Foreword

The Future of Nuclear Energy and Research

New ideas are hard to accept; popular mistrust and opposition often hinder the exploration and application of new sciences and technologies. We have to look only at the work and struggle of Galileo, Newton, and Einstein, among many others, to realize what obstacles there were in their paths.

There can be no question that nuclear energy will become more important in the future in spite of the fact that there is general opposition toward the use of this form of energy. Conventional energy sources will soon become less available. Oil and gas are becoming more expensive and no great reserves appear to be available. Coal supplies are likely to last longer but I expect it to become more expensive even within this century. The other sources, like hydroelectricity, solar energy and geothermal energy will be in many cases important, but they will remain local and limited. I firmly expect that the source that will become of lasting and general importance for the world is nuclear energy.

As we see it at the present, uranium will remain a satisfactory energy source for the third millennium. Energy from thorium (by transformation into uranium 233) is likely to remain available even longer. One obstacle appears to remain: fear of radioactivity. My main point is that the fear is not justified.

Consider the damage in the last few decades due to the use of nuclear reactors, divided by the amount of available energy produced. Two well-known examples of such damage are at Three Mile Island in the United States in 1979, and even more at Chernobyl in the Soviet Union in 1986. Both of these were caused by human error. At Three Mile Island, the economic damage was great, but there was hardly any effect on health. In Chernobyl, the effect on human health was considerable, but still small compared to the publicity it generated.

The main problem in nuclear energy is the fight against hysteria. I hope and believe that ways will be found to overcome such hysteria. I want to make just one recommendation. In developing nuclear energy for the future, primary emphasis should be given to one problem with double aspect. One aspect is safety of future nuclear reactors; the other is the public understanding of this safety. This is the field in which innovations are most necessary.

For this, we need three things: one is careful planning and operation of nuclear energy production; other improvements in nuclear energy production will be made, but these are unimportant compared to the needed improvements in safety. The second point is the review of past damage in all phases connected with nuclear energy. The third and most important part is the work for and execution of plans for the use of nuclear energy for the whole world, advanced and underdeveloped, with primary emphasis on safety and objective reporting.

An important part of all this is widespread understanding of a field that is novel, but basically not particularly difficult to understand. This major five-volume publication is exceedingly useful for further research, understanding and application of the chemical aspect of nuclear science.

E. Teller[†]

[†]**Editors' note:** The above sentences were dictated by Professor Edward Teller to his secretary in March 2003. The text was to be the Foreword of the first edition of the Handbook of Nuclear Chemistry (HNC) published in November 2003. Professor Teller died on September 9, 2003, just a few months before the book was released. We still deeply regret that we lost the opportunity to present him with a complimentary copy of HNC as a token of our gratitude for his support. However, his words have not lost their timeliness over the years. We have decided to have them published unchanged thus expressing our respect for his memory.

Preface

In the twentieth century, 57 Nobel Prizes honored the chemical and physical results achieved by theoreticians and experimenters who can be rightly called nuclear scientists. This number alone proves that nuclear science was recognized as one of the most powerful engines pushing science to new heights in the past century, often referred to as the **Nuclear Age**.

It is interesting to mention that until the middle of the twentieth century, the ratio of Nobel Prizes that honored nuclear results was 2:1 for physics and chemistry. However, after 1950, only two chemical results were awarded by this prize: E. M. McMillan and G. T. Seaborg for the production of $_{93}\text{Np}$ and $_{94}\text{Pu}$ in 1951, and W. F. Libby for working out the ^{14}C age determination in archeology and geophysics in 1960. R.S. Yalow was honored by the Nobel Prize in 1977 for a medical result. She developed the radioimmunoassays of peptide hormones. All other Nobel Prizes for nuclear results were awarded in the field of physics. The Nobel Prizes achieved by nuclear scientists are listed in [▶ Table 1](#).

A correlation between the period of the research work and the date of the award is demonstrated in [▶ Fig. 1](#).

One needs little imagination to foretell that the flagships of science will be informatics and biology in the twenty-first century. Nevertheless, there are many signs making us firmly believe that nuclear science will remain important in the future as well, in spite of the antinuclear sentiments caused by the unfortunate Chernobyl accident in 1986. Radiopharmaceutical chemistry is stimulating biomedical research and nuclear medicine (diagnosis and therapy). The development of particle physics keeps its dynamism as demonstrated by the Nobel Prizes awarded in this century (2002, 2004, and 2008.)

There are well-supported opinions that nuclear fission and fusion will be among the important sources of energy in the twenty-first century. We cite George A. Olah who was awarded the Nobel Prize for his contributions to carbocation chemistry in 1994. He wrote (Olah GA (1998) Oil and hydrocarbons in the 21st century. In: Barkan P (ed) Chemical research 2000 and beyond. Amer Chem Soc, Washington, DC/OUP, New York, pp 40–54):

- ▶ *Generating energy by burning non-renewable fossil fuels including oil, gas and coal is feasible only for the relatively short future and even so, faces serious environmental problems. The advent of the atomic age opened up a wonderful new possibility, but also created dangers and concerns of safety. I feel that it is tragic that the latter considerations practically brought further development of atomic energy to a stand still at least in most of the Western world. Whether we like it or not we have in the long run no alternative but to rely increasingly on clean atomic energy, but we must solve safety problems including those of disposal and storage of radioactive waste-products. Pointing out difficulties and hazards as well as regulating them (within reason) is necessary. Finding solutions to overcome them, however, is essential.*

(Olah 1998, pp 40–54)

The editors of this handbook hope that this work contributes to the activity of a research field that helps us to learn more and more about nature and will remain dynamic for a long time.

■ Table 1

The results of nuclear scientists honored by Nobel Prizes

The honored results as phrased by the Nobel Committee	The period of the activity resulting the Nobel Prize	The name(s) of the awarded person(s)	The year of distinction
In recognition of the extraordinary services he has rendered by his discovery of spontaneous radioactivity	1896	H. A. Becquerel	1903 (physics)
In recognition of the extraordinary services they have rendered by their joint researches on the radiation phenomena discovered by Professor Henri Becquerel	1897–1903	M. Curie P. Curie	
In recognition of her services to the advancement of chemistry by the discovery of the elements radium and polonium, by the isolation of radium and the study of the nature and compounds of this remarkable element	1898	M. Curie	1911 (chemistry)
For his investigations into the disintegration of the elements, and the chemistry of radioactive substances	1898–1900	E. Rutherford	1908 (chemistry)
In recognition of the services he rendered to the advancement of physics by his discovery of energy quanta	1901	M. Planck	1918 (physics)
For his services to theoretical physics, and especially for his discovery of the law of the photoelectric effect	1905	A. Einstein	1921 (physics)
For his work on the elementary charge of electricity and on the photoelectric effect	1910–1914	R. A. Millikan	1923 (physics)
For his method of making the paths of electrically charged particles visible by condensation of vapor	1912	C. T. R. Wilson	1927 (physics)
For his discovery of cosmic radiation	1912	V. F. Hess	1936 (physics)
For his work on the use of isotopes as tracers in the study of chemical processes	1913–1935	G. Hevesy	1943 (chemistry)
For his contributions to our knowledge of the chemistry of radioactive substances, and his investigations into the origin and nature of isotopes	1913–1916	F. Soddy	1921 (chemistry)
For his discovery of the effect named after him	1923	A. H. Compton	1927 (physics)
For the discovery of the Exclusion Principle, also called the Pauli Principle	1925	W. Pauli	1945 (physics)
For the discovery of new productive forms of atomic theory	1926	E. Schrödinger P. A. M. Dirac	1933 (physics)

For the invention and development of the cyclotron and for results obtained with it, especially with regard to artificial radioactive elements	1929–1932	E. O. Lawrence	1939 (physics)
For his resonance method for recording the magnetic properties for atomic nuclei	1930–1939	I. I. Rabi	1944 (physics)
For the coincidence method and his discoveries made therewith	1930–1940	W. Bothe	1954 (physics)
For his development of the Wilson cloud chamber method, and his discoveries therewith in the field of nuclear physics and cosmic radiation	1931–1933	P. M. S. Blackett	1948 (physics)
For the discovery of the neutron	1932	J. Chadwick	1935 (physics)
For his discovery of the positron	1932	C. D. Anderson	1936 (physics)
For their pioneering work on the transmutation of atomic nuclei by artificially accelerated atomic particles	1932	J. D. Cockcroft E. T. S. Walton	1951 (physics)
For his contributions to the development of the molecular ray method and his discovery of the magnetic moment of the proton	1933	O. Stern	1943 (physics)
For his contributions to the theory of the atomic nucleus and the elementary particles, particularly through the discovery and application of fundamental symmetry principles	1933–1937	E. P. Wigner	1963 (physics)
In recognition of their synthesis of new radioactive elements	1934	F. J. Curie I. Curie	1935 (chemistry)
For the discovery and the interpretation of the Cherenkov effect	1934–1937	P. A. Cherenkov I. M. Frank I. E. Tamm	1958 (physics)
For his demonstrations of the existence of new radioactive elements produced by neutron irradiation, and for his related discovery of nuclear reactions brought about by slow neutrons	1934–1936	E. Fermi	1938 (physics)
For his prediction of the existence of mesons on the basis of theoretical work on nuclear forces	1935	H. Yukawa	1949 (physics)
For his contributions to the theory of nuclear reactions, especially his discoveries concerning the energy production in stars	1938	H. A. Bethe	1967 (physics)
For his discovery of the fission of heavy nuclei	1938	O. Hahn	1944 (chemistry)

Table 1 (Continued)

The honored results as phrased by the Nobel Committee	The period of the activity resulting the Nobel Prize	The name(s) of the awarded person(s)	The year of distinction
For their discoveries in the chemistry of the transuranium elements	1940	E. M. McMillan G. T. Seaborg	1951 (chemistry)
For his method to use carbon-14 for age determination in archaeology, geology, geophysics, and other branches of science	1946	W. F. Libby	1960 (chemistry)
For their development of new methods for nuclear magnetic precision measurements and discoveries in connection therewith	1946–1948	F. Bloch E. M. Purcell	1952 (physics)
For their fundamental work in quantum electrodynamics, with deep-ploughing consequences for the physics of elementary particles	1946–1948	S.-I. Tomonaga J. Schwinger R. P. Feynman	1965 (physics)
For his development of the photographic method of studying nuclear processes and his discoveries regarding mesons made with this method	1946–1950	C. F. Powell	1950 (physics)
For their discoveries concerning nuclear shell structure	1948–1954	O. M. Goeppert-Mayer J. H. D. Jensen	1963 (physics)
For the invention of the bubble chamber	1952	D. A. Glaser	1960 (physics)
For the discovery of the connection between collective motion and particle motion in atomic nuclei and the development of the theory of the structure of the atomic nucleus based on this connection	1953	A. N. Bohr B. R. Mottelson L. J. Rainwater	1975 (physics)
For his pioneering studies of electron scattering in atomic nuclei and for his thereby achieved discoveries concerning the structure of the nucleons	1953–1960	R. Hofstadter	1961 (physics)
For the detection of the neutrino	1953–1960	F. Reines	1995 (physics)
For his contribution to the development of high-resolution electron spectroscopy	1954–1958	K. M. Siegbahn	1981 (physics)
For their discovery of the antiproton	1955	E. G. Segre O. Chamberlain	1959 (physics)

For his decisive contributions to elementary particle physics, in particular, the discovery of a large number of resonance states, made possible through his development of the technique of using hydrogen bubble chamber and data analysis	1955–1957	L. W. Alvarez	1968 (physics)
For the development of neutron spectroscopy	1955–1960	B. N. Brockhouse C. G. Shull	1994 (physics)
For pioneering contributions to astrophysics, in particular, for the detection of cosmic neutrinos	1955–1972	R. Davis M. Koshiba	2002 (physics)
For their penetrating investigation of the so-called parity laws, which has led to important discoveries regarding the elementary particles	1956	T. D. Lee C. N. Yang	1957 (physics)
For his theoretical studies of the physical processes of importance to the structure and evolution of the stars	1962–1971	S. Chandrasekhar	1983 (physics)
For his theoretical and experimental studies of the nuclear reactions of importance in the formation of the chemical elements in the universe	1956–1965	W. A. Fowler	
For his researches concerning the resonance absorption of gamma radiation and his discovery in this connection of the effect that bears his name	1958	R. Mössbauer	1961 (physics)
For their contributions to the theory of the unified weak and electromagnetic interaction between elementary particles, including, inter alia, the prediction of the weak neutral current	1958–1970	S. L. Glashow A. Salam S. Weinberg	1979 (physics)
For the development of radioimmunoassays of peptide hormones	1959	R. S. Yalow	1977 (medicine)
For his contributions and discoveries concerning the classification of elementary particles and their interactions	1960–1965	M. Gell-Mann	1969 (physics)
For the discovery of the mechanism of spontaneous broken symmetry in subatomic physics	1960–1973	Y. Nambu	2008 (physics)
For pioneering contributions to astrophysics, which have led to the discovery of cosmic X-ray sources	1960–1980	R. Giacconi	2002 (physics)

Table 1 (Continued)

The honored results as phrased by the Nobel Committee	The period of the activity resulting the Nobel Prize	The name(s) of the awarded person(s)	The year of distinction
For the neutrino beam method and the demonstration of the doublet structure of the leptons through the discovery of the muon neutrino	1963	L. Lederman	1988 (physics)
		M. Schwartz	
		J. Steinberger	
For the discovery of violations of fundamental symmetry principles in the decay of neutral K-mesons	1964	J. W. Cronin V. L. Fitch	1980 (physics)
For their pioneering investigations concerning deep inelastic scattering of electrons on protons and bound neutrons, which have been of essential importance for the development of the quark model in particle physics	1968	J. I. Friedman	1990 (physics)
		H. W. Kendall	
		R. E. Taylor	
For his invention and development of particle detectors, in particular, the multiwire proportional chamber	1968	G. Charpak	1992 (physics)
For the discovery of the origin of the broken symmetry, which predicts the existence of at least three families of quarks in nature	1970–1973	M. Kobayashi, T. Maskawa	2008 (physics)
		M. J. G. Veltman G. 't Hooft	
For elucidating the quantum structure of electroweak interactions in physics	1972	M. J. G. Veltman G. 't Hooft	1999 (physics)
For his theory for critical phenomena in connection with phase transitions	1972	K. G. Wilson	1982 (physics)
For the discovery of asymptotic freedom in the theory of the strong interaction	1973–1974	D. J. Gross	2004 (physics)
		H. D. Politzer	
		F. Wilczek	
For their pioneering work in the discovery of a heavy elementary particle of a new kind	1974	B. Richter S. C. C. Ting	1976 (physics)
For the discovery of the tau lepton	1974	M. Perl	1995 (physics)
For their decisive contributions to the large project that led to the discovery of the field particles W and Z, communicators of weak interaction	1983	C. Rubbia S. van der Meer	1984 (physics)

■ Fig. 1

A presentation of the time passed between the discoveries and Nobel Prizes related to the development of nuclear science and subatomic concepts (Nagy S (2007) Radiochemistry and nuclear chemistry. In: Encyclopedia of Life Support Systems (EOLSS), Developed under the auspices of the UNESCO. Eolss Publishers, Oxford [<http://www.eolss.net>]). The length of each drop-line shows the delay between award and achievement. Note that some achievements had been awarded almost promptly, whereas the longest delay was almost half a century. The drop-lines of the first few points are meaningless, as the Nobel Prize was first awarded in 1901

The chapter Nuclear and Radiochemistry – the First 100 Years, dealing with the history of nuclear chemistry, was updated by Professors Friedlander and Herrmann in the Fall of 2008 and in the Spring of 2009. Alas, it was submitted for the 2nd edition by Professor Herrmann alone because Professor Friedlander died on September 6, 2009. Gerhart Friedlander was born on July 28, 1916, in Munich. He was a veteran of the Manhattan Project and a pioneer of nuclear chemistry who later exploited the first particle accelerators to do major research as head of the chemistry department at Brookhaven National Laboratory. Many of us, nuclear chemists, used one of Professor Friedlander's monographs to learn the basics of this field of science (e.g., Friedlander G, Kennedy JW, Macias ES, Miller JM (1981) Nuclear and radiochemistry. Wiley, New York). We warmly suggest that those who wish to get a bird's eye view of the field of nuclear science should read the chapter Nuclear and Radiochemistry – the First 100 Years. They will find it not only enjoyable as a 'story' but also useful as a guide to all the main areas of interest, heights, crossroads, and the paths connecting the individual spots of the landscape underneath.

The editors acknowledge the valuable work of Professor Gábor L. Molnár who conceptualized and edited all the appendixes of the first edition. He died on January 6, 2004, and he could not see and enjoy the success of his work as a part of the Handbook of Nuclear Chemistry.

We are sure that Gábor L. Molnár's work, which is mostly integrated into the 2nd edition as well, remains an important contribution to the mission of the Handbook of Nuclear Chemistry.

The 63rd General Assembly of the United Nations adopted a resolution that 2011 would be the Year of Chemistry. The motivation was that Marie Curie was awarded the Nobel Prize of Chemistry a century ago, in 1911. This prize honored results achieved in the field of radio- and nuclear chemistry. It is a great pleasure for us that the 2nd edition of the Handbook of Nuclear Chemistry can welcome the start of the Year of Chemistry.

The Editors
October 2010

Editorial Board

Attila Vértes (Türje, 1934) is a Professor Emeritus of nuclear chemistry at Eötvös Loránd University, Budapest. He studied the scattering of beta particles for his Master's thesis in 1958 and has been dealing with different topics of nuclear chemistry ever since (e.g., Mössbauer and positron annihilation spectroscopy).

Academic career highlights in Hungary include graduating from the Technical University of Budapest (MSc), 1958; Doctor of Science, Hungarian Academy of Sciences, 1973; Corresponding Member of the Hungarian Academy of Sciences, 1993; Ordinary Member of the Hungarian Academy of Sciences, 1998.

Abroad, Prof. Vértes studied at Lomonosov University and became a Candidate of Science, Russian Academy of Sciences, 1965. He was a Visiting Scientist at the University of New Castle (England) and a Humboldt Fellow at the Technical University, Munich (Germany) as well as a Guest Professor at Lehigh University, Bethlehem (USA), Tokyo University (Japan) and Johannes Gutenberg University, Mainz (Germany).

He has published more than 500 papers in scientific periodicals and edited/authored nine monographs. Prof. Vértes is an Honorary Doctor of Glasgow Caledonian University (England, 1996). He was awarded the Széchenyi Prize (given by the President of the Republic of Hungary, 2001) and the Hevesy Medal (Guildford, 2004).

His significant position in the community is seen in his active participation in the Hungarian Academy of Sciences where he chaired the Division of Radiochemistry (1993–2002). He was also a member of the International Board on the Applications of the Mössbauer Effect (IBAME; 1990–1998) and holds editorial spots on some of the top journals in the field.

More about him at his site: www.chem.elte.hu/departments/magkem/vertesa/vertesaeng/index.html.

Sándor Nagy (Budapest, 1949) is a committed teacher of nuclear sciences employed by the Institute of Chemistry, Eötvös Loránd University (ELTE), Budapest. He graduated from chemistry in 1972, but his formal education also includes applied mathematics. He has been working for ELTE since his graduation there with some officially approved detours in the meantime. Thus he spent 14 months at the Sinclair Laboratory of Lehigh University, Bethlehem, USA (1979–1980); another 22 months at the Chemistry Department of Drexel University, Philadelphia (1987–1989); and paid several short visits to Belgium, Canada, Cuba, Denmark, Germany, Kazakhstan, the Netherlands, Romania, and Russia.

Prof. Nagy has published over 100 scientific papers and a number of books and book chapters in English and Hungarian. Between 2005 and 2007, he acted as an Honorary Theme Editor of the theme Radiochemistry and Nuclear Chemistry for EOLSS (www.eolss.net/E6-104-toc.aspx). He is an IUPAC Fellow and a member of the Board of Associate Editors of the Journal of Radioanalytical and Nuclear Chemistry. He also won some professional/teaching awards from the Institute of Chemistry, from the Faculty of Science, from ELTE and also from the Ministry of Education of Hungary. His latest pet project is developing a Nuclear Glossary in Hungarian (inspired by Rick Firestone, one of the Authors of this Handbook) stuffed with animations and simulations provided by scientists and teachers all around the world (www.chem.elte.hu/Sandor.Nagy/NewClearGlossy/).

Apart from science, a few decades ago, he also authored some award-winning books on bicycling, and translated science fiction and children's books etc. to Hungarian. He is also an enthusiastic gardener and the proud father of five daughters.

For more details, visit his site at www.chem.elte.hu/Sandor.Nagy/.

Zoltán Klencsár (Kaposvár, 1971) is a senior research fellow at the Chemical Research Center of the Hungarian Academy of Sciences, Budapest.

Dr. Klencsár received his PhD in physics from Eötvös Loránd University in 1999. He has been working as a researcher for the Hungarian Academy of Sciences (1998–2004, 2008–) and as an assistant and associate professor for the University of Kaposvár, Hungary (2002–2008). His main field is Mössbauer spectroscopy and its applications in physics and chemistry. He has published over 50 articles in international journals, and authored several book chapters and lecture notes in the field of physical sciences. He is also an enthusiastic computer programmer who has developed numerous applications over the past two decades. In the field of Mössbauer spectroscopy he is recognized worldwide as the author of a software package used at many laboratories for the analysis of Mössbauer spectra.

For more details see: www.siaweb.hu/klencsar/

Rezső G. Lovas (Debrecen, 1946) is a Research Professor at the Institute of Nuclear Research of the Hungarian Academy of Sciences in Debrecen, Hungary.

Graduated from the University of Debrecen, he has been affiliated with the Debrecen Institute throughout his career. Meanwhile, he spent sabbatical-like years at the Nuclear Physics Laboratory, Oxford, at Daresbury Laboratory, at Kernforschungszentrum Karlsruhe and medium-term visits at the University of Utrecht, at Manne Siegbahn Laboratory, Stockholm, and at Niigata University. He was Director of the Debrecen Institute from 1997 to 2007. He is a Titular Professor at the University of Debrecen (1993) and a Corresponding Member of the Hungarian Academy of Sciences (2004). Formerly, he was member of the Board of the Nuclear Physics Division of the European Physical Society and of the Editorial Board of Nuclear Physics News International. At present he is Vice-President of the Physics Section of the Academy, member of the Council of the Research Institutions of the Academy, and chairs the Working Group on Energy Strategy of the Academy.

His research field is nuclear theory: reactions, clustering, cluster decay and light exotic nuclei. He is a coauthor of the monograph *Structure and Reactions of Light Exotic Nuclei* (2003).

Frank Rösch (Chemnitz, 1955) is a Professor of nuclear chemistry at Johannes Gutenberg University, Mainz, Germany.

He studied chemistry at the Technical University Dresden from 1976 to 1981. His diploma work was on the *Production of ^{211}At and investigations on cationic species of Astatine and their reactions* and his PhD thesis 1984 *On the chemistry of At(I)-complex formations*.

At the Joint Institute for Nuclear Research, Dubna, Sowjet Union, Laboratory for Nuclear Problems (1984–1987) he investigated *Basics and perspectives of the continuous electromigration measurement of γ -emitting radionuclides in homogeneous aqueous electrolytes free of supporting materials*. Back in Germany, he spent some years (1987–1991) at the Central Institute for Nuclear Research (ZfK) Rossendorf, Department of Radioactive Isotopes, turning his research activities into the application of radionuclides in life sciences. In 1988 he succeeded with his habilitation and obtained the *venia legendi* for radiochemistry.

His research on the production and potential medical application of radionuclides continued at the Institute of Nuclear Chemistry, Research Centre Jülich GmbH, Germany, from 1991–1996. In 1996 he was appointed a University Professor for Nuclear Chemistry at the Institute of Nuclear Chemistry, Johannes Gutenberg-University Mainz, Germany. His current research activities are focused on the development and evaluation of PET radiopharmaceuticals, including radionuclide generator-based radionuclides.

He was honored with scientific awards of the ZfK Rossendorf and the JINR Dubna, and received other national prizes. He has published more than 200 papers in peer review journals and edited/authored various book chapters.

[†]Deceased

Abstract: This chapter gives a brief overview of the development of nuclear and radiochemistry from Mme. Curie's chemical isolation of radium toward the end of the twentieth century. The first four sections deal with fairly distinct time periods: (1) the pioneering years when the only radioactive materials available were the naturally occurring ones; (2) the decade of rapid growth and expansion of both the fundamental science and its applications following the discoveries of the neutron and artificial radioactivity; (3) the World War II period characterized by the intense exploration of nuclear fission and its ramifications; (4) what can be called the "golden era" – the 3 to 4 decades following World War II when nuclear science was generously supported and therefore flourished. In the final section, research trends pursued near the end of the century are briefly touched upon.

1.1 The Pioneering Years

The field that became known as *radiochemistry*, dealing with the chemical manipulation of radioactive materials and the application of radioactivity to basic and applied chemical problems, originated very soon after Henri Becquerel had discovered the phenomenon of radioactivity during his studies of the fluorescence of uranium compounds (Becquerel 1896). The term "radiochemistry" for this field was introduced quite early, as indicated by the fact that it appeared in a book title in 1910 (Cameron 1910). However, the same term was for some time also applied to what is now called "*radiation chemistry*," the chemical action of radioactive (and other ionizing) radiations. Later, after the concept of the atomic nucleus was introduced in 1911 and especially after the discoveries of nuclear transmutations (1919) and of artificially produced radioactivity (1934), chemists became involved more broadly in the study of the production, properties, and reactions of atomic nuclei; in the 1930s, the term "*nuclear chemistry*" gained currency for this branch of the chemical sciences, quite analogous to organic chemistry being concerned with the synthesis, properties, and reactions of organic molecules. The creation, in 1937, of a new chair of "Chimie Nucléaire" for Frédéric Joliot at the Collège de France was perhaps the first official recognition of the new branch of chemistry. At about the same time, Otto Hahn's treatise *Applied Radiochemistry* (Hahn 1936) clearly outlined the now generally accepted definition of "radiochemistry."

Almost immediately after the discovery of radioactivity, Marie Skłodowska Curie and Pierre Curie began more detailed studies of the new phenomenon. Guided by their observation that some natural uranium ores, such as pitchblende, were more highly radioactive than corresponded to their uranium content (Skłodowska Curie 1898), they fractionated the ores chemically, using the intensity of radioactivity in the fractions as evidence for further radioactive substances. The result was the discovery, in June 1898, of a new radioactive element in the bismuth fraction (Curie and Curie, 1898); the Curies named it *polonium* in honor of Marie's homeland. A few months later, in December 1898, they were able to report the discovery of another radioactive element, this one in the barium fraction separated from pitchblende (Curie et al. 1898); they named it *radium*. The subsequent isolation of radium from barium was accomplished by fractional crystallization of barium chloride, with radium chloride always being enriched in the crystalline phase. It soon became possible to characterize radium spectroscopically by optical emission lines (Demarçay 1898) and, thus, to confirm the discovery by an independent identification. By 1902, M. Curie had isolated 120 mg of pure

radium chloride from the residues of about 2 t of pitchblende, a heroic radiochemical enterprise. By then, she was able to determine the atomic weight of radium. The result, 225, provided the final proof that radium is the heaviest alkaline earth element (Curie 1902).

In 1898, M. Curie (Sklodowska Curie 1898) (and independently Gerhard Schmidt) found that not only uranium, but also thorium emits radioactive radiations, and in the following decade numerous other radioactive substances, all of them ultimately assignable to elements between mercury and uranium in the periodic table, were chemically isolated in various fractions from uranium and thorium ores. Eventually, all the newly discovered radioactive substances could be assigned to three separate *decay chains*, originating from uranium (^{238}U), thorium (^{232}Th) and from actinium (^{227}Ac) respectively, the last discovered (Debiere 1899; Giesel 1902) in the lanthanum fraction obtained from pitchblende. Each of the decay series involves a number of α and β decays and terminates in one of the stable lead isotopes ($^{238}\text{U} \rightarrow ^{206}\text{Pb}$, $^{232}\text{Th} \rightarrow ^{208}\text{Pb}$, $^{227}\text{Ac} \rightarrow ^{207}\text{Pb}$). Among the pioneers who contributed to our knowledge of the naturally occurring radioactivities one should further mention Bertram Boltwood, Julius Elster, Kasimir Fajans, Hans Geitel, Georg von Hevesy, Lise Meitner, Stefan Meyer, Fritz Paneth, Egon von Schweidler, and Frederick Soddy (see, e.g., Meyer and Schweidler (1916, 1927), Jauncey (1946), Soddy (1975)).

When the chemical properties of members of the three naturally occurring decay series were investigated, it became clear that some of the radioactive species represented elements that had previously been blank in the periodic table. For example, radium (element 88) was surely the next higher homologue of barium; polonium (84) could be placed below tellurium after it had turned out that it was identical with the radio-tellurium discovered by Wilhelm Marckwald (Marckwald 1903), and actinium (89) was positioned below lanthanum. They were later attributed to ^{226}Ra , with a half-life ($T_{1/2}$) of 1,600 years, ^{210}Po (138 days), and ^{227}Ac (21.8 years). But some of the radioactive species were chemically indistinguishable from existing elements or from each other. For example, the so-called radium D (22 years, ^{210}Pb), a member of the uranium series, could not be chemically separated from ordinary lead. Similarly, ionium (8×10^4 years, ^{230}Th) was chemically indistinguishable from thorium. Furthermore, each of the three series contained at least one relatively short-lived member that was chemically identical with lead, one identical with bismuth, etc. These observations led to the concept of *isotopy*, clearly enunciated by Soddy in 1911 and somewhat later named by him (Soddy 1911, 1913a). Initially it was thought that only radioactive elements have isotopes, i.e., chemically identical species of different atomic weights, but already in 1913, Joseph J. Thomson showed by deflection of positive ions in electric and magnetic fields that ordinary neon consisted of two isotopes of atomic weights 20 and 22 (Thomson 1913). Soon it became apparent that isotopy is a general phenomenon among naturally occurring elements.

Two important developments in the early history of radioactivity were (1) the recognition of the three different *types of radiation*, α , β , and γ rays, distinguished by their very different penetration in matter and (2) the realization that in each of the three decay series there existed a product that behaved chemically like an inert (also called: rare or noble) gas. Through experiments involving deflection in magnetic and electric fields, α and β “rays” were soon identified as streams of helium ions and electrons, respectively, and γ rays, undeflected by such fields, were recognized as a form of electromagnetic radiation akin to X-rays.

As early as 1900, Rutherford was able to show that the erratic electrometer readings he observed when measuring the radioactivity of thorium compounds were due to the emanation of a radioactive gas into the ionization chamber (Rutherford 1900). The observation that a sample of the radioactive gas faded away within a few minutes according to a characteristic

exponential decay law with a well-reproducible decay constant λ (where $\lambda = \ln 2 / T_{1/2}$) was one of the fundamental conclusions from these simple experiments. Perhaps even more surprising was the observation that the gaseous radioactivity could be “milked” repeatedly from the thorium sample and that the buildup with time in the source occurred with the same time constant as the decay process. Furthermore, it was found that even after the emanation had decayed away, radioactivity persisted as an “active deposit” consisting of nonvolatile decay products. Thus, this special case of a natural radiochemical separation of a gaseous component from a solid component gave the first hint that radioactivity is accompanied by a *transmutation of elements*, and it showed clearly that chemical separations are an excellent tool for the unraveling of decay sequences. Radium and actinium compounds were found to exhibit the same phenomenon, i.e., gaseous emanations leading to active deposits, but with quite different half-life patterns. Detailed studies identified the emanations as inert gases of high molecular weight, attributed to a new element, the heaviest noble gas, radon (element 86).

The various developments just mentioned led Rutherford and Soddy to formulate a *theory of radioactive transformation* published in a remarkable series of papers that has remained valid in its essentials to this day (Rutherford and Soddy 1902, 1903). They posited that radioactive decay involves the spontaneous transformation of atoms of one element into those of another, accompanied by the emission of particles. With this hypothesis, they thus introduced the rather revolutionary notion that atoms, previously thought to be immutable “elementary particles,” are in fact composite structures capable of subatomic change. This was a particularly remarkable proposal when one considers that it preceded by some 8 years the concept of the atomic nucleus.

Once the nature of α and β particles had been established and radioactive decay had been recognized as involving subatomic change, it became possible to formulate rules for the placement of radioelements in the periodic table. These so-called *displacement laws*, enunciated in 1913 (Fajans 1913; Soddy 1913b), state that the product of α decay is the element two columns to the left of the parent element, whereas β decay involves a one-column shift to the right. On the basis of these rules it was now possible to place all the known, naturally occurring radioactive species of the three decay series into the periodic table with the inclusion, as already mentioned, of numerous isotopic species. Each of the series also contains examples of so-called branching decays, i.e., instances of a given species decaying by both α and β decay. With the discovery of the long-lived ^{231}Pa (3.3×10^4 years) as the parent of ^{227}Ac (Hahn and Meitner 1918), the major routes of the three decay series were established. The observation (Hahn 1922) that the position of ^{234}Pa in the uranium decay series is shared by two species with different half-lives (1.17 min and 6.7 h) remained a curiosity for many years, until it was understood as the discovery of *nuclear isomerism*, representing the ground and a metastable, excited state. Further work on the natural series was devoted to rare decay branches.

The first realization that radioactivity was not confined to the heaviest elements came with the observation in 1906 of weak β radioactivity in potassium and rubidium (Campbell and Wood 1906). As measurement techniques became more and more sensitive, weak radioactivity was discovered in several other naturally occurring elements (e.g., In, Nd, Sm, Gd, Lu, Hf, and Re).

The identification of radioactive decay as a subatomic process led, of course, to theories of atomic structure. After various models had been suggested – none of them totally satisfactory – the big breakthrough came with Rutherford’s classic 1911 paper (Rutherford 1911) in which he proposed, on the basis of careful, quantitative experiments on the scattering of α particles from thin metallic foils, that most of the mass of an atom must be concentrated in a *positively charged*

nucleus, extremely small when compared to the size of the atom; the positive nuclear charge was thought to be balanced by an equal negative charge carried by electrons surrounding the nucleus. Based on this concept and on Coulomb's law, Rutherford was able to derive a formula that gives detailed predictions of α -particle scattering and its dependence on nuclear charge. Experimental verification of these predictions led to a widespread acceptance of the nuclear model and to the realization that an element's *atomic number*, hitherto merely indicating the element's placement in the periodic table, is in fact its nuclear charge (in units of the electronic charge e). Once Rutherford's *nuclear model of the atom* was accepted, elucidation of atomic structure made rapid strides, important milestones being Niels Bohr's theory of electron orbits (Bohr 1913) and the quantum revolution of the mid-1920s.

With time, the pioneers of radiochemistry developed a great variety of *chemical separation techniques* for the unraveling of the natural decay series, including co-crystallization, adsorption, volatilization, and electrochemical deposition. The quantities of the radioisotopes handled – as estimated from the decay rate – were often smaller by orders of magnitude than could be detected by any other method. Hence, studies of the chemistry of extremely low, “imponderable” quantities became a major research field of radiochemists during the first decades of the twentieth century (see, e.g., Hahn 1936). At such a level, deviations from the behavior of macroscopic amounts are not unexpected. For example, the vapor pressure and the evaporation rate are normally governed by the cohesive forces between the molecules of the species itself. In case of a monomolecular layer covering a backing, they depend, however, largely on the interaction between species and backing material. On the other hand, when radiochemists want to ensure “normal” chemical behavior of a trace quantity of a radionuclide, they add a macroscopic quantity of a *nonradioactive carrier*, usually of the same element in the same chemical form in which the trace element is thought to be present.

Path-breaking work that eventually spawned whole new fields was done in those early years. For example, the potential of *radioactive decay* to serve as a *clock* for geological processes was realized by Rutherford as early as 1906 (Rutherford 1906) when he proposed the amount of helium in uranium ores as a measure of the time since crystallization of the ore. This *He/U method* provided the first proof that geological processes must have occurred over times of the order of 10^8 to 10^9 years, orders of magnitude longer than indicated by previous methods. This revolutionary conclusion was confirmed in 1907 when lead was recognized as the final, stable product of uranium decay (Boltwood 1907), which meant that the Pb/U ratio could be used as a chronometer. Further refinement of this Pb/U method became possible when precise atomic weight determinations showed (Richards and Lambert 1914; Hönigschmid and Horovitz 1914) the lead in some uranium ores had an atomic weight close to 206 rather than the usual 207.2, thus identifying it as radiogenic.

Also of far-reaching consequences was the idea (Hevesy and Paneth 1913) to use *radioisotopes as indicators or tracers* in chemical, physical, and biological studies because radioactive and stable isotopes are chemically indistinguishable. Hevesy and Paneth determined the solubility of sparingly soluble lead salts by labeling the samples with radioactive lead and measuring the radioactivity in the solution after equilibration. The result can be obtained by other techniques too, but not in such a simple way as with radioactive indicators. This holds for most indicator applications.

However, it was realized early on that there is a category of problems that can be attacked *only* with radioactive (or stable isotope) indicators: the behavior of an element in some chemical form in the presence of the same element in a different chemical form. The first example was Hevesy's work on the exchange of lead between solid lead metal and its ions in

solution (Hevesy 1915), in which the dynamical exchange process postulated as a fundamental concept of chemical kinetics was directly verified. Even the fate of a species in an identical environment can be followed, as he showed for the self-diffusion of lead in molten (1920) and solid (1929) lead metal. The most seminal development was the extension of the tracer technique to life sciences by Hevesy and his coworkers. In 1923, they studied the uptake and transport of lead in plants (horse beans) including the proof that transport and fixation occur in ionic form (Hevesy 1923); a year later came the first tracer study in animals, a report on the circulation of bismuth in rabbits (Christiansen et al. 1924). As early as 1927, an application to human subjects was reported (Blumgart and Weiss 1927), the study of blood circulation by injection of ^{222}Rn decay products. This work represents also a generalization of the tracer concept beyond the original idea of isotopic tracers.

Though the potential of the tracer technique was clearly demonstrated in such studies, the input to chemistry and other fields remained somewhat limited as long as radioactivity was confined to the heaviest elements occurring in the natural decay series. The epoch-making event that led to a vast expansion of nuclear and radiochemistry was Irène Curie's and Frédéric Joliot's discovery of *artificially produced radioactivity* (Curie and Joliot 1934). Nuclear transmutation by α -particle bombardment – specifically the nuclear reaction $^{14}\text{N}(\alpha, \text{p})^{17}\text{O}$ – had been discovered by Rutherford in 1919 when he observed energetic protons during the bombardment of nitrogen with α particles from a natural source (Rutherford 1919). The new phenomenon of induced radioactivity appeared, e.g., in bombardments of aluminum with α particles as a nuclide decaying with 3 min half-life that could be chemically identified with phosphorus. The process involved was immediately understood as a nuclear reaction, $^{27}\text{Al}(\alpha, \text{n})^{30}\text{P}$, this time leading to an unstable rather than a stable product nucleus.

1.2 The Growth Spurt of the 1930s

The discovery of artificially produced radioactivity came on the heels of several other crucial events: the discoveries of the neutron (Chadwick 1932) and of deuterium, the heavy isotope of hydrogen (Urey et al. 1932), and the invention of devices – electrostatic generator (Van de Graaff et al. 1933), cyclotron (Lawrence and Livingston 1931), voltage multiplier (Cockcroft and Walton 1930, 1932) – capable of accelerating charged particles to energies needed for nuclear transformations. The invention of a very versatile, electronic counter for radioactivity (Geiger and Müller 1928) was another important step. *Neutron capture* in nuclei was discovered by Enrico Fermi and coworkers (Fermi et al. 1934) as an alternative and efficient method for the production of radioisotopes, such as ^{128}I ($T_{1/2} = 25$ min) from the $^{127}\text{I}(\text{n}, \gamma)$ reaction. The activations could be carried out with small neutron sources consisting of beryllium powder mixed with ^{226}Ra as α -particle source (i.e., using the $^9\text{Be}(\alpha, \text{n})^{12}\text{C}$ reaction) soon available in many radiochemical laboratories, and the yields could be increased substantially with neutrons slowed down in hydrogen-containing material (Fermi and Rasetti 1935; Pontecorvo 1935).

Also in 1934, Leo Szilard and T. A. Chalmers observed that neutron capture is accompanied by chemical effects (Szilard and Chalmers 1934); when ethyl iodide was irradiated with neutrons, about half of the produced ^{128}I was not organically bound, but could be extracted with water in the form of iodide. The recoil energy transferred to the iodine atom by the emitted γ ray exceeds by more than one order of magnitude the energy of the carbon-iodine

chemical bond and is thus sufficient to break the bond. This work opened the new research field of chemical effects of nuclear transformations, often referred to as *hot-atom chemistry*.

These developments, all within a time span of 5 years, led to rapid burgeoning of nuclear physics and chemistry in the 1930s. *New nuclear species* – nuclides as they came to be called – were discovered every week, with half-lives ranging from fractions of a second to thousands of years. Among the newly discovered nuclides were many that later gained great importance as tracers in medical practice and in industry, including ^{131}I , ^{60}Co , ^{32}P , and ^{14}C . By the outbreak of World War II in 1939, several hundred artificially produced radioactive nuclides were known (see, e.g., Seaborg 1940) and at the end of the century the number was somewhere around 3,000.

One might ask why chemists, along with physicists, got into the game of discovering, identifying, and studying radioactive nuclei and their properties as well as investigating the mechanisms of the nuclear reactions producing them. To some extent this came about because irradiation of a given target element with a given projectile often led to a variety of radioactive products that had to be separated and identified chemically. But there was also the intrinsic interest of the subject matter and the obvious parallels between chemical and nuclear reactions, as well as between atomic and nuclear structures.

1.2.1 Nuclear Reactions

By the late 1930s, the systematic study of nuclear reactions induced by various projectiles – protons, neutrons, deuterons, and α particles – at the range of particle energies then available (up to about 40 MeV) led to an understanding of the prevalent reaction mechanism in terms of Niels Bohr's *compound-nucleus model* (Bohr 1936). In this model, the incident particle amalgamates with the target nucleus to form a so-called compound nucleus, in which the particle's kinetic and potential energy is shared by all the nucleons. The compound nucleus may be thought of as the nuclear analogue of the excited, quasi-stationary transition state in chemical reactions. After many collisions among the nucleons, taking typically 10^{-14} – 10^{-19} s (a long time in nuclear dimensions), enough excitation energy may be concentrated by statistical fluctuations on one nucleon (or cluster of nucleons such as an α particle) to allow it to escape from its confinement in the potential well of the nucleus. This slow second step is called “*evaporation*,” in analogy to the escape of molecules from a drop of hot liquid, a concept introduced into nuclear physics in the mid-1930s (Frenkel 1936; Bohr and Kalckar 1937) and soon widely accepted. An essential point of the compound-nucleus model is the independence of the evaporation step from the mode of formation of the compound nucleus, and this was confirmed in the 1950s and 1960s by radiochemical studies of the production of radioactive nuclides via the same compound nucleus formed in different ways.

Although the compound-nucleus model accounts well for a large body of nuclear reactions, it became clear early on that there are exceptions. For example, in some deuteron irradiations it was found that protons are emitted preferentially in the forward direction, whereas the compound-nucleus picture (evaporation) would predict an essentially isotropic emission. These (d,p) reactions are interpreted as “stripping” reactions, i.e., the deuteron's neutron is stripped off by the target nucleus and the proton just continues on its path (Oppenheimer and Phillips 1935). This is an example of so-called *direct reactions*, which can occur with the transfer of larger pieces also, e.g., transfer of an α particle from a ^{12}C projectile to the target nucleus.

Direct reactions in the opposite direction, i.e., transfers from target to projectile, also occur and are referred to as “pick-up” processes.

Another major turning point in the history of nuclear science came with the *discovery of fission* by Otto Hahn and Fritz Strassmann in December 1938 (Hahn and Strassmann 1939a, b). In several laboratories in Rome, Berlin, and Paris, a complex series of β -decay chains resulting from neutron irradiation of uranium had been investigated since 1934, and these chains had been assigned to putative transuranium elements formed by neutron capture in uranium with subsequent β^- transitions increasing the atomic numbers (see [Sect. 1.2.3](#)). But then evidence appeared that known elements in the vicinity of uranium, such as radium, were produced as well. When Hahn and Strassmann attempted to prove this by a classical fractional crystallization separation of radium from barium serving as its carrier, the radioactivity turned out to be barium, not radium; hence, new and totally unexpected type of nuclear reaction had to be invoked.

Lise Meitner and Otto Frisch immediately provided the basic explanation of the fission process, again relying on the liquid-drop model of the nucleus (see [Sect. 1.2.2](#)) and the formation of a compound nucleus (Meitner and Frisch 1939). In the very heavy uranium nucleus, collective vibrations were thought to take place after neutron capture, leading to elongation and eventual breakup into two major pieces. Most stunning was the conclusion that in this breakup about 200 MeV of energy should be liberated, far more than in any other nuclear reaction. These energetic fragments were very soon observed in several, almost simultaneously performed experiments, the first carried out by Frisch (Frisch 1939). Niels Bohr supported this explanation of the process and suggested that fission should be more probable in the rare isotope ^{235}U than in the abundant ^{238}U (Bohr 1939), as soon was experimentally confirmed with tiny samples separated in a mass spectrometer (Nier et al. 1940). As early as the summer of 1939, a comprehensive *theory of fission* was worked out by Bohr and John Wheeler on the basis of the liquid-drop model (Bohr and Wheeler 1939). Cornerstone is the concept of a fission barrier, which stabilizes heavy nuclei although they are thermodynamically unstable against breakup into two fragments. A certain energy is required to deform a nucleus until a critical shape (the saddle point) is reached from where it moves to scission. The capture of a thermal neutron in the rare ^{235}U provides just enough energy to carry it over the barrier, whereas this is not the case in the more tightly bound, abundant ^{238}U .

In 1940, Georgi Flerov and Konstantin Petrzhak showed that natural uranium *fissions spontaneously*, albeit with an extremely low rate (Flerov and Petrzhak 1940; Petrzhak and Flerov 1940). As spontaneous fission was subsequently studied in other nuclei, it was found that its rate increases steeply with atomic number. This decay mode may thus finally terminate the periodic table of elements.

The ramifications of the discovery of fission were, of course, vast – the twin developments of nuclear reactors and nuclear bombs having had scientific, political, military, economic, and social impacts worldwide. For nuclear chemists, fission opened a rich field of research in the identification and characterization of *fission products* with half-lives ranging over about 13 orders of magnitude.

1.2.2 Nuclear Properties

Another field of basic nuclear science that became a major preoccupation of chemists, starting in the 1920s, was the study of the nuclear properties of radioactive nuclides – their half-lives and the radiations emitted by them.

In many ways, α decay presents the simplest situation. As early as 1906, Rutherford had noted that the shorter the half-life of an α emitter, the longer is the range of the emitted α particles in air (i.e., the larger is its kinetic energy), and in 1911, a quantitative relation between decay constant and range was formulated (Geiger and Nuttall 1911). The theoretical basis for understanding this relationship came with the advent of quantum mechanics: In 1928, George Gamow as well as Ronald Gurney and Edward Condon, developed the theory of α decay as a tunneling phenomenon through the energy barrier that confines the α particle within the nucleus (Gamow 1928; Gurney and Condon 1928, 1929). This concept explains the very steep inverse dependence of the half-life on the α -particle energy: for energies spanning a factor of five, the half-life covers 30 orders of magnitude (according to current data). *Quantum-mechanical tunneling* was thus introduced as a concept soon taken over in many scientific fields. Since the kinetic energy carried by the α particles reflects the mass difference between the initial and final nucleus, nuclear masses for unstable nuclei became available. When in the 1930s, α -particle spectra began to be studied with high resolution by magnetic deflection, it became obvious that α particles of more than one energy can be emitted by a given species (Rosenblum 1930). The product nucleus is formed not only in its ground state but also in various excited states, which then de-excite by γ -ray emission. The detailed study of the energy levels involved and their quantum-mechanical properties turned into the field of *nuclear spectroscopy*.

Whereas α -particle spectra consist of discrete lines, β particles are emitted with a broad continuous energy distribution in which the energy difference between decaying and product nucleus appears only as the very weakly populated end point of the energy spectrum and is therefore difficult to determine with great accuracy. The average energy carried by the β particle is only about one third of that “expectation value.” This was very hard to reconcile with a transition between discrete energy levels of the initial and final nucleus. Further problems were noted with the balance of angular momentum and spin in β transitions. This raised the troubling question whether the fundamental laws of energy and momentum conservation are invalid at nuclear dimensions. In 1930, Wolfgang Pauli came up with a privately communicated (Pauli, 1994), surprising suggestion for resolving this puzzle: He postulated a neutral, massless particle, emitted along with the β particle and carrying away the missing energy, momentum, and spin. In 1934, Fermi then developed a complete *theory of β decay* incorporating this idea and naming the particle neutrino (Fermi 1934a), at that time a purely hypothetical construct. Its reality was experimentally proven in 1953 by Fred Reines and Clyde Cowan with the intense neutrino fluxes provided by a nuclear reactor (Reines and Cowan 1953; Reines et al. 1960).

Since β decay occurs throughout the periodic table, it offers a wider field of study than α decay, which is largely confined to heavy elements. The term β decay encompasses both β^- (negatron) and β^+ (positron) emission (Curie and Joliot 1934) as well as the process of *orbital electron capture* discovered in 1937 (Alvarez 1937) which, like β^+ emission, leads to a one-unit decrease in atomic number. In each of the three processes a neutrino is emitted (in β^- emission it is an antineutrino). The systematic of β decay has been worked out and selection rules for β transitions in terms of spin and parity changes have been established. Many if not most β transitions lead to excited states of the product nuclei.

