s mean life is 26 ns). At present, mostly surface muons are used for studies in materials science. Negative muons cannot be produced on the surface because negative pions – as soon as they stop – get absorbed by nuclei well before they could decay.

28.3.3 The μ SR Method

μ SR stands for muon spin rotation, relaxation, and resonance. As mentioned before, positive muons are used to measure local magnetic fields. When polarized muons are stopped in a sample material with some magnetic field, the muons will precess around the field lines and the positrons will be preferentially emitted along the muon spin (➔ Fig. 28.1).

Thus, if one measures the time between the muon stops and then decays (this can be done by using a positron detector set at a given angle to the beam direction), one shall have an exponential decay curve of the muon’s 2.2 ns lifetime with a superimposed sinusoidal whose frequency will be the *Larmor precession* frequency of the muon spin:

$$\nu = \frac{2\mu_\mu B}{\hbar} = 1.355 \frac{\text{MHz}}{T} B \quad (28.3)$$

where B is the magnetic flux density and μ_μ is the magnetic moment of the muon.

The time distribution of the recorded positron counts will be of the form:

$$\frac{dN(t)}{dt} \propto \frac{1}{\tau_\mu} e^{-\frac{t}{\tau_\mu}} \left[1 + \bar{a}P(t) \int f(\omega) \cos(\omega t + \varphi) d\omega \right] \quad (28.4)$$

where $\tau_\mu = 2.2 \mu\text{s}$ is the lifetime of the free muon, $f(\omega)$ is the distribution of the $\omega = 2\pi\nu$ angular Larmor frequencies, φ is the angle of the axis of the positron detector (usually a series of scintillation counters) to the original muon polarization and \bar{a} is the observed average amplitude of the asymmetry. If all positrons were detected with the same efficiency \bar{a} would be 1/3; in practice $\bar{a} > 1/3$ due to the lower detection efficiency of the lower energy positrons. A typical μ SR spectrum (Kojima 1995) is presented in ➔ Fig. 28.2.

■ Fig. 28.1

Scheme of the μ SR method. The incoming polarized muon passes two-beam detectors (M_1 , M_2), and after stopping in the target, it precesses in the local magnetic field of its environment. The positron is emitted preferentially toward the S_μ spin direction of the decaying muon at an angle $\theta = \phi + \omega t$ and produces an oscillating signal in the positron counters (E_1 , E_2) with a frequency $\nu \propto B = |\mathbf{B}|$, where \mathbf{B} is the magnetic flux density vector

The degree of polarization of the decaying muon, $P(t)$, may assume an exponential time dependence,

$$P(t) = e^{-\frac{t}{T_1}} \quad (28.5)$$

where T_1 is the longitudinal or spin-lattice relaxation time.

In the case of muonium formation, the integral in ► Eq. (28.4) can be approximated by an exponential decay of the muonium frequency ω_0 :

$$\int f(\omega) \cos(\omega t + \phi) d\omega \approx e^{-\frac{t}{T_2}} \cos(\omega_0 t + \phi) \quad (28.6)$$

where T_2 is the transverse or spin-spin relaxation time.

28.3.4 Applications in Solid-State Physics and Chemistry

Applications of the μ SR method can be followed by the regular μ SR conferences (μ SR conferences from 1990 onward), and one can consult the home page of International Society for μ SR Spectroscopy (<http://musr.triumf.ca/~isms/>) for recent developments in the field.

■ Fig. 28.2

Typical μ SR spectrum (number of detected positrons against muon lifetime). The exponential muon decay is superposed (*upper spectrum*) by a signal oscillating with the muon precession frequency $\nu \propto B$. The lower spectrum shows the slowly relaxing asymmetry curve with the exponential removed

The formation of various muonic species in a system can be investigated by observing the characteristic precession frequencies and determining their initial amplitudes and decay rates. Three types of muonic species can be identified by their precession signals:

- Free muons in a diamagnetic environment give rise to Larmor precession according to Eq. (4.3).
- In weak magnetic fields ($B \leq 1$ mT), half of the free Mu atoms precess at $14 B$ MHz/mT the other frequency being too high to resolve experimentally.
- In strong magnetic fields ($B \approx 0.1$ T), several muonic radicals were observed because of their characteristic *split muonium* frequencies.

The measured amplitudes are usually scaled to give fractional diamagnetic, muonium, and muonic radical polarizations, directly related to the formation probabilities of the species.

Muonium, similarly to positronium, can be considered a light hydrogen isotope with almost the same binding energy and Bohr radius as hydrogen (see [Table 28.2](#)) and may be

■ Table 28.2

Properties of exotic hydrogen atoms (Horváth and Lambrecht 1984)

Exotic atom	Ground-state binding energy (eV)	Reduced mass (m_e units)	Bohr-radius (fm)
$H = pe^-$	13.6	1.0	5.3×10^4
$Ps = e^+e^-$	6.8	0.5	10.6×10^4
$Mu = \mu^+e^-$	13.5	0.995	5.3×10^4
$p\mu^-$	2,531	186.0	285
$p\pi^-$	3,236	237.9	222
pK^-	8,618	633.4	84
$p\bar{p}$	12,498	918.6	58
$p\Sigma^-$	14,014	1,030.0	51

expected to undergo similar chemical reactions with some isotope effects. For a review on muonium chemistry, see, e.g., Roduner (1988).

In solid-state physics, positive muons are used to measure the local magnetic induction at the site of the muon. Constant fields are measured via the (28.3) precession frequency, whereas fluctuating fields via relaxation. This makes μ SR a method analogous to nuclear magnetic resonance (NMR) or electron paramagnetic resonance (EPR) with the advantages that no radiofrequency field or macroscopic populations of the resonant species are needed. Muons are also easy to use in a cryogenic environment as both the fast muon and the decay positron easily traverse vacuum separation windows.

As a rule, in solids, muons occupy sites of positive ions, e.g., proton sites as demonstrated by comparing NMR and μ SR spectra of gypsum (Brewer and Crowe 1978). In metals, there are no ion sites where the muon could be electrically equivalent, so the positive muon must be either interstitial or trapped at vacancies, dislocations, or other defect centers. The motion of the muon is governed by thermally activated hopping between sites, showing slower spin relaxation at higher temperatures, which is analogous to the motional narrowing effect in NMR. Muon diffusion in solids is one of the major topics of μ SR studies.

Measuring the Larmor precession one can determine the local magnetic flux density at the muon site, which in solids can be described as

$$B_\mu = B_{\text{ext}} + B_{\text{dm}} + B_L + B_{\text{dip}} + B_{\text{hf}}. \quad (28.7)$$

In order to produce a slow, monochromatic muon beam, muons can be decelerated down to ~ 10 eV using a foil moderator and then reaccelerated to the desired energy. For experimental studies of solid surfaces and thin films, however, very slow muons can be produced by stopping surface muons in a thin layer of van der Waals-bound solid like solid nitrogen deposited on a properly microstructured metal substrate (Morenzoni 1999) in ultra-high vacuum. The slow muons cannot ionize or produce muonium, and, as a result of soft muon–atom elastic collisions, they are scattered out of the surface at epithermal energies (i.e., between ~ 0.5 eV and ~ 100 eV). The total efficiency of conversion from an energetic surface muon to an epithermal one is about 10^{-5} – 10^{-4} . Such an apparatus is described by Morenzoni et al. (2001).

28.3.5 The Anomalous Magnetic Moment of the Muon

Polarized muons provide a sensitive tool to test field theory as well. The magnetic moment of a charged particle is $gS\mu_{\text{part}}$ where g and S are the g factor and the spin of the particle, respectively, and μ_{part} is the particle magneton. The theory of the electromagnetism, quantum electrodynamics (QED), predicts that a charged particle is “swimming” in a medium of virtual particle–antiparticle pairs that blink in and out of existence. Without those, the g factor of the magnetic moment of the electron and muon would be the same, i.e., $g = 2$, but the QED contributions from the virtual particles make it $g = 2(1 + a_\mu)$ for the muon, where a_μ measures the relative anomaly of the magnetic moment. Muons are two orders of magnitude heavier than electrons, so the possibilities of having particle–antiparticle pairs in a muon field are much more favorable than for the electron. Thus, measuring the anomalous magnetic moment of the muon (see [Table 10.3 of Chap. 10](#), Vol. 1, on “Standard Model of Elementary Particles”) can hint at new phenomena in physics if the results are different from those predicted by the theory.

In a not too strong magnetic field, the muon has two different movements around the field lines: a cyclotron motion with an angular frequency $\omega_c = eB/(m_\mu c)$, and a Larmor precession with a frequency $\omega_s = g_\mu eB/(2m_\mu c)$. Longitudinally polarized muons moving in a toroidal magnetic field of a storage ring will precess at the difference $\omega_a = \omega_c - \omega_s$, which is proportional to the anomalous part of the magnetic moment containing a_μ . This kind of experiment is called $(g - 2)$ measurement (Hughes [1988](#); Brown et al. [2001](#)). The precision is increased if one uses relativistic muons with $\gamma^2 = 1/(1 - v^2/c^2) \gg 1$ in a magnetic storage ring,

$$\omega_a = -\frac{e}{m_\mu} \left[a_\mu \mathbf{B} - \left(a_\mu - \frac{1}{\gamma^2 - 1} \right) \boldsymbol{\beta} \times \mathbf{D} \right]. \quad (28.8)$$

where ω_a , \mathbf{B} , $\boldsymbol{\beta}$, and \mathbf{D} are the three-dimensional vectors of the Larmor frequency, magnetic flux density, relative velocity, and electric displacement, respectively. The increased precision is due to three things: (1) the relativistic longevity of the muon, (2) at the magic momentum 3.094 GeV/c, where $\gamma = 29.3$, the second term of [Eq. \(28.8\)](#) vanishes, and so (3) the focusing electric fields will not affect the muon motion. Such experiments were performed earlier at CERN and recently at BNL (Hughes [1988](#); Brown et al. [2001](#)). The results do not quite agree with the predictions of the Standard Model (see [Table 10.3 of Chap. 10](#), Vol. 1), although the difference is not statistically significant.

28.4 Theory of Exotic Atoms

28.4.1 Formation of Exotic Atoms

The negative particle entering an absorber (gas or condensed matter) loses its kinetic energy via ionization in collisions with atoms of the medium and in the *last* collision gets stuck in a binding orbit. The higher the overlap between the wave functions of the ejected electron and the particle, the more probable the formation of the exotic atoms. Thus, the initial bound state will be geometrically close to that of the ejected electron. This and the equality of the binding energies of the captured antiproton and the released electron (Massey conditions, Mott

and Massey 1965) mean that the freshly formed exotic atom will be in a highly excited state, with a principal quantum number of the order of

$$n = \sqrt{\frac{m}{m_e}} \quad (28.9)$$

where m and m_e are the masses of the particle and the electron, respectively.

For details of the theory of atomic capture see, e.g., Fermi and Teller (1947), Ponomarev (1975), Cohen (1989), Hartmann (1999), and Yamazaki et al. (2002).

The energy levels of an isolated exotic atom in a state of principal quantum number n and angular momentum j for a point-like nucleus are given by Measday (2001)

$$E_{n,j} = \frac{mc^2}{1 + m/m_N} \frac{(Z\alpha)^2}{2n^2} \left[1 + \left(\frac{Z\alpha}{n} \right)^2 \left(\frac{n}{j + 1/2} - \frac{3}{4} \right) \right], \quad (28.10)$$

where Z and m_N are the atomic number and the nuclear mass ($\sim A$ where A is the mass number), and α is the fine structure constant.

28.4.2 Coulomb Capture Ratios

Numerous models have been proposed for describing the formation of exotic atoms via Coulomb capture. The muons in atoms do reach the atomic ground state (as opposed to hadronic atoms), and the lack of strong interaction effects makes them good probes to study Coulomb capture. One of the most important experimental methods is measuring *Coulomb capture ratios*. In a mixture of two elemental gases (e.g., $N_2 + O_2$) or in binary compounds, one can determine the amount of muons captured in the different elements by summing up the amplitudes of the muonic Lyman series, the ($n p \rightarrow 1s$) transitions.

The main difficulty when comparing experiment with theory is created by the chemical effects: chemical bonds are shown to distort the atomic cascade. As the possibility of studying binary atomic mixtures of elements is restricted to mixtures of noble gases, two attempts were made to overcome the dispersion of individual measurements. All experimental Coulomb capture ratios, measured in binary systems to date, were collected and compared with theoretical predictions by Horváth and Entezami (1983). Average Coulomb capture ratios were deduced by von Egidy et al. (1984) using all measurements made in binary oxides. None of the models agrees well with experiment, although those which assume the weaker-bound electrons to be more efficient in capture (Schneuwly et al. 1978) seem to be better. This conclusion has been recently confirmed by classical trajectory Monte Carlo and Fermi molecular dynamics calculations (Cohen 1997, 2000, 2002).

28.4.3 Deexcitation of Isolated Exotic Atoms

The deexcitation will start via Auger processes, while the level spacing is small (as its rate weakly depends on the ΔE transition energy) and there are electrons to be ejected, and then via radiative transitions as the probability of the latter is roughly proportional to $(\Delta E)^3$. The initial population of the atomic states will be related (though not exactly proportional) to the available density of states, so for any given principal quantum number n the higher orbital momenta will be more populated.

As the Auger transitions do not change the shape of the angular momentum distribution, the particle quickly reaches the ($l = n - 1$) orbits (Hartmann 1989) and from those – owing to the $\Delta l = \pm 1$ rule – can make circular, $(n, l = n - 1) \rightarrow (n - 1, l = n - 2)$ transitions only (► Fig. 28.3). Typical exotic-atoms X-ray spectra are presented in ► Fig. 28.4: note that the spectra are dominated by circular transitions from highly excited states.

There are several cascade codes developed for reproducing the cascade decays of exotic atoms (see, e.g., Borie and Leon 1980; Markushin 1999; Jensen and Markushin 2002). The cascade process is studied by detecting X-rays and Auger electrons from transitions in all exotic atoms and via laser spectroscopy in metastable antiprotonic helium (see ► Sect. 28.6.3.2). It was experimentally observed that medium-heavy muonic atoms such as $\mu^- \text{Ar}$ lose all atomic electrons via Auger effect by the time the muon reaches the ground state (Bacher et al. 1988).

The decay of the exotic atom can be a simple decay of the exotic particle in the case of light muonic atoms; however, due to the strong nuclear interaction in hadronic atoms, the negative hadron can be absorbed by the nucleus leading to nuclear reaction (► Fig. 28.5).

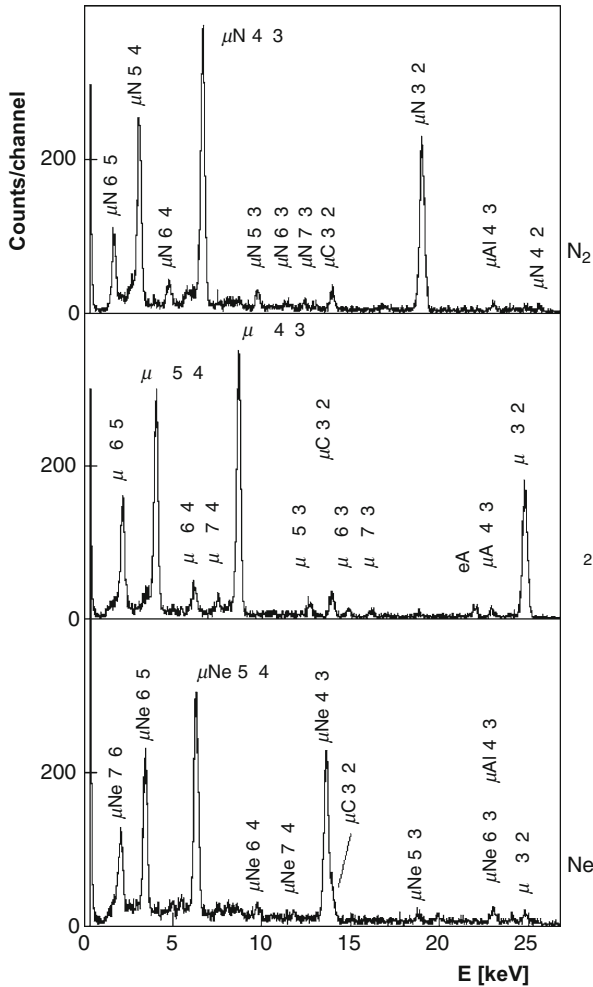

■ Fig. 28.3

Deexcitation of a muonic atom. From highly excited states Auger transitions prevail, in the lower region X-ray emission. The X-ray region can be divided into three subregions: (I) strong electron screening effect, (II) low electron screening, negligible nuclear interaction, (III) interaction with the nucleus

■ Fig. 28.4

X-ray spectra from muonic atoms as measured in nitrogen, oxygen, and neon using a Si(Li) detector (Kirch et al. 1999). The spectra are dominated by circular transitions from highly excited states. The spectra show lines of muonic aluminum and carbon from muons stopping in the container wall of the gas target and in scintillators around it

The above picture was theoretically assumed by Fermi and Teller in 1947 and experimentally proven in the 1990s by a measurement of the initial state populations of antiprotonic helium (Yamazaki et al. 2002; Hayano et al. 2007).

28.4.4 Exotic Atoms in Condensed Media

In media of not too low densities the deexcitation process is dominated by collisions. Collisions can cause external Auger effect when the exotic atom loses excitation energy by ejecting an

■ Fig. 28.5

Deexcitation of the pionic oxygen atom. For the highly excited states, see ► Fig. 28.3. In the lower X-ray region, strong interaction with the nucleus shifts and broadens the states with low orbital momentum, and there is strong nuclear absorption from the lowest ns states. Y is the yield of a transition, Γ is the level width

electron from another atom of the medium, or Stark mixing when the energetically degenerate states of various orbital momenta mix in the external electric field of another atom, thereby enabling the exotic atom to make an otherwise forbidden high- Δn radiative transition from a circular state.

28.4.5 Exotic Hydrogen Atoms

The exotic hydrogen atoms, systems consisting of a proton and a negative particle, or a positive particle and an electron, are special in many aspects (Eides et al. 2001). Their basic properties are summarized in ► Table 28.2.

Exotic hydrogen atoms are created when a negatively charged particle is captured in an atomic orbit on a proton. Because normally hydrogen is always bound in molecules, the negative particle must replace a binding electron to form exotic hydrogen. The latter is small, electrically neutral, and has no electrons to feel Pauli repulsion, so it can penetrate the electron shells of other atoms. This can lead to *transfer* when the negative particle moves from the exotic hydrogen atom to another, heavier atom.

The theory of transfer has been developed by Gershtein (1963). He has shown that at small distances between $p\mu^-$ and a heavier nucleus Z , the ground state of muonic hydrogen transforms into a state of a *united atom* $pZ\mu^-$ and the level crossing of $p\mu^-$ and $Z\mu^-$ makes adiabatic transfer possible in slow collisions. Gershtein's theory had an immediate success as it had predicted that muon transfer to helium cannot go this way, and a great suppression of muon transfer to helium was observed, indeed.

Exotic hydrogen atoms have no atomic electrons so their deexcitation is different: at the highest levels Coulomb deexcitation in atomic collisions dominates, then external Auger transitions, i.e., ejection of electrons of other atoms in collisions, before X-ray transitions take over (Jensen and Markushin 2002). Coulomb deexcitation can lead to acceleration thereby producing a hot exotic hydrogen atom as observed experimentally for pionic hydrogen. The atomic cascade in muonic hydrogen is measured to study QED effects and nuclear properties: the Lamb shift, i.e., the energy difference between the 2s and 2p states, e.g., depends on r_p^2 , where r_p is the charge radius (see “Charge Radii” in [Chap. 2](#), Vol. 1) of the proton (Eides et al. 2001).

28.4.6 Muon Capture in Nuclei

In its atomic ground state, the exotic particle has a Bohr radius that is close to or even smaller than the nuclear radius, so it will interact with the nucleus. Muon capture in nuclei (Measday 2001) is governed by the weak interaction between a lepton and a proton (*semi-leptonic process*):

$$\mu^- + p \rightarrow n + \nu_\mu \quad (28.11)$$

This reaction most frequently leads to nucleons or nuclear fragments to be ejected from the nucleus, while most of the released kinetic energy is taken away by the neutrino.

28.4.7 Strong Interaction Effects in Hadronic Atoms

Due to a strong interaction with the nucleus, hadrons cannot reach ground state in exotic atoms as they are captured by the nucleus via strong absorption from higher n s levels where their orbit is closest to the nucleus. As a result of the strong interaction, the hadronic energy levels are broadened and shifted more and more as they get closer to the nucleus.

Using exotic atoms, one can separately study the distributions of protons and neutrons in the nucleus by comparing muon and pion absorption. Muons are absorbed by the protons only, whereas the strong interaction is independent of the electric charge, so hadrons (pions, kaons, and antiprotons) interact equally with protons and neutrons.

Nuclear capture of hadrons can lead to fission of heavy nuclei because the reaction of a negative hadron with a nucleon releases as much energy as the mass of the particle, which is an order of magnitude more than that binding the nucleus.

Muons bound in an atomic orbit in transuranium elements can also cause nuclear fission, but that mechanism is quite involved (Measday 2001). There are two types of fission events, prompt and delayed. The prompt events are induced by energy from the atomic cascade of the muon, whereas the delayed events are from muon capture via the weak interaction.

28.4.8 Doubly Exotic Atoms

In decays of heavy unstable particles many charged mesons can be emitted simultaneously. If two of them are oppositely charged and have close trajectories, they can form a bound state. Nemenov (2000) quotes the experimental study of $\pi^+\mu^-$, $\pi^+\pi^-$, and π^+K^- atoms from which scattering lengths were deduced for the two-particle systems involved.

28.5 Muonic Atoms

28.5.1 Muonic Hydrogen

As hydrogen gives up its only atomic electron in order to establish its chemical bond, the exotic particle first *replaces* its molecular binding electron before it can settle on the proton. As proposed by Ponomarev (1975), this means a temporary formation of a *large mesic molecule*, and as a heavy atom provides a lot more available states for the particle than hydrogen, the probability that the particle will eventually form exotic hydrogen with a proton (and not be captured by the heavier atom) is roughly proportional to Z^{-2} , where Z is the atomic number of the atom binding the hydrogen atom.

The exotic hydrogen isotopes (see [Table 28.2](#)) provide numerous interesting processes, like the transfer of the exotic particle from a hydrogen isotope to a heavier nucleus; the formation of exotic molecules, which makes the muon catalysis of nuclear fusion possible; or measuring the electron density on the hydrogen in molecules using the pionic hydrogen atom.

As mentioned before, the neutral exotic hydrogen atom (having neither Coulomb nor Pauli repulsion) can penetrate other atoms and lose its exotic particle to a heavier nucleus. As the rate of this reaction is proportional to the number of collisions, it can be detected for hadronic atoms but it is really dramatic for muonic hydrogen as its lifetime is many orders of magnitude longer: in the muon-catalyzed fusion measurements, for example, the concentration of heavy impurities has to be below 10^{-8} to avoid the distortion of the results by transfer. This feature was used to study muon capture in rare gas isotopes as it is sufficient to have less than 1% krypton in hydrogen to have all muons ended up in muonic krypton states.

28.5.2 Muon-Catalyzed Fusion

The muon, entering, e.g., a deuterium + tritium ($D_2 + T_2$) mixture, forms a $d\mu^-$ or $t\mu^-$ atom. From the former, in a collision, the muon gets transferred to tritium:

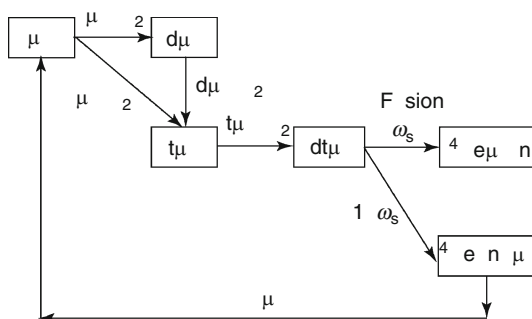

as it is more favorable energetically, and this way practically all of the muons end up in $t\mu^-$ even in mixtures with a small amount of tritium only. The most important process is the formation of a muonic molecule in a collision:

in such a highly excited state that the vibration states of the molecule in the square brackets, consisting of the positive $dt\mu^-$ molecule ion and the deuteron as nuclei with the two electrons,

■ Fig. 28.6

Scheme of muon-catalyzed fusion in a deuterium–tritium mixture. As a result of the fusion 17.6 MeV is released per ${}^4\text{He}$ atom (ω_s is the sticking probability)

can absorb the tiny binding energy of the $(dt\mu)^{-*}$ molecule ion. The process mentioned above has a resonance as a function of ambient temperature through the kinetic energy of the $d\mu^{-}$ atom. With the deexcitation of the $dt\mu^{-}$ molecule ion, the muon *compresses* the two nuclei inducing thereby a nuclear fusion process (with 17.6 MeV energy release) and then it becomes available to restart the whole cycle as a real catalyst (► Fig. 28.6).

After the prediction (Vesman 1967) and first observation (Bystritskii et al. 1979) of the resonant formation of muonic molecules in Dubna, muon-catalyzed fusion (μCF) became the leading field in exotic atoms research (Petitjean 1989), with its own journal and biennial conferences (see MuCF07 (2007) for the latest one). Although there were attempts to propose possible uses of muon-catalyzed fusion in energy production, at present nobody expects reactors to produce fusion energy using muon catalysis soon. Nevertheless, μCF research gave an enormous impetus to the research of basic processes of exotic atoms and of atomic physics in general.

28.5.3 Heavy Muonic Atoms

As shown in ► Fig. 28.3, in the upper region of the X-ray transitions, the particle may interact with and thus probe the electronic shell, while in the lower one it already probes the atomic nucleus as its wave function partially penetrates it. The region between is also interesting as those transitions are weakly influenced both by the remaining or recombined electrons and by the field of the nucleus; there one can get information on the properties of the captured particle or test the effects of quantum electrodynamics. As an example, ► Fig. 28.7 presents (Horváth and Lambrecht 1984) the various energy terms in the $5g\ 9/2 \rightarrow 4f\ 7/2$ transition in muonic lead; here the contribution of the Lamb shift, which is the dominant such term in ordinary atoms, is quite small as compared to the other vacuum polarization effects.

As the X-ray transition energies are proportional to the reduced mass of the system and may be split due to spin–orbit and spin–spin interactions, studies in the intermediate region of the atomic cascade are used to measure the mass, charge, and the magnetic moment of certain negative particles. Such an example will be shown later for the case of the antiproton.

■ Fig. 28.7

Test of quantum electrodynamics in muonic lead: contributions of higher-order processes to the energy levels as predicted by field theory. The height of the shaded block on the right shows the uncertainty of the theoretical value

28.6 Hadronic Atoms

28.6.1 Study of Nuclear Structure

Hadronic atoms provide an excellent tool for studying the nuclear structure and nuclear matter. This is very important as one cannot apply perturbative approximations to the theory of strong interactions (quantum chromodynamics) at low kinetic energies. The particles used, i.e., π^- , K^- , Σ^- , and \bar{p} have much longer natural lifetime (the antiproton is even stable) than the typical slowing down times in condensed media and the atomic timescales. Therefore, after stopping a negatively charged hadron in matter, well-defined atomic states are established. The overlap of the atomic orbitals with the nucleus covers a large range of nuclear densities, and thus the density-dependence of the hadronic interaction can be directly studied (Batty et al. 1997).

Strong interaction between the captured hadron and the nucleus shifts and broadens the energy levels; this makes it possible to study strong interaction effects using X-ray spectroscopy. The shift and broadening of the atomic s and p levels in the antiproton–proton system are

■ Fig. 28.8

Neutron skin and neutron halo in heavy nuclei. The neutron radius of heavy nuclei is observed to be larger than the proton radius. A uniformly *overhanging* neutron distribution is called neutron skin (*on the left*), whereas a gradually diminishing one is a neutron halo

directly related to the complex scattering length and the volume of the antiproton–nucleon system; thus spectroscopy of hadronic atoms is equivalent to scattering experiments at the energy threshold (Gotta 1999).

Physical information can be obtained, e.g., by measuring the shift and broadening of the energy levels of the hadron in the atom due to nuclear interactions as compared to a purely electromagnetic case. The shifts and widths can be measured for one or two levels only in each kind of hadronic atom as the strong nuclear absorption – which causes the level broadening – terminates the atomic cascade at a certain principal quantum number n_{\min} . This lowest n sensitively depends on the mass of the particle and on the atomic number of the nucleus: $n_{\min} = 1$ for pionic oxygen and 8 for antiprotonic nickel.

In heavy nuclei with more neutrons than protons the neutron distribution is observed to have a larger radius than that of the protons. This is in agreement with the observation that nuclear mass radii tend to be larger than charge radii (see Sect. 2.2.3.1 in Chap. 2, Vol. 1, on the “Basic Properties of the Atomic Nucleus”). Hadronic atoms are very sensitive to this: in heavy antiprotonic atoms the antiproton interacts with the outermost part of the nucleus only and it annihilates predominantly in interaction with neutrons rather than protons (Trzcinska et al. 2001) as seen from the summary charge of the decay products. There is a general disagreement, however, about the shape of the neutron distribution, whether it is a *neutron skin* or a *neutron halo* (see Fig. 28.8). Radiochemical experiments definitely prefer a neutron halo (Trzcinska et al. 2001), pionic X-rays seem to disagree with it (Batty et al. 1997), whereas according to Wycech (2001) from the antiproton data one can reject or confirm neither.

As pionic hydrogen atoms found important applications in chemistry most of this chapter is devoted to that particular topic and the rest of hadronic atoms is only briefly summarized.

28.6.2 Pionic Hydrogen Atoms

Pion chemistry, i.e., the use of pionic hydrogen in physical chemistry, was invented in Dubna more than 40 years ago (Petrukhin et al. 1967). As shown by the experimental studies of Petrukhin et al., the probability, W_Z , that a pion stopped in a compound containing Z–H groups will be absorbed by a proton, i.e., hydrogen bound by Z atoms, depends on the

properties of the Z–H group, and particularly on the electron density at the hydrogen atoms. Pion capture measurements were performed on various chemical systems at various laboratories: JINR, Dubna; LNPI, Gatchina; TRIUMF, Vancouver; and KEK, Tsukuba. For earlier references see the reviews published by Ponomarev (1975), Gershtein et al. (1970), Horváth (1981, 1984a), Measday (1990), and Armstrong (1991); the more recent work at KEK is summarized by Shinohara et al. (1999).

28.6.2.1 Principle of Study

Experimentally, the two-photon decay of neutral pions from the charge-exchange reaction following π^- capture in proton:

is studied by detecting the two photons using total-absorption Cherenkov counters or large NaI detectors. As π^0 production from stopped π^- has 60% probability for protons, 15% for ^3He , and negligible ($<10^{-4}$) for every other nuclide, the upper one of the above reactions is a unique signal to identify the decay (and therefore the formation) of pionic hydrogen atoms.

28.6.2.2 Large Mesic Molecules

The pionic hydrogen measurements were interpreted using the *model of large mesic molecules* (LMM) proposed by Ponomarev (1975). As the hydrogen atom gives up its only electron to establish the Z–H molecular bond, the negative pion, in order to form a $p\pi^-$ atom, must replace first a binding electron. Its initial orbit is geometrically similar to that of the replaced electron, so it is very large on the pionic scale, hence the name of the model.

According to the original LMM model, the probability W that the pion is captured on the proton can be described as the product of three probabilities (Fig. 28.9),

$$W = PQR, \quad (28.14)$$

those of the formation of a $Zp\pi^-$ molecule (P), of the transition of the pion from the molecular orbit to a $p\pi^-$ atomic state (Q), and the probability R that from the pionic hydrogen atom the pion will be absorbed by a proton (not necessarily the original one) and not transferred to a heavier nucleus.

28.6.2.3 Pion Capture in Hydrogen-Bonded Liquids

An excellent example for the application of pions in chemistry is the study of the relation between hydrogen bonds and electron density using the pion capture method. This research work began in Dubna (Kachalkin et al. 1979; Horváth et al. 1991b) by a measurement of pion capture in water as a function of temperature from ice to supercritical fluid. As shown in Fig. 28.10, the W probability of pion capture is constant in ice, i.e., below the melting point, T_m , then steeply increases in the liquid phase, and levels off again above the critical temperature, T_c .

■ Fig. 28.9

The fate of a slow negative pion in matter containing hydrogen bound to atom Z (Horváth 1984b). The pion can be captured in a molecular orbit with probability P or in atomic orbits on Z or H (the latter, D , is negligible), from the molecular orbit it goes to H or Z, and from the $p\pi^-$ it can be transferred to a heavier atom or captured in the proton. The probability that a slow pion gets absorbed in a proton is $W = PQR$, because E is also negligible in comparison with QR

The overall temperature dependence of the probability $W(T)$ showed a remarkably good agreement with the so-called *bond-breaking* or *mixture* model of water structure (Haggis et al. 1952; Luck 1979) with one adjustable parameter only,

$$Q = \frac{W(T > T_c)}{W(T < T_m)} \quad (28.15)$$

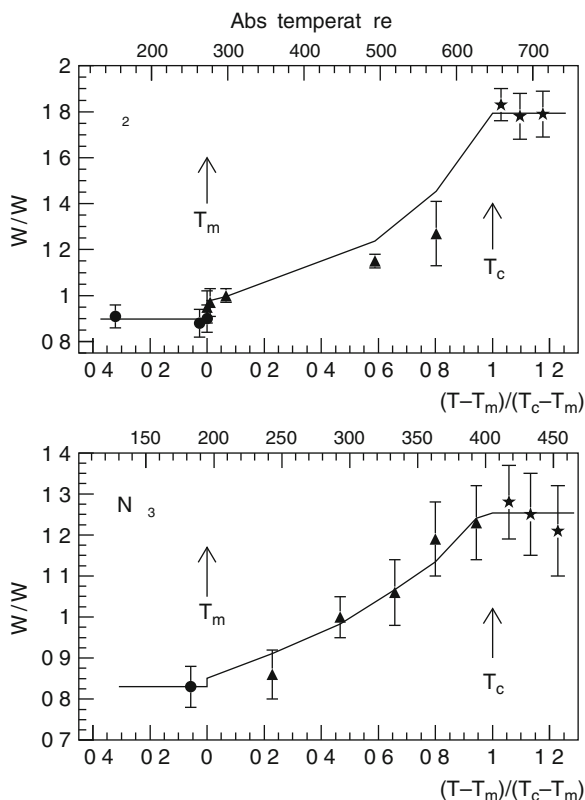

which had a surprisingly high value, $Q(\text{H}_2\text{O}) = 2.0 \pm 0.1$, indicating a large difference between the probabilities of pion capture in ice and in supercritical water.

It is generally assumed that in ice, all protons are bound in hydrogen bonds, while above the critical temperature, there are very few hydrogen bonds; thus the value of $Q(\text{H}_2\text{O})$ should reflect a difference between the proton states inside and outside of hydrogen bonds. However, reliable theoretical estimations predict only about 10% difference between the electron densities of the two proton states (Schuster 1976). This led to the conclusion that unless the measured $Q(\text{H}_2\text{O}) = 2$ value is a “magic” number connected with the existence of two equivalent oxygen atoms near the proton of the hydrogen bond (as suggested by Ponomarev), the pion capture method somehow *magnifies* the electron density effect.

To clarify the above question the Dubna group studied pion capture in solid, liquid, and supercritical ammonia (Horváth et al. 1982) as well, with results very similar to water (► Fig. 28.10). The hydrogen bond effect was smaller, $Q(\text{NH}_3) = 1.51 \pm 0.12$, but still somewhat “magically” connected to the molecular composition, as there are three protons to two nitrogen atoms in the hydrogen bond network. The pion capture measurement made it possible to estimate the model parameter, the fraction of broken $\text{N}-\text{H}\cdots\text{N}$ bonds, as a function of temperature (Horváth et al. 1982). At TRIUMF, yet another family of hydrogen-bonded liquids with strong $\text{O}-\text{H}\cdots\text{O}$ bonds was studied: alcohols (Luck 1979). For this measurement, one had to separate pion capture in hydrogen atoms bound to oxygen and to carbon using partially deuterated compounds. The result was $Q(\text{CD}_3\text{OH}) = 1.79 \pm 0.11$, close to that of water (Horváth et al. 1991a).

■ Fig. 28.10

Temperature dependence of pion capture probability in water (Kachalkin et al. 1979) and ammonia (Horváth et al. 1982). The probability is normalized to that measured at room temperature. The temperature is expressed as $\Theta = (T - T_m)/(T_c - T_m)$, where T , T_m , and T_c are the temperatures of measurement, melting point, and critical point, respectively. Ordinary temperature scales are also shown above the boxes. The curves represent fits using the bond-breaking (mixture) model of hydrogen-bonded liquids (Haggis et al. 1952; Luck 1979)

28.6.2.4 Development of the LMM Model

It is evident that the LMM picture is an extremely simple and rough approximation: the processes involved are not independent and, as shown by ▶ Fig. 28.9, ▶ Eq. (28.14) reflects just one of the possible paths for the pion to follow in a simple system of hydrogen bound by a heavier Z atom. For the correct interpretation of pion-chemistry results, the primordial populations of pionic bound states and pion transfer to heavier atoms were studied in gas mixtures with and without hydrogen (Horváth 1984b; Muroyama et al. 1999). On the basis of these data several efforts were made to improve on the LMM model, the latest and most successful ones were that by Imanishi et al. (1988) and Shinohara et al. (1996).

28.6.3 Antiprotonic Atoms

28.6.3.1 Antiprotonic Hydrogen

Several protonium ($p\bar{p}$) experiments were performed at the antiproton facilities of CERN (Gotta 1999) in order to estimate the strong interaction parameters from atomic X-ray spectra. Experiment PS207 (a Jülich–Geneva–Ioannina–Islamabad–Neuchatel–Paris–Villigen collaboration) has done that with very high precision using a two-arm bent-crystal spectrometer at CERN (Gotta 1999; Augsburg et al. 1999).

28.6.3.2 Long-Lived Antiprotonic Helium

As mentioned in the introduction, the usual lifetime of the strongly interacting hadrons in condensed media is in the order of 10^{-12} s. However, about 3–4% of the antiprotons stopped in gaseous or liquid helium form metastable states that survive for a time of the order of several microseconds. The metastable state is a three-body system of an antiproton, a helium nucleus, and an electron. When the antiproton is located in an ($n \approx 38$, $\ell \geq 35$) orbit of a neutral $\bar{p}ze^-$ atom, those states from which Auger transitions are suppressed due to high angular momentum exchange ($\Delta\ell > 3$) will become metastable as the electron removes the ℓ -degeneracy of the levels with the same principal quantum number n and also screens the $\bar{p}\alpha$ system from collisions.

The energy levels and populations of antiprotonic helium atoms have been thoroughly investigated both theoretically (Korobov 1996, 1999, Korobov and Bakalov 1997) and experimentally, the results are summarized in reviews (Horváth 1997; Eades and Hartmann 1999; Yamazaki et al. 2002; Hayano et al. 2007). The experiments were performed using laser resonance spectroscopy in the following way: stop a bunch of antiprotons in helium, wait until the promptly annihilating states disappear, and then stimulate the transition from a long-lived state to a short-lived one with a tunable laser. At the resonant frequency corresponding to the transition energy of the antiproton, the laser shot will be followed by immediate annihilation creating a peak in the decay-time spectrum.

The antiproton is the only stable and heavy antiparticle and thus it is used to test the symmetry of matter and antimatter. This symmetry is the consequence of one of the most fundamental principles of field theory, *CPT invariance* (see [Sect. 10.3 in Chap. 10](#) of Vol. 1 for more detail), which states that the physical properties of a free system do not change when one simultaneously switches three kinds of signs: (1) the signs of the charges (C), i.e., replacing particles by antiparticles; (2) the signs (directions) of the spatial coordinates, which means changing the parity P of the system; and finally (3) changing the sign (direction) of time T . Thus, according to the CPT invariance, an antiparticle is equivalent to its ordinary particle counterpart going *backward* in space and time. In spite of its not really plausible nature, CPT invariance is so far supported by all available experimental evidence in the microworld; nevertheless, serious experimental and theoretical efforts are undertaken to study its possible limits (Kostecký 1997; Kostecký and Lehnert 2001).

Antiprotonic helium was used to test the CPT invariance by measuring the difference of charge and mass between proton and antiproton (Hayano et al. 2007). The charge/mass ratio of the proton and the antiproton was determined at LEAR (Gabrielse et al. 1999) by

measuring cyclotron frequencies in a Penning trap. The charge and mass information was separated via studying antiprotonic transition energies in the $\bar{p}\text{He}^+$ as those are proportional to $m(\bar{p})q(\bar{p})^2$.

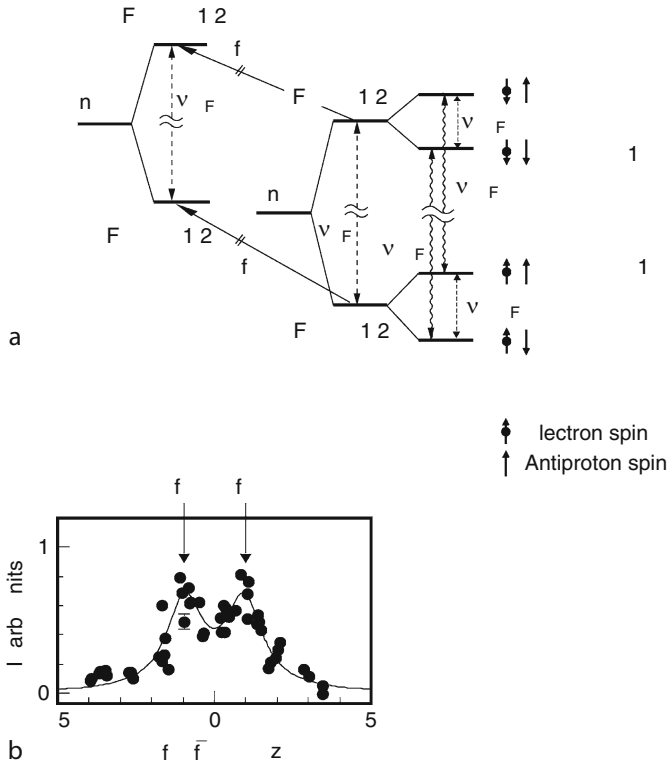

The transitions in antiprotonic helium isotopes studied to obtain a limit on the antiprotonic mass and charge are illustrated in Fig. 28.11. In order to get precise results, one had to minimize the laser bandwidth and the collisional effects by using low temperatures and target densities. The latest result was $|m_p - m_{\bar{p}}|/m_p < 2 \times 10^{-9}$ for the relative mass difference and $|q_p - q_{\bar{p}}|/q_p < 2 \times 10^{-9}$ for the charge difference (Hori et al. 2006). Further plans of the ASACUSA group include using two-photon spectroscopy to eliminate the first-order Doppler broadening of the measured transitions. To date this is the only experimental method to limit the charge and mass difference of protons and antiprotons (Amsler et al. 2008).

Fig. 28.11
Transitions in the $\bar{p}^3\text{He}^+$ and $\bar{p}^4\text{He}^+$ atoms studied using laser spectroscopy in order to measure the mass and charge of the antiproton (Hori et al. 2006). The horizontal lines denote long-lived states, the wavy lines short-lived ones. The arrows indicate experimentally studied transitions with wavelengths in nanometers

■ Fig. 28.12

Hyperfine transitions in the $\bar{p}^3\text{He}^+$ and $\bar{p}^4\text{He}^+$ atoms studied using combined laser and microwave spectroscopy in order to measure the magnetic moment of the antiproton (Widmann et al. 2002) in the atomic bound state: (a) level splitting; (b) the measured spectrum: number of forced antiproton annihilations against the microwave frequency

Another CPT test was done by the same group by measuring the magnetic moment of the antiproton in antiprotonic helium atoms (Widmann et al. 2002). One half of an antiprotonic state, split as a result of the interaction between the electron spin and the total angular momentum of the antiproton in the three-body system, was first partially depopulated using a suitably tuned laser, then repopulated with a microwave of varied frequency, and finally depopulated again with the same laser frequency as first. The relative yield of the second laser resonance was maximum when the microwave frequency corresponded to the hyperfine splitting of the state from which the antiproton magnetic moment could be determined (► Fig. 28.12).

28.7 Antihydrogen

Antihydrogen, the bound system of an antiproton and a positron, stands in the middle of attention of the low-energy antiproton community. The reason is that antihydrogen

spectroscopy offers to test several fundamental principles of physics, the most important ones being CPT symmetry and the weak equivalence principle of gravity (Charlton et al. 1994). According to the CPT invariance an antiproton should accelerate the same way in the gravitational field of an anti-Earth as protons do in that of Earth. The weak equivalence principle states that protons and antiprotons accelerate equally in the gravitational field of Earth. Unfortunately, it is very hard to test experimentally as the gravitational force on an antiproton at the surface of Earth is about the same as the electric force of a point charge (of $1e$) from a distance of 10 cm. Such a test is proposed using the effect of the different gravitational force of the Sun at perihelion (i.e., in the winter in the Northern Hemisphere) and at aphelion (i.e., in the summer) on the atomic transitions of antihydrogen (Charlton et al. 1994).

Antihydrogen atoms were created the first time at CERN in 1995 by crossing a relativistic antiproton beam with a xenon jet target in the LEAR ring (Baur et al. 1996). The antiproton created electron–positron pairs in the field of the Xe nucleus and if the direction of the positron momentum coincided with that of the antiproton, having the same speed near c , they could form an antihydrogen atom that then left the ring through a straight beam line. The antihydrogen atoms were stripped in thin Si detectors; the positron annihilations were detected in NaI X-ray detectors, whereas the freed antiprotons led to a magnetic spectrometer for identification. Eleven antihydrogen atoms were detected with a possible background of 2 ± 1 events.

In order to conduct spectroscopic studies, one needs slow, confined, ground-state antihydrogen atoms. Several schemes have been proposed to produce trapped antihydrogen atoms for spectroscopy in order to take momentum away and increase the production rate. Most of them involve a third colliding partner: another positron, an electron, a resonant photon, or an external radiofrequency field (Charlton et al. 1994). Spontaneous radiative two-body recombination is generally considered to be slow. The antihydrogen atoms are to be formed in a quadrupole (or combined quadrupole–octupole) magnetic field in order to confine half of them: those with the correct orientation of the positron spin. Such traps can only confine cold antihydrogen atoms of temperatures below 1 K and therefore they have to be cooled after formation, for which optical (laser) cooling seems to be feasible at present (Charlton et al. 1994).

The extremely small line width (1 Hz) corresponding to the long lifetime of the metastable $2S$ state makes the $2S$ – $1S$ transition (► Fig. 28.13) the most promising candidate for high-precision measurements; a Doppler-free excitation is possible in the case of simultaneous absorption of two photons from opposite directions. This transition has been measured in hydrogen with a relative precision of 1.8×10^{-11} (Andreae et al. 1992) yielding the most precise up-to-date value of the Rydberg constant. A new apparatus is being developed in Garching, at the Max Planck Institute for Quantum Optics (Haensch 2008).