Excited states of nuclei, whether formed through α or β decay or through any other nuclear process, decay to lower-lying states (including the ground state) by the emission of γ rays. It is in fact the spectroscopy of γ rays occurring in coincidence with preceding α or β particles and within γ -ray cascades, and the measurement of lifetimes in such decay sequences that are most

essential to the determination of *decay schemes*. This term denotes the detailed assignment of all the modes of decay of a given nuclide, the energies, transition rates, and sequences of all the γ transitions involved in the de-excitation of excited states, and the energies, lifetimes, and quantum numbers of all the levels populated in the product nucleus. When highly excited states are populated in β decay, enough energy may be available to evaporate a neutron, proton, or α particle, as was first observed in 1939 as *β -delayed neutron emission* from fission products (Roberts et al. 1939). With every advance in instrumentation and detector technology, increasing amounts of detail and increasingly rare branch decays became accessible, and generations of nuclear chemists and physicists have devoted themselves to the study of decay schemes.

Gamma-ray transitions between states with large differences in spin turned out to be highly forbidden by angular momentum selection rules, which leads to measurable lifetimes for certain excited states, the *nuclear isomers*. A transition from an isomeric to a lower state often takes place by *internal conversion* of the γ radiation, i.e., the emission of an orbital electron (most often an electron from the K shell) instead of the γ ray; the electron energy then equals the transition energy minus the electron's binding energy. Like in electron capture, the vacancy in an inner electron shell is filled by outer electrons and this process is accompanied by the emission of X-rays characteristic of the product nucleus. The measurement of such *characteristic X-rays* is an important tool for the determination of the atomic number of unknown radionuclides. As electrons cascade in from outer shells, the product atom becomes highly ionized and may appear in a chemical form different from that of the decaying isomeric state; this can be used for the *chemical separation of nuclear isomers*, first reported in 1939 (Segrè et al. 1939) for the isomers of ^{80}Br ; when the isomeric state ($T_{1/2} = 4.4$ h) was incorporated into an organic bromide, the ground state (18 min) formed by decay could selectively be extracted into an aqueous phase.

Decay-scheme studies have provided theoretical physicists with a broad range of experimental data for the development of models to interpret nuclear properties. Interestingly, such models take up ideas established for the description of atomic, molecular, or macroscopic systems, in spite of the many orders of magnitude difference in dimensions.

Particularly important was a model describing *nuclear masses* as they were becoming available in the 1930s from mass spectroscopic measurements and nuclear decay and reaction studies. Such a model should form the basis of nuclear thermodynamics and allow predictions of the energetics of nuclear transformations in cases not yet investigated. A first step was Gamow's recognition of the analogy between atomic nuclei and macroscopic drops of a liquid (Gamow 1929). In both systems, an attractive force acts between the constituents, increasing the binding energy with size and leading to spherical shapes maintained by surface tension. In nuclei, however, this trend is counteracted by the Coulomb repulsion between protons, which decreases the binding energy as Z increases. Carl Friedrich von Weizsäcker pursued the *liquid-drop model* further in 1935, after the neutron had been established as a constituent of nuclei (Weizsäcker 1935). His semiempirical *equation for nuclear masses* takes as the leading term the binding energy proportional to the number of nucleons, with corrections for surface nucleons, Coulomb repulsion, and the fact that equal numbers of protons and neutrons are energetically preferred. This equation is, in its modern versions, still the backbone of nuclear thermodynamics in that it covers the major, smooth trends of nuclear masses with proton and neutron number.

With improved knowledge of excited nuclear states, it became obvious that they frequently exhibited patterns similar to those known from molecular spectroscopy: vibrations of a (slightly perturbed) harmonic oscillator as well as rotations of a nonspherical structure.

Hence, nuclei can vibrate around the spherical ground state. Moreover, they can be permanently deformed into *prolate* (cigar-like) or *oblate* (disk-like) shapes rotating around an internal symmetry axis. Overlaid on the smooth trends are properties of nuclei with certain proton and neutron numbers (2, 8, 20, 28, 50, 82, 126) standing out in many different respects, as already recognized in the 1930s (Elsasser 1933, 1934). For example, lead nuclei ($Z = 82$) are the end points of the natural decay chains, and extraordinarily high energies are released in the α decay from polonium (84) into lead nuclei. Among the stable nuclei, ^{48}Ca ($Z = 20$, $N = 28$) is unusually neutron rich, and tin ($Z = 50$) has more isotopes than any other element. Most directly, the extra stability associated with these “*magic*” numbers becomes evident in their nuclear masses. The situation was clearly reminiscent of the closed electron shells in atoms, but it was only in 1949 that a quantum-mechanical concept for nuclear shells was developed (see ▶ Sect. 1.4.2).

1.2.3 New Elements

One major field of endeavor of nuclear chemists has long been the *search for* and characterization of *new elements*, i.e., elements not previously found in nature. This field was much stimulated by H. G. J. Moseley’s X-ray studies (Moseley 1913, 1914) indicating still existing gaps in the main body of the periodic table. Further gaps remained even after the extensive studies of the natural decay chains had filled in most of the elements between bismuth and uranium. In the 1930s, the elements 43, 61, 85, and 87 were still missing. Each of them had at various times been claimed to exist in nature, but none of these claims could be substantiated. The growing knowledge of nuclear transformations now made it possible to consider synthesizing missing elements in the laboratory.

Element 43 was the first element produced by an induced nuclear transformation; it was discovered in 1937 (Perrier and Segrè 1937a, b) as a 92 d activity present in molybdenum sheets exposed to deuterons at a cyclotron, i.e., produced by the $^{96}\text{Mo}(\text{d}, \text{p})^{97}\text{Tc}$ reaction. The element followed the chemistry of its supposed homologue rhenium. When it became clear that no stable or extremely long-lived isotopes of element 43 exist in nature, the discoverers proposed in 1947 the name *technetium* for this element, emphasizing its status as the first artificial element. Element 61 in the lanthanide series was unambiguously identified in 1945 (Marinsky et al. 1947) among the fission products of uranium, thanks to the ion-exchange techniques for separating rare earths developed in the Manhattan Project. The discoverers named the new element *promethium*.

Elements 85 and 87 fall into the region covered by the natural decay series and could therefore be expected to be fed by rare decay branches. As early as 1914, α particles were observed in carefully purified ^{227}Ac ($Z = 89$), which implied the formation of element 87 (Meyer et al. 1914). However, the work of Marguerite Perey in 1939 is credited with the discovery of element 87 – the last discovery of a new element in nature (Perey 1939a, b). She proved that a 21 min β^- emitter ($^{223}\text{87}$) growing from ^{227}Ac had chemical properties akin to cesium, and named the element *francium* (Fr). Element 85, *astatine* (At), the heaviest known halogen, was first produced artificially in 1940 as $^{211}\text{85}$ ($T_{1/2} = 7$ h) by ($\alpha, 2\text{n}$) reaction on ^{209}Bi (Corson et al. 1940a, b) before short-lived isotopes were found also in rare branches of the decay series.

Extension of the periodic table beyond uranium by the transmutation of elements was first attempted by neutron irradiation of uranium. Because neutron capture reactions in heavy

isotopes of an element are generally followed by β^- decay to the next heavier element, neutron capture in uranium should yield element 93. After preliminary studies in Rome (Fermi 1934b), more extended studies in Berlin (Hahn et al. 1936; Meitner et al. 1937) presented evidence for several transuranium elements, chemically identified on the premise that element 93 should be a homologue of rhenium, and the elements 94 to 96 should follow the chemistry of the platinum metals. In 1938, contradictory results in Paris (Curie and Savitch 1938) led Hahn and Strassmann to experiments culminating in the discovery of fission (Hahn and Strassmann 1939a, b) (see ► Sect. 1.2.1). Quite soon, it became clear that all these supposed “transuranium” nuclides were in fact fission products.

Now the question whether *transuranium elements* were within range was again open. Edwin McMillan obtained a first hint when he irradiated thin uranium layers with neutrons (McMillan 1939). Whereas the fission products recoiled out of the target, the already known 23 min ^{239}U formed by neutron capture in ^{238}U remained in the target along with a β^- emitter with 2.3 d half-life. A year later, he and Philip Abelson were able to show by a radiochemical milking experiment that the 2.3 d nuclide is the decay product of ^{239}U ; hence it is $^{239}\text{93}$, the first transuranium element (McMillan and Abelson 1940). They named it *neptunium* (after Neptune, the next planet after Uranus). Their further chemical studies of element 93 on the tracer scale revealed uranium-like properties with two oxidation states similar to U(IV) and U(VI), completely different from the expected rhenium-like behavior. Thus, it became clear that the periodic table must have some unexpected features in the vicinity of uranium, later associated with the onset of the *5f electron series* (see ► Sect. 1.3). Since ^{239}Np decays by β^- emission, its daughter clearly had to be another new transuranium element, 94, of mass number 239. Its discovery turned out to be difficult, however.

1.2.4 Hot-Atom Chemistry and Tracer Applications

As mentioned at the beginning of ► Sect. 1.2, *hot-atom chemistry*, i.e., the chemistry of atoms originating from nuclear transformations with kinetic energies far in excess of the usual thermal reaction energies, began in 1934 with the observation that ^{128}I formed by neutron capture in an organic iodide appears as an inorganic species (Szilard and Chalmers 1934). Since the extract contained only traces of stable iodine, this effect allowed, even with the weak neutron fluxes then available, the production of radioactive samples with high specific activity (i.e., activity per weight unit) as often required in tracer applications. Very soon, such so-called *Szilard–Chalmers procedures* were developed for a variety of nuclides accessible by (n, γ) and (n,p) reactions.

In a first study of the organic fraction remaining after such a procedure (Glückauf and Fay 1936), it turned out that a considerable part of the radioactive ^{128}I was present not in the form of the irradiated molecule, but appeared as derivatives. For example, irradiation of CH_3I produced not only CH_3^*I , but also $\text{CH}_2\text{I}^*\text{I}$ ($^*\text{I} = ^{128}\text{I}$) and, when a mixture of CH_3I with C_6H_6 was irradiated, $\text{C}_6\text{H}_5^*\text{I}$ was one of the reaction products. Since in gaseous organic halides all carbon–halogen bonds were found to break in the nuclear process, the apparent “*retention*” of the radioisotope in the original compound observed in condensed states must be due to secondary interactions of the liberated hot atoms with their environment. Hot-atom reactions were also observed in inorganic systems. Already during the Rome group’s systematic exploration of neutron activations (Fermi et al. 1934), it was found that most of the ^{56}Mn ($T_{1/2} = 2.6$ h) produced by irradiation of solid KMnO_4 can be collected, after dissolution, as MnO_2

(D'Agostino 1935). Studies of hot atoms, their reaction mechanism, and use for labeling molecules became a hot topic for radiochemists in the following decades.

With radioisotopes now available for many elements, the tracer technique became generally applicable. New variants were developed, such as *neutron activation analysis*, which was introduced in 1936 for the determination of dysprosium in rare-earth samples (Hevesy and Levi 1936) and subsequently became a widely used technique for sensitive trace analyses, particularly when much larger neutron fluxes became available with the advent of nuclear reactors. Another frequently applied method for trace determination is *isotope dilution*: the species to be determined in the sample is diluted by addition of a known amount of the same species labeled with known specific activity. From the specific activity then resulting and measured, the original quantity of the species is derived, even if only a fraction of the species is finally recovered. The impact on biosciences was revolutionary, when suitable isotopes of key elements in the biosphere were soon discovered: ^{13}N ($T_{1/2} = 10$ min) was one of I. Curie and Joliot's early discoveries, and ^{32}P (14 d) and ^{128}I (25 min) were reported by Fermi's group; ^{11}C (20 min), ^{15}O (2.0 min), ^{35}S (88 d), ^{131}I (8.0 d), and ^3H (12 years) followed soon at the early charged-particle accelerators. Of particular importance was the 1940 discovery of the long-lived ^{14}C (5,730 years) (Ruben and Kamen 1940a, 1941, see also Kamen 1963).

Hevesy was the first to apply the new tracers to *biosystems* in a series of studies all performed with ^{32}P , which was produced by the $^{32}\text{S}(\text{n},\text{p})$ reaction in large volumes of carbon disulfide and isolated by extraction with water. The pioneering experiment, performed in 1935 (Chiewitz and Hevesy 1935), was devoted to phosphorus metabolism in rats. It showed that the skeleton is not static but is dynamically replaced with an average holdup time for a phosphorus atom of about 2 months. Other early work dealt with ^{32}P -labeling of red blood corpuscles for the determination of blood volume; this method became a standard in medical practice.

Early tracer studies with cyclotron-produced nuclides were reported beginning in 1937. Most seminal was the first work on *photosynthesis*, performed in 1940 with the short-lived ^{11}C (Ruben et al. 1940; Ruben and Kamen 1940b). The tracer, made by $^{10}\text{B}(\text{d},\text{n})$, was fed as $^{11}\text{CO}_2$ to *Chlorella* algae, which were killed after various times, and the appearance of ^{11}C in various chemical fractions was followed. The authors concluded that carbon fed as CO_2 is fixed only in the dark and that, in the first step, it is incorporated in the carboxyl group of a species with molecular weight of about 1,000. Some studies were done early on with organic molecules chemically synthesized with ^{11}C labels at specific carbon positions. The study of the uptake of ^{131}I in the thyroid gland of human patients with thyroid malfunctions or goiter, performed by recording the ^{131}I activity in vivo with a counter placed close to the thyroid gland was also path breaking (Hamilton and Soley 1939, 1940).

Although these pioneering studies paved the way for a rich panoply of biological and medical tracer applications, the field came nearly to a halt during World War II and was revived with new vigor after a hiatus of several years.

1.2.5 Geo- and Cosmochronology

As noted in Sect. 1.1, the potential of radioactive decay to serve as a “clock” for geological processes was recognized very early. The amount of helium in uranium and thorium ores should generally be considered to give only lower limits for the ages of mineral deposits because of the likelihood of helium loss during geological times. The probability that there have been no losses (or gains) is intrinsically greater for lead than for helium, and the lead/uranium and lead/

thorium age determination methods, based solely on chemical analyses for Pb, U, and Th, were therefore thought to be more definitive than the He/U and He/Th methods. However, major progress in the reliability of *age determinations* came only with the advent of isotopic analyses by mass spectrometry. The first investigations of the isotopic compositions of lead from various sources were published in 1938 (Nier 1938). The realization that the amount of ^{204}Pb , the only non-radiogenic lead isotope, could be used to correct for the contributions of the other lead isotopes present at the time of formation of a uranium or thorium mineral paved the way for much improved geological age determinations.

Although potassium had been known since 1906 to be radioactive, it was only in 1935 that the rare isotope ^{40}K was discovered mass-spectrometrically (Nier 1935) and found to be responsible for the radioactivity. In 1937, Weizsäcker speculated – correctly as it turned out – that ^{40}K decays to ^{40}Ar by electron capture and proposed the measurement of ^{40}Ar in potassium minerals as a *geochronological dating* method (Weizsäcker 1937). This was the key to the postwar development of the potassium–argon method of age determination which, because of the ubiquity of potassium in nature, has much wider applicability than the methods based on uranium and thorium. Weizsäcker’s speculation was supported by the observation that the abundance of ^{40}Ar is anomalously large in the Earth’s atmosphere as a result of the decay of ^{40}K in the Earth’s crust.

Other techniques that later found extensive use in nuclear geology and other fields also had their roots in the 1930s. An apparatus for obtaining long ocean cores was first described in 1936 (Piggott 1936). In the following years, it was applied in the first investigations of the radioactivity in such cores to deduce time relations from the results. The preparation of thick photographic emulsions for α -particle autoradiography was published in 1935 (Baranov and Kretschmer 1935) for precisely locating radioactive constituents in rocks. This work led to the development of a variety of thick photographic emulsions of different compositions and grain sizes, collectively known as *nuclear emulsions*. In addition to being important in mineralogy and geology, they became widely used after World War II as particle detectors in cosmic-ray research as well as in nuclear and particle physics.

Quite early in the development of nuclear science it had been realized that the huge amounts of *energy radiated by stars* like our Sun must be produced by nuclear rather than chemical processes. The notion that *nuclear fusion* might be what fuels the stars was first proposed in 1919 by Jean Perrin (he called it “la condensation d’atomes légers en atomes lourds”) (Perrin 1919). In 1926, Arthur Eddington refined this idea by postulating the conversion of hydrogen into helium as the most likely candidate (Eddington 1926). But it was only with the more detailed understanding of nuclear reactions achieved in the 1930s that specific mechanisms for this conversion could be formulated. In 1938, Hans Bethe described a sequence of reactions now known as the carbon–nitrogen cycle that fills the bill (Bethe 1939). It starts with the reaction $^{12}\text{C}(\text{p},\gamma)^{13}\text{N}$ and, after a series of such (p,γ) reactions interspersed with positron decays, ends with the reaction $^{15}\text{N}(\text{p},\alpha)^{12}\text{C}$; thus ^{12}C is regenerated in this cycle and can be thought of as a catalyst, with the net reaction being the conversion of four protons to ^4He (plus two positrons and two neutrinos). Bethe’s paper spawned the important and fascinating field of *nuclear astrophysics*.

1.3 World War II

Within a few months of the discovery of nuclear fission, it became evident that this reaction involves a very large energy release as well as the emission of neutrons, and this quickly led to

speculation about the possibility of a chain reaction. With the outbreak of World War II and the possibility of developing a bomb based on an *explosive nuclear chain reaction*, further work on fission in a number of countries soon became shrouded in secrecy, with the US effort (known as the *Manhattan Project*) being by far the most ambitious (for a comprehensive history of the Manhattan Project, see Rhodes 1986). On December 2, 1942, only 4 years after the discovery of fission, the first man-made self-sustained chain reaction was achieved in Chicago by Fermi and his team, using natural uranium as nuclear fuel, embedded in a lattice of very pure graphite as moderator. By then, the US government had decided on a crash program to achieve its goal of a fission bomb and it took a mere 2½ years more to produce the two nuclear bombs dropped on Hiroshima and Nagasaki. The realization of an explosive chain reaction on this incredibly short timescale involved a veritable army of scientists charged with finding solutions to an enormous variety of nuclear, chemical, and engineering problems. Thus, a whole new generation of chemists and physicists was rapidly trained and educated in nuclear science. This new supply of highly skilled nuclear experts, along with the spectacular success of the Manhattan Project, set the stage for the burgeoning of nuclear physics and chemistry in the postwar decades. The massive wartime effort, involving the collaboration of many scientists and interdisciplinary teams, also presaged the age of “*big science*.” Subsequently, this “big science” emerged as the prevalent mode of doing research, first in particle physics and later also in nuclear science and consequently it has become increasingly difficult to single out individual contributions among the large group efforts.

The initial thinking about achieving an explosive chain reaction focused on separating fissile ^{235}U from ^{238}U , and several *isotope separation methods* (thermal diffusion, gaseous diffusion, electromagnetic separation, and centrifugation) were pursued in parallel. But another key development was the *discovery of element 94* and its fissionability by slow neutrons, which opened a second path to a fission bomb. As mentioned in [Sect. 1.2.3](#), the identification of ^{239}Np as a β^- emitter led inevitably to a search for the next element. However, because of its long half-life and unknown chemistry, the decay product ^{239}Pu was difficult to find. Rather, element 94 was discovered in February 1941 in the form of the shorter-lived isotope ^{238}Pu ($T_{1/2} = 88$ years) by deuteron bombardment of uranium (Seaborg et al. 1946a, b). First studies of its chemical behavior were performed on the tracer scale (Seaborg and Wahl 1948). A few months later, Glenn Seaborg’s team (Kennedy et al. 1946) was able to produce a sufficient quantity (about 0.5 μg) of ^{239}Pu to detect its α activity and to find that ^{239}Pu is even more fissile by slow neutrons than ^{235}U . The half-life was later measured to be 2.41×10^4 years. The new element was called *plutonium* (Pu) after the planet Pluto, as uranium and neptunium had been named after Uranus and Neptune.

Initial studies of the *chemistry of neptunium and plutonium* actually preceded the official establishment of the Manhattan Project. But as soon as the project got underway, they became the subject of intensive investigation at several of the Manhattan Project laboratories (Seaborg and Katz 1954). Both elements turned out to have four major oxidation states +3, +4, +5, +6, similar to uranium, but plutonium is unique in that these four states can all exist simultaneously in aqueous solution. Microchemical techniques were applied to prepare and study microgram quantities, such as the first weighable sample of a man-made element, 2.77 μg PuO_2 , in September 1942 (Cunningham and Werner 1949). At the Los Alamos Laboratory, chemists and metallurgists learned to produce metallic plutonium and studied its complex properties, which eventually turned out to involve no less than six allotropic phases, more than any other element.

Quite remarkable is the fact that, based on laboratory experiments on a microgram scale, radiochemists under the leadership of Seaborg were able to devise the methods that were soon

successfully used to separate kilograms of plutonium from reactor-irradiated uranium and fission products. This was achieved by coprecipitation of Pu(IV) with bismuth phosphate. In the first postwar years this batchwise procedure was replaced by continuous solvent extraction processes such as the extraction of both Pu(IV) and U(VI) from nitric acid into tributyl-phosphate, followed by selective reduction of Pu(IV) to Pu(III) and its back-extraction into an aqueous phase.

Also already during World War II the next two elements, 95 and 96, subsequently named *americium* (Am) and *curium* (Cm), were synthesized (Seaborg et al. 1949a, b), using α -particle bombardments of uranium and plutonium, respectively: ^{241}Am (432 years) resulted from (α ,n) reaction on ^{238}U via the β decay of the primary product ^{241}Pu (14.4 years); ^{242}Cm (163 d) was directly formed in the $^{239}\text{Pu}(\alpha, n)$ reaction. The studies of their chemical properties were started, although the realization that their most stable oxidation state is +3 did not come until shortly after the end of the war. It was this observation more than anything else that led Seaborg to his daring concept of the actinide series (Seaborg 1945, 1954) – a major revision of the periodic table.

Detailed studies of the vast array of fission products occupied a small army of chemists at the “Metallurgical Laboratory” in Chicago (Coryell and Sugarman 1951, see also Siegel 1946). The individual nuclides had to be identified, their nuclear properties determined, and their yields in fission measured. One of the important general results was the realization that, under slow-neutron bombardment, ^{235}U and ^{239}Pu split *asymmetrically* into two fragments of unequal mass, whereas the liquid-drop model predicts a symmetric mass split. This behavior remained an intriguing puzzle for 3 decades.

Although the focus has been on the US developments during World War II, one should note that work along some of the same lines went on in other countries as well, albeit on a much more modest scale. In Germany, a small group of chemists in Otto Hahn’s laboratory, using fairly weak neutron sources and unaware of the secret work in the USA, managed to accumulate considerable information on fission products (Seelmann-Eggebert and Strassmann 1947) and on neptunium chemistry on a tracer scale (Strassmann and Hahn 1942). A search for element 94 emerging from the β^- decay of ^{239}Np was not undertaken, however. The German efforts to achieve a self-sustaining chain reaction with natural uranium as fuel and heavy water as moderator never came to fruition.

1.4 The Golden Era

As already indicated, the early postwar decades saw an enormous growth of both basic and applied nuclear research. Almost everywhere, certainly in the USA, Western Europe, the Soviet Union, and Japan, governments supported nuclear science on a scale never before experienced. At the first “*Atoms for Peace*” Conference convened in 1955 at Geneva under the auspices of the United Nations, a vast amount of previously classified information was publicly presented for the first time (PUAE 1956). This conference gave a considerable impetus to the dissemination of nuclear research and the worldwide use of nuclear technology.

The development of new tools, some of them the direct outgrowth of wartime work, was another crucial ingredient. Nuclear reactors provided neutron fluxes many orders of magnitude greater than had ever been available before, and with these fluxes it became possible to make a wide variety of radioactive nuclides of almost any desired intensity, either by (n, γ) reactions or as fission products. *New accelerator designs* – betatrons, synchrocyclotrons, synchrotrons, and linear accelerators – opened up new energy regions for the study of nuclear reactions

(see, e.g., Livingston and Blewett 1962). Moreover, the invention of *new detector types* – solid and liquid scintillators as well as semiconductors – revolutionized radiation detection (see, e.g., Price 1958; Bertolini and Coche 1968). As *computers* became more and more powerful and available, they transformed the performance and interpretation of experiments, the collection and analysis of data, and the calculation of theoretical models. *Textbooks* (Friedlander and Kennedy 1949, 1955; Wahl and Bonner 1951) helped disseminate the rapidly evolving knowledge and educate a new generation of students.

1.4.1 Nuclear Reactions

At the *higher bombarding energies* that became available after World War II – first in the hundreds of MeV with synchrocyclotrons, later into the GeV region with proton synchrotrons – the compound nucleus picture that had accounted well for most nuclear reactions up to about 40 or 50 MeV excitation energy began to fail. As with fission, these high-energy reactions were found to lead to multitudes of radioactive (and stable) products with a wide range of mass and atomic numbers. The unraveling of these complicated mixtures was a natural task for chemists, since the first step normally involved chemical separation of individual elements.

The observed reaction patterns, with a great variety of products formed even in the bombardment of a given target with a given projectile, were accounted for by a two-step model proposed in 1947 by Robert Serber (Serber 1947). In the first step, the high-energy incident particle is thought to interact with individual nucleons, thus setting off a so-called *intranuclear cascade*. In this phase, energy is transferred among a relatively small number of nucleons, some of which may have sufficient energy to escape from the potential well, while others will make further collisions and thus distribute energy among other nucleons. This cascade phase lasts of the order of 10^{-22} s and leaves behind a highly excited nucleus, which can then emit additional particles by *evaporation* (or undergo fission) on a much slower timescale. This cascade/evaporation model, when incorporated in computer codes (Metropolis et al. 1958a; Dostrovsky et al. 1959), was quite successful in accounting for the cross sections of a large body of reactions, referred to as *spallation reactions* because they involve the spalling-off of small fragments from the excited nucleus (in contrast to fission that is essentially a binary breakup). The observed energy spectra of particles emitted in these reactions are also fairly well reproduced by the model.

In the high-energy region just discussed, proton-induced reactions were the ones most widely studied, but other projectiles including deuterons and α particles were also used, and some work on pion-induced reactions has been reported. In the energy regime above a few hundred MeV, the production and subsequent interactions of pions during the intranuclear-cascade phase of reactions are believed to play an important part in facilitating the deposition of large amounts of energy in nuclei. It was only with the inclusion of pion production and pion interactions that the theoretical models were able to account for the pattern of spallation reactions experimentally observed (Metropolis et al. 1958b).

In the early 1950s, the study of the reactions induced by ions heavier than α particles was started (see, e.g., Bromley 1984), and since the 1960s the investigation of *heavy-ion reactions* has become one of the most active areas of nuclear research. New accelerators, designed specifically for producing increasingly intense beams of heavy ions all the way up to uranium ions were developed and, as a result, an enormous variety of reactions became accessible. The basic mechanisms mentioned for light-ion reactions, including *compound nucleus formation*, stripping reactions, and other forms of *direct interactions* appear to be of importance for heavy ions also. But an

additional process, first invoked in 1959 (Kaufmann and Wolfgang 1959, 1961) and later termed *damped collision*, has been found to play an important role in heavy-ion interactions. Projectile and target stick together in a transitory collision complex, but instead of continuing to amalgamate into a compound nucleus, the system is driven apart under the action of the Coulomb repulsion in a fission-like process, yielding a broad distribution of fragment masses and charges (Wilczynski et al. 1967, see also Schroeder and Huizenga 1977).

As will be discussed in [Sect. 1.4.3](#), heavy ion reactions made possible the upward extension of the periodic table that has been one of the triumphs of nuclear chemistry in recent decades.

An overwhelming amount of information on fission was accumulated. The *asymmetric mass split* (see [Sect. 1.3](#)) was found to be a general phenomenon in low-energy fission (see, e.g., von Gunten 1969). Regardless of the mass of the fissioning nucleus, the heavy fragment is located around mass number 130 (i.e., by fragments from tellurium to barium) whereas the light fragment moves with increasing fissioning mass toward the heavy fragment until fission becomes symmetric for fermium nuclei ($Z = 100$). The fact that the heavy fragments are positioned close to the $Z = 50$, $N = 82$ shells led to the suggestion that shell effects in the nascent fragments play a role. V. M. Strutinsky (Strutinsky 1967) showed how to correct the liquid-drop fission barrier (see [Sect. 1.2.1](#)) for shell effects in spherical as well as deformed nuclear shapes. It turned out that the barrier is double humped with a first saddle point located close to the ground state of the fissioning nucleus and a second saddle in a strongly deformed shape state close to the scission point. In between is a minimum at a certain deformation due to the shell closure in the deformed shape. This new picture of the fission barrier was supported by several experimental observations, most convincingly by the shape isomers discovered by Sergei Polikanov (Polikanov et al. 1962), which are spontaneously fissioning elongated nuclei located in the minimum; $^{242\text{f}}\text{Am}$ ($T_{1/2} = 14$ ms) was the first case. The new picture suggested that the mass asymmetry is formed late in the deformation process. Model calculations (Wilkins et al. 1976) showed indeed that at the scission point the fissioning nucleus is asymmetrically deformed. The asymmetric mass distributions and other features of low-energy fission were well reproduced.

In 1972, the chance discovery by French scientists (Bodu et al. 1972; Neuilly et al. 1972; Maurette 1976) that uranium from a uraninite ore in the *Oklo mine* in Gabon was markedly depleted in ^{235}U led to the realization that a *naturally occurring chain reaction* had taken place. Isotopic compositions of rare earth elements and other elements in the Oklo ore labeled them unmistakably as fission products. Various dating techniques (see [Sect. 1.4.5](#)) established that the Oklo reactors had been active about 1.9×10^9 years ago (when the abundance of ^{235}U was 3%, approximately the same as in modern light-water power reactors). From detailed studies of isotopic abundances it was possible to deduce that the reactors contained 800 tons of uranium and operated for almost 10^6 years at a power level of approximately 10 kW. About six tons of ^{235}U were consumed, with about two tons of it originating from the decay of ^{239}Pu formed by neutron capture in ^{238}U . An interesting aspect of the Oklo phenomenon, with possible implications for the storage of nuclear wastes from man-made reactors, is that the ore deposit has retained most fission products over geological times.

1.4.2 Nuclear Properties

Like nuclear reaction studies, research on nuclear properties and nuclear structure made rapid strides in the postwar years. *Advances in instrumentation* played an important role, first the

development of the sodium iodide scintillation detectors in the 1950s, which made it possible to record γ radiation with high efficiency and reasonable energy resolution, followed a decade later by the germanium-based semiconductor detectors with even much better resolution. For α - and other charged particles, silicon-based semiconductors became the standard. (see, e.g., Price 1964; Bertolini and Coche 1968).

A breakthrough in understanding nuclear properties came in 1950 with the development of a quantum-mechanical nuclear model by Maria Goeppert Mayer (Mayer 1950) and – independently – by Otto Haxel, Hans Jensen, and Hans Suess (Haxel et al. 1950). They considered the states of a single nucleon, either proton or neutron, in a spherical potential due to all other nucleons. The particles successively fill energy states determined by quantum numbers, which also prescribe how many particles can occupy a given state with pair-wise cancellation of particle spins to zero. After completion of certain states, a large energy gap occurs in the energy level diagram, thus establishing a nuclear shell structure. By introducing strong coupling between spin and orbital angular momentum of the particles, the magic numbers (see [Sect. 1.2.2](#)) could be reproduced. Furthermore, this so-called *single-particle model* accounted for properties like the ground-state nuclear spins of odd-mass (i.e., odd- A) nuclei in terms of the quantum numbers of the unpaired nucleon.

Single-particle and liquid-drop models (see [Sect. 1.2.2](#)) emphasize quite opposite aspects of nuclei: individual versus cooperative effects in a many-nucleon system. As experimental data show, collective and single-particle excitations interfere and mix, often leading to quite complex patterns of nuclear energy levels. A *unified nuclear model* successfully treating collective and single-particle properties on a common basis was developed by Aage Bohr and Ben Mottelson (Bohr and Mottelson 1953). Sven Gösta Nilsson's comprehensive calculations (Nilsson 1955) of single-particle states in regularly deformed nuclei showed that energy gaps occur also at certain deformations, albeit at proton and neutron numbers different from those for spherical nuclei. Novel approaches with emphasis on the interactions of paired nucleons led to an even more general understanding of nuclear structures (Arima and Iachello 1975).

New forms of radioactivity were reported. Proton emission from ground states, predicted as the simplest decay mode of proton-rich nuclei and long searched for, was observed in 1982 for ^{151}Lu (81 ms) produced by a heavy-ion reaction (Hofmann et al. 1982). Unusual large nuclear radii were found for some very light nuclei (Tanihata et al. 1985) and later attributed to neutron haloes, e.g., for ^{11}Li (8.5 ms) to a halo of two neutrons around a ^9Li core. Even a new kind of natural radioactivity was discovered in 1984 (Rose and Jones 1984): emission of ^{14}C nuclei from ^{223}Ra (11 d) leading to ^{209}Pb . Discoveries of other rare decay modes involving the emission of a variety of fragments from very heavy nuclei soon followed.

The exploration of the nuclear landscape on both the neutron-rich and the proton-rich side of the belt of stable nuclei occupied legions of nuclear chemists and physicists. The study not only of the ground-state properties (half-lives, radiations, masses, radii, shapes, spins, and parities) of nuclei but also of the characteristics of their often numerous excited states has revealed the major features of this landscape. Expansion to more *exotic nuclides* required novel, powerful separation techniques, since with increasing distance from stability the half-lives become shorter and shorter and the production processes more and more complex. Since the late 1960s, automated, computer-operated techniques have been developed to separate nuclides at timescales of seconds to microseconds and to provide, by continuous online operation, steady sources of short-lived nuclides for long observation times. The essential step can be the separation of recoil atoms in flight by magnetic and electric fields (see, e.g., Mueller and Sherrill 1993), of ion beams emitted from ion sources by magnetic fields

(see, e.g., Ravn 1979), and of thermalized reaction products by rapid chemical procedures (see, e.g., Herrmann and Trautmann 1982). Laser and ion-trap techniques online opened new avenues such as the precise determination of nuclear radii and masses far off the stability line (see, e.g., Otten 1989; Kluge and Bollen 1992).

About 3,000 nuclides are known and about 7,000 are predicted to exist. They fill – nearly without gaps – the banana-shaped chart of nuclides on both sides of the belt of stable nuclei. The coordinates are the magic numbers at closed neutron and proton shells of spherical shape. Between the shells, nuclei are regularly deformed, either prolate or oblate, and in transition regions between different shapes, more complicated forms are observed. At the proton-rich side, β^+ decay and electron capture dominate, at the neutron-rich side, β^- decay. Somewhere at proton-rich nuclei, an additional proton cannot be bound anymore; this marks the so-called *proton drip line*. This line, located not too far from the stability line, has been reached experimentally over a wide region of the chart up to about lead. The analogously defined *neutron drip line* lies much further away from stability because of the weak binding force and larger distances between neutrons. It is touched only in very light nuclei up to about neon, where the line quickly bends away and soon lies outside the region accessible with present-day nuclear reactions. Its location is a matter of theoretical predictions. Very neutron-rich nuclei may show quite unusual properties: neutron skins or haloes in general, new magic numbers replacing the spherical ones, new modes of collective excitation, etc. At the heaviest elements, α decay and spontaneous fission become essential for the stability limits. There, the chart looks quite different from what had been expected in the 1960s: it extends beyond the actinide elements continuously without forming an island (see ► Sect. 1.4.3). Ultimately the chart of nuclides and, hence, the periodic table may be terminated not by vanishing stability against fission, but by the inability to produce still heavier elements in the laboratory at a detectable level.

1.4.3 New Elements

As discussed in ► Sects. 1.2.3 and ► 1.3, by the end of World War II the periodic table was complete and without gaps up to atomic number 96. The elements 97, *berkelium* (Bk), and 98, *californium* (Cf), were made by bombardment of americium and curium, respectively, with α particles (Thompson et al. 1950a, b). They were chemically identified by cation exchange chromatography: they exactly followed the pattern of their homologous lanthanide elements. This bootstrap method of jumping up two atomic numbers was possible because long-lived americium and curium isotopes were available as target materials, accumulated in reactors by multiple neutron capture in plutonium.

Very unexpectedly, the elements 99 (*einsteinium*, Es) and 100 (*fermium*, Fm) were detected in 1952 in the debris from a thermonuclear explosion. The Es and Fm isotopes found and identified by a collaborative effort of American laboratories (Ghiorso et al. 1955b) were ^{253}Es ($T_{1/2} = 20.5$ d) and ^{255}Fm (20 h). They were presumably produced by the successive capture of 15 or even more neutrons in ^{238}U in an enormous neutron flux on such a rapid timescale that no radioactive decay occurred between neutron captures until the β^- -decay half-lives of the very neutron-rich uranium isotopes became sufficiently short to compete and, thus, to feed long chains of subsequent β^- -decays ending in the heaviest elements. Macroscopic amounts of the elements berkelium to einsteinium were produced since the late 1960s by multiple neutron capture in curium in a high flux reactor in Oak Ridge.

Element 101 (*mendelevium*, Md) was discovered in 1955 by (α ,n) reaction on a target consisting of about 10^9 atoms of reactor-produced ^{253}Es , and the product was ^{256}Md (1.30 h) (Ghiorso et al. 1955a). Its identification by ion exchange chromatography was probably the first example of one-atom-at-a-time chemistry. Later theoretical studies confirmed that under certain conditions single atoms can indeed represent the behavior of macroscopic quantities (Guillaumont et al. 1989, 1991).

At element 101 the (α ,n) reactions with reactor-produced actinide targets came to an end because fermium targets needed to proceed to element 102 cannot be made. To reach heavier elements, *heavy ions* were required *as projectiles* in order to add more than two protons in a fusion reaction. New accelerators were constructed for providing heavy-ion beams, a linear accelerator in Berkeley and a cyclotron in Dubna (Soviet Union). The Berkeley group applied heavy actinides as targets, the Dubna group relied on light actinides. For example, to synthesize element 105, the former group (Ghiorso et al. 1970) used the reaction $^{249}\text{Cf}(^{15}\text{N},4n)^{260}105$, the latter (Flerov et al. 1971) $^{243}\text{Am}(^{22}\text{Ne},4n)^{261}105$. Since a certain projectile energy is required to amalgamate projectile and target, the compound nuclei are quite hot. They cool down by the evaporation of several neutrons to end as the new element. However, this takes place only for an extremely small fraction of the compound nuclei. Rather, fission is much the dominant decay mode for such fragile, hot nuclei. First evidence for a new element is obtained by the observation of reaction products with unusually high α -particle energy, because α energies increase systematically with atomic number. If it can be shown experimentally that this energetic decay leads to a well-known nuclide of the heaviest (or second heaviest) element, then the atomic number of the new element is unambiguously identified.

Five elements, 102 to 106, emerged between 1958 and 1974 from such “hot fusion” reactions. Several discoveries became controversial between the Berkeley and Dubna groups; even different names for the same element were used in East and West. In order to examine the claims impartially, a Transfermium Working Group was established by the International Unions of Pure and Applied Chemistry (IUPAC) and Physics (IUPAP). The group concluded that the credit for the discovery of element 102 should be given to Dubna, for element 106 to Berkeley, and for the elements 103 to 105 it should be shared (Wilkinson et al. 1993). These conclusions were not generally accepted however. The following names and symbols were adopted after further discussions in the scientific community (IUPAC 1997): 102 *nobelium* (No), 103 *lawrencium* (Lr), 104 *rutherfordium* (Rf), 105 *dubnium* (Db), and 106 *seaborgium* (Sg).

In the late 1960s, the perspective for further extension of the periodic table seemed to be limited because of the obviously more and more dominating role of fission in accordance with the liquid-drop model. This perspective changed drastically in 1966 by two theoretical predictions: (1) spontaneous fission should strongly be hindered around the next, yet unknown magic proton number after $Z = 82$ (Myers and Swiatecki 1966), and (2) this should occur at *proton number 114*, not at 126 as one might expect in analogy to the $N = 126$ shell (Meldner 1966; Sobiczewski et al. 1966). A predicted shell closure at $N = 184$ should further contribute to the existence of an *island of stability* around the doubly magic nucleus $^{298}114^{184}$. According to early estimates, the half-lives of these so-called *superheavy elements* could even be long enough to be found in nature (Nilsson et al. 1969; Fiset and Nix 1972). Not unlike “gold fever,” many searches were undertaken (see, e.g., Herrmann 1979) to find evidence for such relic nuclei in all sorts of natural environments. Even with a simple microscope, but with an ingenious choice of a sample, an outstanding discovery could be made. Also, many attempts were made to jump by heavy-ion reactions from the known territory to the superheavy island. Positive claims were raised from time to time but could not stand up under further scrutiny.

In retrospect (Herrmann 2003), this period appears as a colorful intermezzo in superheavy element research.

The element-by-element advance to new elements continued in 1975 with a new concept, “cold fusion,” introduced by Yu. Ts. Oganessian (Oganessian et al. 1975): use of the stable, magic ^{208}Pb and ^{209}Bi as targets to keep the excitation energy of the compound nucleus at a minimum, as is evident from the evaporation of a single neutron. This approach was first pursued for the synthesis of new elements by Peter Armbruster’s group at a new linear accelerator in Darmstadt (Germany). Element 107, *bohrium* (Bh), made in 1981 by the $^{209}\text{Bi}(^{54}\text{Cr},n)^{262}107$ reaction, was the first success (Münzenberg et al. 1981). Five more elements followed until 1996: 108 *hassium* (Hs), 109 *meitnerium* (Mt), 110 *darmstadtium* (Ds), 111 *roentgenium* (Rg), and 112 *copernicium* (Cn). Common to all these discoveries were the low rates of only a few observed events in several days or even weeks of running time and the short half-lives, typically milliseconds. Key to the success was a sophisticated experimental technique: the new elements were separated in flight from the huge surplus of projectiles and concurrent reaction products by passing through electric and magnetic fields. At the end of their flight path, they were implanted in a detector system, which allowed the successive decay events at the point of impact to be followed. Thus, a new element was linked to a long chain of well-known α -particle emitters. In the case of meitnerium, a single event was sufficient to discover a new element (Münzenberg et al. 1982). According to the liquid-drop nuclear model, the barrier against fission should disappear around atomic number 106. Hence, the existence of heavier nuclei decaying by α -particle emission can only be understood as due to the stabilizing action of *nuclear shells preventing fission* (Armbruster 1984).

Evidence for *element 114* and *element 116* was obtained at Dubna in bombardments of ^{244}Pu and ^{248}Cm with ^{48}Ca , an extremely neutron-rich, doubly magic projectile (Oganessian et al. 2000a, b). The decay chains observed in these hot-fusion reactions soon ended in fission with no link to known nuclei, however. The supposed reaction $^{244}\text{Pu}(^{48}\text{Ca},4n)^{288}114$ would represent the closest approach to the $Z = 114$, $N = 184$ “holy grail” possible with present-day techniques, but the neutron number reached, 174, is still far below that goal. According to recent theoretical calculations, however, the next doubly magic spherical nuclei may be located at $Z = 120$, $N = 172$ or $Z = 126$, $N = 184$ (Bender et al. 1999), perhaps not as a peak structure, but as a mesa-like region.

Some basic *chemical properties* of the first *transuranium elements* became already evident in the discovery experiments, in which chemical separations played a crucial role. With time, a vast amount of information has been amassed on the chemistry of the elements available in macro quantities, i.e., all the elements through californium and, to a lesser degree, einsteinium (see, e.g., Katz et al. 1986).

A new research field in the chemistry of neptunium, plutonium, and other light actinides developed in the late 1970s in the context of environmental contaminations and nuclear waste management. The aim was to unravel their *behavior in natural environments* (see, e.g., Watters et al. 1983; Kim 1986). This is a difficult task because of the complex chemistry: many oxidation states, polymerization, interaction with less defined natural partners such as humic acids, clays, and various rocks play a role. Included is also the development of techniques for the determination of actinide elements and their speciation in extremely low concentrations.

Beyond einsteinium, the amount of chemical information becomes increasingly sparse but significant data were obtained in exploratory studies at the tracer scale (see, e.g., Silva 1986) for elements up to the last actinide element, lawrencium (103), and the first transactinide elements, rutherfordium (104) and dubnium (105). From curium on, the chemical properties

resemble closely those of the homologous 4f lanthanide elements. The results are, thus, in full agreement with the concept of the actinide series of 5f elements (see ▶ Sect. 1.3).

Extension of chemical studies to *transactinide elements* became possible in the late 1980s through the availability of isotopes with half-lives in the order of seconds. A strong motivation was the expectation that, with increasing proton number, the electron shell structure should eventually be significantly affected by *relativistic effects* due to the high electron velocity (see, e.g., Fricke 1975). This could result in unexpected chemical properties: element 114 for example, naively located below lead in the periodic table, may rather behave like an inert gas (Pitzer 1975). Sophisticated techniques had to be developed to explore the characteristic chemical properties with single, short-lived atoms on a fast timescale, to detect them by their specific radiation and to run such experiments online over days or weeks to catch the very few atoms produced. Automated, computer-operated procedures were required, based on experience in studies of short-lived fission products (see ▶ Sect. 1.4.2) and pioneering work by Ivo Zvara (Zvara et al. 1971). For a detailed comparison, homologous elements were also studied under the same experimental conditions. Preferred chemical steps were the distribution of transactinide species between aqueous solutions and ion exchangers (Kratz et al. 1989) and their volatilization and deposition on solid surfaces (Gäggeler et al. 1992). *Rutherfordium* and *dubnium* were found to fit, in general, the periodic table as expected, namely as homologues of hafnium and tantalum. In detail, however, there are inversions in the trend within the groups, which can be traced back to relativistic effects, as theoretical studies showed. A particular challenge is the first exploration of the chemistry of a new element and its inauguration in the periodic table. This succeeded for *seaborgium* (Schädel et al. 1997), *bohrium* (Eichler et al. 2000), and *hassium* (Düllmann et al. 2002). Their placement below tungsten, rhenium, and osmium, respectively, seems to be justified too.

1.4.4 Hot-Atom Chemistry and Tracer Applications

Since the fall of 1946, radioisotopes produced in the Oak Ridge nuclear reactor were available to the general public. This gave an enormous impetus to all kinds of tracer applications, strongest in life sciences where compounds labeled with the long-lived tracers ^{14}C and ^3H soon became an essential, often indispensable tool. Labeling was performed by conventional chemical synthesis starting from simple radioactive molecules, or by *biosynthesis* in living organisms that had been fed with labeled precursors (Calvin et al. 1949). The progress thus made becomes evident in an early application – Melvin Calvin and Andrew Benson's work on *photosynthesis*. Using ^{14}C (instead of ^{11}C , see ▶ Sect. 1.2.4), they were able to follow in *Chlorella* algae how carbon dioxide is converted into sucrose via a sequence of reaction products (Calvin and Benson 1949). Most stunning was the short timescale: half a minute after the addition of labeled carbon dioxide, the major portion of the radiocarbon was found in complicated compounds, such as phosphoglyceric acids and hexose phosphates.

Other fields benefited, too, from the strong neutron fluxes now accessible for irradiations. New phenomena were observed, such as the annealing of *hot-atom effects* in inorganic solids by postirradiation heating, leading to an increased retention in the form of the original species (Green and Maddock 1949; Rieder et al. 1950). A new and powerful tool was discovered by Rudolph Mössbauer in 1958: *recoilless emission of γ rays* with natural or nearly natural line width from nuclei embedded in a solid lattice (Mössbauer 1958, 1962). Resonant absorption of such emissions, e.g., the 14.4 keV transition of ^{57}Fe fed in the decay of ^{57}Co ($T_{1/2} = 270$ d), provides

information on the magnetic and electric environment of either the disintegrating nucleus (in so-called source experiments performed with ^{57}Co -bearing samples) or the absorbing nucleus (e.g., in transmission experiments performed with ^{57}Fe -containing samples).

Hot-atom reactions of hydrogen, carbon, and halogens in organic systems became a major research topic in radiochemistry, aimed at exploring the chemical reactivity of such hot-atom species in the context of chemical dynamics (see, e.g., Willard 1953; Wolf 1964). Furthermore, hot-atom reactions offered an elegant alternative for *labeling organic molecules* (see, e.g., Wolf 1960). As early as in 1946, the formation of ^{14}CO , $^{14}\text{CO}_2$, $^{14}\text{CH}_4$, H^{14}CN , and H^{14}COOH during the $^{14}\text{N}(\text{n},\text{p})$ process was observed in irradiations of simple nitrogen compounds (Yankwich et al. 1946). Hot atoms were found to react only as they approach the end of the recoil track, i.e., at energies below about 20 eV. The product spectra are very broad. Radiocarbon, for example, can (1) replace a C or N atom in the substrate, (2) add one additional carbon to the parent compound, (3) react with smaller molecules produced by fragmentation, and (4) find its way into larger buildup products as well as into polymers. Alongside these hot-atom reactions, similar reactions of thermal carbon atoms also occur, which complicate the interpretation of the results. Within a molecule, the labels are neither randomly distributed nor specifically located at a particular atom. Hence, *recoil labeling* is useful mainly for tracer experiments in which the molecule remains intact throughout, rather than for studies on the fate of a particular part of a molecule.