CERN has built a dedicated machine to study the CPT invariance using antiprotons, the AD, which includes two antihydrogen experiments. Quite recently, both of them managed to produce cold antihydrogen atoms in large quantities (Amoretti et al. 2002; Gabrielse et al. 2002). They used the same method for antihydrogen production: a *nested Penning trap* was loaded with positrons and then with antiprotons. With the help of a nested Penning trap one can confine particles of opposite electric charge (in the present case positrons and antiprotons) in a finite volume defined by two electromagnetic potential wells. The outer, larger potential well traps antiprotons and the smaller one, inverted and nested inside the outer, traps positrons. The two kinds of particles can exchange kinetic energy by collisions. The positron cloud *cools* itself (i.e., loses kinetic energy) with synchrotron radiation in the magnetic field of

■ Fig. 28.13

Atomic levels in hydrogen and antihydrogen. CPT symmetry requires them to be exactly equivalent

the trap, and the relatively high-energy antiproton introduced into the outer well will “cool down” in collisions with the cold positrons to the temperature of the positron cloud in seconds. The presence of “cold” interacting particles of opposite charge enables the study of low-temperature recombination processes (Hall and Gabrielse 1996). The ATHENA collaboration (Amoretti et al. 2002) proved the creation of antihydrogen by reconstructing the space–time coordinates of the annihilation of positrons and antiprotons for cold and hot mixing of the constituents – in a hot mix the recombination is suppressed. The ATRAP group (Gabrielse et al. 2002) re-ionized the freshly formed antihydrogen atoms, deducing thereby their quantum states as well. Since then, large numbers of antihydrogen atoms were produced and studied by the two collaborations at the AD, ATRAP and ALPHA (the latter replaced ATHENA), but the problem of confinement of the antihydrogen atoms is not solved yet. A new AD experiment, AEGIS intends to measure the gravitational mass of antihydrogen at a 1% precision. Although CPT invariance states the equivalence of the gravitational force of antimatter to an anti-Earth only, the weak equivalence principle relates them to the gravity of antimatter to Earth.

Abstract: Starting with basic properties of the neutron, this chapter reviews the most important neutron scattering methods that provide valuable information for a chemist. The range of such methods is amazingly wide, from standard methods of crystallography to neutron spin echo spectroscopy. Experimental techniques like neutron reflectometry and small angle neutron scattering are able to probe large-scale structures on the surface and in the bulk, thus providing access to the “nano-world.” Apart from traditional areas of solid-state physics, like studying phonons, a particular emphasis is placed on the microscopic and mesoscopic structure and dynamics in the liquid state. Practical aspects, such as main components of the instrumentation, are also touched upon.

29.1 The Neutron as a Probe

29.1.1 Important Properties of the Neutron

Before going into details of the scattering of neutrons in condensed phases, some basic properties of this elementary particle should be recalled, as these characteristics play a central role in the scattering process (for more details, see Dianoux and Lander (2001)).

The neutron is a particle of mass 1.675×10^{-27} kg, magnetic moment of $-1.913 \mu_N$ (μ_N being the nuclear magneton, 5.05×10^{-27} J/T) and possessing no electric charge. These properties (particularly the electric neutrality) make the neutron one of the most suitable probes for atomic scale structure and dynamics: neutrons can penetrate deep into the bulk of condensed phases without destroying chemical bonds. Since neutrons do not interact with the electrons via Coulomb forces, they are scattered by the nuclei.

The *wavelength* of thermal (and “cold”) neutrons from reactor or accelerator sources varies between about 0.1 and 20 Å (1 Å = 0.1 nm = 10^{-10} m), which corresponds to atomic scale distances. As it will be shown later, for the study of the structure of condensed phases it is the interference of the scattered radiation that is most important: interference effects, in turn, easier to detect if the scattering angle is sufficiently large. In order to achieve sufficiently large scattering angles, the wavelength of the radiation has to be comparable with the distance between scattering centers.

The most probable speed of a thermal neutron is about 2,200 m/s, which means that its *kinetic energy* is about 25 meV (1 eV $\approx 1.602189 \times 10^{-19}$ J); neutron energies between 0.1 meV and 1 eV can routinely be achieved. (Note that the most probable speed u_{mp} of thermal neutrons is the “mode” (See [Chap. 9, Vol. 1](#), on “Stochastics and Nuclear Measurements”) of the Maxwell distribution at 20°C). The average (mean) speed \bar{u} is somewhat greater at any temperature due to the asymmetry of the Maxwellian density function: $\bar{u} = 1.128 u_{mp}$. As the energy of hydrogen bond stretching is around 100 meV, it is obvious that for processes of chemical interest, neutrons provide an excellent probe for the microscopic dynamics in condensed matter: the energy change during the scattering event is easily detectable.

Since the neutron possesses a *magnetic moment*, the study of magnetic materials/properties is also possible using neutron scattering. Although it is not at the forefront of interest of chemists, it has to be mentioned that understanding (and tailoring) the behavior of high-tech instruments, such as magneto-optic devices, has greatly benefited from the application of neutron scattering.

29.1.2 Comparison with X-ray Scattering

Although this chapter is about neutron scattering techniques, one cannot avoid the comparison of their capabilities to available X-ray scattering methods.

First, it has to be noted that X-rays are scattered not by the nuclei, but by their interaction with the electronic cloud; as a consequence of this, the amplitude of the scattered radiation is affected by the distribution of the electrons and therefore, the “strength” of the scattering will be angle-dependent.

As far as *structural studies* are concerned, X-ray diffraction, in general, provides a comparatively cheap and fast complementary means of investigation. Note, however, that for light nuclei, in the presence of heavier ones, X-rays are still not sensitive enough. (This particular issue will be elaborated further later.)

The energy of an X-ray photon with a wavelength of 1 Å is about 12 keV, roughly five orders of magnitude higher than that of a neutron of the same wavelength. This implies that if the H-bond stretching mentioned above is to be investigated by X-rays, the sensitivity of the detection must be five orders of magnitude better than that for neutron scattering. For this reason, studying the *dynamics of condensed phases* by X-ray scattering can be carried out only at the very few (at the moment of writing, three) third-generation synchrotron X-ray sources available. Also note that many of the delicate chemical/biological samples simply cannot stand the bombardment by such energetic particles.

Until very recently, magnetism was an area where X-ray scattering could not be used at all. The situation now is changing but it is expected that neutron scattering applications will dominate the study of magnetic materials.

On the other hand, synchrotron X-rays have a distinct advantage, which is the relatively high *flux density of radiation*. Synchrotron X-ray beams can routinely deliver six orders of magnitude more (monochromatic) X-ray photons (per unit area per unit time) than the best neutron sources available at present. With the advent of free electron laser facilities, the flux difference is expected to grow even larger.

29.2 Scattering of Neutrons by Condensed Matter

In this section, the basics of the scattering process will be discussed. After describing single atom (nucleus) scattering, the formalism suitable for treating (large) collections of scattering centers is introduced.

It is worth mentioning in advance a major difficulty that occurs while establishing the connection between the measured signal and the quantities of interest: while the scattering process can only be treated quantum mechanically, the desired – and tractable – quantities (like the static and dynamic structure factor) are classical statistical averages.

29.2.1 Single Atom Scattering

While passing through matter, neutrons can be scattered by the atoms in two ways: either by the nucleus or by electrons of unpaired spin. This latter way can only happen in magnetic materials and hence the process has the distinct name “magnetic scattering.” In this chapter, magnetic

scattering will not be discussed in detail and therefore, it will only be mentioned if it is absolutely unavoidable.

The other process, “nuclear scattering,” occurs for all atoms and therefore it is the most significant microscopic event from the point of view of this section.

29.2.1.1 Elastic and Inelastic Scattering

Both nuclear scattering and magnetic scattering can be either elastic or inelastic. The former refers to an event where there is no energy exchange between the scatterer and the scattered neutron, whereas the latter signifies microscopic events with exchange of energy. Elastic scattering dominates the signal of diffraction studies, which aim at the determination of the atomic level structure of materials (with the exception of some liquid structures). Inelastic scattering is made use of while investigating microscopic dynamics. The distinction between the two types cannot be made sharp: in general, all events are inelastic, although during some of them, the energy exchange is, indeed, very small. Note that for microscopic events with small, but measurable energy exchanges the word quasi-elastic scattering is used: this type of description is useful, for instance, for the characterization of diffusion processes in liquids.

29.2.1.2 Nuclear Scattering

When a neutron beam, which can be represented by a plane wave of wavelength λ , falls on a single nucleus then the scattering of the wave depends on the interaction potential $V(r)$ that acts between the neutron and the nucleus being at distance r from each other. The value of $V(r)$ becomes zero rapidly beyond nuclear dimensions that are of the order of 10^{-14} m. Since neutron wavelengths are usually of the order of 10^{-10} m (or greater), the nucleus can be considered as a point-scatterer that yields a scattered beam of amplitude $-b/r$ at a distance r from the nucleus (for an incoming beam with a magnitude of unity).

29.2.1.3 The Scattering Length

The constant b determines the “strength” of the scattering from an individual nucleus; it has the dimensions of length and therefore, it is called the (nuclear) scattering length (or scattering amplitude). Since nuclei are point-scatterers, the value of b does not change noticeably over atomic length scales and therefore, there is no angular dependence of it: this greatly simplifies the evaluation of neutron data. (On the other hand, complicated angular dependence *does* occur for the X-ray scattering form factor).

What remains to be seen is that how the scattering length varies over different atoms, or more precisely, over different nuclei. As it may be expected, there is a (rather weak) size dependence (the larger the radius, the larger the value of b), but there is another effect that almost completely disguises the size dependence: this is called *resonance scattering*. There are very few examples where thermal neutrons can excite nuclear resonance energy levels; when this happens, *anomalous scattering* takes place (see, e.g., ^{113}Cd , or ^{149}Sm). However, even

a more remote resonance level influences the actual value of b so much that if the nuclides are arranged according to their Z and N values then their b 's vary seemingly at random from one nuclide to its neighbors.

In ▶ [Table 29.1](#), scattering lengths of some important nuclei are given. A full listing of the most up-to-date values was given by Koester et al. (1991) and Sears (1992), and scattering length values are also available on the Internet (Munter 2003). There are two more points to emphasize: (a) different isotopes of the same chemical element may possess very different scattering length values, which feature is exploited heavily in the practice of neutron scattering (see ▶ [Sects. 29.4.1](#) and ▶ [29.4.3](#)); (b) most scattering length values are positive but some (notably, that of the proton) are negative. Negative values mean that the phase of the neutron “wave” does not change during the scattering whereas a positive b implies a 180° phase alteration.

29.2.2 Scattering by Collections of Nuclei

Phenomena that occur in connection with scattering from a large number of scattering centers, and quantities that characterize them are introduced in the following pages.

■ [Table 29.1](#)

Scattering lengths (b) of nuclei. If more than one isotope is indicated for an element then the average value for the element is also shown

Element	Isotope	$b/10^{-14}$ m	Element	Isotope	$b/10^{-14}$ m
H		−0.374	Ti		−0.34
	^1H	−0.374		^{46}Ti	0.48
	^2H	0.667		^{48}Ti	−0.58
He	^4He	0.30		^{49}Ti	0.08
Li		−0.214	Ni		1.03
	^6Li	$0.18 + 0.025 i$		^{58}Ni	1.44

29.2.2.1 Scattering Cross Sections

In an ideal neutron scattering experiment, a beam of (thermal) neutrons of identical energy E would fall on a target (sample), with the latter being a general collection of scattering centers (atoms). A neutron scattering measurement concerns the scattered neutrons and relevant results can be given in terms of various scattering cross sections. The *total scattering cross section* is defined as

$$\sigma_{\text{tot}} = \frac{\aleph_{\text{tot}}}{\Phi} \quad (29.1)$$

where \aleph_{tot} (pronounce: aleph) is the total number of neutrons scattered per second in all directions, and Φ is the incident neutron flux density, i.e., the number of incident neutrons passing through unit area per second. It can be shown that for a single nucleus $\sigma_{\text{tot}} = 4\pi b^2$ (see, e.g., Squires 1996).

The *differential cross section*, to which the static structure factor – the physical quantity describing the static microscopic structure (see [Sect. 29.2.2.3](#)) – can be related, is defined as

$$\frac{d\sigma}{d\Omega} = \frac{\aleph_{d\Omega}(\theta, \varphi)}{\Phi d\Omega} \quad (29.2)$$

where $\aleph_{d\Omega}(\theta, \varphi)$ is the number of neutrons scattered per second into a small solid angle element $d\Omega$, which is in the direction of (θ, φ) , θ and φ being the polar and azimuthal angle coordinates relative to the original direction of the neutron beam (taken as the z -axis for the usual interpretation of spherical coordinates r, θ , and φ). Further, if the energy of the scattered neutrons is analyzed then one arrives at the *partial (double) differential cross section*, which is related to the dynamics (“instantaneous structure”) of the sample system as

$$\frac{d^2\sigma}{d\Omega dE'} = \frac{\aleph_{d\Omega, dE'}(\theta, \varphi)}{\Phi d\Omega dE'} \quad (29.3)$$

where $\aleph_{d\Omega, dE'}(\theta, \varphi)$ is the number of scattered neutrons per second into a solid angle element $d\Omega$ with final energy between E' and $E' + dE'$. The total and differential cross sections are related to each other as

$$\sigma_{\text{tot}} = \int \left(\frac{d\sigma}{d\Omega} \right) d\Omega = \int \left(\frac{d^2\sigma}{d\Omega dE'} \right) d\Omega dE' \quad (29.4)$$

Much of the theory of neutron scattering concern the elaboration of expressions (closed formulas) for the partial differential cross section, starting from (model) interaction potentials between the neutron and the nucleus (see, e.g., Squires 1996; Lovesey 1987). The final result of these calculations for nuclear scattering will be outlined below.

Taking into account the quantum mechanical probability of the transition of a neutron from a state characterized by wavevector \mathbf{k} and energy E to another state characterized by wavevector \mathbf{k}' and energy E' , caused by scattering from a target-system via potential V (taken as the extremely short ranged Fermi-pseudopotential), one arrives at the following expression for the partial differential cross section (see, e.g., Squires 1996):

$$\frac{d^2\sigma}{d\Omega dE'} = \frac{k'}{k} \frac{1}{2\pi\hbar} \sum_{jj'} b_j b_{j'} \int_{-\infty}^{\infty} \left\langle e^{-i\mathbf{Q}\mathbf{R}_{j'}(0)} e^{i\mathbf{Q}\mathbf{R}_j(t)} \right\rangle e^{-i\omega t} dt \quad (29.5)$$

where $Q = k - k'$, is the so-called *scattering vector*, and the $\mathbf{R}_j(t)$ symbols represent the time-dependent Heisenberg operators (see Squires 1996), defined by

$$\mathbf{R}_j(t) = e^{iHt/\hbar} \mathbf{R}_j e^{-iHt/\hbar}. \quad (29.6)$$

In the latter equation $\mathbf{R}_j [\equiv \mathbf{R}_j(0)]$ describes the position of the j th scattering nucleus and H , the Hamiltonian of the neutron + nucleus system, contains the properties of the scattering system. That is, [Eq. \(29.5\)](#) has to be evaluated individually for each scattering system. For example, crystalline materials behave quite differently from liquids, etc.

29.2.2.2 Coherent and Incoherent Scattering

Even in a scattering system of a single chemical element, the scattering length changes (randomly, but taking well-defined values) from atom to atom, because of the presence of isotopes or/and the variation of the individual nuclear spin. The average values of b and b^2 are

$$\bar{b} = \sum_i f_i b_i \quad \bar{b^2} = \sum_i f_i b_i^2 \quad (29.7)$$

where f_i is the frequency of a given value of b (normalized to unity). Considering [Eq. \(29.5\)](#) again, it is apparent that the right-hand side can be split into two parts, one that contains the sum where $j = j'$ and the other that contains the sum where $j \neq j'$. The first case is termed as *incoherent*, while the second is called *coherent cross section*; these terms possess particular emphasis in neutron scattering. The usual expressions for the coherent and incoherent cross sections are

$$\sigma_{\text{coh}} = 4\pi \bar{b}^2 \quad \sigma_{\text{inc}} = 4\pi (\bar{b^2} - \bar{b}^2) \quad (29.8)$$

Coherent scattering can be considered as scattering coming from a system of equal nuclei with the average (see [Eq. \(29.7\)](#)) scattering length; incoherent scattering is the term that has to be added for recovering the total scattering of the actual system. Incoherent scattering may be thought as arising from the random distribution of the deviations of the scattering length from the average of b_i . In fact, the right-hand side of [Eq. \(29.8\)](#) expresses a simple proportionality between σ_{inc} and the variance of b . (See [Eq. \(9.25\) in Chap. 9, Vol. 1](#), on “Stochastics and Nuclear Measurements.”)

According to the above, if all nuclei are of the same isotope with zero nuclear spin then the scattering is entirely coherent. Pure *isotope incoherence* (or rather, it should be called “disordering”) occurs when the scattering system contains several different isotopes of a single element, with all isotopes having zero nuclear spins and the distribution of the different isotopic nuclei is random. *Spin incoherence* occurs if the system consists of a single isotope with a (nonzero) nuclear spin I and – because unpolarized neutrons can have a spin either $+1/2$ or $-1/2$ – this leads to two different b values, b^+ and b^- . If these values are very different, such as in the case of hydrogen (^1H), and the f_i weighting factors have unfavorable values, then the incoherent scattering cross section can be orders of magnitude larger than the coherent counterpart (see, e.g., Bacon 1977). This is a very unfortunate situation when collective properties, such as the structure of hydrogenous materials, are studied.

It should also be noted that coherent scattering depends on the correlations of the positions of different nuclei, whereas incoherent scattering reflects only correlations between positions of the same nuclei at different times. In other words, *interference effects* occur only for coherent

scattering, which then will be characteristic of collective properties (such as the atomic structure, or collective excitations). On the other hand, incoherent scattering describes the motion of individual atoms (such as, e.g., diffusion).

29.2.2.3 Correlation Functions for Nuclear Scattering

This is a very important section where the connection between experimental data (measurable by neutron scattering) and thermal averages (that are fundamental properties of the scattering system) is established. Thermal averages can be expressed in terms of correlation functions. The distinction between coherent and incoherent parts of the scattering is a basic concept in relating neutron scattering results to well-known physical properties. Following Van Hove (1954) and using the notation of [Eq. \(29.5\)](#), it is customary to define the intermediate scattering function, $I(\mathbf{Q}, t)$ as

$$I(\mathbf{Q}, t) = \frac{1}{N} \sum_{jj'} \left\langle e^{-i\mathbf{Q}\mathbf{r}_{j'}(0)} e^{i\mathbf{Q}\mathbf{r}_j(t)} \right\rangle \quad (29.9)$$

where N is the number of scattering centers (nuclei) in the system. Note that $I(\mathbf{Q}, t)$ does not depend on the actual scattering process. The *Van Hove correlation function* (or time-dependent pair correlation function) is then defined in real space as

$$G(\mathbf{r}, t) = \frac{1}{(2\pi)^3} \int I(\mathbf{Q}, t) e^{-i\mathbf{Q}\mathbf{r}} d\mathbf{Q} \quad (29.10)$$

where $d\mathbf{Q}$ is the volume element in \mathbf{Q} -space and \mathbf{r} denotes particle coordinates. The scattering function or dynamic structure factor can be obtained as

$$S(\mathbf{Q}, \omega) = \frac{1}{2\pi\hbar} \int I(\mathbf{Q}, t) e^{-i\omega t} dt \quad (29.11)$$

that is sometimes referred to as the “scattering law.” From the above equation it is obvious that $G(\mathbf{r}, t)$ and $S(\mathbf{Q}, \omega)$ are Fourier transform pairs related to each other as

$$G(\mathbf{r}, t) = \frac{\hbar}{(2\pi)^3} \int S(\mathbf{Q}, \omega) e^{-i(\mathbf{Q}\mathbf{r} - \omega t)} d\mathbf{Q} d\omega \quad (29.12)$$

and

$$S(\mathbf{Q}, \omega) = \frac{1}{2\pi\hbar} \int G(\mathbf{r}, t) e^{-i(\mathbf{Q}\mathbf{r} - \omega t)} d\mathbf{r} dt \quad (29.13)$$

where $d\mathbf{r}$ is the volume element in real space, normally denoted by dV . It has to be noted, again, that the scattering function depends only on the structure and dynamics of the scattering system and not on the neutron–nuclei interaction – in fact, it does not depend on any particular experimental technique. From [Eqs. \(29.5\)](#), [Eq. \(29.8\)](#), [Eq. \(29.9\)](#), and [Eq. \(29.11\)](#), one arrives at the relation between the partial differential cross section (which is the result of a neutron scattering experiment) and the physics of the scattering system:

$$\left(\frac{d^2\sigma}{d\Omega dE'} \right)_{\text{coh}} = \frac{\sigma_{\text{coh}}}{4\pi} \frac{k'}{k} N S_{\text{coh}}(\mathbf{Q}, \omega) \quad (29.14)$$

The relation of the incoherent scattering cross section with the incoherent scattering function is analogous (see, e.g., Squires 1996).

The classical form of $G(\mathbf{r}, t)$ can be expressed as follows. Ignoring that the Heisenberg operators $\mathbf{R}_{j'}(0)$ and $\mathbf{R}_j(t)$, in general, do not commute and supposing that all nuclei are equivalent (so that the sum over j' can be taken as N times the value for $j' = 0$):

$$G^{\text{cl}}(\mathbf{r}, t) = \sum_j \langle \delta[\mathbf{r} - \mathbf{R}_j(t) + \mathbf{R}_0(0)] \rangle \quad (29.15)$$

where the superscript “cl” stands for “classical” and δ is the Dirac delta (or δ function).

As regards the physical interpretation of $G^{\text{cl}}(\mathbf{r}, t)d\mathbf{r}$, it gives the probability that particle j will be found in volume element $d\mathbf{r}$ (at position \mathbf{r}) at time t provided that any of the particles (including j) was at the origin at time $t = 0$.

For the incoherent scattering part, the Van Hove correlation function becomes a self-correlation function:

$$G_{\text{self}}^{\text{cl}}(\mathbf{r}, t) = \sum_j \langle \delta[\mathbf{r} - \mathbf{R}_0(t) + \mathbf{R}_0(0)] \rangle \quad (29.16)$$

where $G_{\text{self}}^{\text{cl}}(\mathbf{r}, t)d\mathbf{r}$ is the probability that a particle is in volume element $d\mathbf{r}$ (at position \mathbf{r}) at time t provided that the *same* particle was at the origin at $t = 0$. From these interpretations, it can be deduced that

$$\int G_{\text{self}}^{\text{cl}}(\mathbf{r}, t)d\mathbf{r} = 1 \quad \int G^{\text{cl}}(\mathbf{r}, t)d\mathbf{r} = N \quad (29.17)$$

It can be shown that not only the classical, but also the general forms obey the above “sum rules.” If, furthermore, $t = 0$ is taken, then one arrives at a most useful correlation function that characterizes the static structure:

$$G(\mathbf{r}, 0) = \sum_j \langle \delta(\mathbf{r} - \mathbf{R}_j + \mathbf{R}_0) \rangle = \delta(\mathbf{r}) + g(\mathbf{r}), \quad (29.18)$$

where $\mathbf{R}_j = \mathbf{R}_j(0)$ and $g(\mathbf{r})$ is the (static) *pair distribution function* (pdf), which yields the average particle density with respect to any particle at the origin (ratio of the local density at \mathbf{r} and the macroscopic density of the system):

$$g(\mathbf{r}) = \sum_{j \neq 0} \langle \delta(\mathbf{r} - \mathbf{R}_j + \mathbf{R}_0) \rangle. \quad (29.19)$$

Important limits for $g(\mathbf{r})$ are

$$g(\mathbf{r}) = 0 \quad |\mathbf{r}| \rightarrow 0; \quad g(\mathbf{r}) = 1 \quad |\mathbf{r}| \rightarrow \infty \quad (29.20)$$

It is helpful to define the Fourier transform pair of $g(\mathbf{r})$, the so-called *static structure factor*, via the “0th energy moment” of the dynamic structure factor:

$$S_0(\mathbf{Q}) = \int_{-\infty}^{\infty} S(\mathbf{Q}, \omega) d(\hbar\omega) = I(\mathbf{Q}, 0) = \frac{1}{N} \sum_{jj'} \langle e^{i\mathbf{Q}(\mathbf{R}_j - \mathbf{R}_{j'})} \rangle = 1 + \int g(\mathbf{r}) e^{i\mathbf{Q}\mathbf{r}} d\mathbf{r} \quad (29.21)$$

In the following discussion the subscript “0” will be omitted. The static structure factor can be expressed in relation to the differential cross section as

$$\left(\frac{d\sigma}{d\Omega} \right)_{\text{coh}} = \frac{\sigma_{\text{coh}}}{4\pi} N S_{\text{coh}}(\mathbf{Q}) \quad (29.22)$$

where the “static approximation” ($k = k'$) has also been made use of (where $k = |\mathbf{k}|$). It is the main goal of a generic scattering experiment to determine $S(\mathbf{Q}, \omega)$ over a scattering vector and energy range as wide as possible; arguably, among the available experimental techniques, neutron scattering provides the widest access to the dynamic structure factor. Unfortunately, the instrumentation is cumbersome, neutron fluxes are very limited and furthermore, very different types of instruments have to be built for accessing different parts of $S(\mathbf{Q}, \omega)$.