The application of radiotracers in medical diagnostics grew rapidly with the development of labeling techniques. *Radiopharmaceuticals* labeled with ^{131}I (8.0 d) were introduced in the early 1950s. *Radioimmunoassay*, invented in 1956 by Salomon Berson and Rosalyn Yalow became a widely applied in vitro technique for sensitive measurements of body constituents, e.g., hormones and enzymes (Berson and Yalow 1957, see also Yalow 1978). Based on the principle of isotope dilution analysis, it uses the competitive binding of natural and ^{131}I -labeled antigens to antibodies. The in vivo diagnostics of thyroid diseases with ^{131}I was greatly improved by imaging techniques for extended γ -ray distributions: first by the step-by-step radioactivity scanners (Cassen et al. 1951; Curtis and Cassen 1952) and in 1958 by the NaI scintillation camera (Anger 1958). A later example of a widely applied tracer technique is the study of myocardial perfusion with ^{201}Tl (73 h) (Lebowitz et al. 1975).

For in vivo diagnosis of humans, short-lived tracers are most desirable in order to minimize the damaging effects of radiations, but there were not many places where facilities and staff for isotope production, chemical labeling, and medical diagnostics were at hand. An important step was therefore the development of *radionuclide generators* for short-lived nuclides that grow from long-lived parents. The parent nuclide can then be shipped to the user in a form that allows repeated stripping of the short-lived decay product. Most successful was the *technetium generator*, developed in 1958 (see, e.g., Richards et al. 1982; Molinski 1982). The generator contains the parent ^{99}Mo (66 h), a fission product, fixed on a column from which the grown-in $^{99\text{m}}\text{Tc}$ (6.0 h) is eluted from time to time. Later, “kits” were developed with all ingredients required to release $^{99\text{m}}\text{Tc}$ from the generator in the chemical form to be administered to the patient (Eckelman and Richards 1970). This made $^{99\text{m}}\text{Tc}$ – an isotope of an element that does not occur naturally on Earth – into the backbone of routine imaging in nuclear medicine (see, e.g., Jones 1995), often replacing other radiotracers such as the iodine isotopes and ^{201}Tl .

In the late 1960s, cyclotrons were installed in medical institutions, and in the following decade computer tomography was introduced for the scanning of the γ radiation. This led to a revival of ^{11}C for the specific labeling of organic molecules (see, e.g., Wolf and Redvanly 1977) starting from ^{11}CO , $^{11}\text{CO}_2$, or H^{11}CN produced when ^{11}C is made by the $^{11}\text{B}(\text{p},\text{n})$ or $^{14}\text{N}(\text{p},\alpha)$

nuclear reactions in the presence of oxygen or hydrogen, respectively, and applying a new technology of automated fast chemical synthesis (see, e.g., Stöcklin and Pike 1993). The positron emitter ^{11}C became one of the first tracers for *positron emission tomography* (PET), a technique for the in vivo three-dimensional location of the radiation source based on the fact that the two 511 keV quanta in positron annihilation are emitted in opposite directions. PET found its widest application with ^{18}F (1.83 h) produced by the $^{18}\text{O}(\text{p},\text{n})$ or $^{20}\text{Ne}(\text{d},\alpha)$ reactions. It is introduced into organic molecules by replacement of a hydrogen atom. A breakthrough in PET came in 1978 with the development of ^{18}F -labeled 2-FDG by Alfred P. Wolf's group. (Ido et al. 1978); 2-FDG is a fluoro derivative of deoxy-D-glucose, which is phosphorylated in cells like glucose but does not undergo further metabolic degradation. It is still the only method for measuring quantitatively and in an essentially noninvasive manner the local glucose metabolism in the human brain, the heart, and in tumors. Thus, PET has become an important tool for understanding the functional anatomy and biochemical activity of the normal human brain and in pathological conditions including Alzheimer's disease and the effects of drug abuse. It is also important for diagnosis of heart disease, cancer, stroke, and epilepsy. Thanks to the development of relatively compact, tailored cyclotrons combined with automated chemical synthesizers for standard radiopharmaceuticals, positron emission tomography is becoming more and more incorporated in medical practice.

1.4.5 Geo- and Cosmochronology

The postwar period saw the rapid development of new and improved ways of using *radioactive decay as a clock* for a great variety of processes in the Earth's crust, the atmosphere, the biosphere, the oceans, meteorites, and eventually the Moon. These processes were spurred by advances in instrumentation, such as improved mass spectrometers for precise measurements of isotopic ratios.

A very important observation, made in 1956 by Claire Patterson (Patterson 1956), was that a plot of the relative abundances $^{207}\text{Pb}/^{204}\text{Pb}$ vs. $^{206}\text{Pb}/^{204}\text{Pb}$ for many meteorites differing widely in these individual ratios is a straight line, termed an *isochron*, with a slope corresponding to an age of 4.55×10^9 years. Since the isotope ratios of ordinary terrestrial (non-radiogenic) lead fall on the same isochron, the *age of the Earth* as an isolated system is also inferred to be about 4.55×10^9 years. From the close coincidence between the age of the Earth and the time of solidification of the much smaller (and therefore rapidly cooling) parent bodies of meteorites it followed that the entire solar system originated about 4.6×10^9 years ago (see, e.g., Kirsten 1978). Taking history even further back, the time between the production of the heavy elements composing the solar system and the formation of the solar system was estimated as only about one or two hundred million years, as deduced from the presence, in meteorites, of the decay products of extinct radionuclides such as ^{129}I ($T_{1/2} = 1.57 \times 10^7$ years) and ^{244}Pu (8.08×10^7 years) (see, e.g., Wetherill 1975).

Once the decay of ^{40}K (1.28×10^9 years) to ^{40}Ar was established (see ▶ Sect. 1.2.5), the potassium/argon method for *geological age determination* was on a sound footing, particularly through the pioneering work of Wolfgang Gentner (Gentner and Kley 1955, see also Schaeffer and Zähringer 1966). Because argon is an inert gas, it can be safely assumed that at the time of crystallization of a potassium-bearing rock all previously formed ^{40}Ar had escaped. Any ^{40}Ar found in a sample has thus presumably been accumulated since crystallization and serves as a measure of the geological age of the sample. In principle, any long-lived radionuclide and its

stable descendant can serve as a chronometer. Probably the most important parent–daughter pair for geological dating is ^{87}Rb (4.8×10^{10} years) and its decay product ^{87}Sr (Hahn et al. 1943, see also Faure and Powell 1972). One of the triumphs of isotopic dating came in the 1970s when an enormous amount of detailed information on the history of the Moon was gleaned from examination of returned lunar samples with all the available techniques (see, e.g., Wetherill 1971).

When Fritz Paneth's group in 1953 tried to determine meteorite ages by the He/U method (Paneth et al. 1953), they found much larger amounts of helium than could be accounted for by uranium decay and thus stumbled on the discovery of *cosmic-ray-induced nuclear reactions* in meteorites that subsequently became the subject of extensive research. Many radionuclides with half-lives ranging from days to millions of years as well as some stable spallation products have been identified in meteorites. From the amounts found, the exposure ages of meteorites in space and the average cosmic-ray flux and its time variation can be deduced (see, e.g., Schaeffer 1968).

The cosmic-ray impact that has found the most wide-ranging application is the formation of ^{14}C in the Earth's atmosphere by the $^{14}\text{N}(\text{n},\text{p})$ reaction. The ^{14}C dating technique proposed by Willard Libby in 1946 (Libby 1946, 1952) is based on the assumptions that (1) the cosmic-ray intensity has been essentially constant over many ^{14}C half-lives and (2) the ^{14}C produced in the atmosphere becomes equilibrated with the entire biosphere, so that all living matter has the same specific activity. Thus, the time since any carbon-containing material has been removed from the exchange reservoir can be determined from its residual ^{14}C content. With low-level counting techniques, the method has been used to date innumerable objects of archaeological and historic interest with ages up to about 40,000 years; accelerator mass spectrometer methods for measuring $^{14}\text{C}/^{12}\text{C}$ ratios have extended the range even further (see, e.g., Litherland 1980).

Since all the elements and isotopes in various parts of the universe were presumably formed from primordial matter by nuclear reactions, the details of this so-called *nucleosynthesis* have been of great general interest. Whereas hydrogen and helium and lesser amounts of a few other light elements are believed to have been created in the *big bang*, first proposed by George Gamow (Gamow 1946), the synthesis of other elements occurred and is still occurring in stellar interiors. As a starting point for any theory of nucleosynthesis, it was important to know the elemental and isotopic abundances in the Earth, meteorites, the Moon, the planets, the Sun, and other stars. By the mid-1950s, thanks to the work particularly of Hans Suess and Harold Urey, fairly detailed information on *elemental abundances* in the solar system was available (Suess and Urey 1956). Based on these data, and on measurements of stellar spectra and nuclear reaction rates, it was then possible to develop the comprehensive picture of nucleosynthesis and *stellar evolution* that was first presented in the famous 1957 paper by M. Burbidge, G. Burbidge, W. Fowler, and F. Hoyle (often referred to as BBFH) (Burbidge et al. 1957).

In basic outline, the BBFH picture is still valid (Fowler 1984). A newly formed star contracts gravitationally until the temperature in its center can sustain the reaction $\text{p} + \text{p} \rightarrow \text{d} + \text{e}^+ + \nu$. This reaction and the follow-up reactions $\text{p} + \text{d} \rightarrow {}^3\text{He} + \gamma$ and ${}^3\text{He} + {}^3\text{He} \rightarrow {}^4\text{He} + 2\text{p}$, in other words the *thermonuclear fusion* of four protons to form a ${}^4\text{He}$ nucleus, provide the energy output of the Sun and all so-called main-sequence stars; this fusion energy counterbalances the gravitational force thus stabilizing the star. When hydrogen becomes depleted, contraction takes over again and successively more complex fusion reactions set in, eventually followed by (α,n) reactions, which in turn provide sufficient neutron fluxes to allow (n,γ) reactions. This continues until iron and nickel are reached with the most stable nuclei in terms of binding energy per nucleon.

Elements beyond the iron/nickel region are believed to be built up by neutron capture followed by β^- decay to the next higher element. There are two quite different processes. In the so-called *s-process*, neutrons are captured on a timescale slow enough to allow β^- decay to proceed before another neutron is captured; this process happens around the stability valley. The *r-process*, rapid neutron capture, takes place in such a high neutron flux that many neutrons are captured successively before β^- decay can compete. Its pathways involve nuclides far on the neutron excess side of stability, a largely unexplored region (see [Sect. 1.4.2](#)). Hence, theoretical models often have to be invoked. About half of the solar abundances of elements beyond iron and most of the heaviest elements are believed to be created by the *r-process*, but its mechanism and astrophysical side remain major questions in nucleosynthesis. Nevertheless, on the basis of calculated production rates for very long-lived natural nuclides such as ^{232}Th , ^{235}U , and ^{238}U and their observed solar abundances, the age of the Galaxy is predicted to lie in the range of $(12\text{--}15) \times 10^9$ years (Cowan et al. 1991).

An area that was pioneered by nuclear chemists is the search for *solar neutrinos*. Although main-sequence stars, of which the Sun is a typical representative, have for decades been believed to derive their energy from the series of fusion reactions mentioned above, there was no direct observational evidence for this until Raymond Davis in the 1960s undertook to measure the flux of neutrinos from the Sun which accompany these reactions (Davis et al. 1968; Cleveland et al. 1998). The experiment involved measuring the number of ^{37}Ar atoms (35.0 d) formed by neutrino capture in ^{37}Cl in a tank of perchloroethylene. With only a few atoms of ^{37}Ar per month extracted from over 600 t of liquid, this was indeed the ultimate low-level radiochemical separation. Nevertheless, the experiment was successful in detecting the neutrinos, but ever since the first data appeared in 1968, the measured neutrino flux persisted in being only one third of what was expected from model calculations, and this so-called solar neutrino puzzle literally gave rise to a whole new field – *neutrino astronomy*.

Davis's experiment motivated additional experiments. In the early 1980s, two international collaborations undertook radiochemical experiments with massive gallium detectors in deep underground facilities in the Gran Sasso Tunnel (Italy) (Anselmann et al. 1992a, b) and the Baksan Valley (Caucasus) (Abazov et al. 1991), respectively. Here the aim was neutrino capture in ^{71}Ga to form ^{71}Ge (11.4 d), a reaction principally sensitive to the low-energy neutrinos from the primary $p + p$ reaction in the Sun, whereas the chlorine experiment detects only high-energy neutrinos from rare branch reactions. These gallium experiments showed that, indeed, fewer low-energy neutrinos arrive at the Earth than expected from the energy production in the Sun. Physical experiments with real-time detection of neutrinos followed. Eventually the totality of the experiments and theoretical developments led to the unequivocal conclusion that the expected quantities of electron neutrinos are indeed produced in the Sun, but that some of them are transformed by so-called *neutrino oscillations* into other types of neutrinos, which are not detectable by the chlorine and gallium detectors. Since neutrino oscillations are possible only if one or more of the neutrino types have a finite rest mass, the “solar neutrino puzzle” posed by a radiochemical experiment led to a profound new result in particle physics.

1.5 Current Trends

There is no sharp endpoint to the “golden era.” But the climate for nuclear research and development markedly changed in the 1980s. Government budgets for nuclear science tended to level off after 3 decades of remarkable growth; institutions established for nuclear research

focused on other fields, fewer university departments offered courses in nuclear and radiochemistry, and when nuclear chemistry faculty positions fell vacant, they were often filled with chemists in other specialties.

Several contributing factors are easily identifiable: The accidents at the nuclear power plants at Three Mile Island (1979) and Chernobyl (1986) greatly increased the public's fear of everything nuclear. In the USA and the former Soviet Union, vast amounts of waste streams containing fission products and actinides were left over from plutonium production plants that must be disposed of safely. Furthermore, any country using nuclear energy on a large scale is confronted with the problem how to treat nuclear waste and store it permanently. This negative attitude, however, seems to change in recent years in the context of the worldwide concern about the Earth's climate. Nuclear power becomes more and more accepted as a large-scale energy source with no output of greenhouse gases; its future role is currently not yet recognizable, however.

Another significant change that has gradually come about is that many techniques pioneered by radiochemists turned out to be so successful that they became subsumed in other fields. In particular, the use of radioactive tracers is so pervasive in various areas of chemistry and life sciences that it has simply become a standard tool, like microscopy, mass spectrometry, and nuclear magnetic resonance in the chemist's or biologist's arsenal rather than a branch of chemistry with a clear identity. Thus, tracer techniques play an important role also in such forefront areas as molecular biology and genetic engineering. Needless to say, there still are areas in which the skills of radiochemists are indispensable, such as the development and preparation of complex radiopharmaceuticals labeled with short-lived nuclides for nuclear medicine applications, e.g., for positron emission tomography.

An obvious way to counteract the scarcity of resources and manpower for nuclear research is the collaboration of scientists from many institutions, large and small, and frequently of long duration. Good examples are the efforts to solve the nuclear waste problem in nationwide coordinated programs as established in several countries. The basic decision – disposal of used fuel elements without reprocessing or chemical treatment with solidification of the waste in form of glasses or ceramics – has to be met at the political level. The next decision, whether storage in granite, tuff, clay, or salt is to be preferred, depends on the geological situation. But once a site is envisaged, its suitability has to be proven by a thorough multidisciplinary research program. The task of the radiochemists is to study, at a strictly scientific level, the interactions of long-lived fission products and actinides with the barrier materials including the geological shield in order to ascertain that they protect the environment over very long times. An unconventional approach to the nuclear waste problem is the “incineration” of very long-lived radionuclides into much shorter-lived components by bombardment with intense proton beams.

Collaboration on an international level is essential in “big” science. These trends began with work centered at large facilities such as big accelerators but have also penetrated into areas of “small” science. Research on the chemistry of the heaviest elements concentrated at the few suitable heavy-ion accelerators is an obvious and successful example. Small groups take over at their home institutions a considerable part of the development of fast single-atom chemistry; each element and each class of compounds requires a specific approach; they test it in model experiments at smaller facilities. Eventually, the external groups and the in-house experimentalists join up at the heavy-ion accelerator to perform the major experiment.

Production and properties of exotic nuclei are the focus of another forefront development: accelerators capable of producing, in a first step, beams of radioactive nuclei, which are then

used, in a second step, as projectiles for nuclear reactions. Beams of neutron-rich projectiles, generated, e.g., by nuclear fission, could thus give access to the still unexplored region of extremely neutron-rich nuclei where unique nuclear properties are expected and the r-process path is located, the key to understanding the nucleosynthesis of the heavy chemical elements. Several such facilities are at the planning stage.

One can perhaps take it as a sign of the continued vitality of nuclear and radiochemistry reviewed in this brief chapter that the field's first century is framed by two Nobel Prizes: the 1903 Prize awarded to Becquerel and the Curies, and Raymond Davis's 2002 Prize. That both were awarded in the field of physics should not detract from the fact that the work honored could not have been done without a great deal of chemistry. It is indeed a major strength of our field that it has had wide-ranging impacts on other sciences.

Abstract: In this chapter, four topics are treated. (1) Fundamental constituents and interactions of matter and the properties of nuclear forces (experimental facts and phenomenological and meson-field theoretical potentials). (2) Properties of nuclei (mass, binding energy, spin, moments, size, parity, isospin, and characteristic level schemes). (3) Nuclear states and excitations and individual and collective motion of the nucleons in the nuclei. Description of basic experimental facts and their interpretation in the framework of shell, collective, interacting boson, and cluster models. The recent developments, few nucleon systems, and ab initio calculations are also shortly discussed. (4) In the final section, the α - and β -decays, as well as the special decay modes observed far off the stability region are treated.

2.1 Nucleons and Nuclear Forces

2.1.1 Fundamental Constituents and Interactions of Matter

According to the present knowledge of the science community, the *fundamental constituents* of matter are *quarks* and *leptons*. Both quarks and leptons are pointlike and structureless on a scale of $\leq 10^{-17}$ m. These particles may interact with each other via four apparently different fundamental interactions: strong, weak, electromagnetic, and gravitational interactions. It is generally accepted that any interaction is mediated by the exchange of specific interaction quanta. Some of the most important properties of quarks and leptons are summarized in [Table 2.1](#). The table contains also the properties of quanta of electromagnetic, weak, and strong interactions. (For a detailed review of particle properties see Particle Data Group [2008](#).) The characteristic scale for gluons is < 0.1 fm (i.e., $< 10^{-16}$ m).

Quarks and gluons have quantum numbers called “color.” The primary, basic colors may be called red, green, and blue. Of course, these “colors” have no relation to ordinary, real colors. The quarks interact strongly by color exchange, which means that the quanta of the strong interaction, the gluons, are colored objects. All bound states of quarks observed in nature are “colorless” or “white.” Leptons do not have color quantum numbers.

The visible matter consists of atoms, and atoms contain nuclei and electrons. The constituents of atomic nuclei are called *nucleons*. The two types of nucleons are protons and neutrons.

A nucleus containing Z protons and N neutrons (i.e., $A = Z + N$ nucleons) is to be denoted by A_ZX_N , where X is the chemical symbol of the element with Z protons. Nucleons contain quarks of two types: *up* and *down quarks with some additional dynamical (or sea) quark contributions*, i.e., quark–antiquark pairs created and annihilated in very short time intervals. In nuclear decay electrons, positrons, electron neutrinos, and antineutrinos may also be involved. Thus the visible world (nuclei, atoms, and molecules) is built up mainly from up and down quarks, as well as from electrons, electron neutrinos, and the corresponding antiparticles. Quarks and leptons appear in a variety of types or “flavors.” The flavor quantum numbers define three families of particles. The members of the first family are the u , d quarks and e^- , ν_e leptons. The c , s quarks and μ^- , ν_μ leptons belong to the second, the b , t quarks and τ^- , ν_τ leptons to the third family. The heavier quarks and leptons are similar to the lighter ones (with the same electric charges), except mass. At present, it is not known why quarks and leptons are tripled.

Table 2.1

Properties of fundamental constituents of matter: quarks, leptons, and field quanta (gauge bosons). R, G, and B denote red, green, and blue colors. Neutrinos are longitudinally spin-polarized. If Z denotes the direction of velocity, for neutrinos $S_Z = -1/2$ (left-handed), for antineutrinos $S_Z = +1/2$ (right-handed). Associated with quarks and leptons there are antiquarks and antileptons, too, which have exactly the same mass and half-life as their partners, but opposite electric charge and magnetic moment. The antiquarks have anticolors

	Name	Symbol	Rest energy	Electric charge (e)	Spin (\hbar)
F l a v o r	Color				
	Quarks				
	Up	$u(u_R, u_G, u_B)$	1.5–3.3 MeV	+2/3	1/2
	Down	$d(d_R, d_G, d_B)$	3.5–6.0 MeV	−1/3	1/2
	Charmed	$c(c_R, c_G, c_B)$	1.27 GeV	+2/3	1/2
	Strange	$s(s_R, s_G, s_B)$	104 MeV	−1/3	1/2
	Top	$t(t_R, t_G, t_B)$	171.2 GeV	+2/3	1/2
	Bottom	$b(b_R, b_G, b_B)$	4.20 GeV	−1/3	1/2
	Leptons				
	Electron	e^-	0.511 MeV	−1	1/2
	e^- neutrino	ν_e	<2 eV*	0	1/2
	Muon	μ^-	105.658 MeV	−1	1/2
	μ^- neutrino	ν_μ		0	1/2
	Tau	τ^-	1,777 MeV	−1	1/2
	τ^- neutrino	ν_τ		0	1/2
	Field quanta				
	Photon	γ	0	0	1
	Weak Bosons	W^+	80.398 GeV	+1	1
		W^-	80.398 GeV	−1	1
		Z^0	91.188 GeV	0	1
	Gluons ($i = 1 \dots 8$)	g_i	0	0	1

*From tritium decay.
Data from Particle Data Group (2008).

The nucleons interact through their constituents, and their strong interaction can also be depicted as boson exchange. (All interaction quanta are bosons, i.e., particles with integer spins.) The strongly interacting bosons (particles with integer spins), which take part in the nucleon–nucleon interaction, are called *mesons*. These are π^+ , π^0 , π^- , K^+ , K^0 , K^- , η^0 , ρ^+ , ρ^0 , ρ^- , ω^0 , etc.

The common name of strongly interacting fermions (particles with half-integer spins) is *baryon*. The members of the baryon family are the nucleons (protons and neutrons), as well as different *hyperons*: Λ , Σ^+ , Σ^0 , Σ^- , Ξ^0 , Ξ^- , Ω^- , etc.

Hadron is a common name for baryons and mesons, i.e., for strongly interacting particles.

Of the four *fundamental interactions* – strong, electromagnetic, weak, and gravitational – gravity is far the weakest, so it plays no observable role in nuclear physics. All others do. Some of the particles are electrically charged, some are not. The charged particles take part in electromagnetic interactions. Leptons, in addition, enter into weak interactions. Quarks (and antiquarks) interact with all four interactions. The characteristic features of the interactions are summarized in ► [Table 2.2](#).

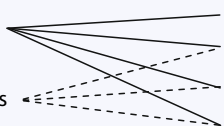

The square of coupling constants, characteristic of the strengths of the interactions, determines the decay probability of the particles and the reaction cross sections primarily. Some examples for the decay and reactions are as follows. (The rest energy of the Δ^{++} baryon is 1,232 MeV.)

Strong interaction	Decay $\Delta^{++} \rightarrow p + \pi^+$
	Reaction $p + \pi \rightarrow p + \pi$
Electromagnetic interaction	Decay $\pi^0 \rightarrow \gamma + \gamma$
	Reaction $p + \gamma \rightarrow p + \pi^0$
Weak interaction	Decay $n \rightarrow p + e^- + \bar{\nu}_e$
	Reaction $p + \bar{\nu}_e \rightarrow n + e^+$

The theories of electromagnetic and weak interactions have been unified in 1967–1968 by Glashow, Salam, and Weinberg. According to the electroweak theory, the coupling of intermediate W^\pm , Z^0 bosons to leptons and quarks is the same, as the coupling of photons to leptons and quarks. Thus, the W^\pm , Z^0 particles behave like heavy photons.

■ **Table 2.2**

Fundamental constituents and interactions of matter according to the “Standard Model.” The data give only rough estimates

Fundamental constituents		Field quanta	Interaction		
<div>Quarks </div> <div>Leptons</div>	Gluon	Strong			
	Photon	Electromagnetic			
	W^{\pm}, Z^0	Weak			
	Graviton	Gravity

Properties							
p	\bar{p}	938.2720	+1	1/2 ⁺	1/2	+1/2	∞
n	\bar{n}	939.5654	0	1/2 ⁺	1/2	−1/2	885.7

The weak interactions change quark and lepton “flavors,” e.g., a d -quark into u -quark or a muon into an electron (this latter, e.g., in the $\mu^- \rightarrow e^- \bar{\nu}_e \nu_\mu$ process). The quark structures of the proton and neutron as well as the *properties of nucleons* are presented in ▶ [Table 2.3](#). The baryons are built up from three (valence) quarks and massless gluons, but they contain also dynamical (or sea) quarks (quark–antiquark pairs) in a small quantity. The mesons are built up from quark–antiquark pairs and gluons.

The radii of nucleons (see later ▶ [Sect. 2.2.3](#)) can be determined, e.g., from different scattering (i.e., elastic collision) experiments. For the proton the following charge radius has been obtained: 0.875 ± 0.007 fm. The sizes of mesons are between the scales of nucleonic (~ 1 fm) and quark (< 0.01 fm) constituents.

2.1.2 Properties of Nuclear Forces

2.1.2.1 General Properties of Nuclear Forces

One can get *experimental information* on the nucleon–nucleon (NN) interaction from the following sources.

- Properties of the deuteron, the simplest bound-state nuclear system (binding energy, spin, parity, magnetic dipole and electric quadrupole moments, size of the nucleus).
- Characteristic features of the nucleon–nucleon (np, pp, nn) scattering at low, intermediate, and high bombarding energies (differential and integral cross sections, scattering length, effective range, phase shift, polarization, etc.).
- Scattering of pions and heavier mesons on nucleons, pion–pion interaction.
- Properties of light and heavy nuclei (binding energy, volume, density, nuclear moments, excitation levels, compressibility, etc.).

Next some *elementary experimental results* concerning nuclear forces are shortly enumerated.

- Nuclear forces are able to keep the nuclei in stable, bound states, in spite of the electric repulsion acting among protons. Consequently, the nuclear forces are basically attractive.
- Rutherford’s α scattering and later the proton–proton scattering experiments have shown that if the interparticle distance in the course of the collision is $> 10^{-14}$ m, only Coulomb

force acts between the particle and nucleus. Thus, the range of nuclear forces, which could modify the scattering picture, is small.

- The proton separation energies (S_p) generally increase with increasing neutron number (N) and neutron separation energies (S_n) increase with increasing proton number (Z). Consequently, a strong attractive interaction must exist between protons and neutrons.
- On the other hand, proton separation energies generally decrease with increasing Z (at constant N) and neutron separation energies decrease with increasing N (at constant Z). This means that the residual interaction (see [Sect. 2.3.1.3](#)) between like nucleons is generally repulsive. An exception from this general rule is the pairing interaction between like nucleons, which causes a fluctuation in the general trends. Nuclei with even numbers of protons and/or neutrons are more stable. There must be a special attractive “pairing” interaction between like nucleons, which couples them to spin-zero, positive parity states.
- Many properties of the deuteron can be explained by supposing that the nuclear potential is central.
- The deuteron occurs in nature only with parallel proton and neutron spin alignments. The spin of even- Z – even- N nuclei in ground state is always zero, and the binding energies in these nuclei are especially large. These facts and also the NN scattering experiments show unambiguously that the nuclear forces depend on the spin states of the nucleons.
- From the study of the deuteron, one can conclude that the nuclear potential energy is ≤ -26 MeV at internucleon distance $d \approx 2 \times 10^{-15}$ m. At the same time, the electrostatic energy of the repulsion between two protons is only ~ 0.7 MeV (at $d = 2 \times 10^{-15}$ m). The magnetic interaction energy, arising from the magnetic dipole moments of the protons is more than one order of magnitude smaller than the electrostatic energy. From these facts it follows that the nuclear interaction is stronger than the electromagnetic, and also the weak and gravitational, interactions ([Table 2.2](#)).
- The similarity of level systems in some light nuclei and also the scattering experiments indicate that the nuclear forces are almost fully independent of the electric charge of nucleons.
- For the interpretation of the observed quadrupole moment of the deuteron, it was necessary to assume that the nucleon–nucleon interaction contains a noncentral, tensor interaction term too (see [Eq. \(2.1\)](#)).
- On the basis of polarization experiments ([Fig. 2.1](#)), one can conclude that the nucleon–nucleon force depends on the relative alignment of the spins with respect to the relative orbital angular momenta. The spin–orbit interaction term depends, indirectly, on the relative velocity.
- The binding energy per nucleon is approximately constant in medium-heavy and heavy nuclei. This property is called the “saturation character” of the nuclear forces. With purely attractive potentials the saturation of nuclear forces cannot be understood. Only the joint effect of a strong repulsion at short distances (≤ 0.5 fm) and the quantum–mechanical exchange interactions can explain the saturation. The existence of strong repulsion at small internucleon distances is shown also by scattering experiments at high energies.
- It is obvious from these properties that the nuclear forces are very intricate. A further complication arises from the fact that many-body interactions (i.e., interactions involving more than three bodies) cannot be treated with exact mathematical methods.
- In principle one cannot exclude the existence of three- or, in general, multinucleon interactions.

■ Fig. 2.1

Schematic drawing of a polarization experiment and illustration of the spin–orbit interaction. The bombarding particle is polarized during the scattering on nucleus No. 1. This means, that its spin will be oriented, e.g., into the reaction plane. As a result, the scattering by nucleus No. 2 will be asymmetric; e.g., more particles will be scattered in direction A than in direction B

- Although the nuclear potentials are very intricate, in simple models one can use short-range, central potentials. The dependence of the nuclear potential on the distance can be approximated in different ways (➤ Fig. 2.2). The parameters of these potentials (such as V_0 , r_0 , R_N , r_c , a) can be adjusted to experimental data. The nuclear force $\mathbf{F}(\mathbf{r})$ is then obtained from the potential by partial derivation: $\mathbf{F}(\mathbf{r}) = -\nabla V(\mathbf{r})$. In quantum mechanics the equation of motion (the Schrödinger equation) contains the potential; therefore the force itself is rarely referred to. This makes it possible to use the sloppy term “force” for the potential itself.

If the treatment of the problem requires the introduction of noncentral (tensor, spin–orbit, etc.) interactions, too, the radial dependence of the potential may be different for the different interaction terms.

2.1.2.2 Phenomenological Nucleon–Nucleon Potentials

Experience shows that the nuclear forces are very complicated. Therefore, in the construction of phenomenological NN potentials, some general principles are invoked. Such as:

- Limitations from space–time symmetry considerations: translational and Galilean invariances, space reflection and time reversal invariances, rotational invariance in space, and invariance with respect to exchanging neutrons with protons (charge invariance, see ➤ Sect. 2.2.3). These problems are treated in detail, e.g., in Eisenbud and Wigner (1941), Bohr and Mottelson (1969), and Ring and Schuck (1980). It is advisable from the beginning to use only potentials that satisfy the above criteria.
- The generalized Pauli principle allows only certain states for the two-nucleon systems (see, e.g., Fényes 2002).
- As mentioned above, it is generally accepted that all four basic interactions of nature (strong, electromagnetic, weak, and gravitational) are mediated by field quanta. For the nuclear (strong) interaction meson (or, at quark level, gluon) exchange is responsible. The meson field theories have gone through an enormous development from the 1930s,

■ Fig. 2.2

Schematic illustration of simple, central nuclear interaction potentials

and presently they can describe many properties of nuclear forces correctly. Thus, in the construction of NN phenomenological potentials, the predictions of meson field theories are usually taken into account.

- It is usually assumed that the potential energy (V) of a multinucleon system can be composed as a sum of two-nucleon interactions:

$$V(1, 2, \dots, n) = \sum_{i < j=1}^n V(i, j),$$

where n is the number of nucleons. The correctness of this assumption is not perfectly proved, but it seems that one can understand most of the traditional nuclear structure problems without the introduction of three-body forces. For recent results see [Sect. 2.3.7.2](#). Although V is a potential energy, in quantum mechanics it is usually called potential.

In the 1960s, the rapidly growing experimental data made it possible to construct phenomenological potentials that could describe various effects of NN interaction. Such are the Hamada–Johnston potential with hard core (Hamada and Johnston 1962), the Yale potential with hard core (Lassila et al. 1962), the nonlocal Tabakin potential (Tabakin 1964), and the Reid potential with soft core (Reid 1968).

In the hard-core potentials, infinitely strong repulsions are used at distances < 0.5 fm. The Reid potential is also very repulsive in the core region, but it is gradually growing as the distance between the nucleons decreases. The explicit form of the Hamada–Johnston potential is as follows:

$$V = V_C + V_T S_{12} + V_{LS}(\mathbf{LS}) + V_{LL} L_{12}, \quad (2.1)$$

where the subscripts C, T, LS, and LL indicate central, tensor, linear, and quadratic spin–orbit interactions, and

$$V_C(r) = 0.08(0.333m_\pi)(\boldsymbol{\tau}_1 \boldsymbol{\tau}_2)(\boldsymbol{\sigma}_1 \boldsymbol{\sigma}_2)Y(x)[1 + a_c Y(x) + b_c Y^2(x)],$$

$$V_T(r) = 0.08(0.333m_\pi)(\boldsymbol{\tau}_1 \boldsymbol{\tau}_2)Z(x)[1 + a_T Y(x) + b_T Y^2(x)],$$

$$S_{12} = [3(\boldsymbol{\sigma}_1 \mathbf{r})(\boldsymbol{\sigma}_2 \mathbf{r})/r^2] - (\boldsymbol{\sigma}_1 \boldsymbol{\sigma}_2),$$

$$V_{LS}(r) = m_\pi G_{LS} Y^2(x)[1 + b_{LS} Y(x)],$$

$$V_{LL}(r) = m_\pi G_{LL}[Z(x)/x^2][1 + a_{LL} Y(x) + b_{LL} Y^2(x)],$$

$$L_{12} = \delta_{LJ} \mathbf{L}^2 + (\boldsymbol{\sigma}_1 \boldsymbol{\sigma}_2) \mathbf{L}^2 - (\mathbf{LS})^2,$$

$$Y(x) = \frac{e^{-x}}{x}, \quad Z(x) = \left(1 + \frac{3}{x} + \frac{3}{x^2}\right)Y(x).$$

m_π is the pion mass ($m_\pi c^2 = 139.4$ MeV was used in numerical calculations), x is the internucleon distance, measured in m_π^{-1} (see in [Sect. 2.1.2.3](#)), \mathbf{L} is the resulting orbital angular momentum vector, \mathbf{S} is the resulting spin, $\mathbf{S} = \mathbf{s}_1 + \mathbf{s}_2$, $\mathbf{s} = \boldsymbol{\sigma}\hbar/2$ is the spin vector operator (see later in [Sect. 2.2.2](#)), $\mathbf{t} = \boldsymbol{\tau}/2$ is the isospin vector operator (see later in [Sect. 2.2.3](#)), r is the internucleon distance.

The repulsion is infinitely large in the core region, $r_{\text{core}} \leq 0.485$ fm, which corresponds to $x_c \leq 0.343$. The adjusted parameters are as follows:

S	L	a_c	b_c	a_T	b_T	G_{LS}	b_{LS}	G_{LL}	a_{LL}	b_{LL}
0	Even	8.7	10.6	—	—	—	—	−0.000891	0.2	−0.2
1	Even	6.0	−1.0	−0.5	0.2	0.0743	−0.1	0.00267	1.8	−0.4
0	Odd	−8.0	12.8	—	—	—	—	−0.00267	2.0	6.0
1	Odd	−9.07	3.48	−1.29	0.55	0.1961	−7.1	−0.000891	−7.26	6.92

The potential contains 28 fitted (nonzero) parameters. The Hamada–Johnston potential predicts the following data for the deuteron ($S = 1$, L even):

Binding energy	$E_B = 2.226$ MeV
Electric quadrupole moment	$Q_d = +2.85$ mb
D-state probability	$P_D = 6.97\%$

The corresponding experimental data are: $E_B = 2.224566$ MeV (Audi et al. [2003](#)), $Q_d = 2.86(2)$ mb (Stone [2005](#)). There is no direct access to P_D .

2.1.2.3 Nucleon–Nucleon Potentials from Meson Field Theories

According to quantum electrodynamics, the electromagnetic interaction is mediated by photons. For instance, one of the electric charges emits a photon, and the other one absorbs it. Yukawa (1935) supposed that the interaction between nucleons is also mediated by the exchange of field quanta, and the predicted rest energy of the field quantum (called meson) is ~ 140 MeV. After the discovery of π mesons (Lattes et al. 1947) the quanta of the meson field have been identified with π mesons, which have approximately the same rest energy.

According to experiments, the π mesons exist in three charge states: π^+ , π^0 , π^- . From a pseudoscalar theory, taking into account all three charge states in a symmetric way, the following expression was obtained (see, e.g., Bohr and Mottelson 1969) for the asymptotic behavior of the so-called *one-pion exchange nucleon–nucleon potential* (V_{OPEP}):

$$V_{\text{OPEP}} = 0.333 m_\pi c^2 \frac{g^2}{4\pi\hbar c} (\boldsymbol{\tau}_1 \boldsymbol{\tau}_2) [(\boldsymbol{\sigma}_1 \boldsymbol{\sigma}_2) + S_{12} f(r)] \frac{\exp(-r/\lambda)}{r\lambda}, \quad (2.2)$$

where m_π is the mass of the π meson, c is the speed of light in vacuum, g is the “mesonic” charge, analogous to the electric charge, $\hbar = h/2\pi$ is the rationalized Planck constant, $\mathbf{s} = \boldsymbol{\sigma}\hbar/2$ is the spin operator, $\mathbf{t} = \boldsymbol{\tau}/2$ is the isospin operator, $S_{12} = 3(\boldsymbol{\sigma}_1 \mathbf{r})(\boldsymbol{\sigma}_2 \mathbf{r})/r^2 - (\boldsymbol{\sigma}_1 \boldsymbol{\sigma}_2)$, $f(r) = 1 + \frac{3}{r/\lambda} + \frac{3}{(r/\lambda)^2}$, $1/\lambda = m_\pi c/\hbar$, r is the distance between two nucleons.

The potential shows similarity to the interaction potential of two remote, pointlike magnetic dipoles, but the electromagnetic field has vectorial character, while the character of the meson field is pseudoscalar (the spin of π meson is zero).

The one-pion exchange potential (V_{OPEP}) is actually dominant only far from the core region ($r > 2$ fm). The numerical value of the potential can be determined from the analysis of the scattering of π mesons on nucleons.

The values of the parameters are:

$$\frac{1}{\lambda} = \frac{m_\pi c}{\hbar} = 0.70 \text{ fm}^{-1}, \quad \frac{g^2}{4\pi\hbar c} = 0.081 \pm 0.002.$$

It must be remarked that in the short-range region an additional “contact” term appears in [Eq. \(2.2\)](#) that induces a strong repulsion at very small distances.

The one-pion exchange potential contains central and tensor potentials. The interaction has a short range and it is independent of electric charges.

The one-pion exchange potential shows a reasonable agreement with the Hamada–Johnston potential far from the hard core ($r \geq 2$ fm). At small distances there are deviations. A detailed comparison of different nucleon–nucleon potentials can be found, e.g., in Fényes (2002).

If two nucleons are close enough to each other, exchange of two or more π mesons, as well as exchange of heavier mesons (ρ , η , ω) may occur between them, too. Beginning from the 1970s, meson field theoretical potentials have been deduced, which take into account these possibilities and give a better description of experimental data at small distances ($r \leq 2$ fm) than V_{OPEP} does.

Paris potential. Cottingham et al. (1973) and Lacombe et al. (1975) have derived a nucleon–nucleon potential which includes one pion and correlated and uncorrelated two- π and ω meson-exchange potentials. The theory gives a realistic description of the interaction in the

distant and medium-far regions ($r \geq 0.8$ fm). The Paris potential has been parameterized later in a simple analytical form.

Bonn potential. Machleidt et al. (1987) proposed a comprehensive field-theoretical meson-exchange model for nucleon–nucleon interaction. The potential contains many components (one- π , two- π , ρ , η , ω , etc. meson exchange).

The overall description of NN scattering and deuteron data with the Bonn and parameterized Paris potentials is very good. See ▶ Table 2.4 for some deuteron data.

Machleidt et al. (1987) conclude that the many-body forces need not play an important role in traditional nuclear structure calculations. Nevertheless, the recent ab initio Green’s function Monte Carlo calculations show that the three-nucleon interactions give a significant fraction of the nuclear binding energy in few-nucleon systems. The ratio of the expectation values of the three-/two-nucleon interaction potentials ($\langle V_{ijk} \rangle / \langle v_{ij} \rangle$) is about 7% in the $A = 8$ nuclei and $\langle V_{ijk} \rangle$ gives up to one half of their binding energy (Pieper et al. 2001). Details see later in ▶ Sect. 2.3.7.

Although it is widely believed that the fundamental theory of strong interactions can be understood on the basis of quantum chromodynamics (QCD), the non-perturbative character of QCD for low energies raises very serious mathematical problems, and one is far from the quantitative understanding of the NN interaction in the framework of QCD.

Meson-field theoretical NN potentials give a reasonable guidance for the construction of phenomenological potentials, too. At the same time, both the phenomenological and the realistic, meson-field theoretical potentials are very complicated, and their application in nuclear structure calculations is rather difficult.

Therefore, simple “effective” potentials are also widely used in structure calculations. In these potentials, only the main properties of realistic potentials are preserved. In addition to their simplicity, the effective potentials have the advantage that from them it is easier to draw conclusions with clear physical meaning.

■ Table 2.4

The predictions of the Bonn and parameterized Paris meson exchange potentials in comparison with experimental results

Deuteron property	Experimental value ^a	From Bonn ^b full potential	From Paris ^c parameterized potential
Binding energy, E_B (MeV)	2.224575 ± 0.000009	2.22465	2.2249
D-state probability, P_D (%) ^d	(5 ± 2)	4.249	5.77
Quadrupole moment Q_d (fm ²)	0.2859 ± 0.0003	0.2807	0.279
Magnetic dipole moment μ_d (μ_N)	0.857406 ± 0.000001	0.8555	0.853
Root-mean-square radius (fm)	1.9635 ± 0.0045	2.0016

2.2 Properties of Nuclei

2.2.1 Nuclear Mass and Binding Energy

The masses of atomic nuclei can be determined by mass-spectrometers or from nuclear reaction and decay energies. According to Einstein's theory of relativity, the energy (E) and mass (m) are related by equation $E = mc^2$, where c is the speed of light in vacuum. The binding energy U_B is the equivalent mass, obtained by subtracting the mass of the nucleus from the sum of the masses of the constituent nucleons. [Figure 2.3](#) shows the mean binding energy per nucleon (E_B/A) as a function of mass number A for nuclei lying in the stability valley. Above $A \approx 20$ the E_B/A values vary very slowly and regularly: they remain in the 7.5–8.8 MeV/ A interval.

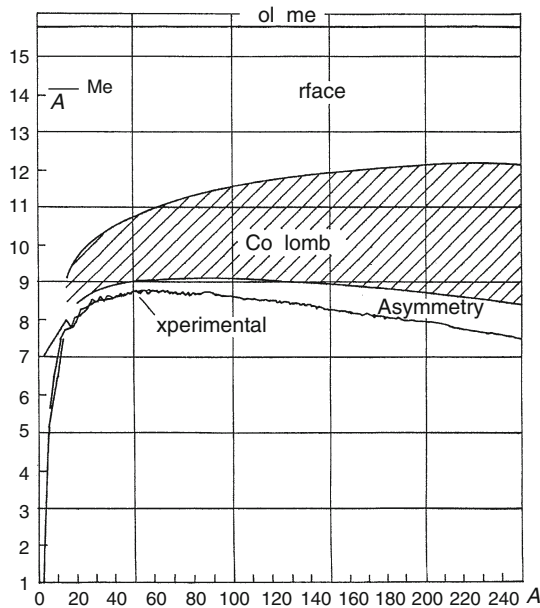

The main features of this behavior can be understood on the basis of the liquid drop model (von Weizsäcker 1935; Bethe and Bacher 1936). According to this model, the nucleus is an incompressible liquid drop, in which the electric charge is distributed uniformly. The binding energy E_B is described by the Weizsäcker formula:

$$E_B = \alpha A - \beta A^{2/3} - \gamma \frac{Z^2}{A^{1/3}} - \zeta \frac{(N - Z)^2}{A} \pm \frac{\delta}{A^{3/4}}, \quad (2.3)$$

where the successive terms express the volume, surface, Coulomb, and asymmetry energies. The last, pairing energy term is equal to $+\delta/A^{3/4}$ for even- Z and even- N , zero for odd- A

■ Fig. 2.3

Mean binding energy per nucleon E_B/A for nuclei lying in the stability valley as a function of the mass number A . The approximate contribution of different terms in [Eq. \(2.3\)](#) is also shown (Based on Kravtsov 1965)

and $-\delta/A^{3/4}$ for odd-odd nuclei. The parameters $\alpha, \beta, \gamma, \zeta, \delta$ are fitted to experimental data. The approximate contribution of different terms to E_B/A is also shown in [Fig. 2.3](#).

A substantial improvement can be obtained, if the parameters in [Eq. \(2.3\)](#) are fitted to experimental values for magic nuclei, and a sixth term ($-\kappa P$) is added to the right-hand side. Here $P = ZN/(Z+N)$ is the “promiscuity” factor. Angeli proposed the following new formula (Angeli 1991b):

$$E_B = \alpha_c A - \beta_c A^{2/3} - \gamma_c \frac{Z^2}{A^{1/3}} - \zeta_c \frac{(N-Z)^2}{A} \pm \frac{\delta_c}{A^{3/4}} - \kappa \frac{ZN}{A}, \quad (2.4)$$

where the subscript c means “closed” shell, and the constants (all values in MeV) are

$$\alpha_c = 15.15, \quad \beta_c = 15.94, \quad \gamma_c = 0.665, \quad \zeta_c = 21.57, \quad \delta_c = 22.4, \quad \text{and} \quad \kappa = 1.42 \pm 0.06. \quad (2.5)$$

In the last 60 years, the binding energy (or mass) formulae have been improved in different directions. One type of formulae is based mainly on the liquid drop model (Myers and Swiatecki 1966, 1967, 1969; Strutinsky 1968; Spanier and Johansson 1988; Möller et al. 1988; Möller and Nix 1988); another type of formulae has been modified starting from the nuclear shell model (Zeldes 1967; Zeldes et al. 1967; Möller et al. 1986, 1992; Tashibana et al. 1988; Han et al. 1992; Lazarev et al. 1994). Finally, some formulae are based on inherent phenomenological relationships between the experimentally determined nuclear masses (Garvey et al. 1969; Garvey 1969; Comay et al. 1988; Jänecke and Masson 1988; Avotina et al. 1995). A survey of mass formulae was given by Tarantin (1995) and Lunney et al. (2003).

Möller et al. (1995) calculated the atomic mass excess and nuclear ground-state deformation for 8,979 nuclei from ^{16}O to $A = 339$ between the proton and neutron drip lines (see [Fig. 2.7](#)). The calculations with the finite-range droplet model (FRDM) contain 16 mass-like and 22 other parameters. In the framework of FRDM it is possible to calculate a large number of nuclear structure properties in addition to the ground-state masses, such as even multipole ground-state deformations ($\varepsilon_2, \varepsilon_4, \varepsilon_6$), β -decay properties, pairing quantities, odd-particle spins, α -decay properties, octupole properties (ε_3), etc.

Proton S_p and neutron S_n (mass-equivalent) separation energies can be derived from the following combinations of atomic masses:

$$S_p = -M(A, Z) + M(A-1, Z-1) + M(1, 1),$$

$$S_n = -M(A, Z) + M(A-1, Z) + M(1, 0),$$

where $M(1,1)$ and $M(1,0)$ are the mass of the hydrogen atom ^1_1H and the neutron ^1_0n , respectively. Evaluated numerical data for masses and binding energies can be found in Wapstra et al. (2003) and Audi et al. (2003). From the separation energies S_p and S_n , one can calculate the pairing energy, which is defined as

$$\begin{aligned} P_p(A, Z) &= 0.25(-1)^{Z+1} [S_p(A+1, Z+1) - 2S_p(A, Z) + S_p(A-1, Z-1)], \\ P_n(A, Z) &= 0.25(-1)^{A-Z+1} [S_n(A+1, Z) - 2S_n(A, Z) + S_n(A-1, Z)]. \end{aligned} \quad (2.6)$$

The pairing energies can also be determined from the ground-state energies of nuclei. The average behavior of pairing energies can be described by a simple expression $P_{n \text{ (or } p)} \approx 12/A^{1/2}$ MeV (Zeldes et al. 1967), although rather large deviations can be observed from this simple formula, especially at closed shells.

2.2.2 Spin, Electric, and Magnetic Moments

2.2.2.1 Spin

One of the measurable properties of atomic nuclei is the total angular momentum (\mathbf{I}) called nuclear spin of the state. (The nuclear spin symbols I and J are used in this chapter alternatively, in accordance with notations in the corresponding literature.) The components of vector \mathbf{I} satisfy the commutation relations

$$I_x I_y - I_y I_x = -\frac{\hbar}{i} I_z$$

and similar expressions with cyclic permutations of the components. According to quantum mechanics, only \mathbf{I}^2 and one of the components of \mathbf{I} (e.g., I_z) can be determined exactly at the same time (they are “commuting” quantities). The eigenvalues of \mathbf{I}^2 and I_z can be written as $I(I+1)\hbar^2$ and $m\hbar$, respectively, where $I \geq 0$ is an integer for even- A , and half-integer for odd- A , and $m = I, I-1, \dots, -I$. The value of I is an important characteristic of a nuclear state.

2.2.2.2 Electric Moments

The electric moments of a nucleus can be introduced, e.g., in the following way. Let the origin of a Cartesian coordinate system x_n, y_n, z_n coincide with the center of the nucleus (• Fig. 2.4a). Then the electric potential $V_n(\mathbf{r})$ of the nucleus is given by

$$V_n(\mathbf{r}) = \int \frac{\rho^e(\mathbf{r}_n) dV_n}{|\mathbf{r} - \mathbf{r}_n|}, \quad (2.7)$$

■ Fig. 2.4

(a) Position vector in a coordinate system fixed to the nucleus (illustration to the determination of nuclear electric moments). (b) Angular momentum in an axial-symmetric deformed nucleus. \mathbf{I} is the total angular momentum (spin) of the nucleus. K is the projection of total angular momentum to the symmetry axis

where ρ^e is the nuclear charge density and dv_n is the volume element. The integration must be performed over the whole volume of the nucleus.

Let the vector \mathbf{r} point to the z_n direction. The angle between \mathbf{r} and \mathbf{r}_n is just the polar angle θ . Using the cos law one obtains

$$|\mathbf{r} - \mathbf{r}_n| = \sqrt{\mathbf{r}^2 + \mathbf{r}_n^2 - 2r r_n \cos \theta}.$$

When $(r_n/r) \ll 1$, one can make the following expansion:

$$\frac{1}{|\mathbf{r} - \mathbf{r}_n|} = \frac{1}{r} \sum_{l=0}^{\infty} \left(\frac{r_n}{r} \right)^l P_l(\cos \theta), \quad (2.8)$$

where $P_l(\cos \theta)$ is the Legendre polynomial:

$$P_0(\cos \theta) = 1, \quad P_1(\cos \theta) = \cos \theta, \quad P_2(\cos \theta) = \frac{1}{2}(3\cos^2 \theta - 1), \text{ etc.}$$

Thus the potential $V_n(\mathbf{r})$ can be written in the form:

$$V_n(\mathbf{r}) = \frac{\int \rho^e(\mathbf{r}_n) dv_n}{r} + \frac{\int \rho^e(\mathbf{r}_n) \mathbf{r}_n dv_n}{r^2} + \frac{1}{2} \frac{\int \rho^e(\mathbf{r}_n) (3z_n^2 - r_n^2) dv_n}{r^3} + \dots, \quad (2.9)$$

where, by definition,

$$Ze = \int \rho^e(\mathbf{r}_n) dv_n$$

is the electric monopole moment (i.e., the full nuclear charge), the quantity

$$\int \rho^e(\mathbf{r}_n) z_n dv_n$$

is the electric dipole moment,

$$\int \rho^e(\mathbf{r}_n) (3z_n^2 - r_n^2) dv_n \quad (2.10)$$

is the electric quadrupole moment, and $z_n = r_n \cos \theta$.

Higher multipole moments can also be defined: octupole (2^3 -pole), hexadecapole (2^4 -pole), hexacontatetrapole (2^5 -pole), etc. Nevertheless, higher-order multipoles do not play important roles in nuclear physics, because the weight of subsequent terms in [Eq. \(2.9\)](#) is strongly decreasing.

The definition of the moments becomes unambiguous by specifying the orientation of the nucleus. By convention, in the definition of the electric multipole moments the nuclear angular momentum is assumed to be aligned along the z_n axis. The intrinsic electric quadrupole moment Q_0 is then defined as

$$Q_0 \equiv \int \rho^e(\mathbf{r}_n) (3z_n^2 - r_n^2) dv_n. \quad (2.11)$$

The quadrupole moments are measured in units of barn (b), $1 \text{ b} = 10^{-24} \text{ cm}^2$. If the rotation ellipsoid is prolate, $Q_0 > 0$, if it is oblate, $Q_0 < 0$.

The quadrupole moment can be determined also in a laboratory system, with x, y, z coordinates ([Fig. 2.4b](#)). The quadrupole moment Q in the laboratory frame (also referred

to as spectroscopic quadrupole moment) is expressible in terms of the density in the intrinsic frame similarly. The integral over the rotational variable factors out and yields:

$$Q = \frac{3K^2 - I(I+1)}{(I+1)(2I+3)} Q_0. \quad (2.12)$$

Usually this moment (Q) is measured in experiments. (See later in [Sect. 2.3.4.2](#), “Theory of nuclear rotation.”) This implies that if $I = 0$ (even–even nuclei) or $I = 1/2$, the quadrupole moment is zero in the laboratory system. This is so even if the intrinsic quadrupole moment differs from zero.

2.2.2.3 Magnetic Moments

According to classical electrodynamics, the energy of the nucleus in a magnetic field can be written in the form

$$E = -\boldsymbol{\mu} \mathbf{B},$$

where $\boldsymbol{\mu}$ is the magnetic dipole moment of the nucleus and \mathbf{B} is the magnetic induction. A particle, moving on a circular orbit, generates a magnetic dipole moment

$$\boldsymbol{\mu} = g_l \frac{e}{2m} \mathbf{L},$$

where e and m are the charge and mass of the particle, respectively, c is the speed of light in vacuum, \mathbf{L} is the orbital angular momentum vector and g_l is a dimensionless correction factor, the orbital gyromagnetic ratio. In quantum mechanics, \mathbf{L} is measured in units \hbar , thus \mathbf{L} may be substituted by $\mathbf{L}\hbar$. For an electron, the orbital magnetic moment can be written in the form:

$$\boldsymbol{\mu}^e = \frac{e\hbar}{2m_e} \mathbf{L}.$$

For convenience, the following units have been introduced: the Bohr magneton, μ_B , for the electron:

$$\mu_B = \frac{e\hbar}{2m_e} = 5.7883817555(79) \times 10^{-11} \text{ MeV/T}$$

and the nuclear magneton, μ_N , for nucleons:

$$\mu_N = \frac{e\hbar}{2m_p} = 3.1524512326(45) \times 10^{-14} \text{ MeV/T}.$$

Due to the mass ratio, the nuclear magneton is about 1,836 times smaller than the Bohr magneton. The total magnetic dipole moment is a vectorial sum of the orbital and spin magnetic moments:

$$\boldsymbol{\mu}_j = \boldsymbol{\mu}_l + \boldsymbol{\mu}_s,$$

where $\mathbf{j} = \mathbf{l} + \mathbf{s}$, and $\boldsymbol{\mu}_l = g_l \mathbf{l}$, $g_l^p = 1$, $g_l^n = 0$, $\boldsymbol{\mu}_s = g_s \mathbf{s}$, $g_s^p = 5.586$, $g_s^n = -3.826$, $\boldsymbol{\mu}_j = g_j \mathbf{j}$, the $\boldsymbol{\mu}$ -s are expressed in nuclear magnetons (μ_N), while the \mathbf{l} , \mathbf{s} , \mathbf{j} moments in \hbar units.

Detailed relations between the $\boldsymbol{\mu}_j$ and \mathbf{j} values for protons and separately neutrons were first derived by Schmidt in 1937 (see, e.g., in Fényes (2002), Sect. IV.5.2). By convention, the nuclear

magnetic moment is the value of μ taken in a state in which the nuclear angular momentum is fully aligned with the magnetic field. It is this value that is actually measured. The magnetic moment connected with the spin has no classical analogue, but it may be characterized also by the expression $\boldsymbol{\mu} = g_s \mathbf{s} \mu_N$, where $s = 1/2$ both for a proton and a neutron. The exact magnetic moments of proton and neutron are (Particle Data Group 2008):

$$\mu_p = 2.792847351(28)\mu_N, \quad \mu_n = -1.9130427(5)\mu_N.$$

2.2.2.4 Experimental Nuclear Moments

The nuclear moments can be measured with many different methods. Spin and magnetic moments can be determined from hyperfine splitting of atomic spectra, hyperfine splitting in external magnetic field, deflection of beams in inhomogeneous magnetic field, nuclear magnetic resonance, perturbed angular correlation of γ rays in strong magnetic fields, etc.

Intrinsic quadrupole moments can be obtained by measuring distances between rotational levels, or reduced electromagnetic transition probabilities $B(E2)$.

Spectroscopic quadrupole moments can be determined by many experimental methods: differential perturbed angular distribution of γ rays following nuclear reactions, low temperature nuclear orientation, optical spectroscopy, Coulomb excitation reorientation, different methods of laser spectroscopy, hyperfine splitting of spectrum lines in inhomogeneous electric field, etc.

The experiments show that in the ground states of nuclei the electric moments of 2^l order with odd l and all 2^l -pole magnetic moments with even l are missing. Only electric monopole, magnetic dipole, electric quadrupole, magnetic octupole, etc., moments are observed in experiments. This means that the 2^l -pole character unambiguously determines whether the moment is electric or magnetic, and these latter attributes may be omitted. This rule can be viewed as a consequence of a symmetry property (parity) of the nuclear states.

A compilation and evaluation of experimental nuclear moments has been published in Raghavan (1989) and Stone (2005). On the basis of the available data one can draw some general conclusions.

The spins and magnetic dipole moments in the ground states of all even–even nuclei are zero, without exception. The spins (I) of the odd- A nuclei have half-integer values (in units of \hbar) and $I \leq 11/2$. The magnetic moments (μ in units of μ_N) are in the intervals determined by the “Schmidt curves”: $-0.5 \leq \mu \leq 7$ for odd- Z , even- N , while $-2.2 \leq \mu \leq 1.5$ for even- Z , odd- N nuclei.

The low values of I and μ show that the orbital and spin angular momenta, as well as the magnetic dipole moments of the individual nucleons, cancel each other to a great extent.

The ground-state spins I of odd–odd nuclei have in all cases integer values (again in units of \hbar) and they remain within the interval $|j_p - j_n| \leq I \leq j_p + j_n$, where j_p and j_n are the total angular momenta of the odd proton and odd neutron, respectively. The magnetic dipole moments of the ground states of the odd–odd nuclei may be either positive or negative, but their absolute values are small (≤ 5 in nuclear magnetons μ_N). In the shell model, the magnetic dipole moments of odd–odd nuclei can be determined from the known configurations of the odd proton and the odd neutron.

The absolute values of the intrinsic quadrupole moments $|Q_0|$ of even–even nuclei are shown in [Fig. 2.5](#). Near magic Z (or/and N) values (2, 8, 20, 28, 50, 82, 126, see in [Sect. 2.3.1.1](#)) the Q_0 moments are close to zero.

■ Fig. 2.5

Absolute values of intrinsic quadrupole moments $|Q_0|$ of even–even nuclei as a function of the atomic number (Z). The $|Q_0|$ values of different isotopes of the given element are scattered within the intervals represented by vertical bars (Data from Raman et al. 1987)

As it was already mentioned, the spectroscopic quadrupole moments of the even–even and $I = 1/2$ nuclei vanish. The reduced $Q/(ZR^2)$ spectroscopic quadrupole moments of the odd- A nuclei are in the range $-10 \times 10^{-28} \leq Q/(ZR^2) \leq 35 \times 10^{-28}$ (for the definition of R , see section “Charge radii”).

Most nuclei have prolate deformation, although small oblate deformations also occur, especially close to magic numbers. In some regions, large quadrupole deformations were measured. In the shell model the spectroscopic quadrupole moments of odd–odd nuclei can be determined from the configurations of the odd proton and odd neutron.

2.2.3 Size, Parity, and Isospin of Nuclei

2.2.3.1 Nuclear Size

Nuclear charge and matter distributions, as well as nuclear radii can be studied by several methods. The most important ones are as follows.

Charge distribution can be extracted from the measurement of elastic electron scattering, X-rays from muonic and ordinary atoms (isotope shifts), and optical spectra (Fricke et al. 1995).

Matter distribution can be determined from elastic p, n, α scattering, π^\pm , K^\pm meson scattering, and cross sections of reactions induced by p, n, antiproton, π , and K beams.

Electrons and muons do not take part in the strong interaction (► Table 2.2) and do not induce substantial rearrangement in the nuclear structure. The laws of electromagnetic interactions are well known. Thus, the methods probing the charge distribution with these projectiles are of primary importance. The nucleon and meson projectiles strongly interact with nuclei, and they are able to give information on the nuclear matter distribution. On the other hand, the evaluation of experimental results is more difficult, because the laws of nuclear interactions are not perfectly known; furthermore, the bombarding particles may perturb the structure of the target nucleus.

Charge Radii

Information on charge radii can be obtained from electron scattering experiments. One can determine the mean square charge radius in a model-independent way:

$$\langle r^2 \rangle = \int_V \rho^e(\mathbf{r}) \mathbf{r}^2 dV, \quad (2.13)$$

where ρ^e is the charge density normalized to the whole charge of the nucleus, dV is the volume element, and V is the volume of the nucleus. From the root-mean-square (r.m.s.) radius, $R_{r.m.s.}$ (which means the square root of the mean square charge radius), one can calculate the radius parameter R of an equivalent uniform charge distribution, for which $\rho^e(r, R) = \rho_0^e$, if $r \leq R$ and $\rho^e(r, R) = 0$, if $r > R$. The ρ_0^e uniform distribution is said to be equivalent to the $\rho^e(r)$ distribution of the nucleus if it contains the same charge and it scatters the low-energy electrons approximately in the same way. The relation between the two radii is:

$$R = 1.291 R_{r.m.s.} \quad (2.14)$$

The experimental charge distribution is shown for some nuclei in ► Fig. 2.6. The nuclear surface is not sharp, the charge density gradually decreases toward larger distances from the center.

The nuclear charge distribution can also be calculated assuming a mean field, in which the nucleons move independently. The short range interactions between the nucleons are replaced usually in a phenomenological way by effective interactions. As ► Fig. 2.6 shows, the theoretical results of Dechargé and Gogny are very close to the experimental ones.

The root-mean-square (charge) radius $R_{r.m.s.}$ depends both on Z and N . At the bottom of the stability valley (see ► Sect. 2.2.4), the atomic number Z_{stab} and mass number A_{stab} are related by

$$Z_{stab} = \frac{A_{stab}}{1.98 + 0.016 A_{stab}^{2/3}}. \quad (2.15)$$

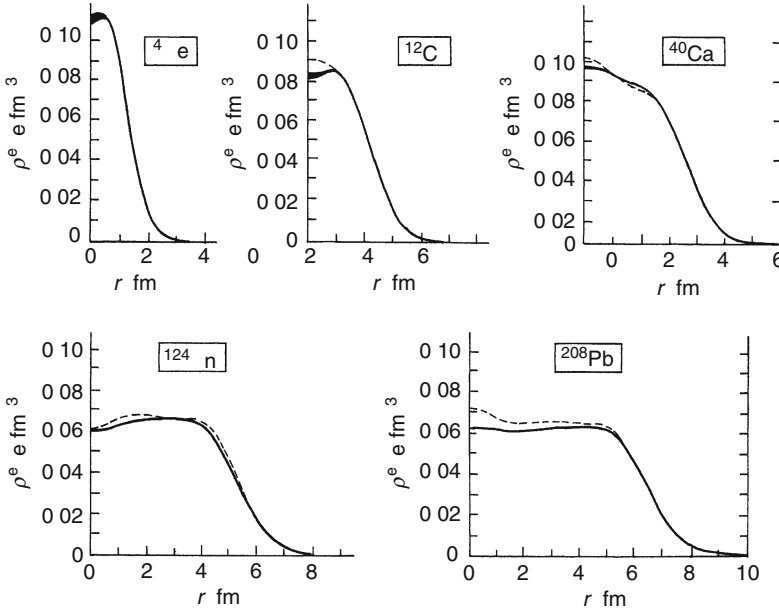

For these nuclei, the dependence of R on the mass number follows the predictions of the uniformly charged liquid-drop model:

$$R = r_0 A^{1/3}, \quad (2.16)$$

where $R = R_{stab}$, $A = A_{stab}$, and $r_0 = 1.23$ fm (for charge distribution). In practice the indices “stab” are usually omitted. According to ► Eq. (2.15), the volume of the nucleus is proportional to the mass number A . The nuclear binding energy per nucleon (► Fig. 2.3)

■ Fig. 2.6

Ground state charge density (ρ^e) distributions in some nuclei from electron scattering and muonic X-ray measurements (Frois 1983). The dashed curves show mean field many-body (microscopic) theoretical results (Dechargé and Gogny 1980)

shows saturation for $A > 10$, which corresponds to $R > 2.6$ fm. The characteristic range of nuclear forces must be close to this distance.

The simple formula [Eq. \(2.15\)](#) only describes the gross structure of nuclear radii. Elton (1961) and Angeli (1991a) proposed formulae which take into account a finite surface thickness.

For isobaric nuclei a symmetry term must be added to the radius formula (see Angeli (1992) and further references therein). Nuclear shell effects were considered in the nuclear r.m. s. radii by Angeli (1991a). A systematics of nuclear charge radii are given in Nadjakov et al. (1994), Angeli (2004), and Fricke and Heilig (2004).

In strongly p- or n-rich nuclei, the diffuseness of the nuclear surface, and thus the radii of nuclei, follows different patterns, and departures are expected from the simple formula [Eq. \(2.16\)](#).

Mass Radii

Nuclear mass distributions can be studied, for example, by the scattering of fast neutrons on nuclei. Such experiments were performed in a wide energy range of bombarding neutrons (14–1,400 MeV) and led to the following result:

$$R = R_0 A^{1/3}, \quad (2.17)$$

where $1.3 \text{ fm} \leq R_0 \leq 1.4 \text{ fm}$. This means that the nuclear mass parameter R_0 is only slightly greater than the charge parameter, $r_0 = 1.23$, shown in [Eq. \(2.15\)](#). In the heavy nuclei

there are usually more neutrons than protons, but the long-range repulsion between proton pairs has a strong effect. A more detailed treatment of nuclear size can be found, e.g., in Fényes (2002).

Note that far from the stability region the separation energy of the outermost nucleons is small. In some cases this may lead to a drastic increase of the size of nucleus: the external nucleon may occupy a distant lying orbit. For example, such proton “halo” exists in ^8B , one-neutron halos in ^{11}Be and ^{19}C , and two-neutron halos in ^6He and ^{11}Li . The radii of these nuclei are extremely large, comparable with that of ^{48}Ca . See Suzuki et al. (2003).

2.2.3.2 Parity

Nuclear states are described in quantum mechanics by eigenvalues and eigenfunctions of the Hamilton operator, to which definite quantum numbers belong. The parity of the wave function is its symmetry property under inversion through the origin of the coordinate system, i.e., when the coordinates x, y, z are transformed into $-x, -y, -z$. This transformation turns a right-handed coordinate system into a left-handed one or vice versa.

The parity is an “observable” physical quantity, which, in the language of quantum mechanics, means that its eigenvalues are real quantities.

It can be proved that an eigenfunction $\Psi(\mathbf{r})$ of the Hamiltonian has definite parity, unless there is degeneracy (i.e., at least two eigenvalues coincide). For stationary states, the wave equation reads:

$$H(\mathbf{r})\Psi(\mathbf{r}) = E\Psi(\mathbf{r}),$$

where $H(\mathbf{r})$ is the Hamilton operator and E is the energy eigenvalue of the state. Inversion through the origin means that one changes the sign of the position vector: $\mathbf{r} \rightarrow -\mathbf{r}$. Experiments show that in strong and electromagnetic interactions the energy of the system is invariant under inversion, that is $H(-\mathbf{r}) = H(\mathbf{r})$. (In [Sect. 2.1.2.2](#) this was an assumption.) Therefore

$$H(\mathbf{r})\Psi(-\mathbf{r}) = E\Psi(-\mathbf{r}).$$

As $\Psi(\mathbf{r})$ and $\Psi(-\mathbf{r})$ satisfy the same equation, $\Psi(\mathbf{r})$ must be proportional to $\Psi(-\mathbf{r})$, $\Psi(\mathbf{r}) = k\Psi(-\mathbf{r})$, where k is a constant (in a nondegenerate case). As \mathbf{r} may take on also value $-\mathbf{r}$, the equation $\Psi(-\mathbf{r}) = k\Psi(\mathbf{r})$ must also be valid. Consequently, k must be either +1 or -1. If $\Psi(-\mathbf{r}) = \Psi(\mathbf{r})$, the function Ψ is said to be even (or it has positive parity $\pi = 1$), if $\Psi(-\mathbf{r}) = -\Psi(\mathbf{r})$, the wave function is odd (it has negative parity $\pi = -1$).

The nuclear states can thus be characterized by a definite parity. It can be shown that the parity is a constant of motion, i.e., it is conserved in closed systems in which only strong and electromagnetic interactions occur. When the weak interaction is included, H contains a term, which changes sign under inversion through the origin, so that the right-handed coordinate system is not equivalent to the left-handed one (see [Sect. 2.4.2.3](#)). But since the weak interaction is almost always negligible in the nuclear structure, the nuclear states can be regarded as having definite parities.

The even- Z -even- N nuclei have even parity in their ground states. The parity of the ground state of odd- A nuclei is determined by $(-1)^l$, where l is the orbital angular momentum of the unpaired nucleon (see in the shell model, [Sect. 2.3.1.2](#)). In the case of the odd-odd nuclei the parity of the ground state is described by the product of the odd proton and odd neutron parities.

2.2.3.3 Isospin

Both the nuclear-binding energies and nucleon–nucleon scattering experiments show that the nuclear forces are almost independent of the types of nucleons; the three types of nuclear interactions (pp)_{nuclear}, pn , and nn are nearly identical.

This property, the charge independence of nuclear forces, can be described conveniently by the isospin formalism introduced by W. Heisenberg. The isospin formalism is completely analogous with the quantum–mechanical formalism of spin 1/2 particles. In the case of a many-nucleon system the total isospin (T) is defined as a sum of the nucleonic isospins:

$$\mathbf{T} = \sum_{i=1}^A \mathbf{t}_i. \quad (2.18)$$

For the z component this reduces to

$$T_z = \sum_{i=1}^A t_{iz}. \quad (2.19)$$

As in ordinary spin algebra, the vector operator \mathbf{T} obeys the angular momentum commutation relations.

The eigenvalues of the operators \mathbf{T}^2 and T_z are thus

$$\mathbf{T}^2 : T(T+1),$$

$$T_z : T, T-1, \dots -T.$$

Here T is either integer or half-integer depending on whether A is even or odd. The eigenvalues of \mathbf{T}^2 and T_z are constructed from those of \mathbf{t}_i^2 and t_{iz} by the rules of angular momentum addition. The eigenvalue of the t_{iz} operator may be either $+1/2$ or $-1/2$ for the two charge states of the nucleon (i.e., $+1$ for p and 0 for n). Here the convention that sign $+$ stands for proton is accepted, but this is arbitrary. As each neutron contributes to T_z with $-1/2$, and each proton with $+1/2$ one can write:

$$T_z = 0.5(Z - N) = Z - A/2. \quad (2.20)$$

Experiments show that in the ground states of most nuclei the isospin is $T = |T_z|$, that is the minimum T value is realized.

The angular momentum and isospin algebras are discussed in detail in basic textbooks of quantum mechanics and nuclear physics (e.g., Schiff 1968; Heyde 1990).

Note, that the isospin symmetry of nuclear forces is not exact. The modern *ab initio* Green's function Monte Carlo calculations show that isospin-breaking terms are necessary in the strong interaction to reproduce the experimental data (Pieper et al. 2001), see later in [Sect. 2.3.7.2](#). The charge symmetry breaking in the strong interaction occurs because the up and down quarks have different masses and quark electromagnetic effects present themselves (Miller et al. 2006).

2.2.4 Chart of the Nuclides

► [Figure 2.7](#) offers a survey of nuclei in the atomic (Z) and neutron (N) number plane. There is experimental information only on $\sim 3,000$ nuclei (including ~ 300 stable ones, with

■ Fig. 2.7

Chart of the nuclides. Black squares show stable nuclides as a function of atomic number Z and neutron number N . S_p zero and S_n zero curves indicate proton and neutron drip lines, respectively, which can be predicted, e.g., from different mass formulae. The B_F curves show limits, where the potential barrier disappears for fission. Grey regions show the domain of known nuclides. Magic numbers are shown by horizontal and vertical lines

$T_{1/2} > 10^9$ years), but approximately 7,000 nuclei can exist in bound states within the proton and neutron drip lines. (At drip lines the separation energies S_p , S_n become zero.) In the light stable nuclei the number of protons is approximately equal to the number of neutrons. This is the result of the exceptionally strong interaction between the protons and neutrons. Furthermore, in the light nuclei the weight of the contribution of the Coulomb interaction to the total energy is much smaller than the contribution of the strong interaction. In the heavier nuclei the neutron number exceeds the number of protons.

Seeking stability, proton-rich nuclei decay by β^+ emission and/or electron capture, and the neutron-rich nuclei by β^- emission into their isobars. Near magic numbers, the nuclei are more or less spherical; far from them, they are usually deformed.

The low-lying energy levels have definite characteristic features in different regions of the chart of nuclides. ▶ [Figure 2.8](#) shows the excitation energy of the first $I^\pi = 2^+$ states, $E(2_1^+)$, in even-even nuclei as a function of neutron number N . The $E(2_1^+)$ values show a decreasing trend with increasing N . However, at magic numbers the $E(2_1^+)$ values are prominently large, while in the $88 \leq N \leq 120$ and $N > 134$ regions they are extremely small. In the latter two regions the nuclei are strongly deformed and the 2_1^+ states have rotational character.

In odd- A and odd- Z , odd- N nuclei usually there are many low-lying levels. The properties of nuclear excitations will be discussed in more detail in ▶ [Sect. 2.3](#). In ▶ [Sect. 2.3.1](#) one shall

■ Fig. 2.8

Excitation energy E of the first $I^\pi = 2^+$ states in even–even nuclei as a function of neutron number N . The lines connect isotopes (Taken from Spear 1989, based on data compiled by Raman et al. 1987)

see that the most important features of the chart of nuclides can be understood on the basis of shell (and other) models, in which the Pauli principle and the Coulomb interaction between protons play important roles.

2.3 Nuclear States and Excitations

2.3.1 Shell Model of Atomic Nuclei

Although many models have been elaborated for the description of nuclear structure, the shell model is of central importance. In this section, the most important experimental facts indicating the existence of magic numbers (closed shells) in atomic nuclei are summarized. Then the independent-particle shell model of spherical and deformed nuclei, and the shell model with multiparticle configurations will be treated.

2.3.1.1 Closed Shells in Atomic Nuclei

The electron shells of atoms are especially stable in noble gas elements: He, Ne, Ar, Kr, Xe, Rn. This is the consequence of the fact that for the “magic numbers” $Z = 2, 10, 18, 36, 54$, and 86 the electron shells are closed.

Similar distinguished numbers have also been observed in atomic nuclei. For Z or $N = 2, 8, 20, 28, 50, 82$, and $N = 126$ the nuclei are particularly stable. Nuclei with $Z, (N) = 40$ and $Z, (N) = 64$ are also rather stable in some specific mass regions (subshell closures).

The existence of distinguished “magic” numbers in atomic nuclei has been proved by many experimental facts.

Chemical element and isotope abundances. The abundance of chemical elements in the solar system (see ▶ Fig. 12.13 in Chap. 12, Vol. 2), as well as in Earth’s crust and seas usually shows maximum values at magic proton and/or neutron numbers (Firestone et al. 1996). The number of stable isotopes and isotones is remarkably high for magic numbers of Z and N (see ▶ Fig. 2.7).

Nuclear binding, separation, and pairing energies. The effect of magic numbers can be well recognized also in nuclear binding energies, in proton and neutron separation, and pairing energies (Wapstra et al. 2003; Audi et al. 2003).

Quadrupole moments of nuclei. The intrinsic quadrupole moments of even–even nuclei usually show very low values near magic numbers (▶ Fig. 2.5). The effect of magic numbers is well observable also in the quadrupole moments of odd- A nuclei.

Nuclear radii indicate sudden changes at definite proton and neutron numbers, in particular for $Z, N = 28, 50, 82$ and $N = 126$ (Angeli 2004; Fricke and Heilig 2004).

Excited states of nuclei. ▶ Figure 2.8 shows the excitation energies of the first 2^+ states in even–even nuclei as a function of the neutron number N . The effect of magic numbers is well observable; the excitation energies have local maxima at magic numbers in the majority of cases.

Alpha-decay energies. The α -decay energies of some nuclei around $N = 126$ are shown in ▶ Fig. 2.33. There is a sharp change in the systematic trend at the magic number 126.

Beta-decay energies. The β -decay energies also indicate very clearly the effect of magic numbers (see, e.g., ▶ Fig. 2.38).

Reduced γ -ray transition probabilities. According to ▶ Fig. 2.14, the reduced transition probabilities $B(E2; 0_1^+ \rightarrow 2_1^+)$ in even–even nuclei have especially low values at magic numbers. See, for example, data for $_{50}\text{Sn}$ and $_{82}\text{Pb}$.

Nuclear reaction data. The nuclear reactions also clearly show the existence of nuclear shells (Haxel et al. 1952). By reactions, it is harder to break up and it is easier to produce a “magic” nucleus than its neighbors.

2.3.1.2 Independent-Particle Shell Model

The atomic shell phenomena (electrons in a central Coulomb field) can be successfully treated with quantum–mechanical methods. In the case of atomic nuclei, the situation is more complicated, because here there is no well-defined central field, the average field of nucleons substantially differs from the well-known Coulomb field (the nuclear forces are very complicated), and there are two different types of nucleons in nuclei (p and n).

The basic assumption of the independent-particle model is that the valence nucleon(s) move in an average field produced by the inert “core” nucleons.

The average field is expected to be roughly proportional to the nuclear density. ▶ Figure 2.6 shows the ground-state charge distributions in several nuclei, determined from electron scattering and muonic X-ray measurements. Based on these and similar mass distribution curves, it appears promising to use a harmonic oscillator potential for the average field in the light nuclei and a Woods–Saxon potential in heavier ones (▶ Fig. 2.2). Nevertheless, one must keep in mind that the harmonic oscillator potential increases into infinity with the radius,

while the nuclear forces have a short range. Thus, at large distances (e.g., in collisions) the harmonic oscillator potential is not realistic.

Central potential. The Schrödinger equation of a particle moving in central potential $V(r)$ is

$$\left[-\frac{\hbar^2}{2m} \nabla^2 + V(r) \right] \Psi(\mathbf{r}) = E \Psi(\mathbf{r}), \quad (2.21)$$

where m is the mass of the particle. In spherical coordinates, the equation has the form

$$-\frac{\hbar^2}{2m} \left[\frac{1}{r^2} \frac{\partial}{\partial r} \left(r^2 \frac{\partial}{\partial r} \right) + \frac{1}{r^2 \sin \theta} \frac{\partial}{\partial \theta} \left(\sin \theta \frac{\partial}{\partial \theta} \right) + \frac{1}{r^2 \sin^2 \theta} \frac{\partial^2}{\partial \phi^2} \right] \Psi + V(r) \Psi = E \Psi,$$

where r is the length of the vector \mathbf{r} pointing to the particle position, θ and ϕ are its polar and azimuthal angles, respectively.

When the potential is spherically symmetric, [Eq. \(2.20\)](#) has solutions that factorize in the radial and angular coordinates. One can get a complete system of solutions in this way. If one substitutes $\Psi(r, \theta, \phi) = R(r) Y(\theta, \phi)$ and divides both sides by Ψ , one gets

$$\frac{1}{R} \frac{d}{dr} \left(r^2 \frac{dR}{dr} \right) + \frac{2mr^2}{\hbar^2} [E - V(r)] = -\frac{1}{Y} \left[\frac{1}{\sin \theta} \frac{\partial}{\partial \theta} \left(\sin \theta \frac{\partial Y}{\partial \theta} \right) + \frac{1}{\sin^2 \theta} \frac{\partial^2 Y}{\partial \phi^2} \right].$$

As one side of the last equation depends only on r , the other one only on θ and ϕ , both sides must be equal to a constant, say λ . Thus, one arrives at the “radial wave equation”:

$$\frac{d}{dr} \left(r^2 \frac{dR}{dr} \right) + \left(\frac{2mr^2}{\hbar^2} [E - V(r)] - \lambda \right) R = 0 \quad (2.22)$$

and the “angular wave equation”

$$\frac{1}{\sin \theta} \frac{\partial}{\partial \theta} \left(\sin \theta \frac{\partial Y}{\partial \theta} \right) + \frac{1}{\sin^2 \theta} \frac{\partial^2 Y}{\partial \phi^2} + \lambda Y = 0. \quad (2.23)$$

This latter equation possesses single valued solutions only for definite λ values: $\lambda = l(l+1)$, where $l = 0, 1, 2, \dots$

If one substitutes $\lambda = l(l+1)$ in [Eq. \(2.22\)](#) and introduces $u(r)$, defined by $R(r) = u(r)/r$, one obtains the radial wave equation in a form which resembles the one-dimensional wave equation:

$$-\frac{\hbar^2}{2m} \frac{d^2 u(r)}{dr^2} + \left[V(r) + \frac{l(l+1)\hbar^2}{2mr^2} \right] u(r) = E u(r). \quad (2.24)$$

A more detailed treatment of angular momenta and the central force problem in three dimensions can be found in basic textbooks (see, e.g., Schiff 1968; Mandl 1992; Heyde 1990).

For a spherical harmonic oscillator $V(r) = m\omega^2 r^2/2$, where ω is the angular frequency of oscillation. If the valence nucleon is proton, $V(r)$ must also contain a Coulomb term.

The solution of [Eq. \(2.24\)](#) is searched for with conditions $u(r=0) = 0$ (i.e., $\Psi(r=0)$ is finite) and $u(r=\infty) = 0$. The detailed calculations show that the energy eigenvalues of [Eq. \(2.24\)](#) have the form:

$$E = (N + 3/2) \hbar \omega, \quad (2.25)$$

where N is the principal or oscillator quantum number; $N = 0, 1, 2, \dots$, and $N = 2n + l$, n is the radial quantum number; $n = 0, 1, 2, \dots$, l is the angular momentum quantum number; $l = 0, 1, 2, 3, 4, 5, 6, \dots$.

The different l states are often marked with letters: s, p, d, f, g, h, i, ...

The notation of a state often contains its sequence number $n + 1$ as well, e.g., 1s, 1p, 1d, 2s, 2p, etc. (Frequently $n + 1$ is called the radial quantum number. The number n or $n + 1$ counts the radial nodes, thus it differs from the principal or azimuthal quantum number used for the classification of the states of the hydrogen atom.)

The parity of levels is given by $(-1)^l$. One can deduce that the oscillator energy quantum ($\hbar\omega$) decreases with increasing mass number (A) according to the approximate equation

$$\hbar\omega \approx 41A^{-1/3} \text{ MeV}. \quad (2.26)$$

This means that the energy spectrum will be compressed for heavier nuclei. If one uses a square well instead of the harmonic oscillator potential, the oscillator levels split up according to different l values (Schiff 1968; Nilsson and Ragnarsson 1995). The harmonic oscillator level system is shown on the left side of [Fig. 2.9](#). The second column presents the “intermediate” energy spectrum, obtained by interpolation between the harmonic oscillator and square well potential levels.

In the independent-particle model the Pauli principle plays the same role as in atomic physics. Each quantum state can only be occupied by one particle of the same type. The quantum state involves the spin degree of freedom as well, thus a level in a potential well can be filled up by two protons and two neutrons. In the ground state the lowest-lying shells are filled up. The magic numbers are reproduced up to neutron number and atomic number 20, but not beyond.

Spin-orbit interaction. A decisive step in the interpretation of the correct nuclear magic numbers was made by Goeppert Mayer (1949) and by Haxel et al. (1949). They proposed that a new term be added to the potential energy in [Eq. \(2.20\)](#), the so-called spin-orbit term:

$$V_{\text{SO}} = V_{\text{SO}}(r)(\mathbf{l}\mathbf{s}), \quad (2.27)$$

where \mathbf{l} and \mathbf{s} are the orbital angular momentum and spin vectors of the particle, and $\mathbf{l} = \mathbf{r} \times \mathbf{p}$, where \times stands for the vector product of two vectors. As $\mathbf{j} = \mathbf{l} + \mathbf{s}$, it follows that $\mathbf{j}^2 = \mathbf{l}^2 + \mathbf{s}^2 + 2\mathbf{l}\mathbf{s}$, and the spin-orbit potential can be written in the form:

$$V_{\text{SO}} = V_{\text{SO}}(r)(\mathbf{j}^2 - \mathbf{l}^2 - \mathbf{s}^2)/2$$

or, with quantum numbers,

$$V_{\text{SO}} = V_{\text{SO}}(r) \frac{j(j+1) - l(l+1) - s(s+1)}{2}, \quad (2.28)$$

$$V_{\text{SO}} = \begin{cases} V_{\text{SO}}(r) \frac{-l-1}{2} & \text{for } j = l - 1/2, \\ V_{\text{SO}}(r) \frac{l}{2} & \text{for } j = l + 1/2. \end{cases}$$

As shown by [Fig. 2.9](#), with the inclusion of the spin-orbit interaction, the observed magic numbers were properly reproduced. The spin-orbit interaction for atomic electrons is a small quantum-relativistic effect. The nuclear spin-orbit coupling is much stronger and results, in addition to relativistic effects, from the spin dependence of the nucleon-nucleon potential.

The independent-particle model with a Woods-Saxon potential was treated, e.g., by Soloviev (1981).

■ Fig. 2.9

Approximate-level scheme for protons. *First column:* level energies of the harmonic oscillator. *Second column:* interpolated level scheme between the harmonic oscillator and square well solutions. *Third column:* splitting of levels after introducing the spin–orbit interaction. Notation of states: $(n+1)l_j$, where n is the radial quantum number ($n = 0, 1, 2, \dots$). *Fourth column:* the number of protons on the indicated subshell (N_j). *Fifth column:* full number of protons up to the level indicated (ΣN_j). The magic numbers are indicated in frames. *Sixth column:* parity of the level, $(-1)^l$. The level scheme for neutrons is similar; in that case N_j refers to neutrons (Based on Goeppert Mayer and Jensen 1965)

With the use of the Hartree–Fock method (Hartree 1928; Fock 1930), one can calculate the average potential starting from an effective nucleon–nucleon interaction. The Hartree–Fock calculations give a firm basis for the nuclear shell model (see, e.g., Heyde 1990) and allow the calculation of many observables of nuclei (nuclear binding energy, mass, charge radius, see section “Charge radii”).

The independent-particle model is best suited for the treatment of nuclei that have doubly closed-shell core ± 1 nucleon. In this case, the core has a rather well-defined spherical shape and the problem of the residual interaction between valence nucleons does not arise.

Somewhat surprisingly, this simple model gives general agreement with experimental data in a much wider region if one adds to it some simple “*jj*-coupling rules.” In this coupling scheme, the total angular momenta (j) of the valence nucleons are coupled into a resulting one (J) according to the quantum-mechanical addition rules.

The experiments show that the even- Z , even- N nuclei have all zero angular momenta. This fact suggests the “seniority rule”: in the lowest-energy state two particles of the same kind (protons or neutrons) are paired off to angular momentum zero. The strong “pairing force” is the consequence of the large overlap of orbits with the same $|j|$ (but opposite projections m) and the short range of nuclear forces.

In the odd- Z , even- N nuclei, the resulting total angular momentum J will be nearly always the angular momentum j of the odd proton. In some exceptional cases J will take on the value $j - 1$.

If N is odd and Z is even, the same rule holds as in the former case, but the resulting angular momentum is determined now by the odd neutron.

Many problems of the odd-odd nuclei can be successfully treated with the “parabolic rule” (Paar 1979). The rule describes the energy splitting of states arising from different couplings of angular momenta j_p and j_n .

The independent-particle model with *jj*-coupling rules can explain many properties of nuclei. Corresponding results are shortly surveyed below.

According to the shell model and the Pauli principle, in low-lying states low-energy shells will be filled when protons and neutrons are added to the nucleus. The model can explain why Z is approximately equal to N in light nuclei: the protons and neutrons fill up the available low-lying states gradually and independently, striving to reach minimum energy. In the heavy nuclei the Coulomb repulsion is rather strong; consequently more neutron states are occupied than proton states. This can explain the neutron excess observable in the heavy nuclei.

The independent-particle model correctly predicts the magic numbers and the subshell closures (► Figs. 2.8 and ► 2.9).

Furthermore, one can understand, at least qualitatively, why the nuclear radii increase with increasing mass number. The nucleons occupy gradually the higher-lying levels, and for these states, the radial wave functions extend to greater radii.

The spins (J) and parities (π) of the even- Z , even- N nuclei are $J^\pi = 0^+$, in agreement with the predictions of the independent particle model.

The experimental J^π values of some odd- A nuclei are compared with the theoretical ones in ► Table 2.5. The predictions of the shell model agree with experimental data in most cases. In ^{23}Na and ^{21}Ne , the anomalous $J = j - 1$ coupling has been observed. In ^{19}F and ^{19}Ne , there is a strong configuration mixing in the ground states (deformation) and low-lying excited levels have been observed with $J^\pi = 5/2^+$, which is expected on the basis of ► Fig. 2.9. A more complete analysis of the ground-state J^π values of odd- A nuclei was given, e.g., by Goeppert Mayer and Jensen (1965).

The low-lying excited levels of (double-magic ± 1) nuclei can be compared with the predictions of the independent-particle model. In almost all cases, the agreement is very good.

Nevertheless, if there are several nucleons in the valence shell(s), the interaction between the valence nucleons may change the level spectrum. The experimental data show that the level sequence of the independent-particle model (► Fig. 2.9) can only be considered in general as a first approximation. The actual level scheme depends not only on the atomic or the neutron number, but also on the mass number.

■ **Table 2.5**

Comparison of the experimental spins and parities of some odd-*A* nuclei with the predictions of the independent particle model. The central part of the table reproduces the level sequence, shown in ► Fig. 2.9, for easier comparison of experimental data with theory. The exponents over the symbols of the orbits stand for multiple occupancy. Negative exponents mean occupancy with respect to full (sub)shells, “hole” in a (sub)shell

*The theory of configuration mixing is explained, e.g., in Fényes (2002).

2.3.1.3 Shell Model with Multiparticle Configurations

The interaction between valence nucleons not included in the average field is called the residual interaction. The residual interaction differs from the interaction between free nucleons in that it cannot result in binding into occupied orbits.

If two valence nucleons move in the average field of the core, the residual interaction between them must also be taken into account. As the residual interaction usually gives a weak contribution to the binding, perturbation theory can be applied. In one type of calculation the residual interaction is approximated by a “schematic” (delta, surface delta, Schiffer, etc.) interaction. In another type of calculation, “realistic” interactions are used, which are derived approximately from free nucleon–nucleon interactions. In most calculations, “empirically determined” parameters are used.

The calculations give a reasonable description of the observed energy spectra, electromagnetic and β -decay transition rates, electromagnetic moments, and many other properties of nuclei with closed shells ± 2 nucleons.

It is also possible to perform shell model calculations for nuclei, which have three or more valence nucleons. Nevertheless, the calculations become rapidly very complex with increasing number of valence nucleons. Large-scale shell model calculations were performed mainly for the light nuclides with $A < 70$.

The shell model calculations are explained in detail in several textbooks and review articles: (Brussaard and Glaudemans 1977; Lawson 1980; Brown and Wildenthal 1988; Heyde 1990; Talmi 1993; Fényes 2002).

The shell model calculations for multiparticle configurations are usually very complicated. Nevertheless, several computer programs exist, which help the numerical calculations. The shell model algorithms were reviewed by Vallières and Wu (see Langanke et al. 1991). Several computer programs were described also by Heyde (1990).

Seniority is defined as the number of unpaired nucleons in a state. In the low-seniority scheme, it is supposed that the ground states of even–even semi-magic nuclei consist of pairs of identical nucleons that are coupled to spin zero. In the excited states, one or more pairs are broken. In the ground state of odd- A nuclei, there is one valence nucleon and in the excited states, 1, 3, 5, etc., valence nucleons. The low-seniority scheme calculations (Lawson 1980; Allaart et al. 1988; Talmi 1993) give a reasonable description of numerous semi-magic nuclei that have not too many valence particles (or holes).

If there are many valence protons and neutrons present in the nucleus, traditional shell model calculations lead to insurmountable difficulties. Fortunately, the Bardeen–Cooper–Schrieffer (BCS) theory provides a good approximation method to the seniority-zero shell model, and allows to describe very complex nuclei, too. In the BCS quasiparticle calculations long chains of nuclei can be treated in a relatively simple way. The method was first applied in the theory of superconductivity by Bardeen et al. (1957), then used for nuclear physics by Bohr et al. (1958), Soloviev (1958), and Belyaev (1959). The quasiparticle concept was introduced into nuclear physics by Valatin (1958) and Bogoliubov (1958). The theory is explained in detail in several textbooks (Lawson 1980; Ring and Schuck 1980; Soloviev 1981; Heyde 1990; Nilsson and Ragnarsson 1995; Fényes 2002).

Far from the stability region the density of the outermost nucleons may be very low. According to theoretical predictions, the pairing interaction is probably stronger, while the spin–orbit interaction is weaker in these regions. A reordering of levels was actually observed (► Fig. 2.10). While in $N \approx Z$ nuclei closed shells appear at neutron numbers $N = 8, 20, 28$, in $N \approx 2Z$ nuclei at $N = 6, 16, 32$.

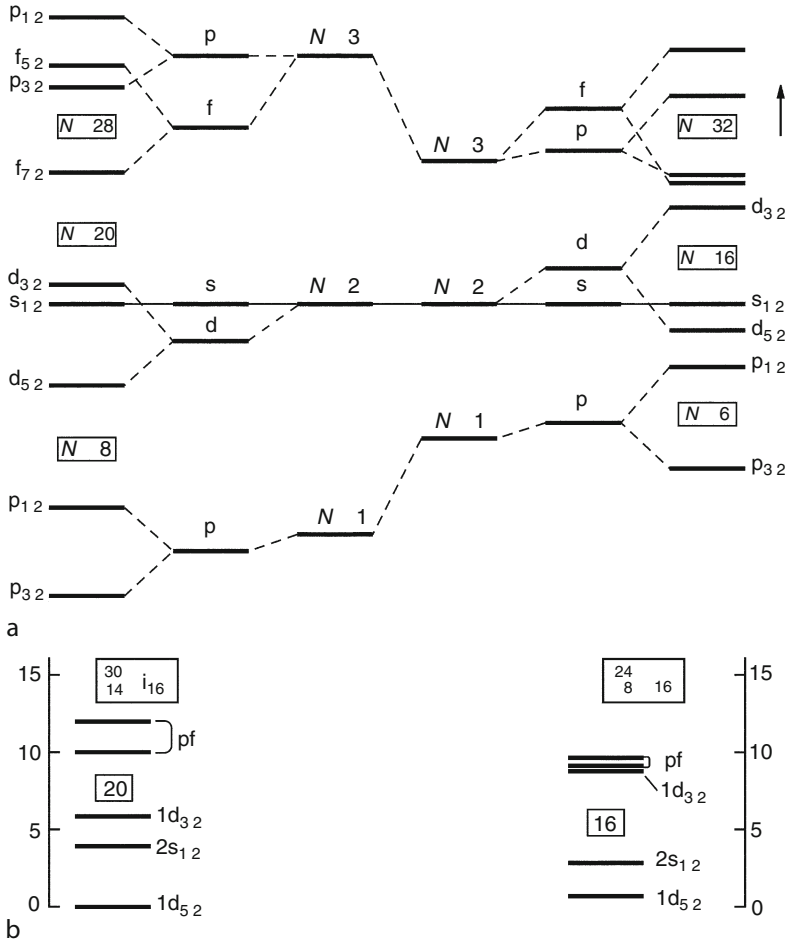

2.3.1.4 Shell Model of Deformed Nuclei

The nuclei are spherical near double closed shells, while in the $150 < A < 190$, $A > 220$ (and other) regions they are deformed. The stable deformation is shown by many experimental facts:

- Large quadrupole moments (► Fig. 2.5).
- Enhanced electric quadrupole transition probabilities (see ► Fig. 2.14).
- Existence of rotational bands. The excitation energies of the “band” members are proportional to $I(I + 1)$, where I is the spin of the state (see ► Sect. 2.3.4).

■ Fig. 2.10

(a) Observed energies of single particle states (E) in the stability region ($N \approx Z$, left side) and far from it ($N \approx 2Z$, right side). (b) Examples for the energy gaps, close to and far from the stability region, are ^{30}Si and ^{24}O , respectively (Based on Dombrádi 2007)

The shell model of deformed nuclei was elaborated by Nilsson (1955) and others. The basic assumptions of the Nilsson model are as follows:

- The shape of the nucleus is an axially symmetric ellipsoid.
- The average potential of the ellipsoidal nucleus is essentially a harmonic oscillator potential (► Fig. 2.2).
- The nuclear matter is incompressible, the nuclear volume is constant.
- There is no friction in nuclear matter.

The detailed mathematical treatment of the theory is described in textbooks (e.g., Nilsson and Ragnarsson 1995). The single particle energies ($\varepsilon_{s,p}$) obtained for medium heavy nuclei are

shown in [Fig. 2.11](#) as a function of the deformation parameter (δ). The explanation of the symbols is as follows.

$\delta \approx \varepsilon_2 - (1/6) \varepsilon_2^2$, $\varepsilon_2 = (c - a)/R_0$, where c and a are half lengths of the longer and shorter axes of the ellipsoid. R_0 is the radius of the sphere, which has the same volume as the ellipsoid.

Ω and Λ are the projections of vectors \mathbf{j} and \mathbf{l} on the symmetry axis (z), respectively. The vector \mathbf{j} is the total, \mathbf{l} is the orbital angular momentum of the particle. N and n_z are quantum numbers of the three-dimensional harmonic oscillator potential of an axially symmetric nucleus, $N = n_x + n_y + n_z$.

For small deformations, the energy splitting of the $|Nljm\rangle$ states is proportional to the deformation parameter δ , the oscillator quantum number N , and Ω^2 . For large deformations, the energy again depends on δ and N linearly, but the slopes of the curves are determined by n_z .