29.2.3 Refractive Index and “Neutron Optics”

So far, the interaction of neutrons with (collections of) point-like scatterers, with δ -function-like neutron-nucleus interaction potential, has been considered. However, provided that the magnitude of the momentum transfer, $Q = |\mathbf{Q}| \ll 1/R_0$ (where R_0 is on the order of the distance between nuclei), i.e., $Q \ll 1 \text{ \AA}^{-1}$, then the sample may be considered as a potential that is “smeared out” homogeneously. This is how optical phenomena, like total reflection, diffraction by a slit, etc., can be explained for neutron beams.

The *refractive index* can be expressed as (Squires 1996; Scherm 1972)

$$n = 1 - \frac{1}{2\pi} \rho \lambda^2 \bar{b} \quad \left(= 1 - \frac{2\pi N \bar{b}}{k_{\text{inc}}^2} \right) \quad (29.23)$$

where ρ is the number of scattering centers (nuclei) per unit volume (“number density”), λ is the wavelength of incident neutrons, \bar{b} is the mean value of the scattering lengths of the nuclei, k_{inc} is the wavenumber (magnitude of the wavevector) of the incident neutrons, and N is the number of nuclei. With typical values of these parameters, the refractive index takes the value of about 0.99995, very close to unity.

However, even this minute deviation from one gives the possibility of making use of the critical mirror angle (see ▶ Sect. 29.5.2.2) for the fabrication of neutron guides. Another important application is *neutron reflectometry*, used extensively for the investigation of (solid and liquid) surfaces (see ▶ Sect. 29.4.4). Neutron reflection can also be used for the accurate determination of the scattering length (Maier-Leibnitz 1962; Koester et al. 1991).

29.3 Neutron Scattering by Crystalline Materials

Chemical crystallography (or “crystal chemistry”) is one of the oldest areas of using neutron scattering in chemical applications: the atomic structure of a material is arguably its most basic property and therefore once a new material is synthesized, its crystalline structure has to be known. X-ray diffraction (mostly laboratory based) is thus a well-known technique to most synthetic chemists. However, there are quite a few cases where neutron diffraction lends itself as the only experimental technique for the determination of the microscopic structure: this happens when the positions of “light” atoms are of particular interest but X-ray scattering from “heavy” atoms dominate the signal. One such best-known situation is obviously when hydrogen positions have to be determined, although oxygen may also be hard to “see” by X-rays in some high-temperature superconductors, for instance.

Note, however, that hydrogenous materials, in general, have to be (at least partially) deuterated before neutron diffraction experiments, since the huge incoherent inelastic cross section of ^1H would hide the structurally relevant information otherwise.

Although magnetism has been deliberately left out from the scope of this chapter, it must be mentioned that the determination of magnetic structures takes probably the largest proportion of neutron diffraction today; this type of investigation was initiated by the Nobel Prize-winning work of C. Shull (1963).

29.3.1 Determination of the Crystalline Structure

Although the correlation function formalism introduced in the previous section (see ▶ Sect. 29.2.2.3) is entirely valid for crystalline materials, it is very rarely applied explicitly. The reason is, as it has been established long time ago (Bragg 1928), that long-range periodic ordering of identical structural units, the unit cells, makes it possible to determine the position of each scattering nucleus in the scattering system. The tools for doing so are well known from crystallography textbooks (see, e.g., Woolfson 1997), or the “International Tables for Crystallography” series (Prince and Wilson 1999; Shmueli 2001; Hahn 2002) and therefore, they are not discussed here. Textbooks on X-ray diffraction may also provide useful sources of information (see, e.g., Warren 1969).

29.3.1.1 Coherent Elastic Scattering, Bragg’s Law

The concept of the *reciprocal lattice* (see, e.g., Ashcroft and Mermin 1976; Woolfson 1997) is central to understanding crystallography. Here it may suffice to remind the reader that each point in the reciprocal lattice refers to a given set of lattice planes of the crystal (in real space), with a well-defined orientation and spacing. A reciprocal lattice vector \mathbf{H} is normal to the corresponding plane in real space and its length is the reciprocal value of the interplanar spacing.

It can be shown (see, e.g., Squires 1996) that coherent elastic (neutron) scattering from a crystal occurs only when the scattering vector is equal to a valid reciprocal lattice vector (note that for arbitrary arrangements, this requirement is not fulfilled and therefore, the special – eligible – orientations of the crystal have to be found):

$$\mathbf{Q} = \mathbf{k} - \mathbf{k}' = \mathbf{H} \quad (29.24)$$

The above condition is an alternative expression of Bragg’s law, known originally from X-ray scattering (Bragg 1928), which means that coherent elastic scattering of neutrons is Bragg scattering. Following a few straightforward steps, one arrives at the familiar form of Bragg’s law:

$$n\lambda = 2d \sin \frac{\theta}{2} \quad (29.25)$$

where λ is the wavelength of incident neutrons, n is an integer, d is the spacing of lattice planes (in real space), and θ is the angle between the incident beam and the scattered beam. ($\theta/2$, also known as the Bragg angle, is actually the angle between the incident beam and the crystal planes; quite frequently, the Bragg angle is noted as θ .)

Bragg’s law (and therefore, the coherent elastic differential cross section) can be exploited for determining the precise crystalline structure. Obviously, neutron scattering from crystals is not restricted to the coherent elastic contribution: scattering observed in between Bragg peaks is called *diffuse scattering*, which is generally connected to some sort of disorder (thermal,

positional, etc.). A recent monograph (Nield and Keen 2001) deals with problems concerning this increasingly important area.

29.3.1.2 Single-Crystal Neutron Diffraction, “Ab Initio” Structure Determination

Structural studies of single crystals were among the earliest applications of neutron scattering in chemically interesting systems (Bacon and Lowde 1948; Bacon 1951; Peterson and Levy 1951). The general aim of investigating single crystals is to explore the largest possible volume of the reciprocal lattice, so that the reconstruction of the original (real space) lattice could be made unequivocally. Experimental results are Bragg intensities in three dimensions, at the appropriate reciprocal lattice points. The diffracted intensity, in turn, is proportional to the square of the amplitude of the scattered wave for each individual Bragg peak (or “Bragg reflection,” as crystallographers call it frequently):

$$I(\mathbf{Q}) \propto |F(\mathbf{Q})|^2 \quad (29.26)$$

where $F(\mathbf{Q})$ is the (static) structure factor. Note that the (static) structure factor $F(\mathbf{Q})$ means basically the same as $S_0(\mathbf{Q})$ defined by Eq. (29.21), but from this point on notations better known in the area of crystallography are adhered to.

Further, the structure factor can be written as the product of its modulus and a “phase factor”:

$$F(\mathbf{Q}) = \sum_j b_j e^{i\mathbf{Q}\mathbf{R}_j} e^{-W_j} = |F(\mathbf{Q})| e^{i\varphi(\mathbf{Q})} \quad (29.27)$$

where W_j is the so-called *Debye–Waller factor* that accounts for the instantaneous displacement of nucleus j from its equilibrium position. The phase factor incorporates everything that cannot be included in the modulus of $F(\mathbf{Q})$.

As the measured intensities provide (after the necessary corrections for background, instrumental resolution, etc.) the moduli of the structure factor, but not the phase factor, the Fourier synthesis (inverse Fourier transformation) cannot be applied to the determination of the nuclei in the unit cell: this is the well-known “*phase problem*” of crystallography.

However, due to the cheap computer power available, evaluation of single-crystal neutron diffraction data (at the level of atomic coordinates in the unit cell and the Debye–Waller factors associated with them) is a routine task nowadays. The trick is to apply “direct methods” of phase determination – methods that depend on the many mutual relationships (inequalities and probabilities) between structure factors and their phases. The simplest such constraint is that scattering power in solids is concentrated on atoms, which are well-defined regions by their size and shape. (For pioneering applications, see the works published by Karle and Karle (1966), Bernal and Watkins (1972) and Jonsson and Hamilton (1972).) Similar conditions cannot be cast into exact mathematical equations, but computer algorithms can easily cope with them.

Naturally, because of the lack of exact relationships between measured data and the desired information, and also, because measured data contain errors, it is of utmost importance to determine the structure factor at as many reciprocal lattice points as possible. It is quite accepted to measure the intensity of several thousand Bragg reflections and therefore,

traditional single-crystal neutron diffractometry is one of the most time-consuming neutron scattering applications.

There are two basic methods for measuring diffracted intensities at well-defined reciprocal lattice points: one is the rotating crystal method and the other is the so-called *Laue method*. The *rotating crystal method* employs a monochromatic beam of neutrons (of wavevector \mathbf{k}) that is incident on a single crystal that can be rotated, so that all orientations can be realized. (For this purpose, most frequently, a 4-circle goniometer is used – for this reason, single-crystal instruments are sometimes also called “4-circle diffractometers.”) At reactor-based neutron sources (see ▶ Sect. 29.5), the majority of single-crystal diffractometers make use of the rotating crystal technique.

The *Laue method*, in contrast, applies a “white beam” of neutrons, containing a continuous spectrum of wavevectors; the sample orientation is kept fixed. Bragg reflections may be detected at several Bragg angles simultaneously. For quite a long period of time, Laue diffraction has mainly been used for the monochromatization of neutron beams (see ▶ Sect. 29.5); lately, however, single-crystal diffractometers have been built that exploit this method.

As for applications, the study of hydrogen bonding in crystalline materials may seem to be the most attractive for a chemist (Peterson and Levy 1952; Williams and Schneemeyer 1973; Preisinger et al. 1982; Nelmes et al. 1985). Determining the structure of materials of biological relevance is still a fast-growing area of research; for an early example, see the single-crystal analysis of sucrose (Brown and Levy 1963, 1973). The enormous power of combining X-ray and neutron single-crystal diffraction must not be left unmentioned: this “X-N synthesis” seems to be the most fruitful approach toward determining electron density maps experimentally (Coppens 1974).

29.3.1.3 Neutron Powder Diffraction, Refinement of the Structure

In contrast to a good single crystal, a good crystalline powder consists of a large number of small crystallites that are oriented randomly with respect to each other. Fulfilling these conditions, there would always be some crystallites that would satisfy the orientation requirements necessary for Bragg scattering the beam of fixed direction. Too big crystallites, or/and nonrandom (“preferential”) orientation cause severe distortion of the signal, many times making proper interpretation impossible – therefore, these are arguably the most problematic aspects of this type of experiment. (This preferential orientation of crystallites is called “texture” as opposed to perfectly random orientation.)

In the standard realization of the powder diffraction experiment, a monochromatic neutron beam, with wavevector \mathbf{k} , falls on a powder sample. For a specified value of $|\mathbf{H}|$, the \mathbf{k}' wavevector of the scattered beam will form a cone, known as the *Debye–Scherrer cone*. Only microcrystals with \mathbf{H} vectors lying on the cone and with axis along \mathbf{k} (satisfying also an angle-constraint, see, e.g., Squires 1996) will contribute to the scattering. (The requirement for randomly oriented microcrystals can now be understood: preferred orientation(s) would corrupt true peak intensities.) According to Bragg’s law, (▶ Eq. 29.25), differences in lattice plane spacing can be measured by moving the detector over the angular range available for the given instrument. This procedure provides an intensity curve as a function of the scattering angle – traditional neutron powder diffraction is a “fixed wavelength (thus fixed energy), angle dispersive technique.” As an example of a powder spectrum, the $S(Q)$ structure factor of “high temperature” D_2O ice (close to the melting point) is shown in ▶ Fig. 29.1.

■ Fig. 29.1

Neutron powder diffraction spectrum of (hexagonal) D_2O ($^2\text{H}_2\text{O}$) ice (phase Ih) at 260 K, close to the melting point. Note the large amount of diffuse scattering under the Bragg peaks, indicating effects of structural disorder (Pusztai and McGreevy 1997, unpublished data)

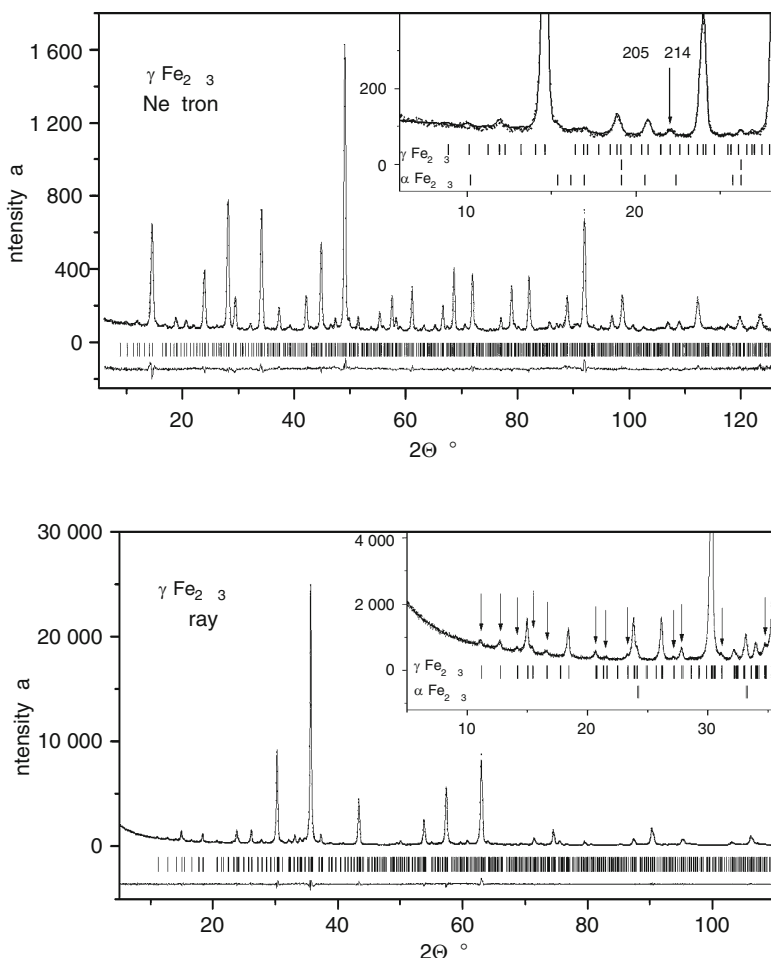

Note that the resulting function depends only on $|\mathbf{H}|$ – which means that the three-dimensional information, available in single-crystal diffraction, is lost, or rather, averaged over the orientations of the crystallites. Since many different \mathbf{H} s may have the same magnitude, peaks (maxima) of the powder spectrum may well receive contributions from more than one reciprocal lattice point (thus the “multiplicity” of the reflections have to be established).

Instead of considering Bragg reflections one by one, evaluation of powder spectra these days is done almost exclusively by a kind of “whole profile fitting structure refinement,” or *Rietveld refinement* (Rietveld 1969; Loopstra and Rietveld 1969). The Rietveld algorithm fits entire observed diffraction patterns using parameters for instrumental characteristics (resolution, etc.), as well as for structural features (cell constants, atomic coordinates, and displacements). The fitting is done by least-squares methods, minimizing the differences between measured and calculated intensities at each experimental point. Although this procedure is extremely powerful, it has to be emphasized that Rietveld refinement is not a method for structure determination since all (including structural) parameters require reasonably good initial values. Simultaneous refinement of neutron and X-ray powder patterns is performed more and more frequently. ▶ Figure 29.2 shows, e.g., X-ray and neutron powder diffraction results obtained in this way for maghemite, $\gamma\text{-Fe}_2\text{O}_3$ (Somogyvári et al. 2002a).

Following the idea of “interpretation-by-fitting-a-model-to-data,” two more methods for the evaluation of powder patterns have to be reported briefly, both with elements of Monte Carlo simulations (for Monte Carlo methods, see, e.g., Allen and Tildesley 1987; Binder and Heermann 1992). One of them, the so-called pair distribution function (PDF) analysis, uses the pair distribution function, (▶ Eq. 29.19), for fitting (in real space) with a model containing as small a number of atoms as possible (Billinge and Egami 1993; Proffen and Billinge 1999). The other, called Reverse Monte Carlo (RMC) modeling (McGreevy and Pusztai 1988),

■ Fig. 29.2

Neutron (upper part) and X-ray (lower part) powder diffraction spectra of maghemite. The two patterns were simultaneously refined by the Rietveld method (the difference between model and measurement can be seen as the bottom curves of both parts). The arrows (in both parts) indicate extra reflections, due to tetrahedral ordering of vacancies in the crystal

employs large models (many thousands of atoms), in order to be able to describe Bragg- and diffuse-, nuclear and magnetic scattering in reciprocal space; the special algorithm for powders is called reverse monte carlo for powder patterns (RMCPOW) (Møllergård and McGreevy 1999). It is expected that with further increase of cheap computer power, these Monte Carlo based methods will be widely used.

There are a number of reasons why the powder technique may be preferred to single-crystal diffraction. The most important are the unavailability of suitable single crystals (catalysts, zeolites, fullerenes, etc.); data taking, handling and interpretation is straightforward and relatively fast, making the method available also to non-crystallographers. Also, in many cases, the powder pattern is exploited as a “fingerprint” of a given material (no two

powder patterns are exactly the same), which approach yields the fastest way of phase identification for materials that may appear in different crystallographic phases as well as for composite samples.

Details of the powder technique can be found, e.g., in the work of Bish and Post (1989) and Young (1993). Up-to-date applications are easiest to find in recent proceedings of the European Powder Diffraction Conference series (Delhez and Mittemeijer 1998, 2000, 2001).

29.3.1.4 Time-of-Flight (TOF) Variants of Neutron Diffraction Methods

Pulsed (mostly spallation) neutron sources (see [Sect. 29.5](#)) are becoming more and more important for the whole area of neutron scattering and therefore, it is essential to develop/improve experimental techniques that are well suited for exploiting features of pulsed beams. In a white beam, neutrons with different wavelengths travel at different speeds. Instead of varying the scattering angle, one measures the *time-of-flight* of neutrons when pulsed beams are applied. This is possible because the time $t = 0$ is naturally signaled by the start of the pulse. For a continuous – reactor based – neutron source, pulsing requires extra instrumentation, the inclusion of beam choppers (see [Sect. 29.5](#)).

For neutron diffraction one substitutes the (de Broglie) neutron wavelength $\lambda = h/p$ (p is the momentum of the neutron, h is the Planck constant) in Bragg's law, ([Eq. 29.25](#)), which (after expressing the lattice plane spacing d for $n = 1$) yields

$$d = \frac{t}{2 \frac{m}{h} L \sin \frac{\theta}{2}} \quad (29.28)$$

where m is the mass of the neutron, L is the total length of the source-to-sample-to-detector flight path, and t is the total time-of-flight. According to the above equation, a whole range of plane spacings can be measured at fixed scattering angle θ ; hence TOF neutron diffraction is called a “fixed angle, wavelength (and energy) dispersive” technique. The resulting powder pattern is the scattered intensity as a function of d -spacing; the corresponding Rietveld refinement algorithm therefore is different from that used for “angle dispersive” patterns.

For single-crystal diffraction, the white-beam-based Laue method can be applied on a TOF instrument. By making use of large-area detectors, covering possibly almost the full solid angle range around the sample, substantial volume of the reciprocal lattice (many reciprocal lattice points) can be explored simultaneously. In this way, the duration of single-crystal structure determinations may be reduced enormously.

Further information on time-of-flight neutron diffraction (and other time-of-flight neutron scattering methods) can be obtained from the Web site of the ISIS Pulsed Neutron and Muon Facility, Rutherford Appleton Laboratory, UK (ISIS 2003).

29.3.2 Dynamical Studies of Crystals

Elementary excitations (“dynamics”) in condensed matter systems may be studied by inelastic neutron scattering. A large proportion of solid-state physics concerns dynamical phenomena (“collective excitations”) in crystalline materials, such as lattice vibrations (phonons), or spin waves (magnons) (see, e.g., Ashcroft and Mermin 1976). These phenomena have been

investigated by neutron scattering for decades – see, for instance, early works considering one-phonon absorption by time-of-flight (Squires 1956) and crystal (“triple axis”) spectrometers (Brockhouse 1960). Browsing through the proceedings of recent neutron scattering conferences (see, e.g., Petry 2002), one quickly realizes that, at the beginning of the twenty-first century, a massive part of all neutron scattering investigations deal with some sort of dynamics in crystals. In this subsection, focus is put on dynamics in crystals that are particularly interesting from the chemical point of view.

As it was discussed in [Sect. 29.2](#), incoherent (inelastic) neutron scattering accounts for the individual motions of atoms. Thus, in the crystalline solid state, in the absence of diffusion, most of the incoherent signals originate from molecular vibrations. Most chemical applications have something to do with the role of hydrogen to which neutrons are more sensitive than any other probe. The reason for this can be understood by looking at the incoherent inelastic cross section, which can be related to the (vibrational, “one-phonon” approximated) density of states distribution function $Z(\omega)$ as (see, e.g., Marshall and Lovesey 1971; Bacon 1977)

$$\left(\frac{d^2\sigma}{d\Omega dE'}\right)_{\text{incoh}} = \frac{\kappa'}{\kappa} \sum_j \left(b_j^2 - \bar{b}_j^2\right) \frac{Q^2 U_j^2}{2M_j} e^{-2W_j} \left(\frac{1}{e^{\varepsilon/kT} - 1} + \frac{1}{2} \pm \frac{1}{2}\right) N \frac{Z(\omega)}{\omega} \quad (29.29)$$

where κ s replace the usual k s, used previously (see [Eq. 29.5](#)) etc.) for denoting wavevector moduli; k now denotes the Boltzmann constant, ω is angular frequency, and $\varepsilon = E - E' = \hbar\omega$ is the change in neutron energy due to the scattering process. The \pm sign is to be replaced by $+$ or $-$ depending on whether the neutrons lose or gain energy. The subscript j runs over the atoms in a molecule. The above expression shows that each vibration is “weighted” by the different atoms taking part in it, according to their incoherent scattering lengths (the term following the summation sign, see [Eq. \(29.8\)](#)), their atomic displacements U_j , and the reciprocal value of their atomic masses M_j . Due to this weighting, neutron spectra will always contain larger contributions arising from hydrogen atoms than their “fair share” considering their number. This is because of the small mass, large displacements, and huge incoherent scattering characterizing hydrogen atoms.

Note that deuteration will decrease enormously the amplitude of peaks related to hydrogen, whereas in infrared (IR) spectroscopy there would only be a change in the vibrational frequency. That is, the information on molecular-scale dynamics can be multiplied if IR, Raman, and neutron spectroscopies are applied together.

As far as applications are concerned, the investigation of the hydrogen bond seems a natural choice, since the bending vibration, for reasons mentioned above, is the most intense band in the spectrum. Indeed, crystalline compounds with strong H-bond have long been subjects of incoherent inelastic neutron scattering studies: substances like KHF_2 (Boutin et al. 1963), CHCl_2 and CDCl_2 (Stirling et al. 1970), and HCrO_2 (Rush and Ferraro 1966) or HCoO_2 (Delaplane et al. 1969) have been considered. As an example, incoherent inelastic neutron scattering data are shown for H_2O ice Ih in [Fig. 29.3](#) (Li 1996).

On the instrumental side, most inelastic neutron scattering setups are capable of molecular spectroscopic experiments; perhaps TOSCA, installed at the ISIS Pulsed Neutron and Muon Facility (UK), should be mentioned as it is dedicated to such studies (ISIS 2003). Data analysis most often includes quantum chemical calculations of the vibrational density of states, which are compared to experiment (see, e.g., Line and Kearley 2000; Fernández-Liencres et al. 2001).

■ Fig. 29.3

Dynamic structure factor S of (hexagonal) H_2O ($^1\text{H}_2\text{O}$) ice (phase Ih), obtained from incoherent inelastic neutron scattering (Li 1996) vs. wave number ν . Note the similarity of the above curve to results of conventional vibrational spectroscopic methods (IR, Raman)

29.4 Neutron Scattering by Liquids

For a chemist, the liquid state holds a special status: most of “traditional” chemistry and a large proportion of “modern” chemistry take place in solutions of some sort. For this reason, neutron scattering by liquids is treated with a particular emphasis here.