With the wave functions of the Nilsson model, it is also possible to calculate the electromagnetic moments and the gamma and beta transition probabilities between single-particle

■ Fig. 2.11

Nilsson diagram. Single-particle energies ($\epsilon_{\text{s.p.}}$ in $\hbar\omega_0 \approx 41A^{-1/3}$ MeV units) as functions of the deformation parameter δ . (Based on Nilsson (1955). The calculations were extended by Bengtsson and Ragnarsson (1985) also to other regions, separately for protons and neutrons and different ϵ_2 , ϵ_4 deformations, see Firestone et al. (1996))

states. The basic formulae can be found, e.g., in Nilsson (1955), Bohr and Mottelson (1974), Soloviev (1981).

A deformed shell model has been elaborated also with the Saxon–Woods potential (see, e.g., Soloviev 1981). In the advanced versions of the theory, pairing correlations, octupole and hexadecapole deformations, and Coriolis mixing have also been included.

The shell model of deformed nuclei was verified for hundreds of nuclei and proved to be very successful. It can account for level schemes, moments, electromagnetic transition probabilities, single-particle transfer reactions, beta-decay properties, etc. in the deformed regions ($A \approx 25$, $150 < A < 190$, $A > 220$).

Note that the quadrupole deformation (which plays a fundamental role in nuclear physics) can be characterized in body-fixed coordinate system by formulae

$$R = R_0[1 + a_{20}Y_{20} + 2a_{22}Y_{22}]$$

or

$$R = R_0[1 + \beta(\cos\gamma)Y_{20} + 2^{1/2}\beta(\sin\gamma)Y_{22}],$$

where R is the radius of the nucleus and Y_{20} , Y_{22} are the spherical harmonic functions. The β parameter describes prolate ($\beta > 0$) or oblate ($\beta < 0$) deformation, while γ characterizes the departure from axial symmetry. In the case of quadrupole deformation $\varepsilon_2 = 0.946 \beta_2$.

2.3.1.5 Calculation of the Total Energy of Nuclei

Taking into account the success of the spherical and deformed shell models, it is tempting to calculate the total energy of nucleus by summation of single-particle proton and neutron energies up to the Fermi level. Then

$$V = \sum_{i=1}^Z e_p^i(\varepsilon_2, \varepsilon_3, \dots) + \sum_{i=1}^N e_n^i(\varepsilon_2, \varepsilon_3, \dots)$$

where V is the sum of single-particle energies in an external potential, e_p^i and e_n^i are the particle energies, and ε_2 , ε_3 are the deformation parameters. (For small values of deformation parameters the radius of the nucleus can be expressed as

$$r = r_0 \left\{ 1 + \frac{2\varepsilon_2}{3} P_2(\cos\theta) - \sum_{\lambda} \varepsilon_{\lambda} P_{\lambda}(\cos\theta) + \dots \right\},$$

where the $P(\cos\theta)$ -s are the Legendre polynomials.) Nevertheless this simple summation of particle energies cannot describe the total energy (and its dependence on deformation parameters) exactly, for example, because problem arises whether or not the contributions from the nucleon–nucleon interactions are double-counted.

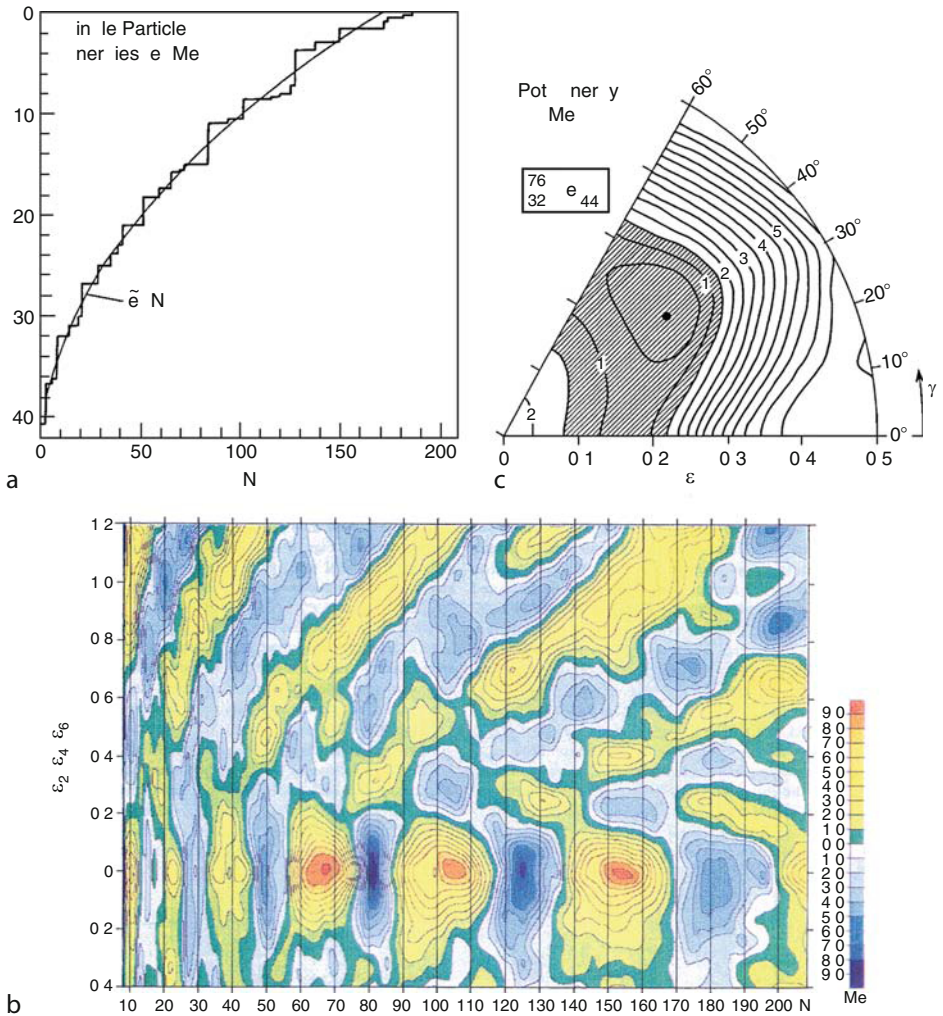

On the other hand, the liquid drop model can correctly reproduce the binding energies of nuclei (see, e.g., [Eq. \(2.3\)](#)), nuclear masses, and the threshold potential of nuclear fission, but it cannot describe the shell effects, ground state spins, and many other quantum characteristics.

Much better results can be obtained, if one combines the shell and liquid drop models, as proposed by Strutinsky (1967, 1968).

[Figure 2.12a](#) shows the theoretical single-neutron energies (e , staircase function) versus neutron number (N). The smooth, average curve $\tilde{e}(N)$ removes local fluctuations. The shell

■ Fig. 2.12

(a) Illustration to the Strutinsky shell correction to liquid drop energy for ^{208}Pb . The figure shows the theoretical single neutron energies ϵ_{STAIR} (staircase function) versus neutron number (N) for a Saxon–Woods-type potential. The smooth, average curve $\bar{\epsilon}(N)$ removes local fluctuations. The shell correction is given by the difference between the two curves up to the given neutron number (Based on Bolsterli et al. 1972). (b) Shell energy (E_{shell}) as a function of the neutron number (N) and deformation parameter ϵ_2 , calculated with a modified oscillator potential using the Strutinsky method. ϵ_2 includes also ϵ_4 and ϵ_6 in such a way that the liquid drop energy should be approximately minimized. The contour line separation is 1 MeV (Taken from Ragnarsson and Sheline 1984). (c) Total (often referred to as “potential”) energy surface for ^{76}Ge as a function of deformation parameters ϵ_2 and γ . The triaxial shape at energy minimum is associated with proton shell gap at $Z = 32$ (From Larsson et al. 1976), see also Ragnarsson et al. (1978). The figure appears in the electronic version in full color

correction (E_{shell}) is given by the difference between the areas under the two curves up to the given neutron number:

$$E_{\text{shell}} = \sum e_i - \sum \tilde{e}_i.$$

If one takes only the fluctuating (staircase) part from the shell model, and the average (smooth) curve is fitted to the liquid drop model values, one can obtain a much better description of the total energies of nuclei. For details of the calculations, see the original publications by Strutinsky or Fényes (2002).

The calculated shell energy (E_{shell}) is shown as a function of neutron number (N) and deformation parameter (ϵ_2) in [Fig. 2.12b](#). One can see that there are numerous local energy minima. The calculations correctly reproduce the magic numbers at zero deformation and predict the existence of many deformed states. The general structure of shell energy is the same for protons and neutrons, and depends on the rotational frequency (see later in [Sect. 2.3.4](#)) only weakly.

[Figure 2.12c](#) shows the potential energy surface of ^{26}Ge in the ϵ_2, γ plane. The energy minimum is obtained at triaxial deformation ($\epsilon_2 \approx 0.27, \gamma \approx 36^\circ$).

2.3.2 Nuclear Transitions, γ Decay, Conversion Electrons

2.3.2.1 Basic Experimental Facts

In atomic nuclei, there are moving protons which have $\rho^e(\mathbf{r}, t)$ charge and $\mathbf{j}(\mathbf{r}, t)$ current densities. Correspondingly, the nuclei can emit or absorb electromagnetic radiation and may have electric and magnetic static moments. As the fundamental laws of the electromagnetic interaction are known, one can obtain valuable information on the nuclear structure from electromagnetic transitions and moments.

The nuclei very often remain in excited state(s) after α or β decay. From these states they decay further to the ground state by γ -ray emission. Nuclear reactions may also lead to excited states, which usually lose their energy first by particle emission (if allowed energetically) and then by γ decay.

The low-lying nuclear states have discrete energies and the corresponding γ rays also have well-defined quantum energies. The wave length of the γ radiation is usually in the range of $10^{-8} < \lambda_\gamma < 10^{-11}$ cm.

The γ quanta may carry away different angular momenta (L). If $L = 1, 2, 3, \dots$ the radiations are called dipole, quadrupole, octupole, etc., respectively. Gamma radiation with $L = 0$ does not exist because the electromagnetic waves have transversal nature (the photons have spin 1). Each multipolarity 2^L is characterized by a specific angular distribution. The radiation may be electric or magnetic, depending on the term of the electromagnetic interaction that is responsible for the particular transition.

For the measurement of lifetimes of excited states, many efficient methods have been elaborated. Some of the direct methods are electronic timing, recoil distance method, Doppler shift and blocking techniques, γ X-ray coincidences; and the indirect methods: Coulomb excitation, (e, e') reactions, resonance fluorescence, particle resonance spectroscopy, etc. The methods were reviewed in Berlovich et al. (1972), Nolan and Sharpey-Schafer (1979), Fényes (1986), and others. Using these techniques, it is possible to measure lifetimes in a very wide ($\geq 10^{-18}$ s) domain.

As an alternative to γ -ray emission, an excited nuclear state can also lose its energy by *internal conversion electron emission*. In this parallel process, the energy of the excited state is transferred directly to an electron of the atomic shell, without previous γ -ray emission. The energy of internal conversion electrons depends on the nuclear transition energy and also on the ionization energy of the K, L, M, ... electrons.

The coefficient of internal conversion is defined as the number of emitted electrons divided by the number of emitted γ quanta:

$$\alpha = N_e/N_\gamma = \alpha_K + \alpha_L + \alpha_M + \dots, \quad (2.29)$$

where $\alpha_K = (N_e)_K/N_\gamma$ is the partial coefficient of internal conversion for K electrons.

The $\alpha_L, \alpha_M, \dots$ coefficients are defined similarly.

According to the theory, the internal conversion coefficient decreases with increasing transition energy and increases with increasing atomic number and multipolarity of γ -radiation. The coefficient α depends also on the electric or magnetic character of the radiation. Internal e^- conversion is possible between 0^+ states, too. If both K and L electron emissions are allowed energetically, the L electron emission is usually weaker ($\alpha_L \approx 0.1\alpha_K$). For $0^+ \rightarrow 0^+$ transitions see the review article by Kibédi and Spear (2005).

The theory of internal conversion is explained in detail, e.g., by Rose (1965). Numerical values of internal conversion coefficients have been published by Band et al. (1976) and Rösler et al. (1978). Selected theoretical partial and total internal conversion coefficients are presented in the form of graphs for M1, M2, M3, M4, E1, E2, E3, and E4 transitions in Firestone et al. (1996). (Here E and M stand for electric and magnetic transitions, and the number following the symbol is just L.) The accuracy of the graphs is 3–5%.

Internal conversion coefficients (ICC) were obtained from relativistic self-consistent-field Dirac–Fock calculations by Band et al. (2002). They presented results for E1,...E5, M1,...M5 transitions in the energy range $E_\gamma = 1 - 2,000$ keV for K, L₁, L₂, L₃ atomic shells of elements $Z = 10 - 126$. The total ICCs and graphs for ICCs were also published. The Dirac–Fock values are in better agreement with experimental results than the relativistic Hartree–Fock–Slater theoretical ones.

A database of available experimental ratios of ICCs for different atomic subshells was published and compared with relevant theoretical results by Raman et al. (2006).

If the energy of the transition is greater than 1.022 MeV, the nucleus may lose its excitation energy also by *internal electron–positron pair emission*. The probability of this mechanism is low; it is usually more than 10^{-3} times smaller than the probability of γ -ray emission. In contrast with the internal conversion electron emission, the internal pair formation coefficient increases with increasing γ -ray energy and decreases with increasing atomic number and multipolarity of transition. A review of internal pair formation was given by Wilson (1965).

The electromagnetic transitions (transition energies, probabilities, multiplicities, selection rules, angular correlation, etc.) offer a very effective tool for the investigation of nuclear states. The systematic study of E0, E1, E2, E3, ... and M1, M2, M3, ... transitions provide information on the quantum numbers of states, on shell structure, core polarization, effective charges, effective gyromagnetic ratios, particle and hole states, collectivity of states, vibrational and rotational excitations, coupling of single particles with collective motion, etc. In this respect, the works of Morinaga and Yamazaki (1976), Brussaard and Glaudemans (1977), Lawson (1980), as well as Ejiri and de Voigt (1989) are referred to.

2.3.2.2 Theory of γ Decay

Basic Formulae

The Hamiltonian of a nuclear system consists of the kinetic and three potential energy terms which contain the strong, electromagnetic, and weak interactions. (The weakest, i.e., the gravitational force can be completely neglected in a nuclear system, see [Table 2.2](#).) The sum of the strong and the electric monopole (Coulomb) interactions determines the wave functions and energy eigenvalues to a very good approximation, and the other electromagnetic multipole interactions (which are at least about two orders of magnitude weaker than the strong interaction) are only perturbations, which may induce transitions between nuclear states. The weak interaction is about four orders of magnitude weaker than the electromagnetic one. Thus, it may play an important role in nuclear processes only in cases when both particle emission (by strong interaction) and γ transition (by electromagnetic interaction) are forbidden. Such a case is the β decay from ground (or long-lived isomeric) states.

The quantum-mechanical transition probability (P) between the initial and final states is given by perturbation theory:

$$P = \frac{2\pi}{\hbar} \left| \int \Psi_f^* H \Psi_i d\nu \right|^2 \frac{dn}{dE}, \quad (2.30)$$

where H is the Hamiltonian of the perturbing electromagnetic interaction, Ψ_i and Ψ_f denote the initial and final wave functions, respectively, $d\nu$ is the volume element, and dn/dE is the number of possible final states per unit energy interval.

This formula of the time-dependent perturbation theory was originally derived by Dirac, but it is often referred to as Fermi's "golden rule No. 2."

The theory of multipole radiation and moments is explained in detail in many monographs and textbooks (e.g., Heitler 1947; Blatt and Weisskopf 1952; Sliv 1961; De Benedetti 1964; Moszkowski 1965; Eisenberg and Greiner 1970; Brussaard and Glaudemans 1977). Only the most important theoretical results shall be summarized here.

The Hamiltonian of the electromagnetic interaction can be approximated by

$$H \approx \int \mathbf{j}(\mathbf{r}, t) \mathbf{A} d\nu, \quad (2.31)$$

where $\mathbf{j}(\mathbf{r}, t)$ is the current density in the nucleus, $\mathbf{A}(\mathbf{r}, t)$ is the vector potential of the electromagnetic field, \mathbf{r} is a spatial vector variable, t is the time.

The scalar potential in the rapidly varying electromagnetic field is supposed to be zero. The vector potential \mathbf{A} satisfies the wave equation in free space:

$$\Delta \mathbf{A} - \epsilon_0 \mu_0 \frac{\partial^2 \mathbf{A}}{\partial t^2} = 0.$$

The transverse nature of electromagnetic waves is expressed by the divergence condition: $\text{div } \mathbf{A} = 0$. Then the electric (\mathbf{E}) and magnetic (\mathbf{B}) fields can be deduced from \mathbf{A} by

$$\mathbf{E} = -\frac{\partial \mathbf{A}(\mathbf{r}, t)}{\partial t} \quad \mathbf{B} = \nabla \times \mathbf{A}(\mathbf{r}, t) \equiv \text{curl } \mathbf{A}(\mathbf{r}, t).$$

The quantities \mathbf{E} and \mathbf{B} satisfy Maxwell's equations. Heitler has shown that the γ quantum carries away L angular momentum (with respect to the source of radiation) in electric (EL) or magnetic (ML) 2^L -pole radiation (Heitler 1936). Thus, the multipole character is closely related to the angular momentum of the radiation.

The transition rate (decay constant) $T(\sigma L; J_i \rightarrow J_f)$ for the transition $J_i \rightarrow J_f$ depends on the electric ($\sigma = E$) or magnetic ($\sigma = M$) character as well as on the multipolarity (2^L) of the radiation. The transition rate has been calculated in the long-wavelength approximation for low-energy γ rays ($E_i - E_f = E_\gamma < 10$ MeV). (In the long-wavelength approximation, it is assumed that $2R\pi \ll \lambda$, where R is the nuclear radius and λ is the wavelength of the γ radiation.) The result is as follows (Blatt and Weisskopf 1952):

$$T(\sigma L; J_i \rightarrow J_f) = G_L(k) B_L^\sigma(J_i \rightarrow J_f), \quad (2.32)$$

where $G_L(k) \equiv \frac{8\pi(L+1)}{L[(2L+1)!!]^2} \frac{k^{2L+1}}{\hbar}$, $k = \frac{E_\gamma}{\hbar c}$, $E_\gamma = \hbar\omega$.

Thus, $G_L(k)$ depends on the energy E_γ and on the multipolarity (2^L) of the transition, where $(2L+1)!! = 1 \cdot 3 \cdot 5 \cdot \dots \cdot (2L+1)$. $B_L^\sigma(J_i \rightarrow J_f)$ is called the reduced transition probability. The reduced transition probability is the factor that contains the effect of the structure of the states involved, without the obvious energy dependence. In principle, between a particular initial and final state several multipole transitions may be possible. Nevertheless, $T(\sigma L; J_i \rightarrow J_f)$ strongly depends on L , and thus usually no more than two multipoles are important in the mixing. For example, M1 transition may be mixed with E2. The square of the mixing ratio is defined as

$$\delta^2 = \frac{I_\gamma(E \text{ or } M, L+1; J_i \rightarrow J_f)}{I_\gamma(M \text{ or } E, L; J_i \rightarrow J_f)}, \quad (2.33)$$

where I_γ is the intensity of γ radiation. The transition rate is related to the time scale of the decaying state:

$$T(\sigma L; J_i \rightarrow J_f) = (\ln 2)/T_{1/2} = 0.6931/T_{1/2} = 1/\tau,$$

where $T_{1/2}$ is the half-life and τ is the mean life. The experimental partial γ -ray half-life $T_{1/2}^{\gamma, \text{exp}}(a)$ for the transition (a) and the measured half-life of the level $T_{1/2}^{\text{exp}}$ are connected by the following relation if the level decays by several (e.g., $x = a, b, c$) transitions of different energies:

$$T_{1/2}^{\gamma, \text{exp}}(a) = T_{1/2}^{\text{exp}} [1 + \alpha_{\text{tot}}(a)] \frac{\sum_{x=a}^c I_{\text{tot}}(x)}{I_{\text{tot}}(a)}, \quad (2.34)$$

where $\alpha_{\text{tot}}(x)$ is the total internal conversion coefficient, $\alpha_{\text{tot}}(x) = \alpha_K(x) + \alpha_L(x) + \alpha_M(x) + \dots$, $I_{\text{tot}}(x)$ is the total transition intensity, $I_{\text{tot}}(x) = I_\gamma(x)[1 + \alpha_{\text{tot}}(x)]$.

The electric reduced transition probability $B(EL)\downarrow$ of de-excitation from an initial (upper) state (J_i) to the final state (J_f) is related to the reduced transition probability $B(EL)\uparrow$ for the excitation of the state J_i by

$$B(EL, J_i \rightarrow J_f) \downarrow = \frac{2J_f + 1}{2J_i + 1} B(EL, J_f \rightarrow J_i) \uparrow. \quad (2.35)$$

This means, for example, that if J_i is a 2_1^+ excited state and J_f is a 0_1^+ ground state, then $B(E2, 2_1^+ \rightarrow 0_1^+) \downarrow = (1/5) B(E2; 0_1^+ \rightarrow 2_1^+) \uparrow$.

The level width (Γ) is defined on the basis of the time-energy uncertainty principle by the following expression:

$$\Gamma \equiv \frac{\hbar}{\tau} = \hbar T, \quad (2.36)$$

where $\hbar = 6.582\,118\,99(16) \times 10^{-22}$ MeV s and T is the transition rate. (The time–energy uncertainty relation expresses that the time τ characteristic of the rate of change of the physical properties of the system is related to the change in energy ΔE , as $\Delta E\tau \geq \hbar$.)

Selection Rules

Owing to angular momentum and parity conservation, some electromagnetic transitions are forbidden. If the initial and final angular momenta of the nucleus are denoted by J_i and J_f , respectively, the conservation of angular momentum sets limits to the possible values of L :

$$|J_i - J_f| \leq L \leq J_i + J_f.$$

This relation is referred to as the triangular rule for vectors \mathbf{J}_i , \mathbf{J}_f and \mathbf{L} .

In [Sect. 2.2.3](#) it was shown that the parity (π) of the wave function of a nuclear state may be either positive or negative; furthermore, the parity is conserved in closed systems in strong and electromagnetic interactions. The parity conservation law can be formulated as follows:

$$\pi_i \pi_\gamma \pi_f = +1,$$

where π_i and π_f are the parities of initial and final states, respectively, and π_γ is the parity of the radiation. From the properties of the electric and magnetic transition operators the following selection rules can be derived:

$$\pi_i \pi_f = (-1)^L \quad \text{for electric radiation,}$$

$$\pi_i \pi_f = (-1)^{L+1} \quad \text{for magnetic radiation.}$$

The electric and magnetic dipole, quadrupole, octupole, etc., transitions are denoted by E1, E2, E3, ... and M1, M2, M3, ..., respectively. The selection rules deduced from angular momentum and parity conservation laws for electric and magnetic multipole radiations are summarized in [Table 2.6](#).

As the table shows, the electromagnetic radiation is forbidden between states $J_i = 0$ and $J_f = 0$. There is no monopole radiation since the electric and magnetic field strengths are perpendicular to the direction of propagation. On the other hand, monopole transitions are often observed in internal conversion electron (or internal pair) spectroscopy.

Table 2.6

Selection rules for electromagnetic radiations. The allowed mixing to the dominating radiation is indicated in parenthesis

Change of angular momentum (ΔJ)	Change of parity between initial and final states			
	$\pi_f / \pi_i = -1$		$\pi_f / \pi_i = +1$	
0 ($0 \rightarrow 0$)	Forbidden		Forbidden	
0 ($1/2 \rightarrow 1/2$)	E1		M1	
0 ($J \rightarrow J$) ($J \geq 1$)	E1	(M2)	M1	(E2)
1	E1	(M2)	M1	(E2)
2	M2	(E3)	E2	(M3)
3	E3	(M4)	M3	(E4)
4	M4	(E5)	E4	(M5)
5	E5	(M6)	M5	(E6)

Single-Particle Transition Rates

The calculation of the transition rate is relatively simple if there is only one particle outside the closed core. The starting assumptions of the calculations may be as follows.

- The spin of the nuclear core is zero and the core does not take part in the process. One needs only to know the wave function of the valence particle in the initial and final states.
- It is assumed that the radial wave functions in the initial and final states are constant within a sphere of radius R , that is $R_{nl}(r) = \text{const.} \neq 0$ if $r \leq R$ and zero if $R < r$. This is a rather crude approximation, not taking into account the real shapes of the radial wave functions, but it simplifies the calculations considerably and it is very useful in practice. The reduced transition probability is evaluated for $J_i = L \pm 1/2$ initial and $J_f = 1/2$ final states.

For electric 2^L -pole radiation (EL) the following single-particle transition rate (T_{sp}) was obtained (in s^{-1}):

$$T_{\text{sp}}[\text{EL}; (L \pm 1/2) \rightarrow 1/2] = \frac{4.4 \times 10^{21} (L+1)}{L[(2L+1)!!]^2} \left(\frac{3}{L+3} \right)^2 \left(\frac{E_\gamma}{197} \right)^{2L+1} R^{2L}, \quad (2.37)$$

where E_γ is the energy of the γ quantum in MeV, R is the radius of the nucleus in fm, and $(2L+1)!! = 1 \cdot 3 \cdot 5 \cdot \dots \cdot (2L+1)$.

Note that in the case of E1 transitions the right-hand side of [Eq. \(2.36\)](#) must be multiplied by effective charge-square correction factors: $(N/A)^2$ for protons and $(Z/A)^2$ for neutrons. For $(J_i = L \pm 1/2) \rightarrow (J_f = 1/2)$ magnetic transitions the following formula was obtained:

$$T_{\text{sp}}[\text{ML}; (L \pm 1/2) \rightarrow (1/2)] = 1.94 \times 10^{21} \frac{(L+1)}{L[(2L+1)!!]^2} \left(\frac{3}{L+3} \right)^2 \left(\frac{E_\gamma}{197} \right)^{2L+1} R^{2L-2}, \quad (2.38)$$

where T_{sp} is given in s^{-1} , E_γ is given in MeV, and R is given in fm.

In a more rigorous treatment, a statistical factor $S(J_i, L, J_f)$ appears on the right-hand side of [Eqs. \(2.37\)](#) and [\(2.38\)](#), too (Moszkowski 1965). In [Eqs. \(2.37\)](#) and [\(2.38\)](#) it was set $S = 1$, which is true for $(J_i = L + 1/2) \xrightarrow{L} (J_f = 1/2)$ transitions. [Equations \(2.37\)](#) and [\(2.38\)](#) are called the Weisskopf estimates, frequently used in nuclear spectroscopy.

Substituting $R = 1.20 A^{1/3}$ fm into the formulae, one can express the electric and magnetic transition rates as functions of mass number A and γ -ray energy E_γ ([Table 2.7](#)). Slightly different results were obtained by Moszkowski for magnetic transition rates, which are also presented in [Table 2.7](#).

Half-lives $T_{1/2} = (\ln 2)/T_L^\sigma$ for electric and magnetic multipole transitions are shown as functions of the γ -ray energy in [Fig. 2.13](#). The half-lives embrace more than 32 orders of magnitude from 10^{16} to 10^{-16} s. For comparison the mean lives ($\tau = T_{1/2}/0.6931$) of atomic levels shall be given here:

In the optical region	10^{-6} to 10^{-8} s
In the X-ray region	10^{-16} to 10^{-17} s
Metastable states	~ 1 to 10^{-3} s

[Figure 2.13](#) shows that the half-lives strongly depend on multipolarity. This means, e.g., that, if the selection rules allow M1 radiation, then M2, M3, etc. can be neglected. Similarly, if E1 is allowed, the E2, E3, ... radiations are negligibly weak. At a given energy E_γ the sequence of transition rates is $T(\text{E1}) > T(\text{M1}) > T(\text{E2}) > T(\text{M2}) > T(\text{E3}) > T(\text{M3}) > T(\text{E4}) > T(\text{M4})$.

■ **Table 2.7**

Single particle estimates for electromagnetic transition rates (T_{sp} in s^{-1}) as functions of mass number (A) and γ -ray energy (E_γ in MeV). The Weisskopf estimates were taken from Wapstra et al. (1959) and Blatt and Weisskopf (1952), the Moszkowski estimates from Moszkowski (1965). The statistical factor (S) is not shown in the table, because $S = 1$ for transitions ($J_i = L + 1/2$) \rightarrow ($J_f = 1/2$), and in other $L = |J_i - J_f|$ cases usually it is not far from one, at least it remains in the same order of magnitude (see in detail, e.g., Moszkowski 1965)

Multipolarity	T_{sp} (Weisskopf)	Multipolarity	T_{sp} (Weisskopf)	T_{sp} (Moszkowski)
E1	$1.0 \times 10^{14} A^{2/3} E_\gamma^{-3}$	M1	$3.1 \times 10^{13} E_\gamma^{-3}$	$2.9 \times 10^{13} E_\gamma^{-3}$
E2	$7.4 \times 10^7 A^{4/3} E_\gamma^{-5}$	M2	$2.2 \times 10^7 A^{2/3} E_\gamma^{-5}$	$8.4 \times 10^7 A^{2/3} E_\gamma^{-5}$
E3	$3.5 \times 10^1 A^2 E_\gamma^{-7}$	M3	$1.1 \times 10^1 A^{4/3} E_\gamma^{-7}$	$8.7 \times 10^1 A^{4/3} E_\gamma^{-7}$
E4	$1.1 \times 10^{-5} A^{8/3} E_\gamma^{-9}$	M4	$3.3 \times 10^{-6} A^2 E_\gamma^{-9}$	$4.8 \times 10^{-5} A^2 E_\gamma^{-9}$
E5	$2.4 \times 10^{-12} A^{10/3} E_\gamma^{-11}$	M5	$7.4 \times 10^{-13} A^{8/3} E_\gamma^{-11}$	$1.7 \times 10^{-11} A^{8/3} E_\gamma^{-11}$

As already mentioned, the Weisskopf estimates are calculated in the single-particle approximation, supposing constant radial wave function. The observed transition rates sometimes strongly deviate from the estimated values. Nevertheless, the Weisskopf units (W. u.) are very useful for comparison. For example, enhanced transition rates (compared to the Weisskopf estimate) signal collectivity.

2.3.2.3 Experimental γ -Ray Transition Rates: Isomeric States

The γ -ray transition rates were compiled and evaluated in different mass number regions: $A = 5-44$ (Endt 1993), $45-90$ (Endt 1979), $91-150$ (Endt 1981), $151-190$ (Andrejtscheff et al. 1975). For recent data see the database Evaluated Nuclear Structure Data File (ENSDF) (<http://www.nndc.bnl.gov/ensdf>).

► **Figure 2.14** presents the reduced transition probabilities for transitions ($E2; 0_1^+ \rightarrow 2_1^+$) \uparrow in even-even nuclei. The $B(E2)$ values have the following characteristics:

- They are extremely large for strongly deformed nuclei, in the region $160 < A < 180$ and $230 < A$.
- They are very small around magic numbers, e.g. ^8O , ^{50}Sn , ^{82}Pb .
- They are rather large for spherical nuclei elsewhere.

Endt (1981) evaluated 1,340 γ -ray transitions in $A = 91-150$ nuclei. The transition rates were classified according to electric or magnetic multipole character and were expressed in Weisskopf units. Transitions, which can be mixed in principle, are only listed if the mixing ratio has been measured. The strengths $S = T_L^\sigma / (T_L^\sigma)_{sp}$ usually scatter appreciably, nevertheless, upper limits could be established from the data. These are 0.01, 300, 100, and 30 W. u. for E1, E2, E3, and E4; and 1, 1, 10, and 30 W. u. for M1, M2, M3, and M4 radiations, respectively. For upper limits in other regions see (Firestone et al. 1996). The strengths are usually enhanced for E2, and E3, while the E1, M2 transitions are usually hindered.

Note that if there are more than one valence nucleons outside the double-closed core, the residual interaction between the valence nucleons may cause configuration mixing, which may strongly affect the transition rates.

■ Fig. 2.13

Half-lives ($T_{1/2}$) of electric and magnetic transitions vs. γ -ray energy (E_γ) for ^{165}Ho . Weisskopf estimates, based on calculations of Soloviev (1981). At low energies ($E_\gamma < 0.5$ MeV) the internal conversion may reduce the indicated half-lives by orders of magnitude. The half-lives depend also on the mass number. This dependence can be taken into account by different nomograms (Wapstra et al. 1959; Sliv 1961). The half-lives shown in the figure are partial half-lives, which may also have to be corrected for branching, if there are more than one transition from the given level

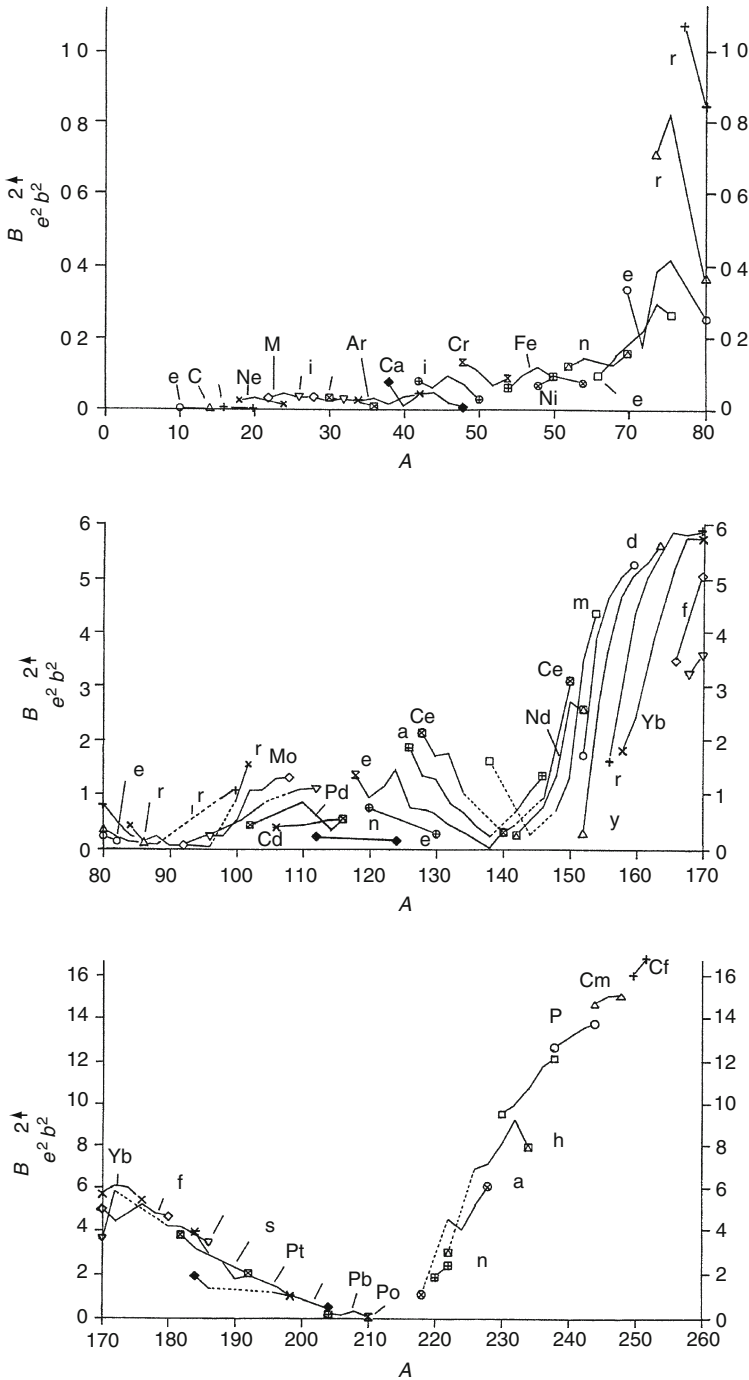

The electromagnetic transitions may be strongly hindered if the spin difference between the isomeric and lower-lying levels is large or the transition energy is very low. The level sequences below magic numbers 50, 82, 126 are as follows (► Fig. 2.9).

Below Z or $N = 50$	Below Z or $N = 82$	Below $N = 126$
$(1g_{9/2})^+$	$(1h_{11/2})^-$	$(1i_{13/2})^+$
$(2p_{1/2})^-$	$(3s_{1/2})^+$	$(3p_{1/2})^-$
$(1f_{5/2})^-$	$(2d_{3/2})^+$	$(3p_{3/2})^-$
$(2p_{3/2})^-$	$(2d_{5/2})^+$	$(2f_{5/2})^-, (2f_{7/2})^-$

This indicates that in these regions large spin differences may occur between levels, and long-lived isomeric states are expected. Indeed, many *long-lived excited (isomeric) states* were observed in these regions. An extensive list of isomeric states (with $T_{1/2} > 10^{-10}$ s) can be found in the

■ Fig. 2.14

Reduced transition probabilities $B(E2; 0_1^+ \rightarrow 2_1^+)$ for even-even nuclei as a function of mass number A . A comprehensive review of the $B(E2; 0_1^+ \rightarrow 2_1^+)$ values is given in Raman et al. (2001)

compilation Kantele and Tannila (1968). See also the database ENSDF mentioned above. The interpretation of many long-lived isomeric states was a great success of the nuclear shell model.

2.3.3 Vibrational Motion

2.3.3.1 Basic Experimental Facts

The experimental evidence on the existence of nuclear surface vibration shall be summarized shortly.

Energy spectra. The systematics of level spectra in even–even nuclei shows that the first excited level is nearly always a 2^+ state with excitation energy $\hbar\omega$, and the next three excited states (with $J^\pi = 2_2^+, 4_1^+$, and 0_2^+) have roughly $2\hbar\omega$ excitation energy. (The subscript on J^π denotes just a sequence number.) Low-lying 3_1^- states have also been observed systematically in even–even spherical nuclei. These regularities can be clearly seen, e.g., in [Fig. 2.15](#) for Te isotopes. [Figure 2.8](#) shows the excitation energies of the first 2^+ states in even–even nuclei as a function of neutron number N . One can see that there exist low-lying 2^+ levels in all even–even nuclei. The level energies generally decrease slowly and monotonously with Z or N , but irregularities are observed at closed- (or nearly closed-) shell nuclei. There are many even–even nuclei in which the $E(4_1^+)/E(2_1^+)$ energy ratio is between ~ 2.0 and 2.4 , characteristic of a vibrator.

Reduced transition probabilities. The systematics of $B(E2; B(E2; 0_1^+ \rightarrow 2_1^+))$ data in even–even nuclei ([Fig. 2.14](#)) shows that the first excited 2^+ states are connected with the 0^+ ground states by fast electric quadrupole transitions. The $B(E2)$ values are usually by order(s) of magnitude larger than the single-particle estimates. The $B(E2)$ probabilities of the $0_2^+, 2_2^+, 4_1^+ \rightarrow 2_1^+$ transitions are comparable with that of the $2_1^+ \rightarrow 0_1^+$ transition (e.g., in ^{114}Cd , [Fig. 2.17](#)). The situation of the 3_1^- states is similar, the $B(E3; 0 \rightarrow 3)$ data are usually order(s) of magnitude larger than the single-particle estimates.

All these data suggest that the lowest states of even–even spherical nuclei cannot be described properly as two (quasi)particle or other single-particle states. These properties are characteristic of a quantum–mechanical vibrator, i.e., an incompressible liquid drop capable of shape vibration.

Fig. 2.15

The positive parity $0_1, 2_1, 0_2, 2_2, 4_1, 6_1$, and negative parity 3_1 levels in even–even Te nuclei

2.3.3.2 Theory of Nuclear Vibration: Comparison with Experimental Data

In [Sect. 2.3.1](#) the *shell model* of spherical and deformed nuclei was discussed. The model gives a good description of various phenomena observed in the light ($A \leq 80$), near double-magic (e.g., around ^{208}Pb) and well-deformed nuclei (e.g., in the regions $150 \leq A \leq 190$, $A \geq 220$). The shell model is a microscopic nuclear model, i.e., it is formulated at the nucleonic level. At the same time, the application of the model far from magic nuclei leads sometimes to very complicated calculations. Furthermore, many observations clearly show the existence of collective behavior in nuclei (surface vibration, collective rotation), which can be treated in macroscopic framework much more simply.

The *liquid drop model* can also explain many nuclear phenomena successfully. The most important ones are as follows: the nuclear volume is proportional to the mass number (A) ([Eq. \(2.15\)](#)); the binding energy per nucleon is approximately constant in a wide mass-number region ([Fig. 2.3](#)); the nuclear masses can be rather well described by the Weizsäcker formula ([Eq. \(2.3\)](#)); nuclear fission (see [Chap. 3](#) in this Volume); Hofstadter's electron scattering experiments show that the nuclear volume is filled up with nucleons rather uniformly. However, the liquid drop model also has its weak points, e.g., it cannot give account of the shell effects.

The basic idea of the *unified model* (Rainwater 1950; Bohr 1952; Bohr and Mottelson 1953) is that the nuclear core can perform collective motion (surface vibration and in the case of deformed nuclei, rotation), while the valence nucleons move on individual orbits.

In the next section, the surface vibration in even–even, odd- A , and odd–odd nuclei shall be discussed.

Even–Even Nuclei

In a hydrodynamical approximation, the nucleus is considered a liquid drop which may perform surface oscillations. The starting assumptions of the theory are as follows.

- The liquid drop has a well-defined surface. This can be described by the radius

$$R(\theta, \phi) = \bar{R} \left[1 + \sum_{\lambda=0}^{\infty} \sum_{\mu=-\lambda}^{\lambda} \alpha_{\lambda\mu} Y_{\lambda\mu}(\theta, \phi) \right] = \bar{R} + \Delta R, \quad (2.39)$$

where \bar{R} is the radius of a sphere which has the same volume as the deformed nucleus, θ and ϕ are the spherical coordinates with respect to an axis fixed to the nucleus, the $Y_{\lambda\mu}$ functions are the spherical harmonics, and μ takes the values $\mu = 0, \pm 1, \dots, \pm \lambda$.

- The nuclear deformation is small, i.e., $\Delta R \ll \bar{R}$.
- The liquid drop is incompressible, i.e., the volume of the droplet ($4\pi\bar{R}^3/3$) does not change during oscillations.
- The fluid moves without friction.
- The velocity field $\mathbf{v}(\mathbf{r})$ of the fluid is irrotational, i.e., $\text{curl } \mathbf{v}(\mathbf{r}) = 0$.
- The oscillation is slow, i.e., the angular frequency of the oscillation is much smaller than the angular frequency of the particle motion ($\omega_{\text{osc}} \ll \omega_{\text{particle}}$).

The hydrodynamical model is described in detail in many publications and books (Bohr and Mottelson 1953; Wohlrab 1960; Alaga 1969; Bohr and Mottelson 1974). Only the most important results of the theory are presented here.

The total energy of the liquid drop consists of three parts: kinetic (T), surface (E_s), and Coulomb (E_C) energies. The calculations give the following result for the total energy of the nucleus (up to second order in $\alpha_{\lambda\mu}$ and in its time derivative):

$$E = E_C(0) + E_s(0) + \frac{1}{2} \sum_{\lambda\mu} B_\lambda \left| \frac{d}{dt} \alpha_{\lambda\mu} \right|^2 + \frac{1}{2} \sum_{\lambda\mu} C_\lambda |\alpha_{\lambda\mu}|^2, \quad (2.40)$$

where $B_\lambda = \frac{1}{\lambda} \frac{3AM}{4\pi} \bar{R}^2$ and $C_\lambda = (\lambda - 1)(\lambda + 2) S_t \bar{R}^2 - \frac{3}{2\pi} \frac{\lambda - 1}{2\lambda + 1} \frac{Z^2 e^2}{\bar{R}}$ are the mass parameter and the stiffness parameter (A is the mass number, M is the average mass of the nucleons), respectively, $\bar{R} = r_0 A^{1/3}$ is the nuclear radius, S_t is the constant of the surface tension, Ze is the charge of nucleus, $E_C(0)$ and $E_s(0)$ are the Coulomb and surface energies of the spherical nucleus, respectively.

As the oscillation is collective, $\alpha_{\lambda\mu}$ and its time derivate are called collective space and velocity parameters, respectively. The third term in [Eq. \(2.39\)](#) is analogous to the classical kinetic energy formula, while the fourth term to the potential energy of the harmonic vibrator ($m\omega^2 r^2/2$). The parameter C_λ corresponds to $m\omega^2$ and $\alpha_{\lambda\mu}$ to the radius. The angular frequency of the 2^λ -pole oscillation is given by

$$\omega_\lambda = \sqrt{C_\lambda / B_\lambda}. \quad (2.41)$$

In the quantum-mechanical theory of collective vibration, one obtains the following energy eigenvalues:

$$E = E_{\text{vibr}} = \sum_{\lambda\mu} \hbar\omega_{\lambda\mu} (n_{\lambda\mu} + 1/2) = \sum_{\lambda} \hbar\omega_{\lambda} \left(n_{\lambda} + \frac{2\lambda + 1}{2} \right), \quad (2.42)$$

where $n_{\lambda} = \sum_{\mu} n_{\lambda\mu} = 0, 1, 2, \dots$, and $n_{\lambda\mu} = 0, 1, 2, \dots$.

This means, that for any λ , the level system of a harmonic oscillator is equidistant. The vibrational quanta with energy $\hbar\omega_{\lambda}$ are called phonons. States with $n_{\lambda} = 0, 1, 2, \dots$ are called $0, 1, 2, \dots$ phonon states. The 2^λ -pole phonons are characterized by their mass (B_λ) and stiffness (C_λ) parameters ($\hbar\omega_{\lambda} = \hbar\sqrt{C_\lambda / B_\lambda}$). Their parity is $(-1)^\lambda$.

The energy spectra of the harmonic quadrupole and octupole vibrations as well as the phonon energies as functions of mass number are shown in [Fig. 2.16](#). The phonon energies ($\hbar\omega_2, \hbar\omega_3, \dots$) decrease with increasing mass number A . This decrease is very steep for the light nuclei and slow for the heavier ones. The figure also shows the possible spin values of the phonon states. In harmonic approximation, the different $2\hbar\omega_2, 3\hbar\omega_2, 2\hbar\omega_3, \dots$, etc. states are degenerate, i.e., the $n\hbar\omega_{\lambda}$ states are degenerate for each n and λ . For example, the $0^+, 2^+$, and 4^+ states of two quadrupole phonons have the same energy. Nevertheless, if one takes into account higher-order terms in $\alpha_{\lambda\mu}$ and in its time derivative in [Eq. \(2.40\)](#), i.e., in anharmonic approximation, the degenerate levels will split, so that the states with different spins will have different energies (not shown).

Brink et al. (1965) proposed a semiempirical method for the description of the energies of multiphonon states. The method requires the knowledge of the first four excitation energies:

$$\begin{aligned} E(2_1^+), \\ E(0_2^+) &= 2E(2_1^+) + \Delta E_0, \\ E(2_2^+) &= 2E(2_1^+) + \Delta E_2, \\ E(4_1^+) &= 2E(2_1^+) + \Delta E_4, \end{aligned}$$

■ Fig. 2.16

(a, b) Energy spectra of the harmonic quadrupole and octupole vibrations, respectively. (c) Phonon energies $\hbar\omega_2$, $\hbar\omega_3$, and $\hbar\omega_4$ as functions of the mass number A . The results were obtained in the hydrodynamical approximation, with a nuclear radius of $R = 1.44 A^{1/3}$ fm (Based on Bohr and Mottelson 1953)

where ΔE_j is the anharmonic correction to the two-phonon energy $E(J^+)$. Then the three- and higher-phonon level energies are expressed as functions of four parameters: $E(2_1^+)$, ΔE_0 , ΔE_2 , ΔE_4 :

$$E_{I\nu}^{(N)} = NE(2_1^+) + \sum_{j=0,2,4} C_{I\nu j} \Delta E_j, \quad (2.43)$$

where N is the number of phonons, I is the spin of the state, ν is the phonon seniority (number of phonons not coupled pairwise to zero), the symbol $C_{I\nu j}$ stands for the so-called boson fractional parentage coefficient, which depends only on quantum numbers (Bayman and Lande 1966).

The numerical calculations in the framework of the geometric collective model are helped by different computer codes, e.g., by the code described by Troltenier, Maruhn, and Hess in Langanke et al. (1991). The applied collective Hamiltonian is able to describe both vibrational and rotational excitations of nuclei. The program makes it possible to compute the energy spectra, transition probabilities, and other properties.

The experimental and theoretical low-lying level schemes are compared for the even-even $^{110-118}\text{Cd}$ isotopes in Fig. 2.17. The “intruder” states, shown in the level spectrum of ^{110}Cd , belong mainly to particle-hole excitations across the major closed shell at $Z = 50$. These are not members of the multiphonon excitations. As the figure shows, the theory reproduces both the level energies and the reduced $B(E2)$ transition probabilities fairly well.

In the harmonic vibration approximation the ratio $E(4_1^+)/E(2_1^+)$ is equal to 2. There are really many even-even nuclei, for which this ratio is between 2.0 and 2.4, especially in the $A \leq 140$ region.

■ Fig. 2.17

Low-lying levels of even–even $^{110-118}\text{Cd}$ nuclei. The experimental level data were taken from Bertschy et al. (1995) for ^{110}Cd , otherwise from Firestone et al. (1996). The ^{110}Cd semiempirical calculations were performed by Kern (1997) with Brink's formula. The “intruder states” are out of the scope of the vibrational model. In the case of ^{114}Cd , the reduced E2 transition probabilities are also shown (relative to the $B(E2; 2_1^+ \rightarrow 0_1^+)$ transition) with the corresponding theoretical results (Alaga 1969; Lopac 1967). For the ^{118}Cd transitions the average $B(E2)$ values are shown for different groups of levels. The theoretical ^{118}Cd energy spectrum was obtained for the two-phonon states on the basis of the anharmonic vibrator model (Arahamian 1986; Brink et al. 1965)

Odd-A and Odd–Odd nuclei

If there is a nucleon outside the even–even core, it may interact with the core oscillations. In the particle (hole)–vibration model it is supposed that the nuclear deformation is small; the radius of the nucleus can be described by Eq. (2.38), and the angular frequency of the surface vibrations is much smaller than that of the particle motion ($\omega_{\text{vib}} \ll \omega_{\text{particle}}$). In this case, the particle will follow the changes of the slowly oscillating nuclear average field adiabatically, i.e., the particle will be in an eigenstate belonging to the momentary average field.

The potential of the vibrating core (U) will be a function of the coordinates (r, θ, ϕ). It is assumed that U vibrates together with the nuclear surface:

$$U(r, \theta, \phi) \equiv U\left(\frac{r}{R}\right) = U\left(\frac{r}{1 \pm \sum_{\lambda\mu} \alpha_{\lambda\mu} Y_{\lambda\mu}(\theta, \phi)}\right) \approx V(r) \mp k(r) \sum_{\lambda\mu} \alpha_{\lambda\mu} Y_{\lambda\mu}(\theta, \phi) + \dots, \quad (2.44)$$

where $V(r)$ is the potential of the spherically symmetric nuclear core, $k(r) = r(dV(r)/dr)$, minus and plus signs refer to particles and holes, respectively. (A hole state is a state in which a nucleon is missing from the fully occupied shell.) [Equation \(2.44\)](#) has been obtained by the use of the approximate equality $(1 \pm x)^{-1} \approx 1 \mp x$ (for small x), following from a Taylor expansion. The quadratic and higher-order terms indicated by [Eq. \(2.43\)](#) are usually neglected and $k(r)$ is evaluated at the nuclear surface. Supposing that $V(r)$ is a square-well potential (see [Fig. 2.2](#)) with jump at R_N , at $r = R_N$ one obtains (Bohr and Mottelson 1974; Alaga 1969):

$$k(r) = r \frac{dV}{dr} = R_N V_0 \delta(r - R_N) \approx 50 R_N \delta(r - R_N) \text{ MeV.}$$

The Hamiltonian of the odd-A nucleus consists of three parts:

$$H = H_{\text{sp}} + H_{\text{coll}} + H_{\text{pvc}}, \quad (2.45)$$

where $H_{\text{sp}} = p^2/(2M) + V(r)$ is the single-particle Hamiltonian in the spherical average field, H_{coll} is the collective Hamiltonian (see [Eqs. 2.39](#) and [2.40](#)), and

$$H_{\text{pvc}} = \mp k \sum_{\lambda\mu} \alpha_{\lambda\mu} Y_{\lambda\mu}(\theta, \phi) \quad (2.46)$$

is the term for the particle-vibration coupling. If the particle and the oscillating-field coupling are weak or intermediate, H_{pvc} can be considered a perturbation.

By the use of the particle(hole)-vibration model it was possible to reproduce the level spectra and electromagnetic properties of the odd-A indium isotopes and many other nuclei.

In odd-odd nuclei the total angular momenta of the odd proton (j_p) and odd neutron (j_n) are coupled to a resulting spin $I = |j_p - j_n|, \dots, j_p + j_n$. According to the “parabolic rule” derived by Paar (1979), the energy splitting $\Delta E_2(j_p j_n I)$ of the $|j_p, j_n I\rangle$ multiplet due to a quadrupole interaction through the nuclear core is:

$$\Delta E_2(j_p j_n I) = A[I(I+1)]^2 + BI(I+1) + C, \quad (2.47)$$

where the parameters A , B , and C depend on j_p and j_n , but not on I . The parabolic rule gives a good description of the energy splitting of the proton-neutron multiplets when the quadrupole collective excitation is pronounced. Near-double magic nuclei or very far from closed shells (where the configuration mixing is strong) deviations may occur from the rule. For a more detailed description of vibrational excitations see, e.g., Fényes (2002).

At high (≥ 10 MeV) excitation energies, in several reactions, broad *giant resonances* were observed for virtually all nuclei. These can be attributed to coherent (volume) oscillations of the protons and neutrons. For a review see Harakeh and Van der Woude (2001).

2.3.4 Rotational Motion

2.3.4.1 Basic Experimental Facts

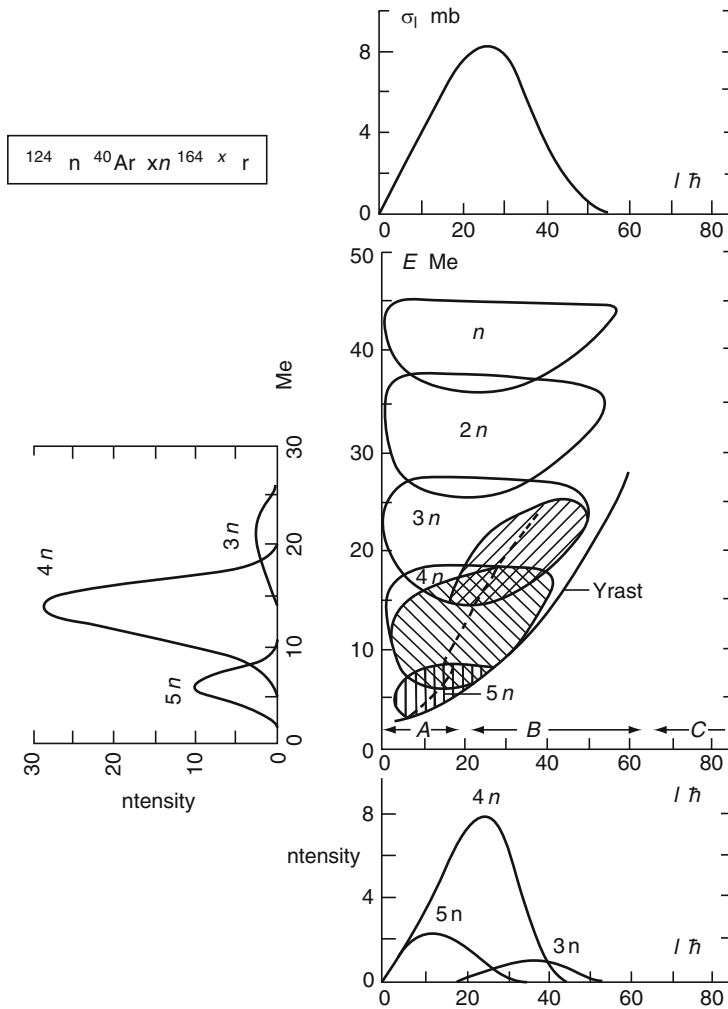

In wide regions of deformed nuclei, one can find low-lying levels with energies approximately proportional to $I(I+1)$, where I is the nuclear spin of the state. As will be seen in [Sect. 2.3.4.2](#), the spectrum of a quantum rotor shows this property. Thus, the existence of such levels may be related to collective nuclear rotation.

Rotational states can be excited in many different ways, through light- and heavy-ion reactions, Coulomb excitation, etc. One of the most effective methods uses heavy-ion fusion reaction.

► **Figure 2.18** shows the statistical model predictions for the reaction $^{124}\text{Sn}(^{40}\text{Ar}, xn)^{164-x}\text{Er}$. The compound nucleus is formed with large average input angular momentum.

■ **Fig. 2.18**

Statistical model predictions for the reaction $^{124}\text{Sn}(^{40}\text{Ar}, xn)^{164-x}\text{Er}$ at 147 MeV bombarding argon energy. The excitation energy of the compound nucleus is 53.8 MeV. Top part: Population of the excited states of the compound nucleus ^{164}Er as a function of input angular momentum I . Middle and lower parts: Calculated population distributions after the emission of 1–5 neutrons as functions of the excitation energy and angular momentum. The hatched areas indicate regions where γ -ray emission competes. Their intensity profiles are shown on the left side and bottom of the figure. The “yrast curve” shows lowest possible energy for a given spin. Based on Hillis et al. (1979). For a detailed analysis of yrast states see Szymański (1983)

As the evaporated neutrons take away relatively small angular momentum, the residual nucleus remains in a high-spin state (which then decays with successive γ -ray emissions). In this way, rotational bands can be excited up to very high spins (e.g., in ^{152}Dy up to $I \approx 60$).

Properties of Rotational States

One of the characteristic features of rotational excitations is that the first excited states have low energies. This can be seen in [Fig. 2.8](#), where the energies of the first 2^+ states are shown versus the neutron number (N) for even–even nuclei. In the regions of strongly deformed nuclei, $56 \leq Z \leq 78$, $Z > 90$; $90 \leq N \leq 112$, $N > 136$ ([Fig. 2.7](#)) the first 2^+ states have very low-excitation energies. [Figure 2.19](#) shows the systematics of the energy ratio $E(I^+)/E(2_1^+)$ for the ground-state bands of deformed even–even nuclei near the stability curve. The predictions of the $I(I+1)$ rotational energy formula is shown by horizontal lines for states $I = 4^+, 6^+, 8^+, \dots, 16^+$. For low spins the experimental data are close to the predicted values. For higher spins the formula predicts larger values.

Fig. 2.19

The energy ratio $E(I^+)/E(2_1^+)$ in the ground-state bands of even–even nuclei in the mass-number region $152 \leq A \leq 186$. The ratio is shown up to $I^\pi = 16^+$ for nuclei which are closest to the stability curve. Data were taken from (Firestone et al. 1996). The horizontal lines show the predictions of the Bohr–Mottelson $I(I+1)$ formula

Rotational bands can be “built” on the ground state, on various vibrational states, and on different single-particle (Nilsson) states.

The most common type of rotational excitations is *collective rotation*, which is characteristic of the strongly deformed nuclei. In this case, many nucleons contribute coherently to the nuclear motion. The reduced E2 transition probabilities from collective rotational states are usually order(s) of magnitude larger than for single-particle transitions. The moment of inertia of strongly deformed nuclei is large. In the low-lying states, the angular frequency of the collective rotation is much smaller than that of vibrations, let alone internal nucleonic motion: $\omega_{\text{rot}} \ll \omega_{\text{vibr}} \ll \omega_{\text{int}}$. In this case, the rotation does not disturb the nucleonic motion strongly, and an adiabatic description may be successful.

Collective rotational states form series, which are called “bands.” The states belonging to a band are specified by a single “intrinsic” state. The states of a band only differ in the amount of rotation they carry, i.e., in the value of the angular momentum (I) of the rotational motion.

High-spin states were observed also in nearly spherical nuclei, e.g., in $^{147}_{64}\text{Gd}_{83}$. In this case, the level scheme does not show the regular pattern of collective rotation, and the reduced E2 transition probabilities are close to the Weisskopf unit. The high-spin states are produced by the alignment of individual nucleonic orbits. This is the case of *non-collective rotation*. The irregularities are related to the occupation of different single-particle states.

In addition to these two extreme types of rotational motion, a combination of collective and non-collective rotational excitations is also possible.

Structural Changes Induced by Rotation

In the low-spin excitation spectrum (up to angular momentum $\sim 20\hbar$, see region “A” in  Fig. 2.18), the nucleus is relatively cold, and the level structure, density of states, and nuclear equilibrium shape can be described in the framework of the shell model of spherical or deformed nuclei. In the region of well-deformed nuclei, which mostly have axially symmetric shapes in their ground states, the rotational bands can be rather well described by the $I(I+1)$ energy law. The $B(E2)$ reduced transition probabilities are large, showing the collective character of the excitation. The pairing correlations play also an important role. Near the ground state, the nuclei are partly in superfluid phase (i.e., the nucleons are paired to angular momentum zero), which is clearly demonstrated by their reduced moments of inertia.

With increasing angular momentum, increasing centrifugal and Coriolis forces act on the nucleons. The Coriolis force tends to break the nucleon pairs, leading to the “Coriolis antipairing” effect (Mottelson and Valatin 1960). Subsequent investigations showed that the neutron pairing completely disappears at angular momenta of $16\hbar$ – $24\hbar$, while the proton pairing vanishes at $\geq 30\hbar$. This superfluid \rightarrow normal phase transition leads to a substantial increase of the moment of inertia. The Coriolis force is especially strong if the nucleon has a large angular momentum (j). Sometimes, the breaking of one high- j pair and the subsequent alignment of the angular momenta along the rotation axis is sufficient for the explanation of the sudden increase of the moment of inertia of the nucleus.

The “back-bending effect,” i.e., the drastic change of the moment of inertia (at about $I \approx 16\hbar$ for some rare-earth nuclei) was first observed experimentally by Johnson et al. (1971). The explanation of the effect, on the basis of sudden nucleon angular momentum alignment, was given by Stephens and Simon (1972).

With increasing angular momentum (see region “B” in  Fig. 2.18), the strong centrifugal force disturbs the shell structure and drives the prolate nucleus into a triaxial deformed shape.

In the triaxial deformation region a lot more collective states occur than in the region of axially symmetric rotor. These states are characterized by strong intraband and weak interband transitions. The nucleus may perform wobbling motion. Parallel to the yrast line many rotational bands may exist and also band-crossings, producing sudden changes of the moment of inertia.

In the next region “C” (• Fig. 2.18), the shell structure melts and the nucleus acquires an oblate shape. Here the regular pattern of rotational states disappears, and the level scheme is determined by individual nucleons having aligned angular momenta along the rotational axis. The reduced transition probabilities between the states are close to the single-particle values. In this region “yrast traps,” i.e., high-spin, long-lived isomeric levels may also occur.

The potential energy calculations performed for high-spin states show that some nuclei may again acquire triaxial equilibrium shape before fission, and that may lead to collective rotational states.

2.3.4.2 Theory of Nuclear Rotation: Comparison with Experimental Data

Rotation of Even–Even Nuclei

The vast majority of well-deformed nuclei have ellipsoidal or other axial- and reflection-symmetric shapes. The reflection symmetry exists with respect to a plane, going through the center of mass and perpendicular to the axis of rotational symmetry. The rotation of such systems can be described simply (Bohr and Mottelson 1974) because the projection of the total angular momentum on the symmetry axis (• Fig. 2.4b) is a constant of motion. In the following the discussion shall be concentrated on nuclei which have both axial and reflection symmetries.

The Hamilton operator of the system can be written approximately in the form

$$H = H_{\text{in}} + H_{\text{rot}} + H_{\text{vib}},$$

where H_{in} describes the internal motion of particles within the body-fixed coordinate system, H_{rot} is the Hamiltonian of the rotation energy, and H_{vib} describes the surface vibration of the nucleus. Neglecting, for the moment, the internal and vibrational degrees of freedom, the Hamiltonian can be written in the form

$$H \approx H_{\text{rot}} = \frac{R^2}{2\mathfrak{I}},$$

where \mathfrak{I} is the moment of inertia. In an axially symmetric nucleus, the axis of collective rotation is expected to be perpendicular to the symmetry axis. Then the angular momentum (\mathbf{R}) of rotation will also be perpendicular to the axis of symmetry, i.e., $K = 0$ (cf. • Fig. 2.4b). In classical mechanics, the energy of a rotating rigid body is given by $E = \mathfrak{I}\omega^2/2$, where ω is the rotational frequency and $\mathfrak{I}\omega = R$ is the angular momentum. In quantum mechanics, the energy eigenvalues of the rotational Hamiltonian are given by the formula

$$E_{\text{rot}} = \frac{\hbar^2}{2\mathfrak{I}} I(I+1), \quad (2.48)$$

where I is the angular momentum (nuclear spin) quantum number. In the ground states of even–even nuclei, $I = 0$. The systematics of energy ratios $E(I^+)/E(2_1^+)$, presented in • Fig. 2.19, shows that the Bohr–Mottelson $I(I+1)$ formula predicts somewhat higher energies than the

experimental values, indicating that in real nuclei the moment of inertia increases slowly and gradually with increasing energy.

Several phenomenological formulae were proposed that better reproduce the energies of rotational states below the lowest backbending (Harris 1965; Mariscotti et al. 1969; Sood 1967, 1968).

Sood (1967, 1968) had summed up the infinite series

$$E(I) = a_1 I(I+1) + a_2 I^2(I+1)^2 + a_3 I^3(I+1)^3 + \dots$$

taking into account a cue from molecular spectra for the interrelation of the coefficients a_1, a_2, a_3, \dots . His formula reads

$$E(I) = a_1 \left[1 - \frac{(a_2/a_1)I(I+1)}{1 + b(a_2/a_1)I(I+1)} \right] I(I+1), \quad (2.49)$$

where b is determined empirically for each region, e.g., for the actinides $b = 3.00 - (I/30)$. This formula gives excellent description of the experimental data up to high spins both in the rare-earth and actinide regions.

Although the above mentioned phenomenological formulae result in good fits to experimental data, the basis of the theoretical interpretation is not perfectly clear. The main reason for the gradual increase of the moment of inertia is probably the Coriolis antipairing effect. With increasing spin, the Coriolis interaction tends to break the pairs and align the angular momenta of nucleons along the rotation axis. The result is an increase of the moment of inertia. A microscopic description of the moments of inertia near ground states was given by Nilsson and Prior (1961). One can distinguish between two kinds of *moments of inertia*, kinematical $\mathfrak{I}^{(1)}$ and dynamical $\mathfrak{I}^{(2)}$:

$$\begin{aligned} \mathfrak{I}^{(1)} &= \hbar^2 I_x \left(\frac{dE}{dI_x} \right)^{-1} = \hbar \frac{I_x}{\omega}, \\ \mathfrak{I}^{(2)} &= \hbar^2 \left(\frac{d^2 E}{dI_x^2} \right)^{-1} = \hbar \frac{dI_x}{d\omega}, \end{aligned} \quad (2.50)$$

where $I_x = [I(I+1)]^{1/2}$ and $\hbar\omega = dE/dI_x$ (Bohr and Mottelson 1981). For the kinematical moment of inertia, the explicit knowledge of the spin is required:

$$\frac{\mathfrak{I}^{(1)}}{\hbar^2} \approx \frac{2I}{E(I+1) - E(I-1)},$$

while the dynamical moment of inertia can be determined from the differences in transition energies (without knowing I explicitly):

$$\frac{\mathfrak{I}^{(2)}}{\hbar^2} \approx \frac{4}{E(I+2) - E(I) - [E(I) - E(I-2)]}.$$

In the detailed theory, simple expressions were derived for the *reduced electric transition probabilities* $B(E2)$ between rotational levels of the axially symmetric deformed nuclei (Bohr and Mottelson 1974, Sect. 3.2). For example, for the $K = 0, 0_1^+ \rightarrow 2_1^+$ transition (Fig. 2.4b):

$$B(E2; 0_1^+ \rightarrow 2_1^+) = \frac{5}{16\pi} e^2 Q_0^2. \quad (2.51)$$

Note that, according to Eq. (2.34), $B(E2; 0_1^+ \rightarrow 2_1^+) = 5B(E2; 2_1^+ \rightarrow 0_1^+)$. Equation (2.50) means that from the measured reduced transition probabilities $B(E2; 0_1^+ \rightarrow 2_1^+)$ one can determine the *internal quadrupole moment* (Q_0) and also the deformation parameter δ , taking into account that

$$Q_0 \approx 0.8Z\bar{R}^2\delta(1 + 0.667\delta). \quad (2.52)$$

The $B(E2; 0_1^+ \rightarrow 2_1^+)$ values have been determined practically for all even–even nuclei, mainly from Coulomb excitation, lifetime measurements, and electron scattering experiments. The results are summarized in Fig. 2.14. In strongly deformed rare-earth nuclei, δ is around 0.30–0.35, and in the vicinity of magic numbers it is much smaller.

Within the same rotational band Q_0 is constant. In this case the $B(E2)$ ratios for different transitions are determined by the Clebsch–Gordan coefficients (tabulated, e.g., in Lawson (1980) and Bayman and Lande (1966)). These relationships were first formulated by Alaga et al. (1955), and they are called *Alaga rules*. Alaga rules have been derived also for interband transitions for $I_i K_i$ to different $I_f K_f$ and $I_f' K_f'$ states. The rules are widely used by experimental physicists for the construction of rotational bands. As an example, the predictions (Soloviev 1981) of the Alaga rules are given here for E2 transitions from band K_i to ground state band $K_f = 0$:

$$\frac{B(E2; 2_i^+ \rightarrow 4_f^+)}{B(E2; 2_i^+ \rightarrow 0_f^+)} = \begin{cases} 2.57 & \text{for } K_i = 0, \\ 1.15 & \text{for } K_i = 1, \\ 0.075 & \text{for } K_i = 2. \end{cases}$$

The great differences in numerical values help determine unknown K_i quantum numbers. The general agreement of the experimental data with the Alaga rules provides important evidences for the existence of axially symmetric deformation in nuclei and for the separability of a rotational factor from the internal wave function. The calculations lead to the following relationship (cf. Eq. (2.12)) between the *spectroscopic* (Q) and *intrinsic* (Q_0) *quadrupole moments* (Bohr and Mottelson 1974):

$$Q = \frac{3K^2 - I(I+1)}{(I+1)(2I+3)} Q_0.$$

For $I = 0$ and $1/2$ the spectroscopic quadrupole moment is always zero, independently of the value of Q_0 . The sign of Q may differ from that of Q_0 . This is the case, if $K = 0$ or $I(I+1) > 3K^2$. If a prolate nucleus rotates around an axis perpendicular to the body-fixed symmetry axis, the laboratory observer sees oblate deformation.

Expressions have been deduced also for *reduced magnetic dipole transition probabilities* $B(M1)$ and moments (μ) (see, e.g., Bohr and Mottelson 1974; Nathan and Nilsson 1965).

The properties of strongly deformed nuclei can be well described assuming axially symmetric shape. However, in the transitional regions it is necessary to consider also triaxial (i.e., not axially symmetric) shapes. The departure from axial symmetry may be either static (stable deformation) or dynamic (γ surface oscillation). The *theory of γ -soft nuclei* was first developed by Wilets and Jean (1956).

The theory of nuclei unstable against γ deformation was able to explain many properties of transitional nuclei. For instance, in the Wilets–Jean model the value of the ratio $E(4_1^+)/E(2_1^+)$ is ≤ 2.5 , which is much closer to the experimental data than the rigid rotor value 3.33. According to the theory, the $2_2^+ \rightarrow 0_1^+$ crossover transition is forbidden in even–even nuclei.

The experimental data show that when the level sequence $0^+, 2^+, 2^+$ appears, the probability of the $2_2^+ \rightarrow 0_1^+$ transition is indeed much smaller than the probability of the $2_2^+ \rightarrow 2_1^+$ one.

In the theory of γ -unstable nuclei, the central potential changes with time. Consequently, no symmetry axis and no simple constants of motion remain.

The $E(2_1^+) : E(4_1^+) : E(6_1^+) : E(8_1^+)$ energy ratios in different models are as follows:

Harmonic vibrator (► Eq. (2.41))	1:2:3:4,
γ -Unstable rotor	1:(2.5):(4.5):7,
Axial-symmetric rotor (► Eq. (2.47))	1:(3.33):7:12.

The predictions of the γ -unstable rotor model are thus between those of the harmonic vibrator and axial-symmetric rotor models.

The *theory of rigid triaxial rotor* was developed by Davydov and Filippov (1958). The theory makes predictions for the energy of the states and for the electromagnetic transitions. The explicit formulae of the Davydov–Filippov model allow easy comparison with experimental data. Thus, the model was very popular for a long time.

The experimental data and nuclear shape calculations convincingly show that the well-deformed nuclei have axial symmetry at low and moderate angular momenta. At the same time in a wider neutron number region ($N = 84$ – 120), departures were observed from axial symmetry in several Nd, Sm, Gd, Pt, and other nuclei. An analysis performed by Casten (2000) shows that the lack of axial symmetry is associated rather with γ -softness than with stable triaxial deformation.

Nevertheless, one cannot exclude the possibility that rigid triaxial rotors exist in nature. An example is the nucleus ^{76}Ge , for which the potential energy surface calculations, as well as the level spectra and $B(E2)$ values alike demonstrate the occurrence of stable triaxial deformation (Larsson et al. 1976; Ragnarsson et al. 1978).

Note that pure rotational motion is rarely realized in nuclei; the rotational and vibrational excitations are usually mixed. It is very general that there are rotational bands built on the 0_2^+ and 2_2^+ vibrational levels, these are the so-called β - and γ -vibrational bands. The *rotation–vibration coupling* is discussed, e.g., in Bohr and Mottelson (1974) and Garrett (2001) publications.

Rotation of Odd-A Nuclei. Particle-Rotor Model

The angular momentum (\mathbf{j}) of a nucleon moving in the average field of an axially symmetric nuclear core may be coupled to the core in different ways. The two possible extreme coupling schemes are illustrated in ► Fig. 2.20. If the deformation is strong, the rotation is slow, and \mathbf{j} is small, then usually the deformation (or strong) coupling scheme is realized in nature. The projections of \mathbf{j} and \mathbf{I} on the symmetry axis (Ω and K , respectively) are equal, and they are constants of motion. However, if the rotation is fast, the strong Coriolis force may decouple \mathbf{j} from the symmetry axis and align it in the direction of the rotation axis. In this case the rotation (or weak) coupling scheme is realized.

In the case of *deformation alignment* (see left part of ► Fig. 2.20), the Hamiltonian of the rotating nucleus can be written in the form

$$H = \frac{\hbar^2}{2\mathfrak{I}} \mathbf{R}^2 = \frac{\hbar^2}{2\mathfrak{I}} (\mathbf{I} - \mathbf{j})^2 = \frac{\hbar^2}{2\mathfrak{I}} (\mathbf{I}^2 + \mathbf{j}^2 - 2\mathbf{jI}), \quad (2.53)$$

■ Fig. 2.20

Illustration of the deformation-alignment and rotation-alignment coupling schemes. j and R are the angular momenta of the particle and the core, respectively. I is the resulting spin of the nucleus. Usually the deformation alignment is realized in nature, if the deformation is strong, the rotation is slow, and j is small, while the rotation alignment is preferred in the opposite case

where \mathfrak{I} is the moment of inertia. Detailed calculations give the following expression for the rotational energy:

$$E_{\text{rot}}(I) = \frac{\hbar^2}{2\mathfrak{I}} \left[I(I+1) + j(j+1) - 2K^2 + \delta_{K,1/2} a(-1)^{I+1/2} (I+1/2) \right], \quad (2.54)$$

where a is the decoupling parameter and $\delta_{K,1/2} = 1$, if $K = 1/2$. If $K \neq 1/2$ and for high j values $j(j+1) \approx K^2$ this formula may be simplified to

$$E_{\text{rot}}(I) \approx \frac{\hbar^2}{2\mathfrak{I}} [I(I+1) - K^2], \quad K \neq 1/2. \quad (2.55)$$

As $I \geq K$, the members of the band have the following spins $I = K, K+1, K+2, \dots$

If the odd particle has a large angular momentum (j), the deformation is not strong, and the rotation of the core is fast, then the Coriolis interaction may align j along the rotation axis and in this way minimize the total energy (Stephens 1975). In the *rotation-aligned case*, when $j \approx j_x$ (► Fig. 2.20), the rotational energy may be written in the form (cf. ► Eq. (2.52)):

$$E_{\text{rot}} \approx \frac{\hbar^2}{2\mathfrak{I}} [I(I+1) + j_x(j_x+1) - 2Ij_x] = \frac{\hbar^2}{2\mathfrak{I}} [(I-j_x)(I-j_x+1) + 2j_x] \quad (2.56)$$

and as $I - j_x \approx R$

$$E_{\text{rot}} \approx \frac{\hbar^2}{2\mathfrak{I}} R(R+1) + \text{const.} \quad (2.57)$$

The energy spectrum of an odd- A nucleus will thus be very similar to that of its even-even neighbor (see ► Eq. (2.47)) and I will take the values of $j, j+2, j+4, \dots$

Examples for deformation alignment and rotation alignment are shown in [Fig. 2.21](#). The right-hand side of the figure compares the energy spectra of the strongly deformed nuclei ^{164}Er and ^{165}Er . The spectra are quite different because the $i_{13/2}$ neutron of ^{165}Er is deformation-aligned and therefore its spectrum may be described by [Eq. \(2.54\)](#) with $I = K, K + 1, K + 2, \dots$

Fig. 2.21

Examples for rotation and deformation aligned bands. Energy levels in some odd-A nuclei, compared with the ground state bands of neighboring even-even nuclei. The energy scale is shifted in the case of odd-A nuclei. The symbols π and ν stand for proton and neutron, respectively. Data from Lieder and Ryde (1978), completed from Firestone et al. (1996)

As the left-hand side of [Fig. 2.21](#) shows, the rotational band based on the $11/2^-$ 0.305 MeV state of $^{131}_{57}\text{La}$ and the $13/2^+$ 0.563 MeV state of $^{155}_{68}\text{Er}$ are very similar to the ground state bands of the neighboring even–even nuclei $^{130}_{56}\text{Ba}$ and $^{154}_{68}\text{Er}$, respectively. This strongly suggests that the $h_{11/2}$ proton in ^{131}La and the $i_{13/2}$ neutron in ^{155}Er are aligned along the rotation axis, and the rotational spectrum is determined mainly by the even–even core.

The rotation alignment is rather common in the weakly deformed nuclei; however, with increasing deformation, intermediate coupling schemes are realized.

A microscopic description of rotational nuclear motion is also possible by the use of the cranked shell model of Inglis (1954). The model is discussed in detail in several monographs (e.g., Szymański 1983; Nilsson and Ragnarsson 1995; Fényes 2002). The cranking shell model calculations satisfactorily account for the absolute values of aligned angular momenta and for the rotational frequencies, at which the alignment of different orbits occurs.

Rotation of Superdeformed and Hyperdeformed Nuclei

A nucleus is called superdeformed or hyperdeformed in states in which the ratio of its axes is approximately 2 or 3, respectively.

[Fig. 2.12b](#) shows the calculated shell energy (and the local energy minima) in the deformation parameter – neutron number plane. The predicted superdeformed shapes may be stabilized by centrifugal and Coriolis forces in rotating nuclei.

The first rotational band, built on a superdeformed state was discovered by Nyakó et al. (1984) and Twin et al. (1985) in the $^{108}\text{Pd}(^{48}\text{Ca},4n)^{152}\text{Dy}$ reaction. The observed γ -spectrum is shown in [Fig. 2.22a](#), and a partial level scheme of ^{152}Dy in [Fig. 2.22b](#).

The existence of superdeformed (SD-1) states in ^{152}Dy is proved by the following experimental results.

- The level energies can be ordered in a very regular rotational band, with no band crossing. The observed SD-1 band consists of 17 γ -transitions with almost constant spacing of $\Delta E_\gamma = 47$ keV.
- The deduced dynamical moment of inertia $\mathfrak{S}_{\text{SD-1}}^{(2)} = 85\hbar^2 \text{ MeV}^{-1}$ is very large and corresponds to the rigid body value.
- According to the Doppler shift measurements, the SD-1 band members are connected via enhanced E2 transitions with reduced transition probabilities $B(E2)_{\text{exp}} = 2,500 \pm 500 \text{ W. u.}$ This is very close to the theoretical value $B(E2)_{\text{theor}} = 2,390 \text{ W. u.}$ predicted for $\beta_2 = 0.6$ deformation.

Several other coexisting nuclear shapes have also been identified in ^{152}Dy with different β and γ deformation parameters ([Fig. 2.22b](#)).

The discovery of superdeformed rotational bands in ^{152}Dy was a very impressive achievement of nuclear spectroscopy from many reasons. From the experimental point of view, it has shown that discrete γ cascades can be observed from states whose excitation energy varies from ~ 12 to ~ 30 MeV and spin from (22) to (60) \hbar . From the theoretical point of view, it has demonstrated that the rotation can stabilize very deformed shapes. In this way, a new possibility has been opened to study the quantal effects at very high spins. There are already ≥ 170 superdeformed bands known in the $A \approx 80, 130\text{--}140, 150, 190$ mass number regions. For detailed description, see Szymański (1983), Nilsson and Ragnarsson (1995), and Fényes (2002).

Krasznahorkay et al. (1998, 1999) and Csatlós et al. (2005) have found also hyperdeformed states in ^{234}U and ^{236}U from the study of $^{233}\text{U}(\text{d,pf})^{234}\text{U}$ and $^{235}\text{U}(\text{d,pf})^{236}\text{U}$ reactions. For

Fig. 2.22

(a) γ -ray spectrum of ^{152}Dy from the reaction $^{108}\text{Pd}(^{48}\text{Ca},4n)^{152}\text{Dy}$ at 205 MeV bombarding particle energy. Counts per energy interval (N_γ) as a function of quantum energy of γ -rays (E), I is the probable spin of the γ -emitting state. (b) Partial level scheme of ^{152}Dy . (The known negative parity states are not shown.) SD-1 and SD-2 show different rotational bands built on superdeformed states. The symbols 0 + X, 0 + Y indicate that the absolute positions of the SD-1, SD-2 bands are not known. Level scheme data were taken from Firestone et al. (1996), deformed parameters from Sharpey-Schafer (1990)

example, the deduced moment of inertia of a ^{236}U state was $217 \pm 38 \hbar^2/\text{MeV}$, which corresponds to a hyperdeformed configuration.

Energy Surfaces at Rotating Nuclei

Strutinsky's shell correction method enables the calculation of the static nuclear energy surface as a function of deformation parameters and neutron (or proton) number (see in [▶ Sect. 2.3.1.5](#)). The total energy of nuclei is obtained as a sum of the shell (E_{sh}), liquid drop (E_{LD}), and rotational kinetic energies:

$$E_{\text{tot}}(\epsilon_2, \gamma, \dots, I) = E_{\text{sh}}(\epsilon_2, \gamma, \dots, I) + E_{\text{LD}}(\epsilon_2, \gamma, \dots, I = 0) + \frac{\hbar^2 I^2}{2\mathfrak{I}_{\text{rig}}(\epsilon_2, \gamma, \dots)},$$

where $E_{\text{sh}} = \sum e_i(I) - \sum \tilde{e}_i(I)$, and e_i is the single particle energy, $E_{\text{LD}} = E_{\text{surface}}(\epsilon_2, \gamma, \dots) + E_{\text{Coul.}}(\epsilon_2, \gamma, \dots)$, $\mathfrak{I}_{\text{rig}}(\epsilon_2, \gamma, \dots)$ the moment of inertia of the rigid body. The calculated energy surfaces of ^{158}Yb are presented in [▶ Fig. 2.23a](#).

The cranked shell model of Inglis offers a microscopic description of the rotational motion. The combination of the above methods gives a new possibility for the nuclear energy surface calculations at high spins. In $^{158}\text{Yb}_{88}$ there are only few particles outside the ^{146}Gd core. In the state $I^\pi = 47^+$ terminating the band the angular momenta of the valence nucleons are quantized along the rotational axis as shown in [▶ Fig. 2.23b](#).

2.3.5 Interacting Boson Models

In addition to the shell model and geometric collective model, there exists a third basic approach to nuclear structure, the *interacting boson model* (IBM). A boson is a particle of integer spin. Bosons obey Bose–Einstein statistics, and the wave function of two identical bosons is symmetric under particle exchange.

In the atomic nuclei, one can observe exact and dynamic symmetries, which play important roles in the understanding of nuclear structure. The symmetry connected with the rotation in three-dimensional space (rotational invariance) is an exact, geometrical symmetry. A consequence of rotational invariance is the conservation of angular momentum. Symmetries that arise from a special form of the interaction are called dynamical symmetries. The invariance transformations of dynamical symmetries can usually be formulated in an abstract, higher-dimensional space, which includes, e.g., also the momentum coordinates, in addition to the space coordinates.

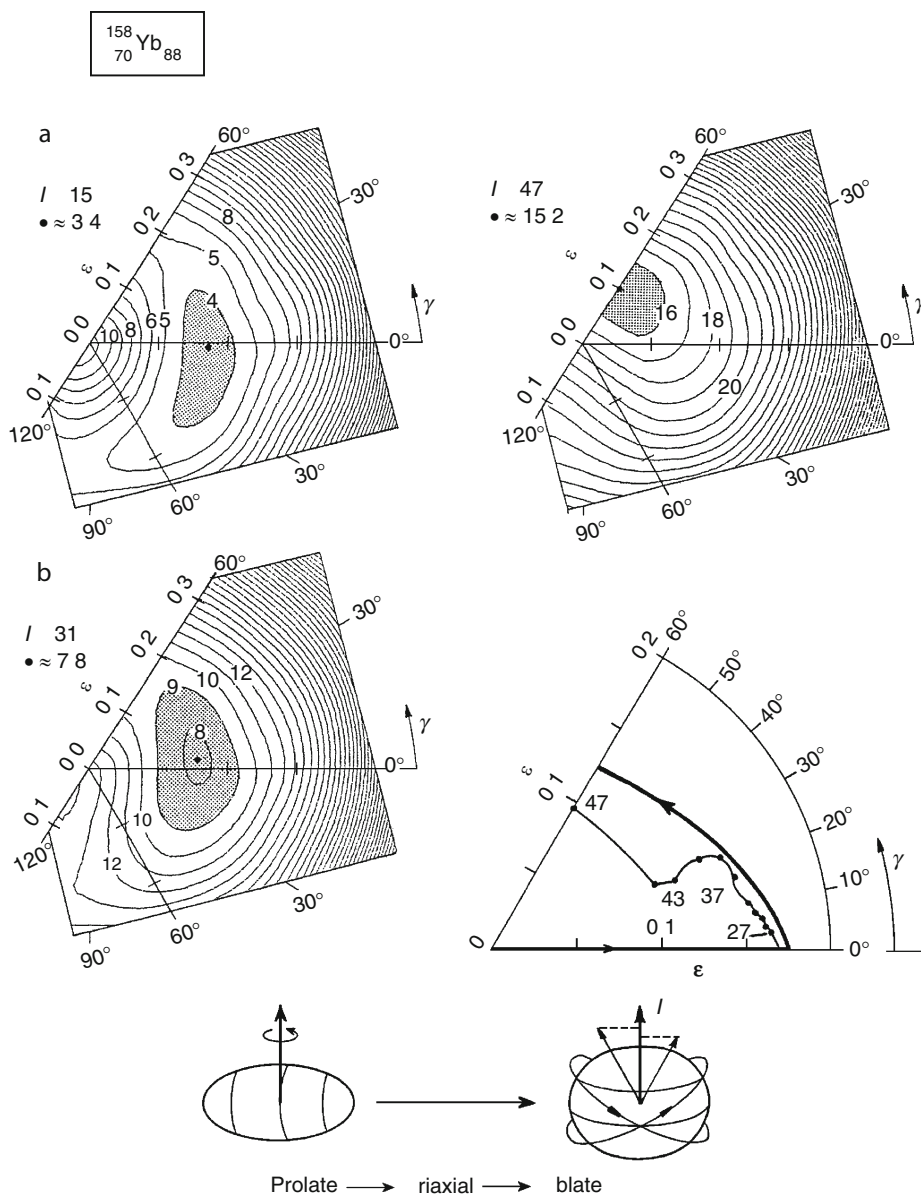

The interacting boson model applies group theoretical (or algebraic) methods and describes nuclear states of various collectivity and symmetry in a uniform framework (see reviews by Iachello and Arima (1987), Iachello and Van Isacker (1991), and Fényes (2002)).

The *starting point* of the interacting boson model is the shell model, but IBM drastically truncates the available configuration space, in order to hold the calculations within reasonable limits. At the same time, the IBM keeps the most important elements substantial for the description of the properties of nuclei.

The first, simplest version of the interacting boson model, the IBM-1 intends to give a description of positive parity levels of medium-heavy even–even nuclei. The model was later considerably extended and now there are versions which are able to treat also negative parity states, both light and heavy, odd-A and odd–odd nuclei, low-lying states and giant resonances, etc.

■ Fig. 2.23

(a) Energy surfaces of ^{158}Yb in the $\varepsilon \equiv \varepsilon_2, \gamma$ plane for configurations terminating in the state $\pi[(d_{5/2})_{3/2}^{-1}(h_{11/2})^6 d_{3/2}] \nu[(f_{7/2} h_{9/2})^4 (i_{13/2})^2]$ at $I^\pi = 47^+$. The subscript 3/2 of $(d_{5/2})_{3/2}^{-1}$ indicates that this hole state contributes to the total spin by 3/2. (b) Shapes of ^{158}Yb corresponding to minimum energy in the $\varepsilon \equiv \varepsilon_2, \gamma$ plane for the above terminating configuration (Based on Bengtsson and Ragnarsson (1985) and Ragnarsson et al. (1986))

The basic assumptions of IBM-1 are as follows:

- The closed proton and neutron shells are inert; they do not take part in the excitations.
- The valence protons and, separately, the valence neutrons are coupled to s and d pairs with angular momenta $J = 0$ and 2 , respectively. See [Fig. 2.24](#).

The numbers of valence protons and neutrons have to be counted from the nearest major closed shells, therefore, the particle and hole states are discussed on equal footing. For example, in $^{176}_{78}\text{Pt}_{98}$ there are $(82 - 78)/2 = 2$ proton bosons and $(98 - 82)/2 = 8$ neutron bosons, altogether 10. In medium-heavy nuclei, the valence protons and neutrons occupy different orbits, therefore, the probability of the creation of pn-pairs is low. IBM-1 does not take into account bosons consisting of pn-pairs.

The bosons are considered, on a phenomenological level, as structureless particles having integer spins. Their states are symmetric with respect to their exchanges, i.e., the interchange of any pair of particles leaves the wave function unchanged. In fact, the bosons may have a rather complicated fermion-pair structure. This structure is investigated in the microscopic theory of the IBM.

The number of valence bosons is finite. This fact leads to important consequences which differ from the predictions of the geometrical collective model.

The truncation of the valence space to s and d bosons is indeed very drastic. Remaining at Talmi's example: $^{154}_{62}\text{Sm}_{92}$ may have $> 3 \times 10^{14}$ different 2^+ states in the shell model. In the IBM this number is reduced by more than 11 orders of magnitude.

- The excitation energy of even-even nuclei depends only on the distribution of valence nucleons into s and d pairs, the energies of the s and d bosons in the field of the central core and the interaction between the bosons, which is assumed to be simple (at most two-body) interaction.

From the above assumptions it follows that group theoretical, algebraic methods can be used in the IBM.

IBM-1 describes the properties of even-even, positive parity levels of medium-heavy and heavy nuclei, the electromagnetic transitions and moments, nuclear radii, transfer reactions, etc. It does not distinguish between pp- and nn-pair bosons.

The IBM-1 is able to treat different collective excitations in a uniform framework. Its *dynamic symmetries* are shown later in [Fig. 2.26](#). The $U(5)$ (five-dimensional unitary group) corresponds to spherical, the $SU(3)$ (three-dimensional special unitary group) to deformed, the $O(6)$ (six-dimensional orthogonal group) to γ -soft nuclei.

Fig. 2.24

Truncation of the configuration space, available for nucleons in IBM-1. The figure is schematic, the truncation is much more drastic in reality

In the IBM-1 simple analytical formulae have been derived for the energy spectra valid in the limiting dynamic symmetries. For example in the U(5) symmetry the level energies (E) are described by the formula

$$E = \varepsilon n_d + \alpha n_d(n_d + 4) + 2\beta v(v + 3) + 2\gamma L(L + 1),$$

where n_d , v , and L are quantum numbers, ε , α , β , and γ are parameters fitted to experimental data. The formula gives a very good description for the energy levels, e.g., built on the ground state of ^{110}Cd (see [Fig. 2.25a](#)).

In contrast with the geometrical collective model, in IBM-1 the number of valence bosons is finite. The consequences of finite boson numbers were verified by the experiments. One can see in [Fig. 2.25b](#), e.g., that the reduced E2 transition probabilities in ^{110}Cd and ^{106}Pd nuclei are better reproduced in IBM-1 calculations than in the harmonic vibrator approximation. In the latter case the allowed phonon number may be infinitely large. (The vibration quanta, i.e., the phonons, are analogous to bosons.)

IBM-1 can also describe rotational bands built on different vibrational levels.

It is a *great merit* of the IBM that it establishes a sound foundation on the connection of the shell model with collective states. It gives an alternative description of collective states based on shell-model considerations.

In view of the simplicity of IBM-1, and the analytical formulae derived from it, the model is used widely for the interpretation of experimental results. Between dynamical symmetries one can use IBM-1 computer programs: PHINT (Scholten 1991) and TQM (Brant et al. 1985, unpublished).

The Bohr–Mottelson geometrical and IBM-1 models give essentially identical results in the phenomenological numerical applications, if the calculations are performed with the same care and with the same number of parameters. Nevertheless the IBM is more comprehensive, and very suitable for numerical calculations with its six parameters. On the other hand, it is rather difficult to find the best IBM fit for individual nuclei; from this point of view the geometrical model can give better results.

The *dynamic symmetries of IBM-1* and the shape transitions among them ([Fig. 2.26](#)) shall now be returned to.

Consider a simple Hamilton operator of the form

$$H = aH_{\text{spher}} - bH_{\text{def}},$$

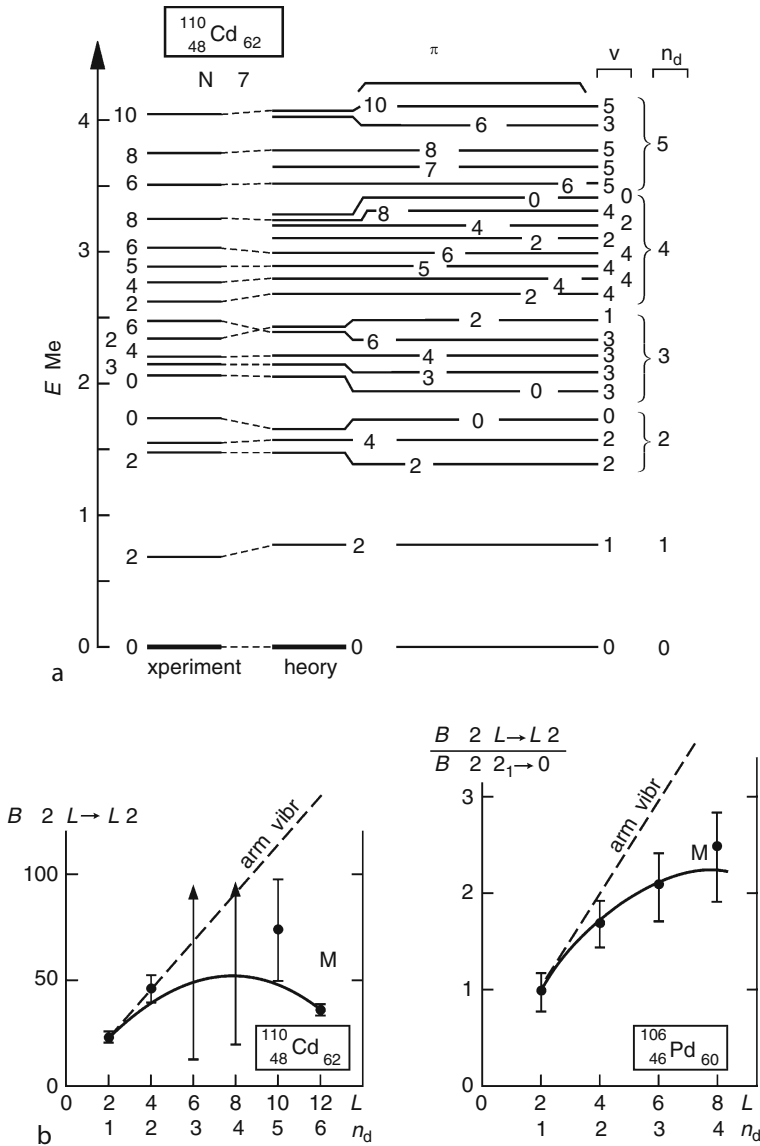

which contains the spherical and deformation driving terms separately (Ising operator). For small b/a values the spherical, for large b/a -s deformed states are characteristic. The Hamilton operator can be written also in the form

$$\hat{H}(N, \eta, \chi) = \eta \hat{n}_d - \frac{1 - \eta}{N} \hat{Q}_\chi \hat{Q}_\chi,$$

where N is the boson number, \hat{n}_d is the number operator of quadrupole bosons, and \hat{Q}_χ is the quadrupole momentum operator of the consistent Q formalism (see, e.g., Iachello and Arima (1987)). Here η and χ are control parameters, playing similar role as the pressure and temperature in statistical physics. The η parameter may change between 0 and 1, the χ between $-\sqrt{7}/2$ (prolate form) and $+\sqrt{7}/2$ (oblate form) values. At $\eta = 0$ the nucleus is deformed and the deformation may be axially symmetric prolate at SU(3), γ -soft at O(6), and axially symmetric oblate at $\bar{\text{SU}}(3)$. If $\eta = 1$, the nucleus is spherical characterized by U(5) dynamic symmetry.