Due to its essential role, determining the microscopic properties of water has long been central to neutron scattering studies. As is well known, water behaves anomalously in many respects (see, e.g., Eisenberg and Kauzmann 1969) and, unfortunately, it presents quite a few experiment-related difficulties that make the understanding of the anomalies harder. Neutrons provide a unique opportunity to study hydrogenous materials, such as water. However, as it will be shown below, what was a great help in studying individual atomic dynamics in the solid may turn into an even greater obstacle when studying the liquid structure.

Before going into details, an important general property of neutron scattering from liquids should be noted. As was derived by Squires (1996), true elastic scattering from a liquid occurs only when $Q = 0$, i.e., for forward scattering. This finding applies to coherent and incoherent scattering alike, which corresponds to the general view that there is no “static” structure for a liquid, in the sense that the atoms have no equilibrium positions around which they oscillate; there is no Bragg scattering, either.

29.4.1 Structure

Again, the main feature of the liquid structure is the lack of structural units and long-range ordering (translational symmetry). Therefore, there is no sense in pursuing the determination of all nuclear coordinates (it is also impossible).

29.4.1.1 Description of the Liquid Structure, Based on Experimentally Available Quantities

Theoretical approaches to the structure of liquids are well developed (see, e.g., Gray and Gubbins 1984; Hansen and McDonald 1986). However, by considering only what is available strictly from diffraction experiments, one has to rely on the pair distribution function given by [Eq. \(29.19\)](#).

Liquids (at least the ones concerned with here) are isotropic, and therefore the correlation function depends only on the magnitude of \mathbf{r} (r), and the structure factor (static and dynamic) depends only on the magnitude of \mathbf{Q} (Q). The relations between the static structure factor and the radially symmetric pair distribution function (also known as the *radial distribution function*, rdf) then can be expressed as (compare [Eq. \(29.21\)](#))

$$S(Q) = 1 + \frac{4\pi\rho}{Q} \int_0^\infty r(g(r) - 1) \sin(Qr) dr \quad (29.30)$$

and

$$g(r) = 1 + \frac{1}{2\pi^2\rho r} \int_0^\infty Q(S(Q) - 1) \sin(Qr) dQ \quad (29.31)$$

It is $g(r)$ that has to be considered as the final result of a neutron diffraction experiment, which means that instead of particle coordinates, only a “distance spectrum” can be obtained. In other words, diffraction experiments can only access two-particle distribution functions of a liquid (and the same applies, naturally, to amorphous solids, as well). The calculation of $g(r)$ from nuclear coordinates can be carried out as follows:

$$g(r) = \frac{dN(r)}{4\pi r^2 \rho dr} \quad (29.32)$$

where $dN(r)$ is the number of atoms in the spherical shell between r and $r + dr$, so that the above equation gives the ratio of local and average number densities directly.

For a multicomponent liquid that consists of at least two different chemical elements, the desired information would be the (possibly complete) set of *partial pair* (or *partial radial distribution functions* (ppdf/prdf)); if there are k different types of scattering centers (nuclei) then there are $k(k+1)/2$ of these partials. For the case of liquid water, which can be considered as a guiding example throughout this section, there are two types of scatterers, H (or D) and O, and the number of prdfs is three: it is possible (and important) to distinguish between O–O, O–H, and H–H partial correlations. What can be measured by diffraction is the total (or “composite”) structure factor, defined as

$$S(Q) = \sum_{i=1}^k \sum_{j=1}^k c_i c_j \bar{b}_i \bar{b}_j S_{ij}(Q) \quad (29.33)$$

where c_i is the molar fraction of component i , $S_{ij}(Q)$ are the partial structure factors whose sine Fourier transforms are the $g_{ij}(r)$ prdfs, according to [Eq. \(29.31\)](#).

For water, the knowledge of the O–H partial radial distribution function is crucial; since it can provide the most decisive piece of information on hydrogen bonding (similar statement

can be made for other liquids with H-bonding). It is obvious, however, that from one measurement, three pdfs cannot be derived unambiguously; possible solutions to this problem will be outlined in the next subsections.

Another related point to note is that direct information on molecular orientations (and on their correlations) *cannot* be obtained from a diffraction experiment. One may speculate about possible orientations that may or may not be consistent with experimental data. In other words, very different *higher order correlation functions* (like those describing mutual orientations of two or more molecules) may average out and provide identical two-particle correlation functions (that can be measured). That is, diffraction data are inherently ambiguous in describing detailed atomic level structural arrangements in liquids; a fact that has to be kept in mind when interpreting the results of neutron diffraction experiments.

29.4.1.2 Determination of the Radial Distribution Function from Neutron Diffraction of Liquids

Although instrumental requirements are very similar, a liquid diffraction experiment is much less a routine task than taking the powder pattern. The reason is that when Bragg scattering is present then Rietveld refinement can work with just the ratio of the Bragg-reflection amplitudes; there is no need for precise absolute values. In a powder diffraction measurement, most frequently only the coherent elastic scattering is important. On the other hand, in the absence of true elastic scattering, the total coherent scattering is measured, so that for being able to carry out the transformation to real space with sufficient accuracy the absolute scale must be established. Also, scattering amplitudes are much lower without Bragg scattering, so that data correction procedures are crucial; therefore, they need to be described at this point briefly.

Generally speaking, the aim of data correction is to convert neutron counts (as received by the detectors) into properly normalized scattering cross sections. For achieving this goal, six measurements have to be made for a total scattering experiment: the sample, the empty container, the empty sample environment (for high/low temperature and or high/low pressure, etc.), a standard incoherent scatterer (usually vanadium) for the absolute normalization, the instrumental background and, finally, a standard sample (usually Ni powder) for the calibration of the instrumental geometry.

Based on the above measurements, the following correction steps are taken (see, e.g., Egelstaff 1994; Nield and Keen 2001):

Attenuation corrections. Scattering from the sample is modified by (instrumental and general) background, container and environment scattering, by attenuation in the sample, the container and the sample environment and also, by multiple scattering of the sample, the container and sample environment.

Normalization. This step is done by dividing the sample scattering intensity by the vanadium standard scattering intensity. The idea behind is that a sample that is almost entirely incoherent scatterer sets the proper “zero level” for the coherent part.

Inelasticity. When measuring total scattering, the integration over energy transfer (see ► Eq. (29.4)), which is done automatically by the instrument, is not done at constant values of Q , but at best at constant angle. Corrections to this problem are instrument dependent and can only be approximated, see (Placzek 1952; Howe et al. 1989). However, these analytical approximations do not work for light atoms, like hydrogen. For hydrogenous materials, inelasticity corrections are the most important, and unfortunately, they are the ones that can

■ Fig. 29.4

Static structure factor of liquid D_2O . Solid line: reactor source (Thiessen and Narten 1982); dots: pulsed source (Soper et al. 1997)

only be handled with great difficulties (if at all). ▶ Figure 29.4 shows the corrected structure factor for liquid heavy water, as measured at a reactor source (Thiessen and Narten 1982) and at a pulsed source (Soper et al. 1997); differences observed between the two curves do not seem to influence the interpretation significantly in this particular case.

Calculating the radial distribution function. This step is, to date, most frequently carried out by simple “forward” transform, according to ▶ Eq. (29.31). For this reason, it is generally believed that a very wide scattering vector range, extending possibly over 20 \AA^{-1} , is necessary when measuring the structure factor (see, e.g., Wright 1994). (The lower limit of Q is usually not smaller than 0.3 \AA^{-1} , due to instrumental restrictions.) Note that there are “inverse” Monte Carlo based modeling methods also available, like monte carlo evaluation of the G of R (MCGR) (Pusztai and McGreevy 1997), which can overcome some of the difficulties concerning truncation errors during Fourier transformations.

If one wishes to determine all the three partial radial distribution functions of a two-component material, like water, then three independent total structure factors must be measured for (chemically) the same material. In this way, the coefficients of the partial structure factors $S_{ij}(Q)$, ▶ Eq. (29.33), will be different, because the scattering lengths will be different. As shown by ▶ Table 29.1, different isotopes of the same element do possess different scattering amplitudes for neutrons. This property made possible the development of the technique called *isotopic substitution* (North et al. 1968). For a two-component system, three different isotopic samples have to be prepared, so that the coefficients of the partial structure factors should differ sufficiently well for being able to solve a set of three linear equations, of the form of ▶ Eq. (29.33), for the three unknown partial structure factor.

Unfortunately, there are no suitable isotopes for each element; “good” elements are, for instance, chlorine and nickel. In many cases, differences between coefficients are not big enough for the matrix inversion; i.e., the set of equations is “ill defined.” Sometimes, application of the Reverse Monte Carlo modeling method can help in separating partial structure

factors, as was the case for molten CuBr (Pusztai and McGreevy 1998). (For synchrotron X-rays, an emerging similar method is anomalous X-ray scattering (Waseda 2002), where it is the Q -dependent atomic form factors, equivalents of b values, that can be varied.)

For a chemist, undoubtedly the best-known isotopic substitution is that of ^1H by ^2H (H to D): neutron diffraction studies of water (Thiessen and Narten 1982; Soper et al. 1997) are the most cited examples of that. Exploiting the substantial difference between the scattering lengths of H and D (Table 29.1), at least three samples (most frequently with 0, 50, and 100% of H_2O) are measured (the rest is D_2O). The huge inelastic incoherent cross section of ^1H has already been mentioned. As a result of this, in the case of the neutron diffraction intensity measured for pure H_2O , less than 5% of the signal contains information on the structure (i.e., more than 95% has to be treated as “background”). Another problem is that H_2O and D_2O are two (although only slightly, but noticeably) different liquids, with different melting points, etc., so that the “identity” of the samples is questionable. For these reasons, there are still controversial issues concerning details of the microscopic structure of pure liquid water (see, e.g., Pusztai 1999), which is demonstrated in Fig. 29.5. This is a really unfortunate situation, since a lot of interesting chemistry, including solutions, complexes, polymers, biological samples, etc., could benefit enormously from a well-established H–D substitution practice.

29.4.2 Microscopic Dynamics in Liquids

In many cases, neutron scattering studies of microscopic dynamics in the liquid state pursue remnants of solid-like behavior, like phonons (see, e.g., Pusztai and McGreevy 1989). Concerning chemical properties, this approach is not relevant. “Molecular spectroscopy,”

Fig. 29.5

O–H partial radial distribution functions of liquid water. *Solid line:* from Soper et al. (1997); *dots:* Reverse Monte Carlo analysis from Pusztai (1999). Note the significant deviation in terms of the position of the first intermolecular maximum, which is characteristic of the hydrogen bond

making use of incoherent inelastic scattering as described briefly in ► Sect. 29.3.2, can also be used in the liquid state. For instance, liquid hydrogen sulfide was investigated by Andreani et al. (2001) using the TOSCA time-of-flight spectrometer mentioned earlier. This approach is useful when local (as opposed to “collective”) vibrational modes are probed. There are, however, further areas, specific to (or at least, more frequent for) liquids; these will be the subjects of the next subsections.

29.4.2.1 Quasi-Elastic Neutron Scattering

Elementary excitations also include “single particle diffusive excitations” beside quantized vibrations (i.e., molecular vibrations and vibrations of the crystal as a whole associated with phonons/magnons). Consider the incoherent dynamic structure factor $S_{\text{inc}}(Q, \omega)$, which is the Fourier transform pair of the time-dependent self-correlation function, $G_{\text{self}}(r, t)$, compare ► Eqs. (29.12), (► 29.13), and (► 29.16), around the elastic ($\Delta E = 0$) peak (measured at a number of Q values). This is the range where for large Q , $S_{\text{inc}}(Q, \omega)$ exhibits a very broad maximum, and for low Q values, below about 1 \AA^{-1} , it peaks sharply (see, e.g., Sköld et al. (1972) for the case of liquid argon). A qualitative explanation can be given on the basis of the properties of Fourier transform pairs: at small values of r and t (large values of Q and ω), the liquid behaves as a perfect (ideal) gas (“free movement”), whereas at the other extreme, large values of r and t , diffusion dominates (many collisions with other atoms). This latter type of behavior is being investigated rather heavily in liquids (which means high demand for beamtime on suitable instruments, like IRIS at ISIS, UK), therefore some of the related basic formulas are given below.

Fick’s (second) law, which is the basic equation of diffusion, reads as (see, e.g., Atkins 1994)

$$\frac{\partial n(\mathbf{r}, t)}{\partial t} = D \nabla^2 n(\mathbf{r}, t) \quad (29.34)$$

where $n(\mathbf{r}, t)$ is the number density at point \mathbf{r} and D is the diffusion coefficient. Owing to its probabilistic interpretation, $G_{\text{self}}(r, t)$ must satisfy the above equation (Squires 1996). Following some algebra, one ends up with the following expression for $S_{\text{inc}}(Q, \omega)$:

$$S_{\text{inc}}(Q, \omega) = \frac{1}{\hbar \pi} \frac{D Q^2}{D^2 Q^4 + \omega^2}. \quad (29.35)$$

The above function has a Lorentzian shape with a maximum at $\omega = 0$, where

$$S_{\text{inc}}(Q, 0) = \frac{1}{\hbar \pi D Q^2}. \quad (29.36)$$

That is, information on the diffusion constant is available directly. Up-to-date information on the current use of quasi-elastic neutron scattering can be obtained from the work of McGreevy (1999).

29.4.2.2 Detecting Very Small Exchanges of Energy: Neutron Spin-Echo

In standard inelastic (coherent or incoherent; time-of-flight) scattering experiments, increasing the resolution (the precision of the determination of energy transfers) by a given factor x costs

reducing the available intensity by a factor of x^2 . This is because one loses a factor of x of the intensity on both the speed selection and speed analysis, before and after the sample. This rate quickly makes the experimenter losing all the intensity around the energy resolution of about 0.1 μeV (which is well into the range of diffusion “excitations”). However, there are important processes, like chain relaxation in polymers, whose study would require even better an energy resolution, since extremely low energy excitations have to be maintained. For that, one has to replace the direct measurement of neutron speed by a more sophisticated method, which is achieved in the technique of *neutron spin-echo spectroscopy* (Mezei 1972, 1979).

A set of polarized particles with a magnetic moment and spin $\frac{1}{2}$ will behave similarly to a small (classical) magnetic moment: when entering a region where the magnetic field is perpendicular to its magnetic moment, Larmor precession (see, e.g., Ashcroft and Mermin 1976) will occur. If a polarized neutron beam (with spins only either “up” or “down”) enters a region of length l with a magnetic flux density \mathbf{B} , the total precession angle will be

$$\varphi_1 = \frac{\gamma B l}{u_1} \quad (29.37)$$

where u_1 is the speed of neutrons and γ is the gyromagnetic ratio of the neutron. Such a beam, with precession angle φ_1 , is incident on the sample and then, the scattered beam passes another region of length l and magnetic flux density $-\mathbf{B}$. If the scattering is elastic then the total precession angle is 0 and at the end of this second region, the original polarized neutron beam is recovered. If, however, the scattering is inelastic and there is a (small) energy exchange $\hbar\omega$, then there will be a net precession angle and the detector signal will be a transmission function. The probability that a neutron is transmitted (at a specific analyzer geometry) is $\cos \varphi$. Remember that at a given value of Q , the probability of scattering with energy exchange $\hbar\omega$ is $S(Q, \omega)$. Taking the expectation value by integrating over all values of ω one obtains

$$\langle \cos \varphi \rangle = \frac{\int \cos\left(\frac{\hbar\gamma B l}{mu^2} \omega\right) S(Q, \omega) d\omega}{\int S(Q, \omega) d\omega} = S(Q, t). \quad (29.38)$$

That is, the measured beam polarization is in a direct relation to the intermediate scattering function at a given value of Q . Details of the instrumentation can be found in ▶ Sect. 29.5 (see also Monkenbusch and Zorn 2000). Applications, mostly for dynamics of polymer melts and solutions, can be browsed in the work of Ewen and Richter (1997).

29.4.3 Looking at Mesoscopic Length Scales: Small Angle Neutron Scattering

As it was mentioned before, when doing standard neutron diffraction, the lowest available value of Q is usually not smaller than about 0.3 \AA^{-1} . Since the purpose of these “wide angle” diffraction measurements is to resolve atomic scale distances, this lower limit is actually sufficient (perhaps with the exception of high-resolution powder diffraction studies of magnetic materials). However, there may be structural features that are manifest at superatomic length scales; examples are colloids, polymers, gels, and precipitations in alloys. Neutron scattering does provide means for investigating such systems, by detecting scattering at the scattering vector range between about 10^{-3} \AA^{-1} and 10^{-1} \AA^{-1} : this technique is the *small angle neutron scattering* (SANS).

If the scattering vectors are limited to below about π/d , where d is a general interatomic distance, about 3 Å, then the discrete positions of scattering centers (nuclei, as point-like scatterers) cannot be resolved; instead, the distribution of scattering lengths can be represented by a continuously varying *scattering length density*, $\rho_b(\mathbf{r})$. If ρ_b is uniformly distributed beyond atomic length scales then there is no small angle scattering signal observable; for this reason, pure liquids normally are not studied by SANS.

Fluctuations of $\rho_b(\mathbf{r})$ can be caused by density or concentration fluctuations. Real density fluctuations in simple (one-component) fluids occur near the critical point, where the isothermal compressibility of the liquid diverges. In multicomponent fluids, the concentration fluctuations can be observed when (at least one of) the components “want” to demix. Naturally, in more complex samples, like colloids in some solvents, fluctuations are present because, on the atomic length scale point of view, there are several (at least two) different phases present. SANS (and also, its X-ray counterpart SAXS) can be applied with success in these latter instances.

Concerning scattering-length densities, contrast is a useful concept when dealing with SANS: it refers to scattering-length density differences between parts of the sample. These parts can be various objects: big molecules, or even parts of very big molecules, associations of particles of a kind, etc. The point to note is that by isotope substitution (► Sect. 29.4.1), the contrast can be varied without changing the chemistry of the system. This powerful methodology has the name of *contrast variation* in the area of SANS.

The SANS scattering function, which is analogous to the structure factor (► Eq. (29.21)), can be written as follows:

$$F_{\text{SANS}}(\mathbf{Q}) = \int_V (\rho_b(\mathbf{r}) - \rho_0) e^{i\mathbf{Q}\mathbf{r}} d\mathbf{r} \quad (29.39)$$

where the integration is over the volume V of the sample, and ρ_0 is the macroscopic (“average”) scattering length density of the system. (In liquid and crystalline powder samples, for their isotropic nature, the vector notation of \mathbf{Q} and \mathbf{r} can be changed to their magnitudes, Q and r). According to the above equation, the SANS scattering function of model structures can be calculated. However, because of the very limited experimental information concerning the Q -space, the distribution of scattering length density cannot be reconstructed directly. For this reason, several approximations have been developed (and are in use) for the interpretation of SANS data.

For all shapes of scattering objects, the equation of Guinier and Fournet (1955) yields the low- Q behavior of the SANS $F(Q)$ for a set of monodisperse, spherical (or at least, not too anisometric) particles:

$$F_{\text{SANS}}(Q) = c_p V^2 (\rho_b(r) - \rho_0)^2 e^{-Q^2 R_g^2} \quad (QR_g < 1) \quad (29.40)$$

where c_p is the concentration and R_g is the *radius of gyration* of the scattering particles. R_g is often considered as a finding of primary interest, since it can be calculated, by taking the slope of the $\log F_{\text{SANS}}(Q)$ vs. Q^2 plot at small Q values, even when only the un-normalized scattering intensity is known. (A word of warning may be appropriate here, since the above relation is usually applied automatically: R_g can be obtained so simply only if all the conditions, particularly the monodispersity and the sphericity, of the Guinier approximation are fulfilled.)

At the high Q end of the SANS region, another approximation, due to Porod (1951), can be used: the signal there is dominated by the interface between the different scattering particles (or regions of different scattering length densities):

$$F_{\text{SANS}}(Q) = 2\pi\Phi(\rho_b(r) - \rho_0)^2 Q^{-4} \quad (Q > 0.1 \text{ nm}^{-1}) \quad (29.41)$$

where Φ is the total interface area per unit volume. By using the above equation, one can calculate Φ from just the intensity curve, but only at the upper limit of Q , and if a clear straight section can be found in the $F_{\text{SANS}}(Q)$ vs. Q^{-4} curve. Porod's law proves to be extremely useful when studying catalysts or other porous materials. Between the Porod and Guinier regions one often finds a power law behavior, reflecting possible fractal nature (i.e., self-similarity over a given size range) of the sample (see, e.g., Teixeira 1987).

The variety of properties that can be investigated by SANS is tremendous: from the determination of the radii of gyration, it extends to the description of fractal behavior. For a general overview of the technique and its application, one can consult the works of Feigin and Svergun (1987) and Brumberger (1995). Detailed information on the appropriate instrumentation can be found on the Internet (see Munter 2003 for reactor sources, and ISIS 2003 for pulsed sources).

29.4.4 Looking at Liquid Surfaces: Neutron Reflectometry

As it was introduced in Sect. 29.2.3, neutrons of sufficiently long wavelength can bring about optical phenomena when encountering boundaries of condensed phases: they, as waves, interact with the continuous potential represented by densely packed atoms. Reflection does occur (although only for very small incident angles, due to the very nearly unity value of the refractive index of most materials for neutrons), which can be exploited for studying liquid (and solid) surfaces (and interfaces) by neutron *reflectometry*.

The specular reflection (for which the incident angle is equal to the outgoing angle) of neutrons can be measured as a function of the scattering vector \mathbf{Q} perpendicular to the liquid surface. The reflection pattern is related to the neutron refractive index profile normal to the surface (or interface), which profile, in turn, is related to the scattering length density profile (see Eq. (29.23), where $\rho_b = \rho b$). Any *off-specular scattering* must come from potential gradients present in the plane of the surface. In this way, the reflectivity pattern provides information on composition and/or density variations at surfaces.

The analysis of reflectivity data is usually done by constructing a model of the interface, containing parallel homogeneous layers. Each layer is characterized by its thickness, d_b , and scattering length density, ρ_b . These parameters (and also, if desired, further ones describing the roughness of the interfaces) are used to calculate the reflectivity profile for the model, according to the “optical matrix” method (Born and Wolfe 1989). The transmission and the reflection from layer to layer are described as a matrix multiplication product for the two adjacent layers. Retrieving the distribution of the scattering length density from the reflectivity curve is obviously a complex problem. Note also that different model profiles can produce the same reflectivity curve within errors. This is sometimes called the “phase problem.” It has a similar origin to what was mentioned while discussing single-crystal diffraction in Sect. 29.3.1.3: measured intensities give information only on the magnitude, but not the phase factor, of the wave function of the scattering system. A review of inversion techniques is available in the work of Zhou and Chen (1995).

The instrumentation of neutron reflectometry can be realized by both monochromatic (angle dispersive) and time-of-flight (wavelength dispersive) methods. The former is capable of measuring smaller reflectivity values due to its lower background, whereas the latter has the advantage of the fixed angle setup. Signal-to-noise ratios of higher than 10^5 can be routinely reached and reflectivities as low as 10^{-7} are measured frequently. As usual, the H/D isotopic substitution gives outstanding opportunities for answering rather specific problems, as the refractive index of hydrogenous and deuterated layers are different while the underlying chemistry remains essentially the same. See the work of Penfold and Thomas (1990) for more details concerning the experimental side.

Applications in the area of surface chemistry are abound. For instance, adsorbed layers of surfactants (Simister et al. 1992) or polymers (Henderson et al. 1993) can be studied in great detail. Finally, it should be noted that the most important solid-state physics/materials science application is *polarized neutron reflectometry*, by which magnetic multilayers are studied (see, e.g., Huang et al. 1993). The current status of neutron reflectometry can be checked in the proceedings of the conference series “Surface X-ray and Neutron Scattering” (Norman and Webster 1998).

29.5 Neutron Scattering Instrumentation

In this section, essential parts of the instruments that can serve for the determination of parts of the $S(\mathbf{Q},\omega)$ function are introduced briefly.