■ Fig. 2.25

(a) The level system built on the ground state of ^{110}Cd . The theoretical results were obtained by the formula $E = \epsilon n_d + \alpha n_d (n_d + 4) + 2\beta\nu (\nu + 3) + 2\gamma L(L + 1)$ of IBM-1 for the U(5) dynamic symmetry. (Based on Bertschy et al. (1995)). (b) Experimental $B(E2; L \rightarrow L-2)$ values (dots) for the ground state bands at ^{110}Cd and ^{106}Pd . The continuous curves denote IBM-1 calculations. The dotted lines show the predictions of harmonic vibrator approximation (Based on Kern (1997))

■ Fig. 2.26

The extended symmetry triangle of IBM-1. At the vertices one can see the dynamic symmetries $U(5)$, $SU(3)$, $O(6)$, $\overline{SU}(3)$, respectively, and some characteristic features of their level systems. The numbers on the transition arrows show relative reduced $B(E2)$ transition probabilities, while $R_{4/2} = E(4_1^+)/E(2_1^+)$ indicates energy ratio. The control parameters of the Ising operator are shown at the key positions. $X(5)$ shows the first-order shape transition between $\beta < 0$ and $\beta > 0$ axially deformed states. η_t denotes a triple point for different transitions (Based on Jolie and Casten (2005) and Iachello (2000, 2001, 2002))

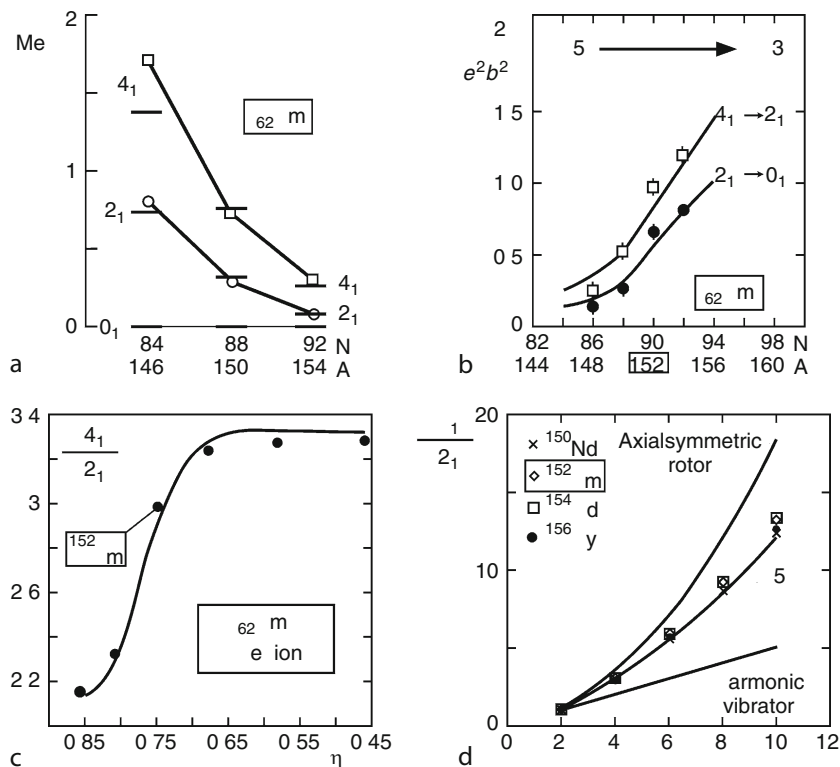

The transition from $U(5)$ to $SU(3)$ symmetry can be seen in ▶ Fig. 2.27a–c for the case of Sm isotopes. Near the magic neutron number $N = 82$, the Sm isotopes are nearly spherical. Here the $E(4_1^+)/E(2_1^+)$ energy ratio is ~ 2 , and the $B(E2; 4_1^+ \rightarrow 2_1^+)$ reduced transition probabilities are small. Far from $N = 82$ the $E(4_1^+)/E(2_1^+)$ energy ratio is ~ 3.3 characteristic of an axially deformed rotor, and the corresponding reduced transition probabilities are large.

^{152}Sm , with some other nuclei, represents an intermediate situation, the $X(5)$ “symmetry” in the coexistence region between the harmonic vibrator and axially symmetric rotor (▶ Fig. 2.27d). At the triple point (η_t) shape transition is possible from spherical to axially symmetric oblate ($\beta < 0$) or prolate ($\beta > 0$) shapes. A good candidate for the triple point behavior is ^{134}Ba . From the triple point, transition is possible also to the triaxial shape (Jolos 2004).

Comprehensive reviews of different versions of the interacting boson and interacting boson–fermion models, as well as surveys of transitions between dynamical symmetries have been published, e.g., by Iachello and Arima (1987), Iachello and Van Isacker (1991), and Fényes (2002).

(b) Reduced $B(E2)$ transition probabilities for Sm isotopes. Dots show experimental, curves IBM-1 theoretical results. The figures a and b are based on Scholten et al. (1978). (c) $E(4_1^+)/E(2_1^+)$ energy ratios in the Sm region versus the control parameter η (fitted to the number of bosons). Dots: experimental data curve: theoretical results. (Based on Jolie and Casten (2005)). (d) The experimental $E(L_1)/E(2_1^+)$ energy ratios for the ground-state band in some rare earth isotopes as a function of angular momentum (L). The curves show predicted values for different symmetries (Based on Iachello (2002))

2.3.6 Clustering

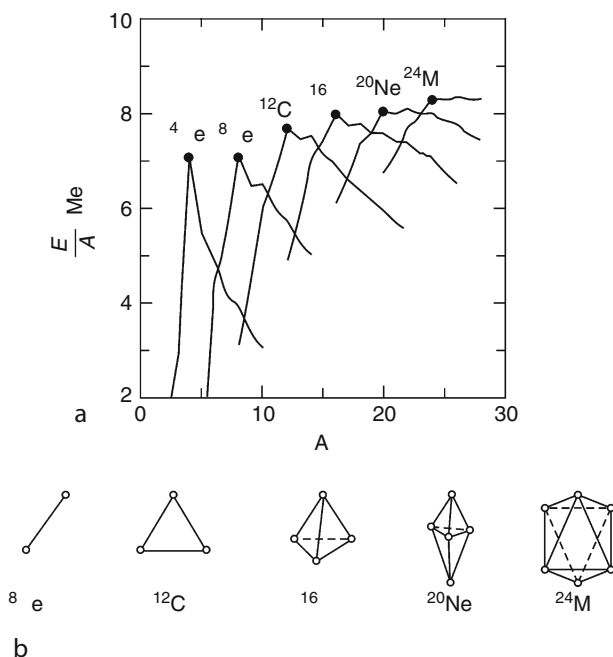

Many nuclear phenomena can be understood better, supposing that the constituents of nuclei are organized into clusters, to be described as coherent superpositions of quasicrystalline structures. The cluster structures were studied already from the very early period of nuclear structure research.

The α -particle is clearly an excellent cluster candidate, as its binding energy per nucleon is extremely high, see Fig. 2.28. The ^8Be , ^{12}C , ^{16}O , ^{20}Ne , and ^{24}Mg nuclei have also outstandingly large binding energy/nucleon indicating α -particle substructures.

A simple phenomenological cluster model has been introduced by Buck et al. (1975). This assumes that some nuclei consist of a structureless core plus an α cluster (i.e., a ^4He nucleus-like composite particle) interacting via simple potentials, and their levels (as well as the

■ Fig. 2.28

(a) Binding energy/nucleon (E_B/A) versus mass number (A) for selected light nuclei. The lines connect data of isotopes of the indicated elements. α -particle cluster candidates are denoted by dots. (b) Possible α -particle quasicrystalline structures in some light nuclei (Based on Hafstad and Teller (1938), Brink (1967), and Freer (2007))

transitions between them) can be understood as the energy levels in this simple potential model. Buck et al. have shown that the model works well for nuclei around the ^{16}O shell closure. Pál and Lovas (1980) applied the alpha-cluster model to nuclei in the ^{40}Ca region, and the basic properties of the lowest-lying rotational-like bands in ^{40}Ca and ^{44}Ti have been well reproduced. In the meantime, the scope of the model has been extended enormously to the Zn, Zr, and Pb regions, to the α -decay, and heavy-cluster decay of all nuclei that decay in these ways; moreover to heavy deformed nuclei, whose decay has not been observed. In the latter cases, the system is described as a composition of two heavy clusters. The model works well in all these cases (Buck et al. 1996, 1997, 1998). More generally, the behavior of light to heavy nuclei is often best understood in terms of their cluster structures.

The existence of cluster substructure in nuclei is supported also by the observation of cluster decay. Besides α particles, the heavy nuclei can emit ^{14}C , ^{24}Ne , ^{28}Mg , ^{32}Si clusters, too. The partial half-lives for these decays depend on the penetrability of the Coulomb barrier in a way very similar to α decay (Mikheev and Tretyakova 1990; see Geiger–Nuttall-type relations in Sect. 2.4.1.1). The heavy cluster decay is a very rare phenomenon. For example, in the decay of ^{223}Ra there were 65×10^9 α particles observed, while only 14 ^{14}C cluster emissions during the same time (Rose and Jones 1984). For the detection of rare clusters solid state track detectors are very suitable.

■ Fig. 2.29

The excitation energy of $^{12}\text{Be}^*$ vs. $J(J+1)$, where J is the angular momentum of the rotating nucleus. The experimental data (dots) are explained supposing $^6\text{He} + ^6\text{He}$ substructure (continuous line) in $^{12}\text{Be}^*$. The dot-dashed line shows extrapolated trajectory of a ground state band in $^{12}\text{Be}^*$ (Based on Freer et al. (1999))

Freer et al. (1999) investigated the breakup of excited $^{12}\text{Be}^*$ nucleus into $^6\text{He} + ^6\text{He}$, using a high-energy ^{12}Be beam inelastically scattered by a C target. The breakup of $^{12}\text{Be}^*$ occurred from rotational states in the 10–25 MeV excitation energy interval, with spins 4–8 \hbar . The inferred moment of inertia is consistent with the decay of $^{12}\text{Be}^*$ from the $(\alpha + 2n) + (\alpha + 2n)$ cluster configuration state (see Fig. 2.29).

For a detailed discussion of cluster structures in nuclei, see the review article of Freer (2007).

2.3.7 Recent Developments

2.3.7.1 Effective Interactions

Nowadays, it is generally accepted that the fundamental theory of the strong interaction is the quantum chromodynamics (QCD). At high energies (and small distances, ≤ 0.1 fm), there is a perturbative theory of the interaction of quarks and gluons, allowing the calculation of measurable physical quantities (cross sections, decay constants, structure functions, etc.) as a function of the coupling constant of the strong interaction. However, at greater distances (≥ 0.5 fm) (in small-energy process) the strength of interaction is so strong that perturbative methods cannot be farther applied. In this region, effective field theories can be used, the meson field theory (see Sect. 2.1.2.3 and Burgess (2007)) and chiral perturbation theory (Bernard and Meissner 2007). These may treat soft hadronic and nuclear processes with success.

For the time being, however, the microscopic theoretical framework for modeling nuclear structure and reactions is mainly quantum mechanics. The most common models are the shell model and its truncated approximations (e.g., IBM), the mean-field theories (like the

Hartree–Fock approach) and the cluster models. The main ingredients of these theories are the effective nucleon–nucleon interactions. The effective interactions usually have simple forms, and are adapted to some special models.

The effective interactions are fitted to nucleon–nucleon collision data and to the properties of nuclei in the stability region. Nevertheless, far from the stability region the effective interactions (e.g., the pairing and spin–orbit interactions) may be different, which must be taken into account.

2.3.7.2 Few Nucleon Systems, Ab Initio Calculations

Recently, major advances have been obtained in the microscopic description of few nucleon systems. Starting from realistic NN -, as well as NNN -interactions (see [Sects. 2.1.2.1](#) and [2.3.1.3](#)), many properties of $3 \leq A \leq 8$ nuclei (energies of ground and excited states, radii, electromagnetic moments, etc.) have been described in agreement with experimental results. These calculations have three different frameworks:

- Variational Monte Carlo (VMC), and a similar Green’s function Monte Carlo (GFMC) method.
- Large-basis no-core shell model (LBNCSM).
- Coupled cluster (CC) expansion methods.

With the latter two methods one can study nuclei up to $A \approx 12$ –16.

These calculations require very large computer capacities, thus they became significant only in the last 2 decades.

The Monte Carlo statistical sampling methods have been known for more than half a century and applied to numerous fields of physics. A simple example for their applications is the determination of the volume of an irregularly shaped body. Let the body be in a unit-volume cube. N points are chosen randomly in the cube, from which N_x falls into the investigated volume. If the number of points is sufficiently large, the expectation value of the sought for volume is N_x/N .

The procedure can be applied also for quantal systems. For example, if one wants to know the ground state energy of a few nucleon system, one may start from a trial wave function $\Psi\{\alpha\}$, where $\{\alpha\}$ denotes variational parameters to be optimized. The expectation value of the Hamiltonian with the trial wave function gives an estimate for the energy of the ground state:

$$E\{\alpha\} = \frac{\langle \Psi | H | \Psi \rangle}{\langle \Psi | \Psi \rangle},$$

where $E\{\alpha\}$ is greater than, or equal to, the true ground-state energy E_0 . If $E\{\alpha\}$ is minimized with respect to all parameters, an approximation to both E_0 and to the wave function of the ground state is obtained. In the variational Monte Carlo procedure the integrals involved in $E\{\alpha\}$ are calculated by the Monte Carlo method.

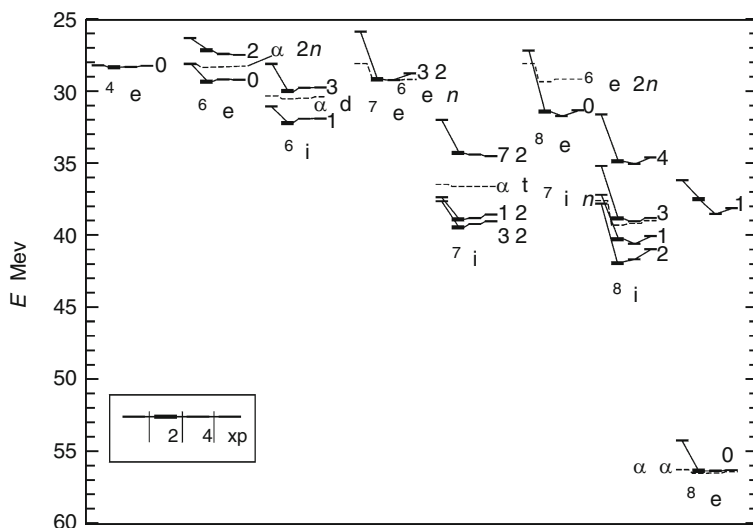

The Green’s function Monte Carlo calculation is very similar; it starts with a trial function Ψ obtained as a result of a variational optimization.

A detailed description of the methods can be found in Carlson and Wiringa (1991), Pudliner et al. (1997), Pieper et al. (2001).

In the calculations of Pieper et al., the Argonne v_{18} two-nucleon potential (v_{ij}), and the Urbana IX (UIX), Illinois 2 (IL2), Illinois 4 (IL4) three-nucleon potentials (V_{ijk}) were used.

For the large-basis no-core shell model calculations see Navrátil et al. (2000), and for coupled cluster calculations Bishop et al. (1990), Heisenberg and Mihaila (1999) as well as Wloch et al. (2005).

The Argonne v_{18} two-nucleon and Urbana (UIX), Illinois (IL2) and Illinois (IL4) three-nucleon potentials were used in the calculations. The *dashed lines* indicate the breakup thresholds

2.4 Nuclear Decay

2.4.1 Alpha Decay

2.4.1.1 Basic Experimental Facts

Among the neutron deficient isotopes of the heavy ($Z \geq 84$) elements, one of the most common decay modes is the α -particle (i.e., ${}^4\text{He}$ nucleus) emission. One can find α activity also in other regions. For example, a number of strongly neutron deficient ${}_{52}\text{Te}$ – ${}_{55}\text{Cs}$ nuclei, rare-earth isotopes with neutron numbers $N \geq 84$, light isotopes of ${}_{72}\text{Hf}$ – ${}_{83}\text{Bi}$ also decay with α -particle emission.

The energy of α particles can be measured with precision magnetic spectrographs, with high-transmission ionization chambers and semiconductor detector spectrometers.

The α particles are emitted with discrete energies. Some typical α -decay schemes are shown in [Fig. 2.31](#). In the α spectrum of even–even nuclei usually the highest-energy α particles have the highest intensity. With decreasing α -particle energy the intensity of the “fine structure lines” of the α spectrum strongly decreases. See, e.g., the α decay of ${}^{220}\text{Rn}$ and ${}^{240}\text{Cm}$ in [Fig. 2.31](#). In the case of odd- A and odd–odd nuclei this regularity is not always experienced.

In some rare cases, α decay can be observed both from the ground state and the excited states of the parent nucleus (e.g., in ${}^{212}\text{Po}$). The α particles emitted from excited states are called long-range (or β -delayed) α particles.

The α -decay energies (Q_α) can be calculated from the atomic masses (M) using the equation

$$Q_\alpha = [M(Z, A) - M(Z - 2, A - 4) - M(2, 4)]c^2, \quad (2.58)$$

where c is the speed of light in vacuum. The α -decay energy is carried away by the emitted α particle and the recoil (daughter) nucleus:

$$Q_\alpha = E_\alpha + E_d = E_\alpha[1 + m_\alpha/m_d], \quad (2.59)$$

where E_α and E_d denote kinetic energies, m_α and m_d are the masses of the α particle and the daughter nucleus, respectively.

[Equation \(2.58\)](#) follows from the momentum conservation law of classical mechanics. In the heavy element region $m_d \gg m_\alpha$, therefore the daughter nucleus carries away only a small part (a few percent) of the total α -decay energy.

From the measured atomic masses one can calculate the α -decay energies. For nuclei, which are stable against β emission and lie on the “nuclear stability line,” the result is shown in [Fig. 2.32](#). Alpha decay is possible energetically already above $A \approx 140$, but owing to the strong dependence of half-lives on α -decay energy, it is observed only for heavier elements (and for the strongly neutron deficient isotopes of medium heavy nuclei).

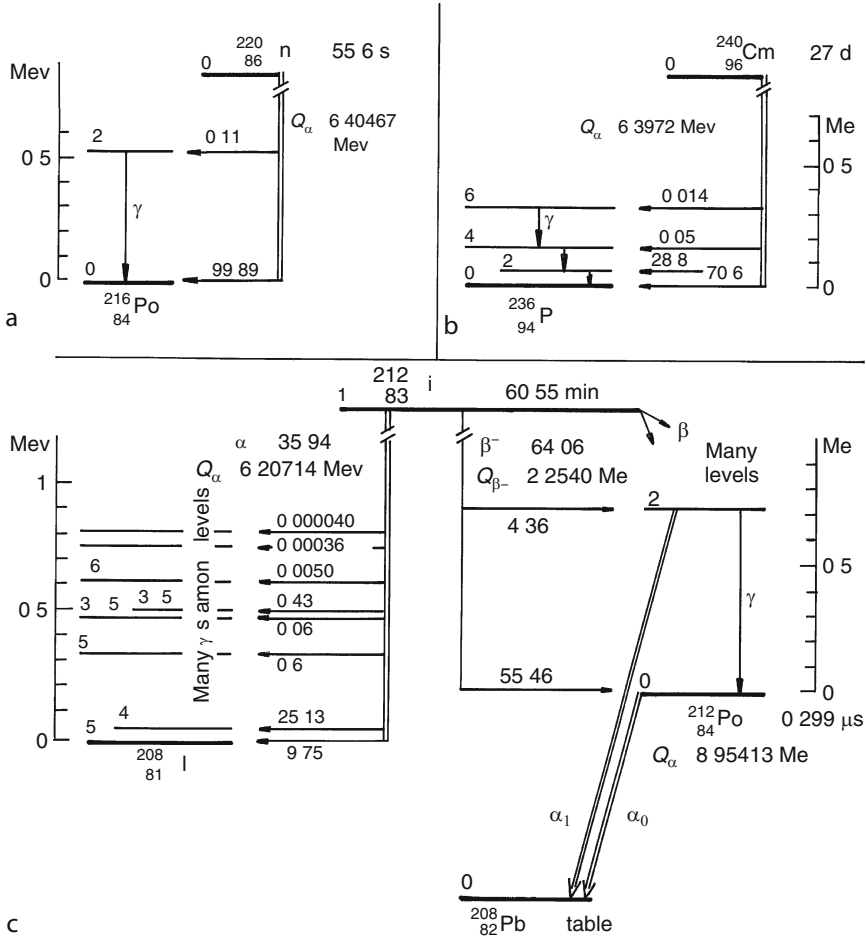

The α -decay energies (Q_α) for some heavy nuclei are shown in [Fig. 2.33](#). It is remarkable that the Q_α curves peak at $N = 128$, which corresponds to the magic $N = 126$ neutron number for the daughter nucleus.

The Weizsäcker semiempirical mass formula ([Eq. \(2.3\)](#)) correctly predicts that α emission can be expected mainly for the heavy elements. Nevertheless, the shell effects, which were not taken into account in the formula, also play an important role in α decay.

The binding energy of the α particle is extremely large, it is 28.3 MeV. The formation of an α particle from two protons and two neutrons leads to a great energy release, provided that the

■ Fig. 2.31

(a) Typical α -decay scheme of an even-even nucleus not too far from the magic atomic number $Z = 82$. (b) Typical α -decay scheme of an even-even nucleus far from magic numbers. (c) α - and β -decay schemes of the odd-odd nucleus ^{212}Bi . From the excited states of ^{212}Po many long-range (i.e., energetic) α -particle groups were observed to the ground state of the double magic ^{208}Pb nucleus, but only two transitions are shown in the figure. The intensity of long-range α_1 particles is several orders of magnitude smaller than the intensity of the α_0 group. The figure is based on data from Firestone et al. (1996)

sum of the binding energies of the decay products exceeds that of the parent nucleus. The heavier the nucleus, the more likely that is the case (cf. [Figs. 2.3](#) and [2.28a](#)). That is why α decay is so common among heavy nuclei, while proton emission occurs only in very neutron-deficient nuclei (e.g., in ^{109}I , $^{112,113}\text{Cs}$, ^{171}Au , and ^{185}Bi).

While the α -decay energies show very little variance ($1.8 \leq Q_\alpha \leq 9.3$ MeV), the observed α partial half-lives span an enormous range from $\sim 10^{-7}$ to $\sim 10^{22}$ s. All the observed half-lives are very long compared to $\leq 10^{-21}$ s, the time needed for an α particle to fly across the nucleus.

Fig. 2.32
 α -decay energies (Q_α) as a function of the mass number (A) for nuclei, which are stable against β emission (Based on Bethe (1937))

Fig. 2.33
 α -decay energies (Q_α) as a function of neutron number (N) in the $122 \leq N \leq 145$ region. Points denote experimental data; the open circles are estimated values from systematic trends. A comprehensive review of Q_α values in different mass regions was given by Audi et al. (2003)

Geiger and Nuttall (1911, 1912) have proposed a simple linear relationship between $\log \lambda$ and $\log R_\alpha$:

$$\log_{10} \lambda = A \log_{10} R_\alpha + B, \quad (2.60)$$

where λ is the decay constant ($\lambda = \ln 2 / T_{1/2}$, $T_{1/2}$ is the α partial half-life), R_α is the range of the α particle in the air, A and B are empirical constants. The range of the α particle in the air depends on its energy E_α approximately as $R_\alpha \approx 0.3 E_\alpha^{3/2}$, where R_α is measured in centimeters (cm), and E_α in megaelectron volts (MeV).

Note that if the nucleus emits both α and β particles, the total decay constant is the sum of the partial decay constants $\lambda_{\text{total}} = \lambda_\alpha + \lambda_\beta$.

On the basis of a much larger database, Taagepera and Nurmia (1961) proposed the following formula, which relates the α partial half-life ($T_{1/2}$) with the α -particle energy (E_α):

$$\log(T_{1/2}) = C_1(Z_d E_\alpha^{-1/2} - Z_d^{2/3}) - C_2, \quad (2.61)$$

where $C_1 = 1.70 \text{ (MeV)}^{1/2}$, $C_2 = 30.0$, $T_{1/2}$ is measured in years, E_α in MeV, and Z_d is the atomic number of the daughter nucleus. Here the α -particle energy (E_α) was used instead of Q_α , which is allowed because in the $140 \leq A_d \leq 240$ region the ratio E_α/Q_α is nearly one (0.973 ± 0.003).  Figure 2.34 shows the α partial half-lives $T_{1/2}$ as functions of $X = Z_d E_\alpha^{-1/2} - Z_d^{2/3}$. The basic line ($H = 0$) goes through the data of ^{215}Rn , ^{226}Ra , ^{238}U , and ^{232}Th . For this line the following constants were obtained:

$$C_1' = 1.61 \text{ and } C_2' = 28.9. \quad (2.62)$$

It is convenient to define a hindrance factor H as

$$H \equiv \log(T_{1/2\text{exp}}/T_{1/2\text{pred}}), \quad (2.63)$$

where $T_{1/2\text{ pred}}$ is predicted using  Eq. (2.60) with parameters of  Eq. (2.61). The experimental $T_{1/2\text{ exp}}$ data can be found between the $H = 0$ and 1.2 lines for α emitters being far from magic numbers. When the α emitters are close to magic numbers, the observed hindrance is greater. The hindrance factors are usually the smallest for even–even and greatest for odd–odd nuclei.

Note that some authors define the hindrance factor as a measure of hindrance with respect to the ground states of even–even nuclei. A survey of hindrance factors for the α decay of the excited states of even–even nuclei, as well as for the odd- A and odd–odd nuclei is given in the heavy element region by Hyde et al. (1964).

Recently Dasgupta-Schubert and Reyes (2007) proposed a new generalized liquid- drop α -decay formula, which was based on experimental data of 373 α -emitting nuclei. According to this formula

$$\log_{10}(T_{1/2}[\text{s}]) = a + bA^{1/6}\sqrt{Z} + \frac{cZ}{\sqrt{Q_\alpha}},$$

where $T_{1/2}[\text{s}]$ is the alpha partial half-life in seconds, Z , A are the atomic and mass numbers of the mother nucleus, Q_α is the energy of α -decay, a , b , c are constants, which depend on the type of the mother nucleus:

Z	N	a	b	c
Even	Even	−25.31	−1.1629	1.5864
Even	Odd	−26.65	−1.0859	1.5848
Odd	Even	−25.68	−1.1423	1.592
Odd	Odd	−29.48	−1.113	1.6971

Logarithm of α partial half-lives $T_{1/2}$ as a function of $X = Z_d E_\alpha^{-1/2} - Z_d^{3/2}$, where E_α is the α -particle energy in MeV, and Z_d is the atomic number of the daughter nucleus (Based on Taagepera and Nurmia (1961))

Alpha decay can also occur from excited state(s) of the parent nucleus. A necessary condition for the practical observability of such long-range α particles is the excitation of high-energy level(s) of the nucleus, generally through previous β decay, from which the

probability of α decay can be comparable with the γ -decay probability. Delayed α radioactivity is expected usually for strongly neutron-deficient nuclei. In the special case of $^{212}\text{Po} \rightarrow ^{208}\text{Pb}$ (► Fig. 2.31c), the α decay is favored, because ^{208}Pb is a double magic nucleus. For the expected regions of β -delayed α radioactivity, see Fényes and Rupp (1968).

The experimental and theoretical problems of the α decay are discussed in more detail, e.g., in the following books and review articles: Hanna (1959), Hyde et al. (1964), Mang (1964), Rasmussen (1965), Marmier and Sheldon (1969), Mukhin (1974), Lovas et al. (1998). Experimentally determined nuclear structure and decay data have been evaluated and are included in the ENSDF (Evaluated Nuclear Structure Data File) database (<http://www.nndc.bnl.gov/ensdf>).

2.4.1.2 One-Body Theory of α Decay

In 1927 Rutherford observed that the 8.78 MeV energy α particles of ^{212}Po were scattered on heavy nuclei according to the Coulomb scattering formula. This indicated that the repulsive Coulomb interaction between the α particle and the target nucleus gives rise to a barrier higher than 8.78 MeV. At the same time, heavy nuclei can emit α particles even with smaller energies. In the framework of classical physics, it was not clear how an α particle can be emitted from the nucleus with an energy that is smaller than the height of the potential barrier (► Fig. 2.35).

■ Fig. 2.35

Coulomb ($V_{\text{COUL.}}$), centrifugal ($V_{\text{CENTRIF.}}$), and total (V) potentials of the α -nucleus interaction as a function of the distance r from the nuclear center. The probability of α -particle emission through the potential barrier strongly depends on the energy of the α particle (E_α) and on the height (and thickness) of the potential barrier (see shaded area). In the $r < R_N$ region the nuclear potential is by far deeper than the figure shows

Gamow (1928) and independently Condon and Gurney (1928, 1929) have shown that such a penetration of an α particle through the potential barrier is possible in quantum mechanics. The mechanism is called tunneling. One can define a penetration factor (penetrability) P which is the ratio of emergent and incident intensities. A detailed quantum-mechanical approximate theory gives the following expression for the penetration factor:

$$P \approx \exp \left[-\frac{2}{\hbar} \int_{R_N}^{r_\alpha} \sqrt{2m \left(\frac{2Ze^2}{r} - Q_\alpha \right)} dr \right], \quad (2.64)$$

where R_N and r_α are radius parameters (Fig. 2.35), R_N is the radius of the daughter nucleus, m is the reduced mass, $m = m_\alpha m_d / (m_\alpha + m_d)$; for heavy elements $m \approx m_\alpha$, $2Ze^2/r$ is the Coulomb potential, $Z (= Z_d)$ is the atomic number of the daughter nucleus, Q_α is the total α -decay energy; for heavy elements $Q_\alpha \approx E_\alpha$, where E_α is the energy of the α particle.

In the one-body model of α decay it is supposed that the α particle has been formed in the surface region of the nucleus with a probability f (for the probabilistic interpretation of the decay constant, see Sect. 9.3.4 in Chap. 9 or Sect. 7.1.2 in Chap. 7), and the probability of α decay, λ , is given by

$$\lambda = \ln 2 / T_{1/2} = fP \approx f \exp \left[-\frac{2}{\hbar} \int_{R_N}^{r_\alpha} \sqrt{2m \left(\frac{2Ze^2}{r} - Q_\alpha \right)} dr \right]. \quad (2.65)$$

The factor f is also called “reduced transition probability.” As in the theory of β decay (Sect. 2.4.2.2) the quantity $T_{1/2} f$ is a measure of the internal decay rate. In the derivation of the formula (2.64), it was assumed that the α particle is emitted with zero angular momentum (and therefore the centrifugal component shown in Fig. 2.35 is zero).

The wave function of the α particle ($\Psi(r) = u(r)/r$) can be determined from the one-dimensional Schrödinger equation

$$-\frac{\hbar^2}{2m} \frac{d^2 u}{dr^2} + \left(\frac{2Ze^2}{r} - Q_\alpha \right) u = 0 \quad (2.66)$$

with appropriate boundary conditions, where m is the reduced mass, and Q_α is the total decay energy for the bare nucleus. Equation (2.65) can be solved, e.g., in the Wentzel–Kramers–Brillouin (WKB) approximation for different regions of the radius, inside and outside the barrier. Bethe (1937) derived an explicit analytical formula for the decay probability λ . The formula is rather complicated, but it can be simplified with convenient approximations introduced by Taagepera and Nurmia (1961). The approximations are as follows.

The factor f before the exponential function in Eq. (2.64) has been found to be approximately proportional to $Z_d^{-4/3}$. For the region $58 \leq Z_d \leq 98$ its value was taken as a constant: $1.9 \times 10^{20} \text{ s}^{-1} = 6.0 \times 10^{27} \text{ a}^{-1}$.

In the exponential factor of Eq. (2.64) the approximation $R_N \approx 1.36 r_0 Z_d^{1/3}$ was used, where $r_0 = 1.5 \times 10^{-13} \text{ cm}$.

It was assumed that the height of the Coulomb barrier is much greater than Q_α . In the $140 \leq A_d \leq 240$ region the α -particle energy E_α was used instead of Q_α , because the recoil energy of the daughter nucleus is very small. With these approximations and with minor fitting of the constant parameters to the experimental data one obtains the Taagepera–Nurmia formula (Eq. (2.60)).

If the α particle carries away an orbital angular momentum l , the height of potential barrier increases with

$$V_{\text{CENTRIF.}} = l(l+1)\hbar^2/(2mr^2). \quad (2.67)$$

Therefore, in the Schrödinger equation (🔗 Eq. (2.65)) the $V_{\text{COUL.}} = 2Ze^2/r$ term must be replaced by $V = V_{\text{COUL.}} + V_{\text{CENTRIF.}}$. According to the calculations of Winslow and Simpson (1954) the effect of the orbital angular momentum (l), taken away by the α particle, on the penetration factor is as follows (🔗 Table 2.8):

■ Table 2.8

Penetration factor for different values of the orbital angular momentum (l) taken away by the α particle

l	0	1	2	3	4	5	6
P_l/P_0	1.000	0.844	0.601	0.363	0.1854	0.0806	0.0299

Rasmussen (1959) derived the following formula for the calculation of the ratio P_l/P_0 :

$$P_l/P_0 = \exp \left[-2.027l(l+1)Z_d^{-1/2}A_d^{-1/6} \right], \quad (2.68)$$

which agrees with the more exact expression up to $l = 6$. The α decay is governed by the strong interaction. Therefore, both the angular momentum and parity conservation laws are valid in the α -emission process. From these conservation laws come the following selection rules:

$$|I_i - I_f| \leq l \leq I_i + I_f \text{ and } \pi_i/\pi_f = (-1)^l, \quad (2.69)$$

where I_i , π_i , and I_f , π_f are the initial and final spins (I) and parities (π) of the nucleus, and l is the angular momentum carried away by the α particle.

The simple one-body model can give a good description of the α decay of even–even nuclei (or in general of the allowed α transitions). The penetration of α particles through the potential barrier plays a central role in the process. It seems that several factors, which were not taken into account in the above treatment, have the same effect on the allowed transitions of different nuclei.

Nevertheless, the applicability of this simple model has severe limitations. It is not expected to give satisfactory results, if the internal structures of the initial and final states of the nucleus are very different. Especially in the case of odd- A or odd–odd nuclei the internal structure can play an important role.

In the one-body model it is supposed that the nucleus is spherical and the potential barrier has a simple form (🔗 Fig. 2.35). In an exact theory, especially in the case of deformed nuclei, more realistic potential barriers must be taken into account. Furthermore the interaction of the emitted α particle with the asymmetric electric field of the deformed nucleus can also modify the α spectrum.

2.4.1.3 Microscopic Theories of α Decay

The microscopic theories of α decay can be divided into several groups. The statistical models were developed in analogy with the statistical theories of nuclear reactions. The α decay is a surface phenomenon, and reliable information on the nuclear surface is available mostly from

reaction data. In these theories, the probability factor f (Eq. (2.64)) is determined from the average-level densities.

Other microscopic models are based on the shell model. In these models, the formation probability of α particles is calculated starting from the nuclear wave function.

In the resonating group model, α -core cluster model configurations are considered, which contain α particles. The shell model can be combined with the cluster model and in this way it can be applied to the description of α decay.

The detailed description of these microscopic models is beyond the scope of the present survey. The interested readers are referred to the review articles of Mang (1964), Hyde et al. (1964), Rasmussen (1965), and Lovas et al. (1998). Only a few works shall be discussed in some detail below.

Spherical Nuclei

In his classical works Mang (1960, 1964) developed an α -decay model in a fairly general form. According to his theory, the α -decay probability λ depends on the penetration factor P_l and the so-called reduced α width δ_{jl}^2 in the following way:

$$\lambda = \frac{1}{h} \sum_{jl} P_l \delta_{jl}^2. \quad (2.70)$$

Here P_l is the same potential-barrier penetration factor as in the one-body model of α decay, δ_{jl}^2/h gives the probability of α particle formation on the nuclear surface in unit time, expressed in terms of the wave functions of the parent and daughter nuclei, and of the α particle, l is the angular momentum of the α particle, and j is the angular momentum of the daughter nucleus. Combination of angular momenta j and l gives J , the angular momentum of the parent nucleus.

Using the measured α -particle energies, Mang (1960) has calculated the δ^2 values for the ground-state to ground-state transitions of even-even (spherical) Po isotopes. Mang's theoretical results reasonably reproduced the ratios of the experimental δ^2 data, for example, the minimum of δ^2 values at the magic number $N = 126$.

Zeh and Mang (1962) have calculated the α -decay probabilities in the Po–Bi region in the vicinity of the double magic ^{208}Pb . The calculations have shown that it is very important to take into account the residual interaction between the valence nucleons. The consideration of the pairing force leads to a substantial increase of the absolute values of the reduced widths (by a factor of ~ 30 or even more), and to a smoothing of the local fluctuations caused by different subshells. The results are sensitive to the shell-model states included in the calculations. The agreement between experimental and theoretical data for the relative values was especially good for even-even nuclei.

Starting from a general theory of nuclear reactions Thomas (1954) deduced the following expression for the α -decay width $\Gamma \equiv \hbar\lambda = \hbar \ln 2 / T_{1/2}$ of a single transition:

$$\Gamma_l(r_c) = 2P_l(r_c) \frac{\hbar^2}{2mr_c} g_l^2(r_c), \quad (2.71)$$

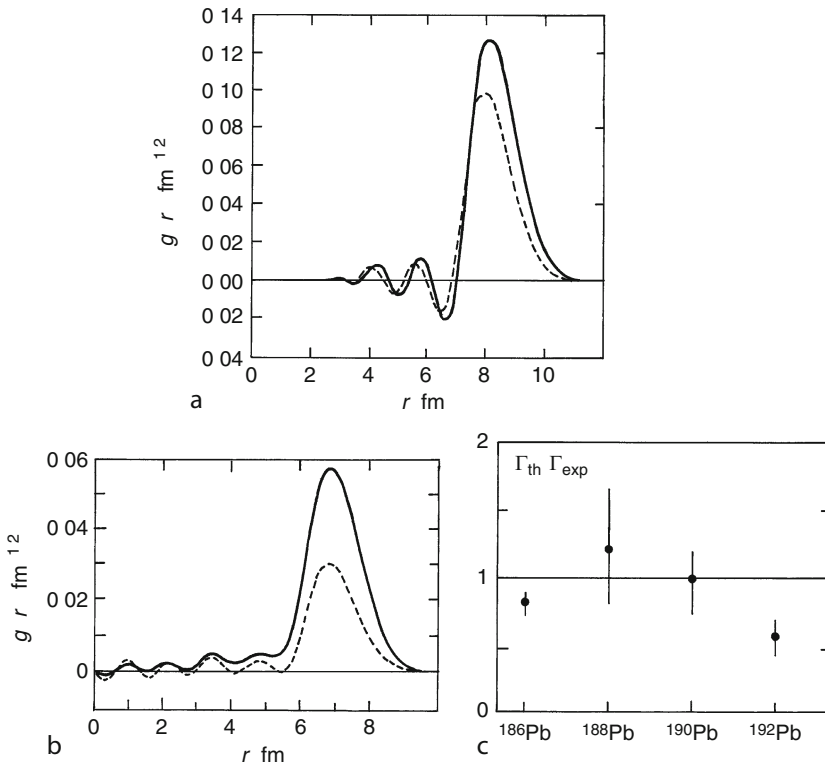

where m is the reduced mass, $g_l(r_c)$ is the formation amplitude of the α particle, which is the projection of the parent state wave function onto the (antisymmetrized) product states of the two fragments, $P_l(r_c)$ is the penetrability of the Coulomb barrier beyond distance r_c from the center.

By using $\Gamma = \hbar\lambda$, one can easily express δ_l^2 in terms of g_l^2 . The width does not depend on r_c , if the latter is chosen beyond the touching point of the α particle and the daughter nucleus, although each factor in ▶ Eq. (2.70) depends on r_c . This formalism, combined with a sophisticated model of the parent nucleus, has been able to reproduce the absolute decay rate (width) of the α decay of ^{212}Po .

By the use of the “cluster-configuration shell model” and the “Gaussian-orbit shell model with preselected random basis,” Varga et al. (1992) and Varga and Liotta (1994) have calculated the $g(r)$ formation amplitude for the $^{212}\text{Po} \rightarrow ^{208}\text{Pb} \alpha$ decay (▶ Fig. 2.36a). For $\Gamma(r_c)$ they obtained 0.72×10^{-15} MeV in the Gaussian shell model and 1.6×10^{-15} MeV in the cluster-configuration shell model, which are close to the experimental value: 1.5×10^{-15} MeV. It was found that the amount of core + α clustering in the ground state of ^{212}Po is 20–30% (Lovas et al. 1998).

■ Fig. 2.36

(a) Radial α -core formation amplitudes $g(r)$ in the ground state of ^{212}Po obtained in the cluster-configuration shell model (solid line) and in the Gaussian shell model (dashed line). See ▶ Eq. (2.70) and Varga and Liotta (1994). (b) Radial α -core formation amplitudes $g(r)$ in the ground state of ^{192}Pb obtained from BCS calculations with proton gaps appropriate for ^{206}Hg (dashed curve) and for ^{188}Hg (full curve) (Insolia et al. 1988). (c) Ratio of theoretical and experimental α -decay widths $\Gamma_{\text{th}}/\Gamma_{\text{exp}}$ for light, spherical Pb isotopes. The theoretical widths were calculated with gaps fitted to the daughter nucleus (Insolia et al. 1988) (The figures were taken from the review article of Lovas et al. (1998))

The pairing interaction gives rise to powerful cluster formation on the nuclear surface, therefore, far from the double magic core nucleus ^{208}Pb , it is reasonable to use the BCS approach to the description of α decay (Lovas et al. 1998).

For the light spherical lead isotopes $^{186,188,190,192}\text{Pb}$ such calculations were performed by Insolia et al. (1988). The results are shown in ► Fig. 2.36b and c. The r_c dependence of the width has a plateau between 8 and 8.5 fm. With such a channel radius and with a prescription simulating the proton–neutron interaction, they obtained a very good agreement with experimental results (► Fig. 2.36c).

Deformed Nuclei

Mang has derived formulae for the treatment of the α decay of deformed nuclei, too, taking into account Nilsson-type wave functions for the nucleons. The calculations of Mang and Rasmussen (1962) for U, Pu, Cm, Cf, Fm isotopes gave reasonable agreement with the experimental results. The calculations again showed that the residual interaction between the valence nucleons plays an important role in the description of α -decay probability.

Following the classical works by Mang (1960, 1964) and using the semiclassical description of barrier penetration by Fröman (1957), the alpha-decay widths Γ_0 have been calculated for the deformed even-even Ra, Rn, and Th isotopes by Insolia et al. (1991) and Delion et al. (1992). They have taken into account the pairing residual interaction and used the BCS approach. The theoretical widths obtained for ground-state to ground-state $l = 0$ transitions are compared with experimental data in ► Table 2.9. The agreement is remarkable. For transitions to the 2^+ states the calculated α -decay widths Γ_2 showed similar agreement with the experimental data.

In the case of spheroidal nuclei the α -particle formation may depend on the direction (in a body-fixed coordinate system). Furthermore, the noncentral electrostatic field of the deformed daughter nucleus may interact with the emitted α particle, causing an increase or decrease of its energy. These problems were discussed by several authors (Hyde et al. 1964). On the basis of these works, one can conclude that the α -particle wave function on the nuclear surface may be quite different for different nuclei. Furthermore, the electric quadrupole field of the strongly deformed daughter nucleus plays an important role in the formation of the intensity of different α -particle groups.

► Table 2.9

Calculated α -decay widths Γ_0 for some even–even deformed nuclei compared with experimental data (Insolia et al. 1991, Delion et al. 1992, Lovas et al. 1998)

Mother nucleus	Experiment (MeV)	Theory (MeV)
^{222}Rn	1.38×10^{-27}	0.70×10^{-27}
^{220}Rn	8.20×10^{-24}	2.7×10^{-24}
^{218}Rn	1.30×10^{-20}	0.25×10^{-20}
^{226}Ra	9.0×10^{-33}	6.6×10^{-33}
^{224}Ra	1.44×10^{-27}	0.83×10^{-27}
^{222}Ra	1.20×10^{-23}	0.52×10^{-23}
^{232}Th	1.01×10^{-39}	0.60×10^{-39}

A systematic survey of a number of At and Rn isotopes shows that the α emission in polar directions is favored mainly by prolate nuclei, while oblate nuclei prefer equatorial emission (Delion et al. 1994).

Note that in some cases the α -particle emission may induce electron knock out from the K or higher electron shells. The effect is very weak. For example the probability of ionization of the K shell in the α decay of ^{210}Po is of the order of 10^{-6} . For a review see Hyde et al. (1964).

2.4.2 Beta Decay

2.4.2.1 Basic Experimental Facts

The β decay of atomic nuclei has three types: β^- and β^+ emission, as well as electron capture (EC). In any of these processes the atomic number of the nucleus changes one unit. In β^- decay electrons (e^-) and in β^+ positrons (e^+) are emitted from the nucleus. In the EC process an electron is captured from the K (or higher) shell. In some cases the same nucleus may undergo β decays of different types (► Fig. 2.37). The β decay may lead to the ground state of the daughter nucleus and/or to excited state(s).

The electron capture process is followed by X-ray and/or Auger electron emission, in which the vacancy in the atomic shell is filled up with an electron from an external shell. As a consequence of the interaction between the nucleus and the electron or positron, a very weak electromagnetic radiation of continuous wavelength distribution (called internal *bremsstrahlung*) is also always present in the radioactive β^\pm and EC decay (Pettersen 1965).

► Fig. 2.37

(a) β -decay modes of ^{40}K (Based on Firestone et al. (1996)). (b) Illustration of the β^+ and β^- decay processes according to the Glashow–Salam–Weinberg theory of weak interaction (see, e.g., Greiner and Müller 1993, Perkins 2000)

Beta decay can take place only when one (or more) of the following mass-energy relations are fulfilled:

$$M(Z, A) > M(Z + 1, A) \quad \beta^- \text{ emission,}$$

$$M(Z, A) > M(Z - 1, A) \quad \text{electron capture,}$$

$$M(Z, A) > M(Z - 1, A) + 2m_0 \quad \beta^+ \text{ emission.}$$

Here the M values denote atomic (not nuclear) masses. $2m_0 = 2 \times 0.511 \text{ MeV}/c^2$ is the sum of rest masses of the emitted β^+ particle and of an atomic electron.

The β -transition energies show a systematic trend, when one plots them as a function of mass number (● Fig. 2.38). The effect of the $Z = 82$ magic number is clearly seen (great gap between the ${}_{81}\text{Tl} \rightarrow {}_{82}\text{Pb}$ and ${}_{82}\text{Pb} \rightarrow {}_{83}\text{Bi}$ transition energies).

The energy of β decay varies from near zero up to 25–30 MeV, while the β partial half-lives vary in a very wide range from $\sim 10^{-3} \text{ s}$ up to $\geq 10^{24} \text{ s}$. The β^+ and β^- energy spectra show continuous distributions (● Fig. 2.39a). As both the initial and final states have well-defined quantum energies, Pauli postulated (in 1931) the existence of a neutral particle (called neutrino), which takes away the missing energy difference. An indirect proof of the existence of the antineutrino was given by Csikai and Szalay (1957) in a cloud chamber photo of the ${}^6\text{He} \rightarrow {}^6\text{Li} \beta^-$ decay (● Fig. 2.39b).

■ Fig. 2.38

β -decay energies (Q_β) of odd- A nuclei from $A = 199$ to 229. Full circles denote experimental values, open circles indicate data estimated from systematic trends. The lines ascending to the right connect isotopes with $N, N + 2, \dots$. The lines descending to the right connect isotones with $Z, Z + 2, \dots$. Open circles are connected by dashed lines for clarity. $Q_{\beta^-} = M(A, Z) - M(A, Z + 1)$, $Q_{\beta^+} = M(A, Z) - M(A, Z - 1)$, where M denotes the atomic mass. A comprehensive review of evaluated Q_β values in different mass regions can be found in Audi et al. (2003)

■ Fig. 2.39

(a) A typical β spectrum. p is the momentum of the β particle (in arbitrary units), $N(p)$ is the number of β particles emitted in a unit momentum interval. (b) Cloud chamber photo of the ${}^6\text{He}$ β^- decay ($T_{1/2} = 0.807$ s). The directions of the tracks of the β^- particle and the recoiled nucleus are not opposite, which indirectly indicates the presence of a third, neutral, undetected particle in the β decay (Csikai and Szalay 1957)

Free antineutrinos were detected directly first from a high-flux reactor through an inverse β -decay process: $p + \bar{\nu}_e \rightarrow n + e^+$ (Reines and Cowan 1959; Reines et al. 1960). The rest mass of the neutrino can be studied, e.g., by a careful analysis of the β spectrum near to the maximum β -ray energy. Some properties of neutrinos (type, mass, charge, spin) are summarized in ► Table 2.1.

The hydrogen burning in the Sun ($4p \rightarrow {}^4\text{He} + 2e^+ + 2\nu_e + Q_{\text{eff}}$) produces low energy (≤ 20 MeV) electron neutrinos, but the flux $\Phi(\nu_e)$ of neutrinos detected fell insistently short of the flux expected. Some of the electron neutrinos produced in the solar core changed flavor. The result, interpreted in this way, is

$$\frac{\Phi(\nu_e)}{\Phi(\nu_e) + \Phi(\nu_{\mu,\tau})} = 0.340 \pm 0.023(\text{stat.}) \pm 0.030(\text{syst.})$$

(Aharmin et al. 2005, Sudbury Neutrino Observatory, Canada). This result clearly shows that $\Phi(\nu_{\mu,\tau})$ is non zero. The KamLAND (Japan) experiment, which studies reactor electron antineutrinos ($\bar{\nu}_e$) traveling ~ 180 km to reach the detector, confirmed the flavor change.

The cosmic rays produce high-energy ($\geq \text{GeV}$) neutrinos in the Earth's atmosphere. One can study the downward-going atmospheric neutrinos in an underground detector, and also the upward-going ones, which come from the opposite side of the Earth, thus traveling much more in the Earth before reaching the detector. The analysis of the Super-Kamiokande (Japan) experimental results shows that some mechanism does change the ν_μ flux

while it is traveling through the Earth. This change-of-flavor effect was confirmed in the accelerator-generated high energy muon neutrino experiments, too. In the MINOS (USA) experiments the accelerator–detector distance was 735 km, in the K2K (Japan) experiments it was 250 km.

Thus there is now compelling evidence that solar, reactor, atmospheric, and accelerator neutrinos change their flavor from one to another.

The neutrino change of flavor can be interpreted also theoretically. It is supposed that the neutrinos are created (or annihilated) in different flavor eigenstates ($|v_e\rangle$, $|v_\mu\rangle$, $|v_\tau\rangle$), which are superpositions of different mass eigenstates ($|v_1\rangle$, $|v_2\rangle$, $|v_3\rangle$). The connection between the different eigenstates can be expressed in matrix form:

$$\begin{pmatrix} |v_e\rangle \\ |v_\mu\rangle \\ |v_\tau\rangle \end{pmatrix} = \begin{pmatrix} U_{e1} & U_{e2} & U_{e3} \\ U_{\mu1} & U_{\mu2} & U_{\mu2} \\ U_{\tau1} & U_{\tau2} & U_{\tau3} \end{pmatrix} \begin{pmatrix} |v_1\rangle \\ |v_2\rangle \\ |v_3\rangle \end{pmatrix}.$$

(Pontecorvo–Maki–Nakagawa–Sakata matrix.)

If all neutrinos were to be massless, there would be no transitions between neutrinos. The above matrix relation assumes that neutrinos have masses, and, if so, the neutrinos in different mass eigenstates may travel with different energies. Thus, according to the Schrödinger equation, phase difference will be created between the neutrino components of different masses, and the difference will depend on the distance. This can lead to the change of neutrino flavor.

If one considers only $v_e \leftrightarrow v_\mu$ transitions, the above matrix equation can be simplified to

$$\begin{pmatrix} |v_e\rangle \\ |v_\mu\rangle \end{pmatrix} = \begin{pmatrix} \cos \theta & \sin \theta \\ -\sin \theta & \cos \theta \end{pmatrix} \begin{pmatrix} |v_1\rangle \\ |v_2\rangle \end{pmatrix}.$$

This transformation contains only one free parameter, the θ mixing angle.

Based on experimental data, one can determine the mass difference square (Δm^2) and mixing angles (θ) for different neutrino transitions. The results are as follows.

From solar and reactor neutrino experiments ($\Delta m_{ij}^2 \equiv m_i^2 - m_j^2$):

$$\Delta m_{\text{solar}}^2 \approx \Delta m_{12}^2 = (7.59 \pm 0.21) \times 10^{-5} \text{eV}^2/\text{c}^4 \text{ and } \tan^2 \theta_{\text{solar}} = 0.47 \pm 0.06.$$

From atmospheric and accelerator neutrino experiments:

$$1.9 \times 10^{-3} \text{eV}^2/\text{c}^4 < \Delta m_{\text{atm}}^2 \approx \Delta m_{23}^2 < 3.0 \times 10^{-3} \text{eV}^2/\text{c}^4 \text{ and } \sin^2(2\theta_{\text{atm}}) > 0.90.$$

This implies that neutrinos have masses and mix. Furthermore the experimental data show quasi-two-neutrino transitions: $v_e \leftrightarrow v_\mu$ for solar and reactor neutrinos, and $v_\mu \leftrightarrow v_\tau$ for atmospheric and accelerator neutrinos.

The neutrino mass, mixing, and flavor change are discussed in detail by Kayser in Particle Data Group (2008).

Detailed investigations show that there are two types of electron neutrinos, which differ in their interactions with matter (different cross sections). The electron neutrino is denoted usually by v_e , the antineutrino by \bar{v}_e . They take part in the β -decay processes as follows:

$$(Z, A) \rightarrow (Z + 1, A) + e^- + \bar{v}_e,$$

$$(Z, A) \rightarrow (Z - 1, A) + e^+ + v_e,$$

$$(Z, A) \rightarrow (Z - 1, A) + v_e,$$

which can be deduced to processes (► Fig. 2.37b)

$$n \rightarrow p + e^- + \bar{\nu}_e,$$

$$p \rightarrow n + e^+ + \nu_e,$$

$$p + e^- \rightarrow n + \nu_e, \text{ respectively.}$$

Since the neutrino does not ionize matter, its magnetic moment (μ_ν) must be very little or zero. It is estimated that $\mu_\nu < 10^{-7} \mu_B$, where μ_B is the Bohr magneton. The measured cross section of the $p + \bar{\nu}_e$ reaction in the experiment by Reines and Cowan (1959) has been found to be $\sigma \approx 10^{-43} \text{ cm}^2$, which, in condensed matter (where the concentration of protons is roughly $n \approx 10^{22} \text{ cm}^{-3}$), corresponds to the average mean free path $\lambda = 1/(n\sigma) \approx 10^{21} \text{ cm} = 10^{16} \text{ km} \approx 1,057 \text{ light years}$. This makes the direct observation of antineutrinos very difficult.

From the relativistic expression of the total energy, $E = m_\nu c^2 (1 - u^2/c^2)^{-1/2}$, it follows that if the neutrino rest mass (m_ν) is close to zero, its speed (u) must be close to the speed of light (c).

The experimental and theoretical problems of β decay are treated in more detail in several review articles and books (Deutsch and Kofoed-Hansen 1959; Wu 1965; Konopinski and Rose 1965; Wu et al. 1965; Wu and Moszkowski 1965; Marmier and Sheldon 1969; Mukhin 1974; Greiner and Müller 1993; Heyde 1999). Experimentally determined nuclear structure and decay data are evaluated and included into the ENSDF (Evaluated Nuclear Structure Data File) database (www.nndc.bnl.gov/ensdf).

2.4.2.2 Theory of β Decay

Based on the analogy with γ radiation, the theory of β decay was formulated first by Fermi (1933, 1934). The basic assumptions of his theory are as follows.

The e^\pm and the neutrino are not present in the nucleus; they are created only in the β -decay process, just as the γ quantum in the γ decay. In contrast with the strong interaction, the “weak interaction” between nucleons can be treated as a very weak perturbation. Then, according to the time-dependent perturbation theory of quantum mechanics, the transition probability in unit time (P_{fi}) between the initial (i) and final (f) states of the system is proportional to the final state density ($\rho_f = dn/dE_0$) and $|H_{fi}|^2$, where H_{fi} is the matrix element of the Hamiltonian H of the weak interaction:

$$P_{fi} = \frac{2\pi}{\hbar} |H_{fi}|^2 \frac{dn}{dE_0}, \quad (2.72)$$

$\hbar \equiv h/(2\pi) \approx 6.582 \times 10^{-16} \text{ eV s}$, E_0 is the total decay energy, and dn is the number of accessible states in the energy interval ($E_0, E_0 + dE_0$) (cf. ► Eq. (2.29)). The matrix element H_{fi} can be expressed as

$$H_{fi} \equiv \int \Psi_f^* H \Psi_i d\tau, \quad (2.73)$$

where $d\tau$ is the volume element, Ψ_i and Ψ_f are the initial and final normalized wave functions. It is useful to consider the different β -decay processes: $n \rightarrow p + e^- + \bar{\nu}_e$ and $p \rightarrow n + e^+ + \nu_e$ in a uniform framework, in which one nucleon is transformed into another one and a pair of leptons are created in the weak interaction. Then “electron” and “neutrino” stand for “positron” and “antineutrino” as well.

The final state density can be derived from Heisenberg's uncertainty relation. The space coordinates shall be denoted by x, y, z , and the momentum coordinates by p_x, p_y, p_z . Then, according to the uncertainty relation (in the form used by Fermi (1934))

$$\Delta x \Delta y \Delta z \Delta p_x \Delta p_y \Delta p_z \approx h^3,$$

that is the product of the uncertainties of the space and momentum coordinates is approximately equal to h^3 . This means a restriction on the possible states in a given phase volume. If the electron can be found in spatial volume $V \approx \Delta x \Delta y \Delta z$, the number of electron states in the momentum interval $(p, p + dp)$ is

$$dn_e = V \frac{4\pi p^2 dp}{h^3}.$$

A similar relation holds for neutrinos. Then the state density dn/dE_0 around the total energy of the electron and neutrino ($E_0 = E + E_v$) can be expressed as a product:

$$\frac{dn}{dE_0} = V^2 \frac{16\pi^2}{h^6} p^2 p_v^2 \frac{dp_v}{dE_0} dp. \quad (2.74)$$

If one considers the neutrino massless, $p_v c = E_v = E_0 - E$ (c is the speed of light in vacuum) and neglecting the small recoil energy of the parent nucleus, one gets

$$\frac{dn}{dE_0} = V^2 \frac{16\pi^2}{c^3 h^6} p^2 (E_0 - E)^2 dp. \quad (2.75)$$

This expression is called a “statistical factor”, which gives the mean density of possible final states in the electron–neutrino field.

The interaction matrix element (Eq. (2.72)) can be written in the form

$$H_{fi} = g \int \psi_f^* \varphi_e^*(\mathbf{r}) \varphi_v^*(\mathbf{r}) M \Psi_i d\tau, \quad (2.76)$$

where $\psi_f, \varphi_e, \varphi_v$ are the wave functions of the final (daughter) nucleus, electron, and neutrino, respectively; g is an empirical coupling constant of the weak interaction. This coupling constant is analogous to the nucleon charge in the γ -ray emission. The full Hamiltonian is gM .

The interaction of neutrinos with the nucleus and surrounding matter is very weak, and therefore the neutrino wave function can be approximated by a plane wave

$$\varphi_v(\mathbf{r}) = V^{-1/2} \exp[i(\mathbf{k}_v \mathbf{r})] \approx V^{-1/2} [1 + i(\mathbf{k}_v \mathbf{r}) - (\mathbf{k}_v \mathbf{r})^2/2 + \dots] \approx V^{-1/2}, \quad (2.77)$$

where $\mathbf{k}_v = \mathbf{p}_v/\hbar$ is the neutrino wave vector and $V^{-1/2}$ is a normalization factor. In the expansion, it is enough to retain only the first term, because the size of the nucleus is very small compared to the volume in which the neutrino can be found, and $p_v = (E_0 - E)/c$. A similar expansion can be applied to the electron wave function, if the electromagnetic interaction between the electron and nucleus is not significant (for light nuclei and electron kinetic energies ≥ 200 keV):

$$\varphi_e(\mathbf{r}) = V^{-1/2} \exp[i(\mathbf{k}_e \mathbf{r})] \approx V^{-1/2} [1 + i(\mathbf{k}_e \mathbf{r}) - (\mathbf{k}_e \mathbf{r})^2/2 + \dots] \approx V^{-1/2}. \quad (2.78)$$

Thus the electron and neutrino wave functions can be considered nearly constant within the nucleus. Then

$$H_{fi} = \frac{g}{V} \int \psi_f^* M \Psi_i d\tau = \frac{g}{V} M_{fi}. \quad (2.79)$$

Here M_{fi} is the transition matrix element between the initial Ψ_i and final ψ_f nuclear states. Its value depends on the overlap of the initial and final wave functions. If they are nearly identical, M_{fi} is large. If Ψ_i and ψ_f are very different, M_{fi} is small. M_{fi} can be computed, if the structures of the parent and daughter nuclei, as well as the Hamilton operator of weak interaction are known. Substituting [Eqs. \(2.74\)](#) and [\(2.78\)](#) into [Eq. \(2.71\)](#) one obtains

$$P_{fi}(p)dp = N(p)dp = C|M_{fi}|^2 p^2 (E_0 - E)^2 dp, \quad (2.80)$$

where $C = g^2/(2\pi^3 c^3 \hbar^7)$ is a constant. Note that the Fermi constant of the weak interaction is defined by the expression $G_F/\sqrt{2} \equiv g^2/(8M_W^2)$ in particle physics (in units $\hbar = 1, c = 1$). The numerical constants of the formula are introduced from historical reasons. M_W is the mass of the W boson. $G_F/(\hbar c)^3 = 1.16637(1) \times 10^{-5} \text{GeV}^{-2}$ (Particle Data Group 2008). The Coulomb interaction between the electric charge of the nucleus and the β^\pm particle can modify the shape of the β spectrum. This effect becomes important especially in the case of heavy nuclei and low-energy β particles. The detailed calculations show that by the introduction of an $F(Z, E)$ factor in [Eq. \(2.79\)](#) this effect can be taken into account:

$$N(p)dp = C|M_{fi}|^2 F(Z, E) p^2 (E_0 - E)^2 dp, \quad (2.81)$$

where Z is the atomic number of the decaying nucleus, E_0 is the total decay energy, E is the kinetic energy of the electron, p is the momentum of the electron,

$$M_{fi} = \int \psi_f^* M \Psi_i d\tau$$

(see [Eq. \(2.78\)](#)), and C is defined as in [Eq. \(2.79\)](#). The numerical values of the Coulomb correction (or Fermi) function $F(Z, E)$ are given in [Fig. 2.40](#).

Experimental and theoretical results can be easily compared by plotting the $[N(p)/(F(Z, E) p^2)]^{1/2}$ values as a function of $(E_0 - E)$, as suggested first by Kurie et al. (1936). [Figure 2.41](#) shows the Kurie plot for the β^- decay of ^{35}S . The straight-line character of the plot indicates that the matrix element $|M_{fi}|^2$ does not depend on the electron energy. The value of $|M_{fi}|^2$ is near to one, as is usual with allowed transitions. For forbidden transitions (see later) $|M_{fi}|^2$ may be much less than one.

The probability of β -decay in unit time (i.e., the decay constant λ) can be calculated by integration of $N(p)dp$ from $p = 0$ up to p_{\max} :

$$\lambda = \frac{\ln 2}{T_{1/2}} = \int_{p=0}^{p_{\max}} N(p)dp = C \int_0^{p_{\max}} |M_{fi}|^2 F(Z, E) p^2 (E_0 - E)^2 dp, \quad (2.82)$$

with $C = g^2/(2\pi^3 c^3 \hbar^7)$. In allowed transitions $|M_{fi}|$ does not depend on the energy thus it can be shifted before the integral. The integral

$$\int_{p=0}^{p_{\max}} F(Z, E) p^2 (E_0 - E)^2 dp \equiv f(Z, E_0) \quad (2.83)$$

has been evaluated and tabulated (Wapstra et al. 1959; Dzhelepov et al. 1972) for different Z and E_0 values (see [Fig. 2.42a](#) and [b](#)). The so-called Fermi integral function $f(Z, E_0)$ is approximately proportional to E_0^5 at the highest transition energies. The probability of β decay sharply increases with increasing decay energy. The quantity

$$f(Z, E_0) T_{1/2} \quad (2.84)$$

■ Fig. 2.40

Coulomb correction factor $F(Z,E)$ for β^+ and β^- emission as a function of the kinetic energy of the β particle (Based on Dzhelepov et al. (1972))

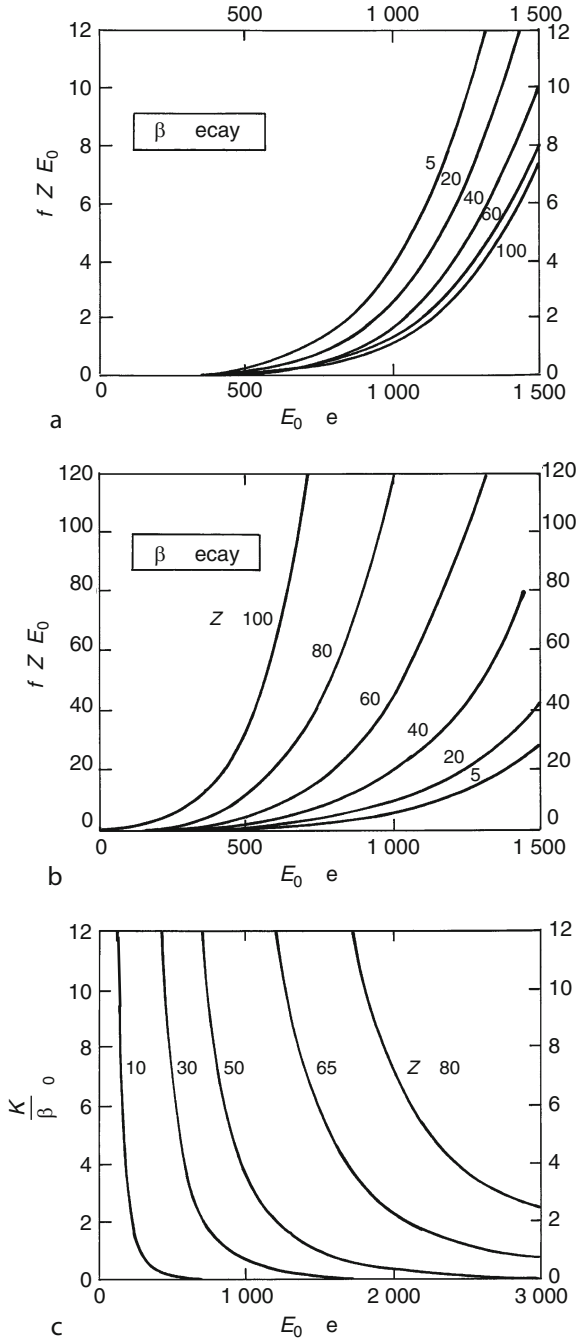

■ Fig. 2.41

Kurie plot for the $^{35}\text{S} \rightarrow ^{35}\text{Cl} \beta^-$ decay ($T_{1/2} = 87.51 \text{ d}$). For notations see Eq. (2.80). Based on Albert and Wu (1948). The intersection with the energy axis is equal to E_0

■ Fig. 2.42

(a, b) The Fermi integral function $f(Z, E_0)$ for β^+ and β^- decay, respectively. E_0 is the maximum kinetic energy of the β particle. (c) K electron capture per β^+ branching ratio $(K/\beta^+)_0$ for allowed transitions as a function of E_0 (The figures are based on Dzhelepov et al. (1972))

is characteristic of the transition matrix element, and it is determined by the structure of the nucleus. The product $f(Z, E_0) T_{1/2}$ is usually denoted by ft , it is measured in seconds and called “comparative half-life.” As the ft values vary in a wide range, the $\log ft$ values are usually given. The β -decay transitions are in general classified according to their comparative half-lives.

For the determination of the $\log ft$ values nomograms have been constructed. The input data are the experimental maximum β^\pm (or K capture) energy, the partial half-life ($T_{1/2}$), and the nuclear charge number (Z) (Wapstra et al. 1959).

Empirical $\log ft$ values for some β decays are presented in ▶ [Table 2.10](#). The first column shows the β transition and the probable valence-orbit shell-model configurations in the mother and daughter nuclei. The next columns give the $\log ft$ value, the spin ($\Delta I = I_f - I_i$), and parity ($\Delta\pi$) changes in the β decay. The table shows that the β transitions can be

■ **Table 2.10**

Empirical $\log ft$ values for some β decays. ΔI and $\Delta\pi$ denote spin and parity changes, respectively. The $\log ft$, ΔI , and $\Delta\pi$ data were taken from Firestone et al. (1996)

	$I_i^\pi \rightarrow I_f^\pi$	$\log ft$	ΔI	$\Delta\pi$	Remark
Superallowed transitions					
$n \rightarrow p$	$s_{1/2+} \rightarrow s_{1/2+}$	3.0	0	No	Mixed Fermi and Gamow–Teller transition

Third forbidden ($n = 3$) transitions					
$^{19}_{19}\text{K}_{21} \rightarrow ^{18}_{18}\text{Ar}_{22}$	$4^- \rightarrow 0^+$	21.0	4	Yes	Unique ($\Delta I = n + 1$)

approximately divided into groups according to their $\log ft$ values. There are superallowed, allowed, first, second, and third forbidden transitions, with ft values increasing by orders of magnitude.

Nevertheless, the classification of β transitions according to ft values can only be made roughly. For the exact classification one must start from the interaction matrix element H_{fi} given in [Eq. \(2.75\)](#), which involves the overlap integral of initial and final nuclear wave functions and the power expansions of φ_ν and φ_e ([Eqs. \(2.76\)](#) and [\(2.77\)](#)).

The first terms in the expansions of φ_ν and φ_e generate allowed transitions. In this case the matrix element is independent of electron and neutrino energies. In allowed transitions there is no parity change between the initial and final nuclear states (“ $\Delta\pi$ no”), and the orbital angular momentum change is zero. If the electron and neutrino are emitted with antiparallel spins ($\downarrow\uparrow$), the allowed transition is called Fermi transition, and the spin change is $\Delta I = 0$. If the electron and neutrino are emitted with parallel spins ($\uparrow\uparrow$), the allowed transition is called Gamow–Teller transition, and the spin change may be $\Delta I = 0$ or ± 1 .

A strong overlap of initial and final wave functions is expected for mirror nuclei, in which the mass numbers are identical, but the atomic number in one nucleus is equal to the neutron number of the other. The large overlap integral results in a very low ft value (superallowed transitions). Most of the known β emitters decay by allowed or superallowed transitions. Among the light nuclides there are many mirror pairs.

The second and following terms in the expansions of [Eqs. \(2.76\)](#) and [\(2.77\)](#) generate first, second, third, etc., forbidden transitions. As the integration in [Eq. \(2.75\)](#) can be confined to the nuclear volume, where r is very small, the weights of the successive terms in [Eqs. \(2.76\)](#) and [\(2.77\)](#) strongly (by orders of magnitude) decrease.

The first forbidden ($n = 1$) transitions are characterized by $\Delta I = 0, \pm 1, \pm 2$ spin and “ $\Delta\pi$ yes” parity changes. If $\Delta I = n + 1$, the transition is called “unique.”

In the “true” second forbidden ($n = 2$) transitions there is no parity change (“ $\Delta\pi$ no”), and $\Delta I = \pm 2, \pm 3$. In unique second forbidden transitions $|\Delta I| = 3$. In another group of second forbidden transitions the spin change is $\Delta I = 0, \pm 1$, and there is no parity change (“ $\Delta\pi$ no”). These latter selection rules are the same as for allowed transitions, but the corresponding transitions are weak, because of the small $(\mathbf{kr})^2$ factors in the electron and neutrino wave functions.

In n times forbidden transitions $\Delta I = n, n + 1$ and $\pi_i\pi_f = (-1)^n$. In the region $6 < \log ft < 9$ both allowed and first forbidden β -transitions occur. For example, the $^{32}\text{P } \beta^- 1^+ \rightarrow 0^+$ and $^{22}\text{Na } \beta^+ 3^+ \rightarrow 2^+$ decays are allowed Gamow–Teller transitions, although they have rather large $\log ft$ values of 7.9 and 7.4, respectively. Second, third, and fourth forbidden transitions were observed rarely; they are mainly in the region $10 < \log ft$.

In the case of the *electron capture (EC) decay*, the capture of an atomic-shell electron by the nucleus can be considered as an inverse β^+ decay: $p + e^- \rightarrow n + \nu_e$. The main difference is that in EC the neutrino spectrum is discrete, because the energy of the captured electron has a well-defined value. The theory of EC is analogous to the theory of β^\pm decay and also starts from [Eq. \(2.71\)](#).

The capture from K-shell is usually about one order of magnitude more intensive than the capture from L, M, ... shells, because the K-electrons are much closer to the nucleus. Nevertheless, when the K-capture is forbidden owing to energetic reasons, an electron may be captured only from L (or higher) shell.

[Figure 2.42c](#) shows the $(K/\beta^+)_0$ branching ratios for allowed transitions. The EC process always accompanies the β^+ decay, but the electron capture usually becomes dominating only in

heavy nuclei and/or at low decay energies. The overlap of K-electron wave function with the nucleus may be significant. If the decay energy is smaller than $2m_0c^2 = 1,022$ keV, only EC decay can occur. In experiments mostly allowed and superallowed EC transitions have been observed.

2.4.2.3 Types of the Weak Interaction

One of the central problems in the theory of β decay is the determination of the Hamilton operator of the weak interaction (Eqs. (2.71) and (2.72)). H should be invariant against proper Lorentz transformation, otherwise it would be possible to determine an absolute time, which is impossible according to the theory of relativity. Then, from Dirac's relativistic wave mechanics for spin 1/2 particles, it follows that there may be five classes of weak interaction terms, each transforming in a particular way under rotation and space inversion: scalar (S), vector (V), antisymmetric tensor of second rank (T), axial vector (A), and pseudoscalar (P). As one cannot exclude any of these from the beginning, a linear combination of all five interactions must be considered:

$$\overline{H} = g \sum_{i=1}^5 C_i \overline{H}_i; \quad \sum_{i=1}^5 |C_i|^2 = 1. \quad (2.85)$$

Here \overline{H} and \overline{H}_i are the generalized Hamiltonians (Wu and Moszkowski 1965) and the C_i -s are the coupling strengths. The \overline{H}_i operators have different shapes for S, V, T, A, and P classes of weak interaction. They are complicated combinations of the so-called γ matrices of the relativistic quantum mechanics.

One can get information on the possible coupling strengths from general symmetry properties of space and time. From the homogeneity of space and time follow the laws of conservation of momentum and energy, respectively, while from the spatial isotropy follows the law of conservation of angular momentum. (Homogeneity of space means that it has equal structure at all positions \mathbf{r} . Isotropy of space means that all directions are equivalent.) The Schwinger–Lüders–Pauli theorem states that the interaction Hamiltonian is invariant under the combined CPT operation, where C denotes charge conjugation (particle \leftrightarrow antiparticle transformation), P is the parity operation ($\mathbf{r} \rightarrow -\mathbf{r}$, space inversion), and T is the time reversal operator ($t \rightarrow -t$). On the other hand, one can draw conclusions on the possible coupling strengths from different experiments. Some of them are as follows.

- Investigation of pure Fermi $0^+ \rightarrow 0^+$ transitions (e.g., $^{14}\text{O} \rightarrow ^{14}\text{N}$, $^{50}\text{Mn} \rightarrow ^{50}\text{Cr}$ decays), in which both the ft and the M_{fi} can be determined and the g_F constant derived (see E. (2.82)).
- The study of neutron β decay: $n \rightarrow p + \beta^- + \bar{\nu}_e$, where the Fermi and Gamow–Teller transitions are equally allowed. As the n and p are mirror nuclei, the matrix elements $|M_F|^2$ and $|M_{GT}|^2$ can be easily calculated. Consequently, one can derive the $|C_{GT}/C_F|^2$ and also the $|g_{GT}/g_F|^2$ ratios using the experimentally determined ft value.
- Electron-neutrino angular correlation experiments.
- Several experiments in connection with parity nonconservation in β decay.

Based on invariance principles and on experimental results, one can make the following conclusions. The possible forms of weak interaction are the vector (V) and axialvector (A)

interactions. Accordingly, the sums in ► Eq. (2.84) contain only two terms. The respective weights, C_V and C_A , are real numbers and they are related by

$$C_A = -(1.259 \pm 0.004)C_V.$$

The coupling strengths of the weak interaction are: $g_V = g_F = 8.96 \times 10^{-5} \text{ MeV fm}^3$, $g_A = g_{GT} = -11.28 \times 10^{-5} \text{ MeV fm}^3$. The polar and axial vectors are defined by their behavior under rotation and space reflection. The difference is that polar vectors change sign under space reflection, whereas axial vectors do not. The vector interaction is analogous to the electromagnetic interaction. The electromagnetic field can be described by a vector potential, from which both the electric and magnetic field can be deduced through differential operators (see ► Sect. 2.3.2). The vector product of two polar vectors, e.g., the angular momentum $\mathbf{r} \times \mathbf{p}$, is an axial vector. The axial vector interaction has a more complicated electromagnetic counterpart: the emission of two quanta.

For a more detailed treatment of conservation laws see Wu (1965), for the experimental determination of the β interaction see Wu et al. (1965), and for the coupling constants see Kofoed-Hansen (1965). The tests of conservation laws are discussed by Wolfenstein et al. in Particle Data Group (2008).

The strength of the weak interaction is extremely small compared with strong and electromagnetic interactions (► Table 2.2). Therefore it can be neglected in the nuclear structure models.

2.4.2.4 Selection Rules in β Decay

In the exact theory of β decay the selection rules are derived from the transformation properties of operators and orthogonality of wave functions of different angular momentum states. For the actual vector and axial vector interactions the following selection rules have been obtained:

For allowed transitions	$\Delta I = 0 \text{ or } \pm 1$	$\Delta\pi$ no
For first forbidden transitions	$\Delta I = 0, \pm 1, \pm 2$	$\Delta\pi$ yes
For true second forbidden transitions	$ \Delta I = 2, 3$	$\Delta\pi$ no
Corrections to allowed transitions	$ \Delta I = 0, 1$	$\Delta\pi$ no
For true third forbidden transitions	$ \Delta I = 3, 4$	$\Delta\pi$ yes

See in detail separately for vector and axial vector interactions, e.g., Dzhelepov et al. (1972).

It follows from simple qualitative considerations that the probability of β decay is large, if the overlap of the initial and final wave functions of the nucleus is large. This implies that in allowed β transitions the change of angular momentum is small, and there is no parity change.

2.4.2.5 Parity Nonconservation in β Decay

Many experiments have been performed to test the parity conservation or violation in β decay (for a review see Wu et al. (1965)). The experiments gave the following results:

- The preferential emission of β^- particles occurs in antiparallel direction to the nuclear spin orientation.

- The antineutrino has positive (or right-handed) helicity, i.e., the spin vector of antineutrino has the same direction, as the linear momentum vector. On the other hand, the neutrino has negative (left-handed) helicity, i.e., it has antiparallel spin alignment. (The helicity is a constant of motion in the zero-mass approximation.)

The conclusion of these works is that the parity (P) invariance and, separately, the charge conjugation (C) invariance are violated in β decay, while the time reversal (T) or combined CP invariance is not. The parity non-invariance (i.e., non-invariance of the Hamiltonian of the weak interaction under space reflection) can be expressed alternatively by saying that the parity is not conserved. This formulation is a consequence of the fact that the parity P is an observable quantity. The presence of two-pion decay mode in the K_L^0 kaon decay implies, however, that even the CP invariance is violated in the weak interaction (Christenson et al. 1964).

The CP non-invariance is demonstrated also in the semileptonic (l) decay modes of K_L mesons, in the $K_L \rightarrow e^+ \nu_e \pi^-$, and $K_L \rightarrow e^- \bar{\nu}_e \pi^+$ processes, as well as similar ones in which muons are involved instead of electrons. The observed asymmetry (Δ_L) of time-integrated semileptonic decay rates is

$$\Delta_L \equiv \frac{\Gamma(K_L \rightarrow l^+ \nu_l \pi^-) - \Gamma(K_L \rightarrow l^- \bar{\nu}_l \pi^+)}{\Gamma(K_L \rightarrow l^+ \nu_l \pi^-) + \Gamma(K_L \rightarrow l^- \bar{\nu}_l \pi^+)} = (3.32 \pm 0.06) \times 10^{-3}.$$

Here Δ_L is actually a weighted average of electron and muon measurements, as well as K_L decays to $\pi^+ \pi^- \gamma$ and $\pi^+ \pi^- e^+ e^-$; see Kirkby and Nir in Particle Data Group (2008).

CP violation has been experimentally established also in B meson decays. However, the observed matter–antimatter asymmetry of the Universe requires additional sources of CP violation.

2.4.3 Special Decay Modes

In the vicinity of the stability region the dominating decay modes are β decay (for light nuclei), and α and β decays (for heavy nuclei). Far from the stable nuclei other decay modes appear, too.

On the proton-rich side there appear β -delayed proton and alpha emissions. From these the delayed proton emission occurs more often, with >120 cases known. β -delayed two-proton emission has also been observed in several (>8) cases.

Proton decay is possible also from ground states or from long-lived isomeric states. These decay modes are common among the strongly proton-rich nuclei. In the $Z > 50$ region already ≥ 41 proton emitters are known, e.g., ^{105}Sb , ^{109}I , $^{112, 113}\text{Cs}$, ^{117}La , $^{160, 161}\text{Re}$, $^{171, 171^*}\text{Au}$, ^{185}Bi . There are several nuclei emitting protons also in the $Z < 50$ region (e.g., ^{53}Co , ^{69}Br).

The study of proton emission may offer very important information on the nuclear structure near the proton drip line. Spectroscopic factors can be derived, providing information on the configurations of the initial and final states. In contrast to α -decay, the formation probability of a proton need not be calculated. The decay constant (λ) is determined mainly by the penetration probability through the potential barrier and the structure of states.

The systematics of experimental data and the theories of proton emission are discussed for example in the review article of Delion et al. (2006).

The emission of two (or four) protons is also expected from even- Z nuclei, if the emission of one proton is prohibited energetically (Thoennessen 2004). It was predicted from known

proton separation energies that ^{45}Fe , ^{48}Ni , and ^{54}Zn may emit two protons. Such decay modes have been experimentally confirmed. Two-proton decay was observed also from the excited states of ^6Be and ^{12}O , which are beyond the proton drip line. In both cases, the decays happen via a three-body breakup with half-lives of the order $\sim 10^{-21}$ s. The two-proton radioactivity is discussed in detail by Blank and Płoszajczak (2008).

β -delayed d-emission has also been observed, e.g., from the excited state of ^6Li (in the $^6\text{He}_4 \xrightarrow{\beta} ^6\text{Li}_3$ decay).

Among the superheavy nuclei spontaneous fission is a common decay mode. At the same time, the cluster (e.g., ^{14}C -, ^{24}Ne -, ...) decay of heavy nuclei is rather rare (see in [Sect. 2.3.6](#)).

Half-lives for proton emission, α decay, cluster radioactivity, and cold fission processes have been calculated in the framework of an effective liquid drop model by Duarte et al. (2002). The comparison with experimental data shows that the model is very efficient to describe these different decay processes in a unified theoretical framework.

On the neutron-rich side β -delayed neutron radioactivity is a very favored decay mode. From the combination of γ -ray and neutron time-of-flight spectroscopy one can obtain detailed information on the level structure of the daughter nuclei.

Based on the S_{2n} and S_{4n} neutron separation energies and systematics of β -decay energies one can expect also β -delayed $2n$ and even $4n$ emission in strongly neutron rich nuclei (Gelbke et al. 2006).

Similarly to the two-proton emission, two-neutron decay is also expected from the ground states of neutron-rich nuclei (e.g., in the case of ^{26}O). The next generation accelerator facilities will deliver hopefully sufficient beam intensity to explore such weak decay channels, too.

Abstract: The investigation and application of nuclear reactions play a prominent role in modern nuclear chemistry research. After a discussion of basic principles and reaction probabilities that govern collisions between nuclei, an overview of reaction theory is presented and the various reaction mechanisms that occur from low to high energies are examined. The presentation strives to provide links to more standard chemical disciplines as well as to nuclear structure.

3.1 Introduction

Current understanding of nuclear reactions has been significantly expanded by developments in accelerator technology, which now provide nuclear science with a highly diverse arsenal of nuclear projectiles. It is possible to probe the nucleus with beams of photons, electrons, mesons, neutrons, antiprotons, and virtually all naturally occurring isotopes of elements ranging from hydrogen to uranium. In addition, there is a growing capability to accelerate radioactive nuclei off the line of beta stability.

This arsenal of tools has allowed the response of nuclei to excitation energy, angular momentum, and neutron/proton asymmetry to be studied. Excitation energies from the smallest allowed (excitation to the first allowed quantum state above the ground state) to that corresponding to the capture of a thermal neutron (one binding energy B_N), to that required to totally vaporize a nucleus with A nucleons (► Fig. 3.1), an excitation energy of the order of AB_N , have all been investigated. The study of highly excited nuclei has provided new insights into nuclear systems with bulk densities both higher and lower than the central density

■ Fig. 3.1

Reconstruction of a highly energetic nuclear collision that disintegrates a gold nucleus into multiple nucleons and light clusters

of ground-state nuclei, densities which nature readily accesses in astrophysical objects. Similarly, the nuclear response to angular momentum from zero to that which prompts nuclei to fission (no matter what position in the periodic table) has been examined. Most recently, the use of secondary beams for reaction studies has allowed the study of nuclei formed in nature during nucleosynthesis of the elements – nuclei that previously had been inaccessible to experiment.

From a broader perspective, progress in related fields of nuclear science has frequently evolved from nuclear reaction studies, as indicated schematically in [Fig. 3.2](#). Reaction studies provide pathways for exploring nuclear structure, the formation of both new elements as well as isotopes of known elements (Loveland 2007), and nuclear astrophysics. At the more practical level, important nuclear applications have resulted from reaction studies, for example, nuclear energy, nuclear medicine (both for diagnostic imaging and therapy), activation analysis, and space-radiation effects due to cosmic-ray exposure.

The vantage point that will be maintained for the bulk of this chapter is that the atomic nucleus can be viewed as a two-component quantum fluid, i.e., the degrees of freedom are those associated with nucleons. Despite the quantum nature of the systems, classical analogs can be of great heuristic value. Leading this list of analogs is that of a charged two-component liquid drop. Here, the quantum aspects are buried in a few well-chosen coefficients of a physical expansion.

The Fermi-Gas Model applies a thin veneer of quantum mechanics to the Liquid-Drop Model (LDM), i.e., the Pauli exclusion principle must be obeyed by the spin $\frac{1}{2}$ nucleons and thus neutrons and protons must occupy distinct quantum levels. The energy of the top-most occupied level in this simple picture is called the Fermi energy, E_F . There is a Fermi energy for neutrons and another for protons, each corresponding to a chemical potential, i.e., the energy associated with the addition or subtraction of a nucleon. The kinetic energies of the nucleons forced by the Pauli principle lead to an internal pressure (intimately related to that which holds up a neutron star against gravitational collapse), but, as the surface of a stable nucleus is stationary, the pressure must return to zero at the periphery (just as it must on the surface of a neutron star or any other self-bound stable object.)

Fig. 3.2

Schematic representation of nuclear reactions as applied to other areas of science and technology

At the next higher level of sophistication, a specific quantization is envisioned by imagining independent particles in a (real) central potential. The consequences of this confinement are the granularization of the single-particle states labeled by orbital angular momentum (ℓ) and its orientation relative to the nucleon's spin (s). The quantum state of the nucleon, either in the entrance or exit channel, can dictate which nuclear reaction channel dominates. Turned around, studying reactions can provide insight into the underlying nuclear structure of the reactants or products.

Beyond the view of nuclei as nucleons moving independently in a mean field, one appreciates that the constituents are often engaged in complex correlations. This is akin to what one finds in water, where correlations (induced by hydrogen bonding) must be understood. However, unlike systems such as water, in which the correlations between identical units determine the interesting material properties, the nuclear system is composed of two distinguishable components.

In-medium correlations have many observable effects. They influence the mass of nuclei and if one were to create a one-body potential to mock up their effects, it would cause clustering of levels around the Fermi surface. This, in turn, changes the density of many-body states $\omega(E^*)$; the number of ways nucleons can distribute themselves into the allowed single-particle states within an excitation energy window. The density of states is Boltzmann's *wahrscheinlichkeit* in the expression $S(E^*) = k_B \ln \omega(E^*)$. For all but the lightest nuclei, the state density forms a quasi continuum as long as the excitation energy E^* is greater than the binding energy of a nucleon. This “high level density” allows for statistical treatments of reactions, in which it is the value of $\omega(E^*)$ associated with a given decay path that controls the probability of that decay. Not surprisingly, the entropy (the measure of the density of states that is extensive in macroscopic systems) and the temperature (the inverse of the rate of increase of the extensive measure of the density of states, i.e., S , with excitation energy) turn out to be useful concepts in explaining the competition between decay channels of an excited compound nucleus, including the fission channel(s), by making use of transition-state theory. This theory was developed by a collaboration between Ewing and Wigner in the 1930s. It is perhaps only from the unique perspective of the nuclear chemist that the utility of this theory to treat both chemical and nuclear reaction rates can be appreciated.

These correlated many-body systems can also be viewed as isolated drops of matter, which, if uncharged, could be infinite. Reaction studies have been called upon to explore the equation of state (EoS) of nuclear matter and to extract any phase transitions that punctuate the phase diagram (► [Fig. 3.3](#)). An equation of state is humankind's attempt to interrelate the variable set of thermodynamics, the absolute minimum set required to describe the macroscopic state of a system. Nuclei, being two-component systems, have a “chemical composition” sector (with chemical potentials and numbers of each as the variables, with one or the other chosen as independent), as well as a “mechanical” sector (P, V) and a “thermal” sector (T, S). Reaction data have been able to place rather tight constraints on the incompressibility of symmetric nuclear matter.

The isothermal incompressibility (the inverse of the compressibility) of an ideal gas is $K = -(V)(dP/dV)_T = P$. It is the equivalent science (although general interest is in the adiabatic compressibility) for nuclear systems that is sought. Insight into how this incompressibility changes with neutron–proton asymmetry is just now becoming available. It is this part of the EoS that dictates the behavior of supernovae, the events leading to neutron star formation, and the structure of such stars.

■ Fig. 3.3

The nuclear temperature–density phase diagram, indicating the nuclear landscape now available for reaction studies. The dotted trajectory shows the stepwise evolution of an energetic nuclear collision, in steps of about 1×10^{-23} s (Adapted from Mueller and Serot 1995)

Phase transitions are the delimiting punctuation of the EoS of any matter. One of the great successes of recent nuclear reaction studies has been to elucidate this punctuation, in particular, the nuclear analog of a liquid–gas phase transition (► Fig. 3.3).

As mentioned above, the perspective of this chapter is that of a nuclear system composed of neutrons and protons. The subnuclear aspects of the field are not addressed, for example, the origin of the nucleon–nucleon force and spin, quark–gluon degrees of freedom, and weak–interaction physics. For an overview of these subjects, see (NRC 1999).

3.2 Basic Concepts

In simplest terms, a nuclear reaction can be defined as a binary collision that alters the nucleon–nucleon associations, just as a chemical reaction is one that alters atom–atom associations. This change in association can produce different nuclei (via the exchange of nucleons or fusion) or can simply excite the nuclei (different correlations within the nucleus that no longer correspond to the ground state.) The latter type of reaction is called *inelastic* excitation. The former type might, or might not, proceed through an intermediate.

The case in which an intermediate state is formed can be written as

where the reactants A and a are the target and projectile that form an excited intermediate species C^* , or *composite nucleus*. The intermediate usually decays into a binary exit channel indicated by the product nuclei b and B . If the reaction loses all recollection of the entrance channel aside from quantities fixed by conservation laws (energy and angular momentum), the

intermediate composite is called a *compound nucleus* (CN), (► Fig. 3.4). In this case, exit-channel products are formed via statistical decay on a time scale longer than $\sim 10^{-21}$ s, a time commensurate with those that characterize either collective nuclear motion (rotation or vibration) or nucleon transit across a nucleus. At the other extreme, *direct reactions* occur on a much shorter time scale ($\sim 10^{-23}$ s), effectively bypassing the composite nucleus state. In reality, there is a continuum of time-dependent processes between compound and direct reactions. Intellectually, this continuum of mechanisms can be organized as viewing each step proceeding toward a CN as a fixed “generation” of nucleon-nucleon collisions. In a simple direct reaction the final state – right-hand side of ► Eq. (3.1) – is reached in the first step. Several steps are required to dissipate entrance channel energy and disperse it statistically among all the nucleon degrees of freedom. In the language of statistical mechanics, the CN is the case where the allowed phase space (that piece of the many-body $6N$ dimensional phase space allowed by conservation laws) has been fully sampled. The kinetic process by which this happens, organized by collision generation, is called the Multistep Compound Model, a model developed by Feshbach, Kerman, and Koonin (Feshbach et al. 1980), and often called FKK for short. The FKK codes commonly in use today are: EMPIRE, TALYS, and GNASH, which can be found on the Web.

In principle, the products of a nuclear reaction can be any species permitted by conservation laws. In practice, direct reaction final channels will be strong if they possess substantial overlap with those of the initial state. Similarly, if the reaction proceeds all the way to a CN, strong channels will be those that capture large portions of the available phase space. Compound nucleus wave functions are intractable objects. This, coupled with the myriad of equally complex final states, allows a statistical analysis to be employed. Even so, the full $6N$ dimensional phase space is far too large to cope with and so insight must be used to calculate the phase space area of relevant parts (e.g., the part of phase space well described by two large clumps of matter, rather than one, will be proportional to the fission yield.)

3.2.1 Shorthand Notation for Nuclear Reactions

The following shorthand notation is frequently employed:

target (projectile, light products) heavy products, or
 $A(a, b)B$.

► Fig. 3.4

Nomenclature for the time evolution of a nuclear reaction in which a composite nucleus is produced and then forms product nuclei

Note that the “products” are in plural; however, either can indicate a single particle. Typical examples, presented in both long- and shorthand notations, for reactions between ${}^4\text{He}$ projectiles and a ${}^{238}\text{U}$ target are:

Note that “one-way” arrows are used in the standard longhand reaction notation. Reaction studies are usually “one-way” exercises, i.e., equilibrium between reactants and products is not achieved. (Notable exceptions are bombs and the National Ignition Facility – NIF). On the other hand, Nature does achieve equilibrium (for many reactions) in the core of stars.

Using the shorthand notation, examples of photon capture, electron knockout and neutron-induced reactions are, respectively:

3.2.2 Mass-Energy Conservation: The Q-Value

The most fundamental constraint on any nuclear reaction is established by mass-energy ($E = Mc^2$) conservation. The **Q-value** for a reaction is the rest-mass energy difference between the reacting nuclei and the product nuclei:

$$Q = \sum M_0(\text{reactants})c^2 - \sum M_0(\text{products})c^2, \quad (3.4)$$

where M_0 is the rest mass of the nucleus. Nuclear mass-energy is tabulated in terms of *mass excess* Δ , which is often given in units of energy rather than mass (see [Sect. 11.6](#) of the Appendix of this Volume, where it is denoted by D):

$$\Delta = (M_0 - A \text{ u})c^2, \quad (3.5)$$

where A is the mass number and u is the *unified atomic mass unit* ($1 \text{ u } c^2 = 931.494 \text{ MeV}$). The Q-value can be rewritten as

$$Q = [\Delta(\text{projectile}) + \Delta(\text{target})] - \sum \Delta(\text{products}) \quad (3.6)$$

Sources of mass-excess values, as well as reaction and structure data, can be found in NNDC (2010). If the rest mass of the reactants exceeds that of the products, the reaction is *exothermic* ($Q > 0$) and there is no energy threshold for the reaction. If Q is negative, the reaction is *endothermic* and projectile kinetic energy must be converted into rest-mass energy to compensate for this deficiency. Elastic scattering is defined by $Q = 0$.

In terms of writing energy-balanced (chemical-like) equations, Q-values correspond to product-side energy release. This is opposite to the sign convention for enthalpies, which can be viewed as reactant-side energy inputs. (Thus a negative enthalpy corresponds to a positive Q-value, i.e., the energy released in the reaction.) In a chemical reaction, the energy change comes from alteration of the atom associations, while in a nuclear reaction, the energy release comes from a change in the associations (i.e., correlations) at the nucleon level.

Two examples of concern in Big Bang nucleosynthesis, also discussed in [Chap. 12](#) of Vol. 2, are:

The first reaction (with a positive Q -value) is an important pathway in element formation; the second (with a negative Q -value) hinders destruction of ${}^4\text{He}$ in stellar environments.

All (n, γ) reactions (called *neutron capture*) on stable target nuclei are exothermic, as are all (p, γ) reactions on stable nuclei. These Q -values are no more than the release of energy corresponding to the binding energy of that nucleon. One can think of this energy as the energy difference between an unbound nucleon at zero energy and the Fermi energy, which while approximately 30 MeV above the bottom of a one-body potential is, by definition, 1 B_N below zero. The condition $B_N = 0$ defines the drip lines, i.e., the limits of nuclear stability with respect to the strong force.

Charged-particle reactions with heavier nuclei can have positive or negative Q -values. If the collective binding energies of the products are greater than that of the reactants, as it would be the case if the products were closer to the peak in the binding-energy curve than the reactants, the Q -value will be positive. Negative Q -values occur, for example, when nuclei on the leading edge of the binding energy curve, such as ${}^{12}\text{C}$ and ${}^{16}\text{O}$, are broken up into still lighter nuclei or when nuclei heavier than Fe fuse to build a heavier nucleus. Cosmic-ray-induced reactions that occur in the atmosphere, relevant to Li, Be, and B nucleosynthesis in nature and also to space travel, are examples of reactions with negative Q -values. (Such reactions are perhaps the principal impediment to long-duration space travel by humans.)

In reactions involving complex nuclei, two important quantities related to the Q -value, and also to the incident beam energy, are the excitation energy E^* (or equivalently U) and the threshold energy E_{th} . The *excitation energy* is the excess energy deposited in the product nucleus (► Fig. 3.5). For excitation energies below one B_N , the discretized nature of E^* is important.

The *threshold energy* is the minimum projectile energy required to form the product nucleus in its ground state. Compound nucleus formation provides a simple example of this concept: target (t) + projectile (p) → CN. In this case, energy and linear momentum conservation require (in the nonrelativistic limit):

$$\text{mass-energy :} \quad \Delta_t + \Delta_p + E_p = \Delta_{CN} + E_{CN} + E^*, \quad (3.10)$$

$$\text{linear momentum :} \quad p_p = \sqrt{2M_p E_p} = \sqrt{2M_{CN} E_{CN}} = p_{CN}, \quad (3.11)$$

$$\text{which gives :} \quad E^* = (A_t/A_{CN}) E_p + Q. \quad (3.12)$$

$$\text{Since when :} \quad E^* = 0, E_p = E_{th}, \text{ then} \quad (3.13)$$

$$E_{th} = (A_{CN}/A_t)(-Q). \quad (3.14)$$

If Q is positive, there is no energetic threshold to limit the reaction. If Q is negative, energy in excess of the Q -value must be supplied to account for the center-of-mass motion of the composite nucleus. Equations for the situation in which two products are formed can be found in standard texts (e.g., Krane 1988; Cottingham and Greenwood 2001).

Under common reaction conditions during