29.5.1 Neutron Sources

As it was already emphasized, maximizing the available flux density of thermal neutrons, including the “cold” as well as the “hot” regions, is vital for neutron scattering applications.

29.5.1.1 Reactor Sources

Nuclear reactors with relatively low thermal power (usually few tens of megawatts), but optimized for neutron yields, serve as reactor sources of thermal neutrons. Most of them exploit the fission process of ^{235}U nuclei, initiated by one thermal neutron and yielding on average 2.5 fast neutrons. These latter have to be moderated to thermal energies for neutron scattering applications. This is done by light or heavy water, which result in different energy distributions of the usable neutrons. An “average” 20 MW reactor source provides a thermal neutron flux of about 10^{14} neutrons $\text{cm}^{-2} \text{s}^{-1}$.

The high flux reactor at the Institut Laue Langevin (ILL) in Grenoble, France, has been recognized as the best steady-state source available for the past 3 decades (Munter 2003). Its single fuel element contains highly enriched (93%) ^{235}U (about 8.5 kg), which is controlled by one central rod and surrounded by D_2O as the reflector medium (diameter: 2.5 m). Outside the reflector vessel is a moderator tank of H_2O , which contains three specific moderator cells (one “hot,” at 2,500 K, one “cold,” at 20 K, and one “ultra cold” at even lower temperature), in order to extend the energy (wavelength) spectrum of neutrons available for the instruments. As a result, neutron wavelengths between 0.5 and 30 Å are routinely available. The thermal flux

density is around 2×10^{15} neutrons $\text{cm}^{-2} \text{s}^{-1}$, which (as both calculations and practice indicate) is about the highest that can be reached by a reactor source. The number of neutron scattering instruments at ILL is about 50.

There are a number of nice features of reactor sources that make data handling in general easier and neater than what must be done at pulsed sources. On the other hand, reactors represent technologies and apply techniques that have been used up to their limits already. This, combined with the fact that beam intensities cannot be increased substantially, suggests that it is not the reactor sources where major breakthroughs can be expected in the future.

29.5.1.2 Spallation Sources

Neutrons can also be produced by a process called *spallation*, in which high-energy particles bombard heavy nuclei (the threshold energy for the incident particle is around 10 MeV; usual bombarding energies are well above 100 MeV). By capturing the high-energy particle, the heavy nucleus gets excited and, by an intranuclear cascade, it emits fast neutrons. Finally, when de-excitation takes place, the target nucleus evaporates various nucleons, including slow neutrons. The total neutron production per incident particle is about 20–30 and, what is also important, the energy released is low compared to that of the fission process. Therefore, in principle, there is no upper limit for the available neutron flux.

Protons are the particles that are most frequently applied as bombarding particles. The usual realization of a spallation neutron source consists of a source of H^- ions, a linear accelerator (LINAC), a synchrotron ring, and finally, a target station that contains heavy nuclei. (The mentioning of H^- ions here is no mistake. H^- ions namely are produced with higher efficiency than H^+ ions, i.e., protons (see [Sect. 50.1.6.2 in Chap. 50, Vol. 5](#), on “Particle accelerators”). The H^- ions are directly accelerated by a LINAC, and then, after “stripping” them, the fast protons thus obtained are further accelerated by a synchrotron. Beam channels are connected via suitable moderator cells that set the required energy range of neutrons.

The brightest spallation neutron source at the moment is ISIS ([ISIS 2003](#)) at the Rutherford Appleton Laboratory (Didcot, UK), where a 52-m diameter synchrotron accelerates protons to their final 800 MeV energy (reaching an average current of 200 μA). The tantalum target is bombarded in pulses, at a frequency of 50 Hz. The target is surrounded by four moderator cells; two of them are light water, one is liquid methane at 110 K, and one is fluid hydrogen at 25 K. An extended beryllium reflector concentrates the neutrons to the regions of the moderators. The effective neutron flux is comparable to that available at the best reactor sources.

Spallation sources have the disadvantage that they must use time-of-flight methods constrained by the frequency of the source. Also, for several technical reasons, data evaluation is much more demanding and less transparent than at reactor sources. However, spallation sources with a projected flux of about an order of magnitude higher are being built, which means that in about 10 years they are likely to change the present neutron scattering landscape dramatically.

29.5.2 Optical Elements

After leaving the moderator, neutrons have to be guided to the sample and then, to the detector. During this process, the state of the neutron, or the shape/size of the beam may have to be changed. Pieces of instrumentation that serve these purposes may be called (neutron) optical devices.

29.5.2.1 Collimators

A collimator defines the shape and divergence of the neutron beam. The most basic collimator is a pair of slits, for which the (maximum) beam divergence is defined as $(a_1 + a_2)/L$, where a_1 and a_2 are the widths of the slits, and L is the collimating distance between the slits.

In order to collimate a beam of larger cross section in one dimension, within a reasonable L , Soller-type collimators have to be applied. Such a collimator is composed of a number of equidistant neutron-absorbing blades, separated by spaces. Blades should be as flat and as thin as possible. The theoretical maximum value for the transmission of a Soller collimator with 10° divergence is 96%.

Soller collimators are most frequently used in combination with single-crystal monochromators (see below), for defining the wavelength resolution of the instrument.

29.5.2.2 Neutron Guides

The principle of *mirror reflection* can be exploited for transmitting neutron beams as far as more than 100 m away from the source. As the refractive index for neutrons is very close to, but slightly less than unity for most materials, total reflection can take place for sufficiently smooth surfaces (at grazing incidence) only. The critical angle, γ_c depends on the neutron wavelength and scattering length of the material as $\gamma_c = \lambda(\rho b_{\text{coh}}/\pi)^{1/2}$ where ρ is the number density of atoms. The value of γ_c for nickel, which was the first material used for fabricating neutron waveguides, is 0.1 \AA^{-1} .

A standard neutron guide element is made of boron glass (boron is used for absorbing neutrons that would leave the guide), assembled into a rectangular cross section of dimensions of max. 200 mm (height) \times 50 mm (width). The reflecting (inner) surface of the guide is coated with a thin layer (of the order of 100 nm) of Ni, ^{58}Ni , or a multilayer structure called a “supermirror” (Mezei 1976). This latter structure consists of appropriately chosen pairs of highly uniform thin layers, with the result of extending the total mirror reflection beyond the critical angle. The extension is commonly described by the factor m that refers to multiples of the critical angle of nickel; the best mirrors have m values of 3 to 4 nowadays. Note that the flux gain (as compared to standard Ni coating) is proportional to m^2 .

Modern neutron guides are evacuated in order to minimize absorption and scattering by air. Neutron guides are frequently curved with a curvature radius of a few thousand meters, so that background radiation would be minimized at the location of the instrument. In addition to this, it is not necessary to pack all the instruments tightly around the source. Several guide systems make extensive use of multiplexing, i.e., putting more than one instrument on a guide sequentially. This technique needs careful planning and the use of high quality optical elements such as monochromator crystals.

29.5.2.3 Monochromator Crystals

Neutron sources provide neutrons with a rather wide energy spectrum, almost like a “white beam.” Bragg reflection from single crystals is the most frequently applied means of selecting a well-defined wavelength (band) from the spectrum, which is used extensively at reactor sources.

The price one has to pay for a wavelength selection (that makes the beam suitable for, e.g., crystal structure determination) is that only a maximum of about 1% of the thermal neutron intensity can be used; the rest is scattered into (and absorbed by) the monochromator shielding. It is essential that monochromator crystals possess high scattering length density and low absorption (and incoherent and inelastic) cross section(s). Most frequently, Cu and Ge are applied. It is also for the optimization of the monochromatic intensity that instead of perfect crystals either mosaic crystals, consisting of small crystallites, or mosaic blocks, with orientation parallel to the crystal surface, or mechanically deformed (large) single crystals are used. This means that a wavelength band broadening of up to about 0.5° is “built in” the monochromator crystal, which is consistent with typical neutron beam divergencies.

It can be shown (Sears 1997) that higher intensities can be obtained in reflection geometry than in transmission geometry. (Note that this “reflection” has nothing to do with the phenomenon of mirror reflection, which was concerned in the previous subsection (see Sect. 29.5.2.2), but it just refers to a particular geometrical arrangement, which utilizes Bragg scattering.) By making use of highly sophisticated crystal fabrication technologies, both horizontal and vertical focusing is possible for investigating small samples. In favorable cases, the intensity gain factor can be as high as five for vertical focusing (Riste 1970; Currat 1973).

29.5.2.4 Velocity Selectors and Choppers

These devices make the wavelength-band selection by taking advantage of measuring the neutron flight time; selectors and choppers are usually chosen if the desired band is fairly wide. A “typical” thermal neutron speed is about 2,000 m/s, which means that it takes about 5×10^{-3} s for a neutron to travel 1 m; this, in turn, makes it possible to determine the time-of-flight very accurately over just a few meters.

Mechanical velocity selectors can be used when a continuous beam is required, with a coarse energy (wavelength) resolution. Consequently, they find their main application in the area of small angle neutron scattering (SANS). Modern selectors are made of lightweight neutron-absorbing blades that are slotted into helical grooves on the rotation axis, while the axis is fixed parallel to the beam direction (Wagner et al. 1992). The neutron wavelength can be tuned by setting the speed of rotation: neutrons that are slower or faster than required will hit the blades and will be absorbed. The best wavelength resolution, $\Delta\lambda/\lambda$, that can be achieved with velocity selectors is about 5%.

Choppers, in contrast to selectors, are used for generating pulsed neutron beams. They are essential whenever time-of-flight instruments are built at a reactor source, as there is no other way of knowing when neutrons start their flight path but pulsing the beam. Up-to-date devices are disc choppers rotating about an axis parallel to the beam direction, with a maximum speed of about 20,000 rpm. The discs are made of neutron-absorbing material and contain slits (apertures) that are transparent to neutrons. The pulse frequency is determined by the number of slits and rotation speed. Two disc choppers, working in phase, are sufficient for pulsing and simultaneously monochromating the beam; the wavelength resolution is limited by the rotation speed. In high-precision instruments, single choppers are routinely replaced by two counter-rotating discs, thus increasing the energy resolution. Note that in practice almost always more than two pairs of choppers are installed, to avoid “time-frame overlaps” between incident and scattered beams.

29.5.2.5 Polarizers

Although in this chapter polarization has only been considered very briefly (mostly because of its limited use in chemical applications so far), it is obvious that its importance is growing extremely fast nowadays. The underlying reason for this development is that the *specificity* of the interaction of nuclei with neutrons can be greatly enhanced if polarized beams (and/or polarized samples, where applicable) are put into use.

The two spin states of the neutron can be distinguished by considering their response to an external magnetic field: a spin “+” would be aligned parallel to the field direction (**B**), whereas a spin “−” would be antiparallel to it. In a non-polarized beam of neutrons the frequency of “+” (and of “−”) spins is 50%. The polarization of a neutron beam (in the direction of **B**), as well as the polarizing efficiency of a polarizer, may be characterized by the parameter *P* defined as $P = (N_+ - N_-)/(N_+ + N_-)$, where N_+ and N_- are the numbers of neutrons with spin “+” and “−,” respectively.

Polarizing a neutron beam requires the removal of neutrons in one of the spin states. This can be achieved via several methods, all of which make use of the (sometimes extremely subtle) difference of some quantity for the two spin states. Ferromagnetic single crystals immersed in a magnetic field that can saturate the atomic moments will diffract neutrons with parallel and antiparallel (to the direction of **B**) spins with different intensities at a given angle. The most widely used such monochromating/polarizing material is the so-called Heusler-alloy, Cu_2MnAl (Delapalme et al. 1971). Polarizing (super)mirrors are made of multilayers, in which one of the layer types is ferromagnetic (e.g., the alternation of Fe and Si thin layers would serve the purpose). The critical mirror reflection angles for spins parallel and antiparallel to **B** differ. Perhaps the most promising variation is the application of polarizing filters in which neutrons in one of the spin states absorb preferentially (Tasset and Resouche 1995). Using ^3He , for instance, $P > 0.95$ can be reached, with acceptable transmission.

Handling a polarized beam is not a trivial matter either, since in zero magnetic field the beam becomes depolarized quickly; the application of a “guide field” over the entire flight path is the most common solution to this particular problem.

29.5.3 Detection of Neutrons

The distinct advantage that neutrons can penetrate deeply in most materials becomes a distinct disadvantage when, as a final stage of any neutron scattering experiment, they have to be detected. Namely, since neutrons are scarce (and therefore, expensive), they have to be detected with a good efficiency. Detection of neutrons always means ceasing their free existence (absorption), by involving them in nuclear reactions. This, in turn, means that it is impossible to measure the energy of a neutron directly: characteristic energy transfers during scattering processes are at most of the order of meV, whereas energies characteristic of suitable nuclear reactions are of the order of MeV. This is one of the important reasons why time-of-flight methods had to be invented in the field of neutron scattering.

Nuclear reactions that are most frequently applied for detecting neutrons are listed in [Table 29.2](#). The resulting particles are all highly energetic and possess electric charge. This latter property can be exploited in the actual detection process.

A *proportional counter* designed to detect neutrons consists of an anode, surrounded by pressurized ^3He or $^{10}\text{BF}_3$ gas. The charged particles, produced by the absorption of neutrons,

■ Table 29.2

Nuclear reactions for neutron detection

Reaction	Cross section/ <i>b</i> (for 25 meV neutrons)	Particles generated	Total energy/MeV
$n + {}^3\text{He}$	5,333	Proton, ${}^3\text{H}$ (triton)	0.77
$n + {}^6\text{Li}$	941	${}^3\text{H}$, ${}^4\text{He}$	4.79
$n + {}^{10}\text{B}$	3,838	${}^4\text{He}$, ${}^7\text{Li}$ (+ γ photon)	2.30
$n + {}^{235}\text{U}$	681	Fission neutrons	1–2

ionize the gas and then, the emitted electrons are accelerated toward the anode and ionize more gas. This avalanche-like process initiates a discharge at the high voltage (1–5 kV) anode. The charge is proportional to the total energy of the reaction, so that neutrons can easily be discriminated against gamma-photons. Proportional counters can reach efficiencies up to about 80% depending on the neutron wavelength. Following the invention of Charpak (1968), large, position-sensitive area detectors could be fabricated by installing more (up to hundreds of) anode wires within one gas chamber. Perhaps the most promising development in this area is the “micro pattern gas counter” (Oed 2001). The best spatial resolution is about 1 mm, and the highest count rate is roughly 20 kHz/mm².

Another possibility is to make neutron-sensitive *scintillation detectors*, in which neutrons are absorbed by ${}^6\text{Li}$ (mixed with ZnS and located within a glass matrix) and the light quanta emitted are collected usually by photomultipliers.

For a more detailed account on radiation detection, see the work of Knoll (1999).

29.5.4 Examples of Complete Neutron Scattering Instruments

Having been acquainted with the components of neutron scattering instruments, two types of complete instruments will be described briefly here: one is “simple,” a standard powder diffractometer, while the other is one of the most complicated, a neutron spin echo spectrometer.

29.5.4.1 Neutron Powder Diffractometer

This section is restricted to the description of an “angle dispersive” device (see ▶ Sect. 29.3.1.4). The instrument that is capable of recording neutron powder diffraction patterns is also called “two axis” neutron spectrometer, after the two principle axes “monochromator-sample” and “sample-detector”; the original design is due to Hewat and Bailey (1976).

This is a very popular and useful instrument and therefore virtually every reactor source has at least one of them. Here the “PSD” powder diffractometer, installed at the Budapest Research Reactor (Hungary), is introduced briefly (Sváb et al. 1996). A top view of PSD is shown in ▶ Fig. 29.6.

The PSD diffractometer is placed on a tangential thermal neutron beam of a medium flux reactor source. Primary collimation is done before the monochromator. The wavelength most

■ Fig. 29.6

Schematic view of the “PSD” neutron powder diffractometer, installed at the 10 MW Budapest Research Reactor (Sváb et al. 1996)

frequently selected from the primary neutron spectrum is around 1 \AA , for which, in the case of a Cu(111) monochromator single crystal (with a mosaic spread of $16'$), a neutron flux density of about $10^6 \text{ n cm}^{-2} \text{ s}^{-1}$ can be achieved at the sample position.

Scattered neutrons are detected at a distance of 1.2 m from the sample by 60 cm position-sensitive ^3He detectors (placed within appropriate shielding), which span a scattering angle range of 25° . In order to cover the whole scattering-angle range up to 110° , data are collected at five different positions of the detector system. The resolution that can be routinely achieved by such a setup is about 10^{-2} , in terms of $\Delta d/d$.

The PSD diffractometer can be used for either standard powder diffraction studies (see, e.g., Somogyvári et al. 2002b), but also, its design allows studying liquids and amorphous materials (see, e.g., Jóvári et al. 2001).

29.5.4.2 Neutron Spin Echo Spectrometer

The main point about neutron spin echo is the manipulation with neutron spins, which has to be carried out rather precisely; this requirement dominates the instrumental realization. (Note that neutron spin echo spectrometers, at present, can only be found at reactor sources.) A schematic drawing of a “generic” spin echo instrument is given in Fig. 29.7.

■ Fig. 29.7

Schematic view of a neutron spin echo spectrometer

Initial wavelength selection is done by a mechanical (rotating) velocity selector, since energy resolution is not an important issue here. Polarized neutrons may be produced by reflection by a magnetic multilayer mirror. Essential parts are the so-called “flippers.” These devices, consisting of flat coils, can change the direction of the neutron spin (which is extremely sensitive to external magnetic fields).

The first ($\pi/2$) flipper rotates the spin to be orthogonal to the first (longitudinal) precession field; the aim of this step is to define the exact initial spin state. During the travel over the first precession coil (which, ideally, is as long as possible, operating at as high a magnetic field as possible), neutron spins acquire a total precession angle. This precession angle is turned round (by 180°) by a π -flipper, situated at (or at least, as close as physically possible to) the sample. Then comes the second precession field, exactly the same as the first one was; as a result, neutrons that travel at the same velocity as they did before the sample (elastic scattering, no energy exchange between the neutron and the sample) will arrive at the end of the second precession coil in the same spin state as they were before entering the first precession coil. Longitudinal polarization is recovered by a final $\pi/2$ flipper that is followed by the analyzer; the analyzer accepts neutrons of one longitudinal spin state, which neutrons then hit the detector. The count rate is proportional to the cosine of the total (cumulative) precession angle.

Acknowledgment

The author wishes to thank Dr. Erzsébet Sváb for her critical reading of the manuscript and suggestions.

Abstract: This chapter presents the basic principles of activation analysis and details its different types. Emphasis is given to instrumental neutron activation analysis and radiochemical separations for the determination of trace and ultra-trace elements. Location sensitive analysis is also included.

30.1 Introduction

In their early experiments with rare earth elements, Georg Hevesy and his student Hilde Levi observed that some elements became highly radioactive when irradiated with neutrons. Hevesy recognized that this method could be used for the qualitative detection of the rare earth elements, and he and Levi were the first to report on the new method of activation analysis (Hevesy and Levi 1936). At that time, element discrimination was based on the half-life rather than the energy of the emitted radiation.

However, the neutron activation analysis (NAA) method was not used much after its discovery. Only when the developing reactor technology of the 1950s made more neutron sources available did a rapid growth in NAA occur. It should be noted that the initial development was combined with skillful advancements in radiochemistry since the radionuclides of interest had to be separated from interfering activities. This growth was further enhanced when proportional counters were replaced with energy-resolving gamma-ray detectors, first scintillation detectors, and later high-resolution semiconductor diode-type detectors coupled to multichannel pulse height analyzers.

By the early 1960s, NAA was an accepted method for highly sensitive single and multielement determinations in many applications and had expanded to the use of other activation methods for many investigations. The developments in activation analysis; their impact on analytical chemistry and trace element research; and the applications of activation analysis in environmental sciences, biology, medicine, archeology, criminology, geo- and cosmochemistry, and industry are well documented in the series of conferences on Modern Trends in Activation Analysis (MTAA), the first held in 1961 at the Texas A&M University in College Station (Brown 1961). However, in recent years, its unique position has been challenged by increasingly sensitive and versatile elemental analysis techniques, such as atomic absorption spectrometry, inductively coupled plasma optical emission spectrometry (ICP-OES), and mass spectrometry (ICP-MS), which are widely used today in applications that had previously been a domain for NAA.

Nevertheless, a variety of activation analysis techniques have emerged that complement classical NAA and increase its capabilities. Consequently, activation analysis (AA) techniques still occupy a solid niche in analytical chemistry because of the nuclear principle of analysis with its specific advantageous characteristics as presented in this chapter.

30.2 Principles of Activation Analysis

30.2.1 Activation Reactions

The basic idea of activation analysis is that irradiation by appropriately chosen penetrating radiation induces nuclear reactions in the nuclei of the analyte, and the reaction products (which usually are radioactive) emit radiations characteristic of the identity and quantity of the

■ Fig. 30.1

The activation analysis principle

elements to be determined. This process is depicted schematically in Fig. 30.1, which shows the possibilities with respect to the type of inducing radiation, the mode of decay, and the type of induced radiation.

While neutrons, charged particles, and gamma photons can be equally used for irradiation, the most frequent choice is the irradiation by neutrons. Since the neutron lacks an electric charge, it is more penetrating and makes the analysis of bulk samples possible. Additionally, the high cross-sections of neutron-induced reactions offer extremely high analytical sensitivities for many elements.

The product nuclide can be either stable or radioactive. In the former case, only gamma de-excitation occurs, resulting in an essentially prompt emission of discrete gamma radiation of usually high energy, up to 8–10 MeV. In the latter case, the radioactive reaction product undergoes one or more decays, and is eventually transformed into a stable nuclide. The radioactive decay is characterized by its half-life, which can be anywhere from a fraction of a second to many years. Although the continuous spectrum of beta electrons or positrons can also be utilized for activation analysis, it is most practical to observe the discrete gamma radiation of the reaction product. This is due to the higher selectivity and penetration of the gamma decay radiation.

The number of radioactive nuclides formed per unit time in a nuclear reaction is determined by the reaction rate:

$$R = \int_{E_{\min}}^{E_{\max}} N_0 \sigma(E) \phi(E) dE \quad (30.1)$$

where $\sigma(E)$ is the *differential cross section* (cm^2), $\phi(E) dE$ is the flux or *fluence rate* of particles with kinetic energy between E and $E + dE$ impinging on the sample (the differential flux $\phi(E)$ is measured in units of $\text{cm}^{-2} \text{s}^{-1} \text{eV}^{-1}$), and N_0 is the number of target atoms of the nuclide that take part in the given reaction. The latter is connected with the mass m (g) of the given element in the sample:

$$N_0 = \frac{m}{M} N_A \quad (30.2)$$

where M is the molar mass of the element (g mol^{-1}), θ is the isotopic abundance and N_A is Avogadro's constant:

$$N_A = 6.02214179(30) \times 10^{23} \text{mol}^{-1}. \quad (30.3)$$

For *thermal neutrons*, the absorption cross section is usually inversely proportional to the neutron speed ("1/v" law), and [Eq. \(30.1\)](#) is reduced to the simple product:

$$R_{\text{th}} = N_0 \bar{\sigma}_{\text{th}} \Phi_{\text{th}} = \frac{2}{\sqrt{\pi}} N_0 \sigma_0 \Phi_{\text{th}} \quad (30.4)$$

where σ_0 is the cross section for the most probable speed of $2,200 \text{ m s}^{-1}$ (neutron energy of 0.0253 eV) that corresponds to the maximum of the Maxwellian speed distribution at room temperature ($T = 293.15 \text{ K}$), and Φ_{th} is the thermal neutron flux. The average neutron energy at room temperature is 0.038 eV . Sometimes, Maxwellian averages for a certain equilibrium temperature (usually 300 K) are given, which are obtained by integration of energy-differential cross sections between the limits of 10^{-5} and 10 eV .

At energies higher than about 1 eV , the reaction cross sections exhibit huge variations with the incident neutron energy and are called resonances.¹ Up to about 0.1 MeV , however, the differential flux, $\Phi(E)$, of partially thermalized neutrons is approximately proportional to $1/E$. Hence, an analogous expression can be derived for epithermal neutron activation:

$$R_{\text{epi}} = N_0 I_0 \Phi_{\text{epi}} \quad (30.5)$$

where I_0 is the integral over all resonances:

$$I_0 = \int_{E_{\text{Cd}}}^{\infty} \frac{\sigma(E)}{E} dE \quad (30.6)$$

and Φ_{epi} is the epithermal flux per unit $\ln(E)$. The lower limit of integration is the effective cut-off energy for a Cd filter, usually about 0.5 eV , which is used to absorb the thermal part of the neutron spectrum, while the practical upper limit is 0.1 MeV .

The *thermal neutron cross section*, σ_0 , and the *resonance integral*, I_0 , are conveniently measured in barn (b) units:

$$1 \text{ b} = 10^{-24} \text{cm}^2. \quad (30.7)$$

This unit for the atomic cross section is very convenient because the molar cross section becomes

$$\sigma N_A \approx 0.602(\sigma/\text{b}) \frac{\text{cm}^2}{\text{mol}}. \quad (30.8)$$

The ratio of the thermal cross section to the resonance integral

$$Q_0 = \frac{I_0}{\sigma_0} \quad (30.9)$$

is used to correct for epithermal neutron activation. For certain nuclides, its value is much larger than unity.

For thermal and epithermal neutrons, the most important activation reactions are neutron capture (n, γ) and fission (n, f); for fast neutrons, other reactions, such as (n, n'), (n, p), (n, α), ($n, 2n$), and (n, pn) reactions, dominate. These fast reactions can occur only if the neutron energy exceeds the threshold E_T . The individual rate for a given type of reaction depends on

$\sigma(E)$, which is also called the excitation function in this range. For a non-monochromatic beam, the reaction rate is obtained by numerical integration of [Eq. \(30.1\)](#).

For a *fission neutron spectrum*, it is possible to define an average cross section:

$$\bar{\sigma}_f = \frac{\int_{E_T}^{\infty} \sigma(E) \phi(E) dE}{\int_{E_T}^{\infty} \phi(E) dE} \quad (30.10)$$

which can be used to calculate the reaction rate of fission neutrons the same way as for thermal neutrons:

$$R_f = N_0 \bar{\sigma}_f \Phi_f. \quad (30.11)$$

Tabulated values of thermal cross sections, resonance integrals, ^{235}U fission-averaged cross sections, and 14 MeV neutron cross sections are available in the literature (Mughabghab et al. 1981; Mughabghab 1984; IAEA 1987; OECD 1994). Recommended data for the most important nuclides can be found in the Appendix of this volume.

The reaction rate for charged particle-induced reactions can be calculated in a similar way, i.e., according to [Eq. \(30.1\)](#), but the flux is usually substituted by the beam intensity I .² The charged particles penetrating the sample continuously lose energy due to their interaction with the atomic electrons. Since the cross section is energy dependent, the reaction rate will vary accordingly. This energy loss per unit path length along direction x is called the *stopping power*³

$$S = -\frac{dE}{dx}. \quad (30.12)$$

Hence, an average cross section can be introduced to take into account the effect of energy loss:

$$\bar{\sigma}_f = \frac{\int_{E_0}^0 \sigma(E) \frac{dx}{dE} dE}{\int_{E_0}^0 \frac{dx}{dE} dE} = \frac{\int_{E_0}^{E_0} \sigma(E) \frac{dE}{S}}{r}. \quad (30.13)$$

Here E_0 is the initial particle energy and

$$r = \int_0^{E_0} \frac{dE}{S} \quad (30.14)$$

is the range of penetration, defined as the integral of the inverse stopping power, [Eq. \(30.12\)](#).⁴ The peculiarities of charged-particle reactions are discussed in more detail in [Chap. 32](#) of this Volume.

In all cases, the reaction rate is proportional to the amount of material to be determined, some value of the effective reaction cross section, and the fluence rate. Taking into account [Eq. \(30.2\)](#), the following expression is obtained for the reaction rate R (s^{-1}):

$$R = N_0 \sigma \Phi = m \left(\frac{\theta}{M} N_A \right) \sigma \Phi. \quad (30.15)$$

This expression is valid, however, only for thin irradiated targets where absorption is negligible. Since all nuclides in the sample contribute to the absorption, this effect can be accounted for by introducing a macroscopic absorption cross section (cm^{-1}):

$$\Sigma_a = \sum_i n_i \sigma_{a,i} \quad (30.16)$$

where n_i is the number density (cm^{-3}) of the i th component, and $\sigma_{a,i}$ is the corresponding microscopic (i.e., atomic) absorption cross section (cm^2), which accounts for all reactions leading to absorption or scattering out of the beam.⁵ For a collimated beam, the attenuation follows the exponential law, hence:

$$R = R_0(1 - e^{-\Sigma_a l}) \quad (30.17)$$

where l is the linear target thickness (cm), and R_0 is the reaction rate for an ideally thin target.

It is customary to introduce a *self-shielding factor*, G , which is the ratio of thick target-to-thin target rates. For a thick foil or slab in a collimated beam, this self-shielding factor is given by:

$$G_{\text{coll}} = \frac{1 - e^{-\Sigma_a x}}{\Sigma_a x}. \quad (30.18)$$

For a foil in a diffused isotropic radiation field, the self-shielding factor is given by:

$$G_{\text{isotr}} = \frac{1 - e^{-\Sigma_a x}(1 - \Sigma_a x) + (\Sigma_a x)^2 \text{Ei}(-\Sigma_a x)}{2\Sigma_a x} \quad (30.19)$$

$$\text{Ei}(-\Sigma_a x) = - \int_{\Sigma_a x}^{\infty} \frac{e^{-z}}{z} dz$$

where Ei is the exponential integral. For more complex cases, convenient formulae can be found, e.g., in De Corte (1987a).

30.2.2 Activation Equation

The activation process and the resulting decays of excited nuclear states are controlled by the laws of nuclear physics and can be fully described by mathematical equations. In the activation reaction, a radionuclide is formed and subsequently decays, as depicted in [Fig. 30.1](#).

The rate of change of the number of radioactive atoms N is thus determined by the differential equation:

$$\frac{dN}{dt} = R - \lambda N \quad (30.20)$$

which accounts for simultaneous production and decay.

Integration gives:

$$N(t) = R(1 - e^{-\lambda t})/\lambda \quad (30.21)$$

where R is the reaction rate from [Eq. \(30.15\)](#), and λ is the decay constant (s^{-1}), giving the probability of decay per unit time. The directly observable quantity is the activity, which is the number of disintegrations per unit time:

$$\begin{aligned} A(t) &= \lambda N(t) = R(1 - e^{-\lambda t}) \\ &= m \left(\frac{\theta}{M} N_A \right) \sigma \Phi (1 - e^{-\lambda t}) \\ &= A_S (1 - e^{-\lambda t}). \end{aligned} \quad (30.22)$$

where A_S denotes the saturation activity, which is given by:

$$A_S = R = m \left(\frac{\sigma \theta}{M} N_A \right) \Phi \quad (30.23)$$

and the expression in brackets is the so-called saturation term. Saturation is reached only when the irradiation time, t_A , is long compared to the decay half-life:

$$T_{1/2} = \frac{\ln 2}{\lambda}. \quad (30.24)$$

For prompt gamma rays, the nuclear levels involved have extremely short half-lives, typically 10^{-15} – 10^{-9} s. Hence this term vanishes and the activity $A(t)$ is always at its saturation value, which is simply equal to the constant reaction rate R according to [Eqs. \(30.22\)](#) and [Eq. \(30.23\)](#).

The induced activity must be measured in order to determine the elemental composition of the sample. This is usually done after the irradiation. The sample will be irradiated for a time, t_A ; the nuclide in the sample will decay for some time, t_D , and will be counted for some time, t_C .

The number of counts accumulated by the detector will be:

$$\begin{aligned} N_c(t_C) &= \varepsilon P A(t_A) e^{-\lambda t_D} \int_0^{t_C} e^{-\lambda t} dt \\ &= \varepsilon P A_S (1 - e^{-\lambda t_A}) e^{-\lambda t_D} (1 - e^{-\lambda t_C}) / \lambda \\ &= A_0 e^{-\lambda t_D} (1 - e^{-\lambda t_C}) / \lambda \\ &= m \left(\frac{P \sigma \theta}{M} N_A \right) \varepsilon \Phi S D C t_C \end{aligned} \quad (30.25)$$

where A_0 is the observed activity, i.e., count rate right after activation referred to later as decay-corrected counting rate; P is the emission probability per decay of the observed radiation (usually gamma or beta); and ε is the corresponding detection efficiency. In [Eq. \(30.25\)](#), terms for the saturation (S), decay (D), and counting (C) correction terms were introduced by using [Eq. \(30.15\)](#):

$$\begin{aligned} S &= (1 - e^{-\lambda t_A}) \\ D &= e^{-\lambda t_D} \\ C &= (1 - e^{-\lambda t_C}) / (\lambda t_C). \end{aligned} \quad (30.26)$$

As shown in [Eq. \(30.25\)](#), the number of counts is directly proportional to the mass of the analyte. The quantities in brackets are characteristic of the observed isotope of the analyte element, and ε and Φ are the features of the detector and the irradiation facility, respectively. The correction factors S , D , C have to be optimized to obtain the highest possible statistics at the lowest possible integral value of background counts.

It is instructive to examine the limits of long and short half-lives with respect to the measurement time for the case $t_D = 0$ (i.e., $D = 1$). Substituting λ with $T_{1/2}$ in [Eq. \(30.25\)](#), one obtains:

$$\begin{aligned}\lim_{T_{1/2} \rightarrow \infty} N_c(t_C) &= \varepsilon PR \frac{t_A t_C}{T_{1/2}} \ln 2 \\ \lim_{T_{1/2} \rightarrow 0} N_c(t_C) &= \varepsilon PR \frac{T_{1/2}}{\ln 2}.\end{aligned}\quad (30.27)$$

Hence, for long half-lives the counting statistics can be improved by increasing the activation and counting times; for short half-lives, the best statistical accuracy is limited by the half-life itself even if the counting immediately follows the activation ($D = 1$). In a real situation, of course, additional limitations arise due to the background count rate.

The induced activity can also be instantaneously measured during the activation. In this case, the irradiation and counting times are equal and the number of counts is governed by a simpler equation:

$$\begin{aligned}N_c(t_C) &= \varepsilon P \int_0^{t_C} A(t) dt \\ &= \varepsilon P A_0 \left(1 - \frac{1 - e^{-\lambda t_C}}{\lambda t_C} \right) t_C \\ &= m \left(\frac{P \sigma \theta}{M} N_A \right) \varepsilon \Phi (1 - C) t_C.\end{aligned}\quad (30.28)$$

For short half-lives, C approaches zero and the counting increases linearly with the measurement time. This is automatically the case when prompt radiation is detected instead of decay radiation. For this reason, prompt gamma activation analysis is inherently more sensitive than delayed gamma activation analysis.

30.2.3 Standardization

[Equations \(30.25\)](#) and [\(30.28\)](#) provide the basis for quantitative activation analysis, hence the unknown mass m_x of analyte x can be determined if all other parameters are accurately known. This is seldom the case, so a comparative analysis with a standard sample containing a known mass, m_s , of the same element is usually performed. If the standard matches the size and composition of the unknown sample, the ratio of counts $N_{c,x}/N_{c,s}$ can be used for the calculation of the unknown mass. Applying [Eq. \(30.25\)](#) one obtains:

$$m_{x(\text{unk})} = m_{x(\text{std})} \frac{(N_{x(\text{unk})}/t_{C(\text{unk})})}{(N_{x(\text{std})}/t_{C(\text{std})})} \frac{(P \sigma \theta / M)_{x(\text{std})}}{(P \sigma \theta / M)_{x(\text{unk})}} \frac{\varepsilon_{\text{std}} \Phi_{\text{std}}}{\varepsilon_{\text{unk}} \Phi_{\text{unk}}} \frac{S_{\text{std}} D_{\text{std}} C_{\text{std}}}{S_{\text{unk}} D_{\text{unk}} C_{\text{unk}}}. \quad (30.29)$$

If the conditions for both irradiation and counting are identical, all parameters cancel, and the ratio of masses becomes equal to the ratio of counts:

$$m_{x(\text{unk})} = m_{x(\text{std})} \frac{N_{c(\text{unk})}}{N_{c(\text{std})}}, \quad (30.30)$$

which is the basis of relative standardization.

It may be difficult and/or time consuming to prepare accurate standards for all possible elements; hence, a monostandard method has been introduced in neutron activation analysis. The so-called k_0 -standardization method is based on the recognition that the ratio of nuclear constants for analyte x and a chosen standard s in [Eq. \(30.29\)](#) can be combined into a single constant (Simonits et al. 1975):

$$k_{0,s}(x) = \frac{(P\sigma\theta/M)_x}{(P\sigma\theta/M)_s}. \quad (30.31)$$

This constant can either be calculated or measured accurately with respect to an adopted standard, which practically serves as the fluence monitor. If the monitor, s , which is usually a gold foil, is co-irradiated with the sample, the mass of the analyte is determined as:

$$m_x = m_{\text{Au}} \frac{(N_{\text{c(unk)}}/t_{\text{C(unk)}})}{(N_{\text{c(Au)}}/t_{\text{C(Au)}})} \frac{1}{k_{0,s}(x)} \frac{\varepsilon_{\text{Au}}\Phi_{\text{Au}}}{\varepsilon_{\text{unk}}\Phi_{\text{unk}}} \frac{S_{\text{Au}}D_{\text{Au}}C_{\text{Au}}}{S_{\text{unk}}D_{\text{unk}}C_{\text{unk}}}. \quad (30.32)$$

The above formulas only illustrate the underlying principles. The practical realization is more complicated and is discussed in the context of the various methods of activation analysis in the following sections.

30.2.4 Advantages and Disadvantages of Activation Methods

All nuclear activation methods have several distinct advantages and disadvantages inherent in the underlying physical principle of the method with some unique strengths and weaknesses attributable to the individual activation and measurement technique. They are methods for the determination of the amount of an element, or more correctly, the amount of an isotope representing the element of interest.

The generation of the analytical signal through a nuclear reaction makes the determinations virtually independent of the chemical form of the elements and their chemical environment. The determinations are, to a certain degree, independent of the sample matrix, and in most cases, can be made free of any blank. The blank-free attribute is aided by the fact that the methods require much less sample manipulation than other techniques and they are not as susceptible to reagent and laboratory contamination. The reduction or elimination of blank contributions includes radiochemical processing performed after irradiation (see [Sect. 30.5](#)), where inadvertent chemical contamination would add only nonactivated analyte that would not contribute to the measured signal.

The range of elements accessible to analysis by nuclear activation methods covers virtually all elements with most of their natural and some artificial isotopes. The nuclear methods, NAA, CPAA, and PAA (see [Sect. 30.3](#)), through their variety of techniques, provide very high sensitivities for a large number of elements. This resulted in the early application of nuclear methods in trace and ultra-trace element analysis. In many instances, nuclear methods have been and continue to be at the forefront of analytical developments concerning the determination of elements at trace and ultra-trace levels. This includes developments in biological, medical, and environmental research, as well as in industrial development, such as in high-tech materials. However, these sensitivities are not equally distributed for the elements in the periodic table or for their isotopes used in the assays. Instrumental neutron activation analysis (INAA) using thermal neutrons can determine two thirds of the elements in the periodic table with sensitivities at the mg/kg (ppm) levels or below, including a number of elements

approaching ng/kg levels. However, INAA is not suitable for many light elements; it is also not suitable for tin and lead, which represent two important examples of heavy elements (although the latter can be determined by CPAA).

Another outstanding feature of activation analysis is the selectivity of the methods. Not only can the decay characteristics of the activation product be used for unique identification and quantitation, but selection and exploitation of a variety of physical parameters in activation, decay, and measurement can optimize the sensitivity and selectivity for the desired determination. Moreover, optimization of the physical parameters is well predicted by virtue of the known activation and measurement relationships.

A prominent feature of nuclear analytical methods is the capability of simultaneous multielement analysis. Activation of a sample will induce activity in many elements contained in the sample. Optimized irradiation and counting cycles involving a combination of various NAA procedures applied to a sample of coal have produced results for more than 50 elements (Germani et al. 1980). The analysis of 20–25 elements in biological and environmental materials can be regarded as routine for INAA (Becker et al. 1994).

In some cases, activation analysis may be regarded as a nondestructive method, i.e., the sample is not significantly altered, neither visually nor chemically. This attribute is obviously exploited in the aforementioned sequential multielement determinations. It is a valuable characteristic for situations where the sample needs to be preserved, such as forensic objects or irreplaceable historical samples, such as ancient coins or paintings. For general analytical practice, this valuable feature can allow reactivation for the determination of additional elements or for full reanalysis, as well as the use, with appropriate precautions, of another analytical method.

Some often cited disadvantages of activation analysis include the requirements of dedicated facilities, high equipment cost, and long turn-around time. These cannot be discounted as myth or as misguided competitive arguments. Many activation analysis procedures are capable of rapid analysis with analysis times ranging from seconds for chlorine (Grass et al. 1994) or oxygen (James and Zeisler 2001), to several minutes for oligo-element determinations in air particulate filters offering 100 sample capacities in an 8 h shift (Heller-Zeisler et al. 1999). The measurement of a full complement of elements with longer-lived activation products requires longer analysis times due to the required irradiation, decay, and measurement times (Greenberg et al. 1984). These long analysis times have kept activation analysis out of most industrial processes, with a few exceptions that exploit PGAA and short-lived nuclides, such as coal conveyor belt monitoring and borehole logging (Clayton and Wormald 1983; Borsaru et al. 2001). The cost involved in operating a neutron source, such as a reactor, is generally not solely charged to the activation analysis users and is usually for multielement determinations in an array of samples at a nominal per unit amount. Other activation sources may be operated at costs comparable to nonnuclear instrumentation. The capital and operational costs for nuclear spectroscopy equipment are certainly at or below the cost of many of today's analytical spectrometry instruments. However, the requirements for a dedicated laboratory facility that meets regulations for radiological safety may be a formidable obstacle to the use of activation analysis.

30.3 Types of Activation Analysis

It is probably easiest to classify activation analysis according to the type of nuclear reaction used to generate the analytical signal. As shown in  Fig. 30.1, the commonly used activation

particles are neutrons of various energy, charged particles, and photons. The following sections will summarize the many forms of activation analysis and discuss some of their advantages and disadvantages. A brief description of the sources of activation particles is included in the respective sections.

30.3.1 Neutron Activation Analysis (NAA)

NAA is the most common form of activation analysis. The activation reaction is induced by the interaction of a neutron with the nucleus of an analyte element. Depending on the energy of the incident neutron and the reaction cross sections of the target elements, different types of reactions can take place, leading to activation products as described in ▶ Sect. 30.2. This reaction is commonly followed by the measurement of a nuclide-characteristic de-excitation step (radioactive decay). It is this characteristic gamma-ray decay that is commonly used in the detection and determination of the element of interest.

30.3.1.1 Neutron Sources

The most practical neutron source for NAA is a nuclear reactor, which produces neutrons via the nuclear fission process (see ▶ Chap. 57 in Vol. 6). Many research reactors are equipped with irradiation facilities that provide a stable, well-tailored, isotropic neutron field with sufficiently high flux. Low-energy (thermal) neutrons comprise the most important part of the reactor spectrum; hence the degree of moderation is an important parameter. The irradiation channels are usually created in moderator layers, such as a thermal column or a Be reflector blanket.

When a reactor is not available, or a portable neutron source is required, isotopic sources (Shani 1990), small mobile reactors (Chung 1990), or neutron generators (Csikai 1987) are possible alternatives. The attainable neutron fluence rates of the various neutron sources are compared in ▶ Table 30.1.

30.3.1.2 Thermal Neutron Activation Analysis (TNAA)

Thermal neutrons, also called slow neutrons because their most probable speed is low ($v \approx 2,200 \text{ m/s}$) with a mean energy of 0.038 eV. Due to the $1/v$ -dependence of the capture cross

■ Table 30.1
Important types of neutron sources used in NAA

Source	Usable neutron flux or production rate	
	Thermal	Epithermal or fast
Large research reactor (>10 MW)	$(10^{14}\text{--}10^{15}) \text{ cm}^{-2} \text{ s}^{-1}$	$(10^{11}\text{--}10^{12}) \text{ cm}^{-2} \text{ s}^{-1}$
Small research reactor (>100 kW)	$(10^{12}\text{--}10^{13}) \text{ cm}^{-2} \text{ s}^{-1}$	$(10^{11}\text{--}10^{12}) \text{ cm}^{-2} \text{ s}^{-1}$
Neutron generator		$(10^9\text{--}10^{12}) \text{ s}^{-1}$
Alpha sources		10^6 s^{-1}
^{252}Cf fission source		$2.34 \times 10^9 \text{ s}^{-1} \text{ mg}^{-1}$

section, thermal neutrons have the greatest probability of interacting with most target elements. For this reason, thermal NAA is the most simple and universal activation analysis technique and remains the workhorse in the activation analysis laboratory.

The nondestructive instrumental (INAA) and destructive radiochemical (radiochemical neutron activation analysis – RNAA) procedures of this method are discussed later in this chapter. Specific problems, such as chain decays, cyclic activation, and interferences, as well as typical applications have recently been discussed by Alfassi (2001) and the references therein.

30.3.1.3 Epithermal Neutron Activation Analysis (ENAA)

Neutrons with slightly higher energies (1 eV to 100 keV) than thermal neutrons are called epithermal neutrons. They serve as activation particles in this special type of NAA, which is based on the selective activation of certain nuclides the cross sections of which exhibit strong individual resonances in the lower part of this energy range. Special facilities to enhance ENAA reactions over thermal NAA are employed in the irradiation location. To suppress the thermal neutron activation of the matrix elements, the sample is covered with a thermal neutron absorber, such as cadmium or boron. As a result, high sensitivities can be attained despite the relatively low activity induced by the epithermal neutrons. Specific problems and typical applications of ENAA have been discussed by Alfassi (2001).

30.3.1.4 Fast Neutron Activation Analysis (FNAA)

Neutrons with energies greater than 0.1 MeV are called fast neutrons. The fission spectrum of a light-water-moderated reactor provides as many fast neutrons as thermal neutrons. Therefore, fast neutron activation of certain elements via (n,p) reactions is a very selective technique, complementary to thermal and epithermal NAA. A typical example is Fe, for which the $^{56}\text{Fe}(\text{n,p})^{56}\text{Mn}$ activation reaction produces a better gamma-ray emitter than the thermal capture reaction.

A common and particularly useful form of FNAA is the instrumental analysis with 14 MeV neutrons that are produced by small accelerators known as neutron generators (14 MeV INAA). This technique is discussed in detail in [Chap. 32](#) of this Volume.

30.3.1.5 Neutron-Induced Prompt Gamma Activation Analysis (PGAA)

PGAA is an instrumental procedure that makes use of the prompt gamma-ray emissions that occur immediately after neutron capture during the de-excitation of the newly formed compound nucleus. The capture can produce nuclear states with energies up to about 11 MeV above the ground state, which usually decay through a cascade of gamma rays. The complexity and broad energy range of these spectra distinguishes PGAA from most other NAA procedures (Molnár and Lindstrom 1998).

The main advantage of PGAA is the ability to obtain gamma-ray spectra from the neutron capture of nuclides that do not produce radioactive isotopes through the (n, γ) reaction. PGAA favorably complements NAA through efficient reactions with the light elements that generally do not produce radionuclides, and also a number of higher *Z* elements with high cross sections

the normal decay products of which may be difficult to measure in the presence of high activities induced in certain matrices. The light elements most often investigated are H, B, C, N, Si, P, S, and Cl, and the heavier elements are Cd, Sm, and Gd. Recent advances and a detailed description of the technique of PGAA can be found in the works of Yonezawa (2001) and Molnár (2003). Specific features of the technique are discussed in [▶ Chap. 31](#) of this Volume.

30.3.1.6 Comparison of NAA Methods

NAA procedures are applicable to most element analysis problems, but are most broadly used to determine trace elements in biological, environmental, geological, and industrial materials. Since many factors, such as chemical composition of the sample and irradiation, decay, and measurement procedures determine the achievable sensitivity for a specific element, [Fig. 30.2](#) shows a “typical” sensitivity for the elements determined by INAA and PGAA in biological and environmental matrices. These numbers have been obtained by a survey of the authors’ analytical experience. Depending on the elemental composition and optimization opportunities as well as restrictions by dominant matrix activities, the quoted sensitivities can be better or worse by orders of magnitude.

As a rule of thumb, it can be stated that thermal NAA is the most sensitive, ENAA the most selective, while PGAA is the most universal of the neutron activation techniques discussed in the present section. There are ways to further enhance the analytical sensitivity and selectivity of NAA via radiochemical separations as discussed in [▶ Sect. 30.5](#).

■ Fig. 30.2

Typical instrumental sensitivities in mg/kg (E + 4 denotes 10^4 , etc.) for thermal NAA of elements in light element matrix (e.g., organic, silicate) biological and environmental samples

[illegible]

30.3.1.7 In Vivo Neutron Activation Analysis

The successful establishment of nondestructive NAA as an analytical technique for the study of the elemental composition of biological materials promoted the evaluation of its feasibility for determining some elements in living subjects by *in vivo* NAA (Anderson et al. 1964). From this first demonstration, the technique rapidly evolved (Ellis 1990). Currently, it is possible to measure total-body H, N, O, Na, P, Cl, K, and Ca and to determine most of the same elements in parts of the body, such as a limb or an organ. In special cases, additional important elements such as I (in thyroid), Cd (in kidney), as well as Mn, Fe, and Cu have been reported. The results of the measurements are used in clinical studies of mineral metabolism, nutrition, body physiology, and alterations in composition from clinical or environmental causes and diseases such as osteoporosis.

The principle of *in vivo* NAA is simple and comparable to the other forms of NAA discussed here. The subject or part of the body is exposed to neutrons from a suitable source and prompt gamma rays, as summarized by Morgan (2000), or delayed gamma rays, as for example described by Ma et al. (2000), are measured. The desired results are calculated by comparison with similar measurements on phantoms with known composition. Neutron sources are most often the radionuclidic type (see Sect. 30.3.1.1), but accelerator-based (cyclotron, 14 MeV generator) sources and thermal neutrons from reactors are also used. The induced activities are measured with whole-body counters or other high-efficiency gamma-ray detection systems. Of course, the applicability of the technique is determined not only by the physical NAA parameters, but also by required radiation exposure limits of the subjects. In general, the dose delivered to the subjects, i.e., in the 1 mSv (100 mrem) range, can be as small as that encountered in an X-ray examination.

The majority of clinical applications of *in vivo* NAA have related to the determination of total-body and partial-body Ca to obtain invaluable clinical data on losses of calcium resulting from diseases such as osteoporosis, osteomalacia, and chronic renal diseases, as well as on the potential effect of drugs or therapy programs attempting to stem these losses (Krishnan 2000). Improvements in the technique, which mainly result in lower doses, allow applications to total-body Ca studies in population groups (Ellis et al. 2001). Other elements of clinical interest, such as Na, Cl, and I have been investigated in conjunction with various human diseases and disorders, while the clinical value of the measurement of major elements such as H, N, O, and P remains uncertain. Ellis (2000) recently reviewed the role of *in vivo* NAA among the *in vivo* methods for the measurement of human body composition.

30.3.2 Charged Particle Activation Analysis (CPAA)

In CPAA, particle accelerators generate activation particles such as protons, deuterons, tritons, ^3He (helions), α , and heavier charged particles. The type of nuclear reaction induced in the sample nuclei depends on the identity and energy of the incoming charged particle. Protons are selected in many instances because they can be easily accelerated and have low Coulomb barriers. The (p,n) and (p, γ) reactions are usually induced by protons up to about 10 MeV in energy. Higher energy protons may also induce (p, α), (p,d), or (p,2n) reactions. Larger incident particles require higher energies to overcome the Coulomb barrier. They then deposit higher energies in the target nucleus during reaction, which leads to a greater variety of pathways for the de-excitation of the activated nucleus. Therefore, a great variety of reactions and measurement options are available to the analyst in CPAA.

CPAA can be regarded as a good complement to NAA since the elements that are easily analyzed are quite different from those ordinarily determined by NAA. The low Coulomb barriers and low neutron capture cross sections of light elements make CPAA the choice for the nuclear analysis of B, C, N, O, etc. Because charged particles may not penetrate the entire sample as neutrons do, CPAA is often used for determinations in thin samples or as a surface technique. The interaction of the charged particle with the sample requires a modification of the activation equation, introduced in [Sect. 30.2](#). The particles passing through a sample lose energy; hence, the cross section for the nuclear reaction changes with depth. The expression for the produced activity, [Eq. \(30.22\)](#), has to be modified to account for this effect:

$$A = nI \int_0^r \sigma(x) dx. \quad (30.33)$$

Here I is the beam intensity (replacing the neutron flux Φ), n is the number density of target atoms of the given nuclide, and r is the penetration range determined by the stopping power of the medium according to [Eq. \(30.14\)](#).

As with NAA, the fundamental equation is not directly used in practice, but a relative standardization (comparator) method is used. A working equation for the comparator method is:

$$m_{x(\text{unk})} = m_{x(\text{std})} \frac{A_{0(\text{unk})} I_{\text{std}} r_{\text{std}}}{A_{0(\text{std})} I_{\text{unk}} r_{\text{unk}}}. \quad (30.34)$$

Here the saturation, decay, and counting factors are omitted; they should be applied the same way as in the case of NAA in [Eq. \(30.29\)](#).

Like in NAA, it is also possible to measure the prompt gamma rays emitted following the charged particles' reaction with the target nucleus. This technique is referred to as particle-induced gamma-ray emission (PIGE), and is discussed in [Chap. 33](#) of this Volume. PIGE is most useful for the determination of light elements ($Z < 15$) and is often used as a complementary technique to particle-induced X-ray emission (PIXE).

There are additional considerations for CPAA. The requirement for an accelerator essentially limits the use to some substantial facilities the primary applications of which are in other research fields, and CPAA must obtain a share of the beam time. Generally, only one beam is available, i.e., only one sample or one comparator standard is irradiated at a time. These disadvantages may be outweighed by combining the quantitative information with spatial and depth information, which can be obtained using focused particle beams and modulation of particle energy to change reaction depth. CPAA has been discussed in more detail by Strijckmans (1994).

30.3.3 Photon Activation Analysis (PAA)

Photons may be used as activation particles. The nuclear reactions depend on the atomic number of the target and on the energy of the photons used for irradiation. The source of photons for PAA is nearly always the bremsstrahlung radiation (synchrotron radiation) produced with electron accelerators. The photon energies are commonly 15–20 MeV, predominantly inducing the (γ, n) reaction. Other reactions that can be used include (γ, p) , $(\gamma, 2n)$, and (γ, α) . The method is complementary to INAA, and the determination of light elements C, N,

O, and F are good examples of PAA where detection limits of $<0.5\ \mu\text{g}$ are possible. One reaction with lower energy photons is the ${}^9\text{Be}(\gamma, n){}^{10}\text{Be} \rightarrow 2\ {}^4\text{He} + 2n$ reaction because of the low neutron-binding energy of the Be. The reaction can be induced by the 2.1 MeV gamma rays from ${}^{124}\text{Sb}$ and measured through the detection of the neutrons. (The same reaction is also used as a neutron source.)

PAA is very similar to NAA in that the photons can completely penetrate most samples. Thus, procedures and calculations are similar to those used in NAA. The method has constraints due to the stability and homogeneity of the photon beam with inherent limitations to the comparator method. Recent developments in bremsstrahlung target technology have improved the photon sources, which greatly benefit the precision and accuracy of the method (Goerner et al. 2001). A detailed discussion of PAA has been given by Kusehevsky (1990).

30.4 Instrumental Neutron Activation Analysis (INAA)

Although this section focuses on INAA, most of the discussed steps in the analytical procedure are applicable to all other forms of activation analysis.

30.4.1 Sample Preparation

Sample preparation for INAA can be limited to the physical treatment of a sample in order to obtain a suitable and representative test portion for irradiation and measurement. The goal of obtaining results from an unaltered portion of the investigated sample can be reached in most instances. Factors that alter the analyte content of a sample, such as increases through contamination or decreases through volatilization or precipitation in chemical sample preparation, are minimized or excluded in INAA. Ideally, the test portion is weighed and directly placed into an irradiation container.

30.4.1.1 Solid Samples

Solid samples are commonly analyzed “as received” by weighing and packaging a suitable test portion into an irradiation container. Frequently it is desirable to remove the test portion from the irradiation container after irradiation to minimize blank corrections. For easier handling of this sample transfer, it has become common practice to prepare pellets from powdery samples with a suitable die. If sample masses must be corrected for moisture, the moisture content is commonly determined in a separate portion following prescribed protocols.

30.4.1.2 Biological Tissues and Fluids

Biological samples can also be analyzed “as received,” although handling can be difficult and removal from irradiation containers for measurement is frequently impossible. Biological samples are often converted to “solid” samples by lyophilization; this may allow treatment like the aforementioned solid samples. Frequently, it is necessary to consider the alteration of biological matrices during irradiation through temperature and radiolysis. The resulting

partial destruction of the sample may cause analyte loss and increase blank contributions by the irradiation container from which the decomposed sample cannot be removed. To minimize losses and contamination, biological tissues are often directly sampled into high-purity quartz vials. After irradiation, they can be measured in these vials, or, if required, extracted in a dissolution procedure.

30.4.1.3 Liquid Samples

Liquid samples are generally prepared 'as received' or they are concentrated and/or lyophilized. Liquids with low concentrations of the elements of interest, such as seawater are often pre-concentrated, sometimes with chemical processing, such as ion exchange. The resulting products are then subjected to INAA or RNAA. It should be noted that many liquid samples are more efficiently analyzed by other techniques, such as ICP-MS.

A special case of liquid samples are elemental solutions prepared as single- or multielement comparator standards for INAA. These calibrants commonly contain higher levels of the analytes of interest. This permits quantitative dispensation onto a "carrier" medium such as a filter paper, drying of the solution, followed by preparation as a solid sample.

30.4.2 Irradiation

The task of placing the sample into and retrieving from the field or beam of activation particles has been solved with many different experimental approaches; sometimes very unique solutions have been implemented to cater to a particular task. Some of the more widely used approaches in NAA will be discussed here, with special emphasis on utility for INAA.

30.4.2.1 Automated Systems

INAA lends itself to the possibilities of implementing a fully automated system that carries out the analytical procedure without operator interaction once the sample has been introduced into the analytical system. Examples of such systems can be found throughout the development of NAA procedures. For reasons of flexibility and optimization for greatly varying analytical tasks, automation is often exploited only in parts of the INAA procedure. One key part concerns the irradiation.

Virtually all research reactors offer pneumatic tube systems for transport of sample capsules to the high flux regions near the core. Similar systems are also used with other irradiation sources. The encapsulated samples are placed into a larger irradiation capsule, commonly called a "rabbit." This rabbit then is moved with a flow of carrier gas (N_2 , CO_2 , or others) to the irradiation position with a system of pneumatic tubes. Sensors determine the arrival at the irradiation position, timers control the irradiation time and the retrieval from the irradiation position, and hence the activation time parameters can be determined with a high degree of precision and accuracy. Transfer times have been reported down to the tens of millisecond range; more common are times in seconds to minutes, depending on the distance the samples are moved to the receiving station(s). Obviously, transfer times influence the feasibility of assays via short-lived radionuclides. Depending on the design of the tube system,

the rabbits, and the conditions in the irradiation position, i.e., thermal, gamma-ray, and neutron field density, the use of these transfer systems may be limited to shorter irradiation times, often in the tens of minutes range. Therefore, pneumatic systems are predominantly used for assays via short-lived nuclides where individual samples, together with flux monitors or primary comparator standards, are irradiated one-at-a-time and returned for counting. This is in contrast to assays via longer-lived nuclides where many samples and standards are irradiated simultaneously. Some pneumatic transfer systems allow longer irradiation times and assays via long-lived nuclides are carried out after irradiation in these facilities.

After irradiation, samples are commonly separated from the rabbit and, if feasible, also from their primary packaging containers to minimize blank contributions from the container materials or external contamination encountered in the irradiation facility. For the measurement of ultrashort-lived nuclides ($T_{1/2} \ll 30$ s) facilities have been designed that automatically separate the sample from the rabbit by mechanical means. Usually these systems are implemented in a fully automated irradiation and counting process (Brätter et al. 1977; Ismail et al. 2001).

30.4.2.2 “In Core” Irradiation

To offer the highest possible neutron fluxes, research reactors often have locations in the fuel assembly grid in which encapsulated samples can be placed, often for prolonged exposure covering an operation cycle or longer times. It should be noted that sample encapsulation for such irradiations must meet very specific requirements. Due to the radioactivity of the substantial encapsulation materials, prolonged decay (“cooling”) times are necessary before the samples can be retrieved for the assays.

Many reactors offer “near core” irradiation positions where mechanical devices can be used during operations for the retrieval of sample capsules; insertion is generally done during reactor shutdown. These devices can include the capability of rotating samples around an axis perpendicular to the flux gradient (Lazy Susan) for homogeneous activation of a large number of samples or of a large individual sample. It should be noted that all these irradiations are subject to considerable variations in the activation parameters, from timing precision to flux density, which will require full complements of monitors, standards, etc. with each irradiation set.

30.4.2.3 External Systems

Irradiation positions in neutron beams extracted from reactors are most commonly used for PGAA. These positions offer a major advantage; namely the samples do not require packaging to withstand mechanical and irradiation stresses, i.e., containment can be minimal or is not required at all. In principle, samples are not limited to a certain size and shape, except by the physical space in the irradiation position, which commonly has shielding elements put in place to protect personnel. Nevertheless, irradiation of entire paintings has been demonstrated (Fischer et al. 1987).

Of course, the distance to the source of neutrons, the reactor core, leads to a significant decrease in the available neutron flux of an external irradiation position. During the past 2 decades, considerable developments have been implemented to increase the available neutron

flux in external positions. Various types of cold sources have been installed in research reactors, which provide sufficiently slow (“cold”) neutrons the long wavelength of which allow effective transport along total-reflecting neutron guides to locations away from the core. Cold beams of neutrons offer fluxes of $10^9 \text{ cm}^{-2} \text{ s}^{-1}$, providing 10–30-fold increases in the sensitivity of PGAA, including the thermal shift to higher activation cross sections of the cold neutrons.

30.4.3 Gamma-Ray Spectrometry

Today, activation analysis procedures rely almost exclusively on the detection of gamma rays for simultaneous qualitative identification and quantitative recording of the decay of the activation products. Exceptions are in the use of purely or predominantly β^- -emitting activation products, such as ^{32}P or ^{31}Si , in conjunction with radiochemical separation to achieve specificity (see ▶ Sect. 30.5). INAA procedures utilize a variety of gamma-ray spectrometry systems the principal components of which are illustrated in ▶ Fig. 30.3. In this section, the components and characteristics of gamma-ray spectrometers used for INAA will be briefly described. More technical details can be found in the excellent monographs available (Knoll 2000; Gilmore 2008; Debertin and Helmer 1988) and in ▶ Chap. 48 of Vol. 5 on radiation detectors.

30.4.3.1 Detector Systems

Gamma-ray spectrometry is efficiently carried out with solid-state semiconductor detectors, such as high-purity germanium (HPGe) detectors from about 40 keV energy, and silicon Si(Li) detectors for the X-ray region. Occasionally inorganic scintillation detectors such as NaI(Tl) or bismuth germanate (BGO) detectors are used because of their higher efficiencies. It should be noted that solid-state detectors are operated at 77 K to reduce the noise, and thus require supplies of liquid nitrogen (LN₂) or electromechanical cooling apparatus.

Gamma-ray detectors are commonly set up surrounded with heavy shielding against background radiation, i.e., radiation fields near a reactor and natural background radiation in locations more remote from the neutron source. The shielding is often a 10 cm thick lead castle in 4 π geometry, lined with absorbers for secondary Pb X-rays, such as 5 mm electrolytic Cu, and with neutron absorbers where appropriate. These shielding structures somewhat limit the access to the detectors, but automated sample changers are available.

The key characteristics of a gamma-ray detector system are the detection efficiency, the energy resolution, the signal-to-background ratio, and the throughput capabilities.

Detection efficiency is to a significant degree a function of the size of the detector; hence the active volume is specified by the manufacturer. In addition, detection efficiency for the ⁶⁰Co gamma ray at 1,332.5 keV relative to a standard 3' \times 3' (7.5 \times 7.5 cm) NaI(Tl) detector is given, i.e., 100% efficiency means the same analytical signal intensity can be obtained with the detectors that are compared in this manner. Of course, size is an essential price factor. Economically valuable HPGe detectors today have 30–40% efficiencies.

The *energy resolution*, which is important for a detector's ability to discriminate among close gamma-ray energies, is defined as the full width at half maximum (FWHM) of the 1,332.5 keV gamma ray, ranging from as low as 1.65 keV to some 2 keV; better resolution being more costly. Low-energy resolution and peak shape properties are additional criteria for the quality of a detector.

The *signal-to-background ratio of a detector system* is determined (1) by its peak-to-Compton ratio, (2) by the quality of shielding and construction materials used, and (3) by the location of the detector. Measures that go to the limits in the improvement of the latter have been described (Lindstrom et al. 1990). The peak-to-Compton ratio of a manufactured detector is determined by its volume and its geometry; good detectors offer values of 60:1 or better. The peak-to-Compton ratio can be significantly improved by the addition of a Compton suppressor annulus, commonly made of BGO or NaI(Tl), that surrounds the central principal detector and registers the Compton-scattered gamma rays escaping from the central detector. Anticoincidence circuitry prevents the registration of such events in the gamma-ray spectrum. Peak-to-Compton ratios exceeding 400:1 are routinely achievable. Landsberger and Peshev (1996) describe the application of anti-Compton (also called anticoincidence) counting in NAA, which greatly increases the detection limit due to the suppression of continuous spectral background (see also Knoll 2000; Alfassi 2001). However, when the sample is not shielded from the Compton suppression annulus surrounding the detector, problems with coincidence summing may occur (Debertin and Helmer 1988).

Further components of a high-performance gamma-ray spectrometer include the high-voltage bias supply, preamplifier, amplifier, and analog-to-digital converter (ADC). Several components can limit the overall performance of the gamma spectrometer in INAA due to the processing times required to convert the charge collected in the detector to a digital signal. The first limiting step occurs in a (conventional) resistive feedback preamplifier, where the required

time for the return to the baseline for processing the next pulse may be undercut by the frequency of the events. The preamplifier will be “saturated” and only few events will be registered. This happens at input count rates of 100 kHz or so. High-rate spectrometers, however, rely on transistor-reset preamplifiers the count rate capabilities of which by far exceed 1 MHz. Still, all other components in the signal-processing chain have their own limitations regarding the signal-processing frequency and the occurrence of pulse pile-up; hence all contribute to the overall dead time of the system. Thus, the count rate affects the quantitative relationship between the emitted activity of the source and the registered quantity, the gamma-ray peak, as well as the quality of the accumulated spectrum. Modern signal-processing technologies such as digital signal processing can reduce the count rate effects. In addition, technologies for the compensation of suppressed signals have been readily available and are currently augmented by so-called loss-free counting (LFC) or zero dead-time spectrometry systems. Accurate determinations utilizing high activity sources have been demonstrated with these systems (Zeisler 2000). Grass et al. (2001) have described comprehensive NAA systems incorporating the digital technology.

30.4.3.2 Analyzer Systems

Storage of the detector pulses is accomplished with a multichannel analyzer (MCA). An MCA, in its most basic form, is an instrument that sorts and counts events in real time. This sorting is based on some characteristics of these events, and events with the same characteristics are grouped together into bins, called channels, for counting purposes. In gamma-ray spectrometry, the MCA performs pulse height analysis (PHA), where signal pulses from a detector (this refers to the combination of the initial transducer and all subsequent electronics) are sorted into channels. The classifying characteristic is the pulse height or voltage that is proportional to the energy deposited in the detector. An analog-to-digital converter (ADC) is used to convert each pulse into a channel number so that each channel corresponds to a narrow range of pulse heights or voltages, i.e., energy increments. As pulses arrive over time, the MCA will collect a histogram of the count of pulses with respect to pulse height in its own nonvolatile memory. This distribution, arranged in order of increasing energy, is commonly referred to as a spectrum. The acquired spectrum is displayed on an x–y diagram (counts per channel against the channel number representing the gamma-ray energy) and is available for storage and/or analysis.

Modern MCAs offer up to 64 K ($= 2^{16} = 65,536$) channels for PHA. Depending on the requirements, frequently determined by the resolution of the detector and the type of radiation measured, smaller increments (512, 1,024, 2,048, etc. channels) may be used, and are often arranged in adjacent groups in the MCA. When energy resolution is not a requirement, single channel analyzers (also called differential discriminators) have their place when a certain energy range is cumulatively registered or used for coincidence–anticoincidence gating purposes.

As instruments, MCAs exist in many forms – as stand-alone analyzers, modular components, and computer interface cards. Obviously the latter, but in most instances all, are supported by a computer system. The philosophy of a stand-alone analyzer that can display spectra, calculate results, store data, etc., has given way to the flexibility of computer-supported MCA systems, frequently not needing more than a conventional PC with communication capabilities and appropriate data acquisition and spectrometry software. Recently, digital

spectrum analyzers have become available. In addition to the increased throughput capability, these devices replace the entire analog signal processing chain, as they directly digitize and store the pulses from the detector's preamplifier (Knoll 2000).

30.4.3.3 Software

Data acquisition software is chiefly concerned with the handling of the MCA system and its components. The programs will link the hardware of the spectrometry system with the storage memory for the data. Critical physical parameters such as starting time, duration, and dead time of the acquisition are recorded with sufficient resolution (best commercially available is 0.01 s) together with the spectral data. Other data, such as the energy calibration (e.g., kiloelectron volt per channel and zero offset), and user information on irradiation, detector system, and sample are often included with the spectral data or linked to it. The acquisition software can also take care of controlling sample changers, advancing storage file names, sequential counting of decaying sources, and many other related tasks. Display packages provide the necessary visual interface with the human operator. Displayed data can be manipulated (expanded, overlapped, subtracted), allowing the operator to clearly identify and evaluate components of the acquired spectral data, also during acquisition. Some MCA and detector systems are controllable in their settings (bias, gain, etc.) from the acquisition software. Quality assurance packages interface with the spectroscopy system for required record keeping.

The tasks of the spectrometry software packages are to identify energy peaks and to accurately evaluate the number of counts associated with the energy peak. Two philosophies are being used: (1) a mathematical model discovers the occurrence of a peak and models a shape to the peak to calculate the peak area in terms of number of counts, and (2) the gamma-ray energies are obtained from nuclide libraries and matched to the actual spectral data, where again a peak model is used to determine the number of counts. Packages clearly vary in the reliability of the process as shown in a number of intercomparisons (Blaauw et al. 1997). Add-on packages provide lists of nuclides, decay corrections, and activities when calibrated and for INAA quantitative results in mass fractions of elements either by comparison with spectra of standards analyzed under identical conditions or with calibration functions. One of the most robust combinations of data acquisition, peak search, and activation analysis routines have been available for workstation computers operating under VMS. Commercial activation analysis packages are also available for PC-based gamma-ray spectrometry systems, but none have gained in popularity or reputation.

30.4.4 Quantitation

The determination of an element is based on the activation equations of [Sect. 30.2.2](#), which offer the possibility for a direct “absolute” quantitative determination to the activation analyst. However, difficulties in accurately determining the flux distribution within a sample, as well as uncertainties in physical parameters such as cross section, half-life, and decay branching ratios would introduce large components of uncertainty.

Therefore, two methods are routinely employed: (1) a “comparator” standard with known elemental content is irradiated and measured under the same conditions as the sample, or

(2) in a parametric method the values for flux and detection sensitivities are obtained for the irradiation facility and spectrometry equipment through calibration, and tabulated experimental parameters are used for the determination of each individual element.

30.4.4.1 Comparator Method

The measurement process for the determination of the mass fraction of an element by INAA in a blank-free environment can be described by the following equation:
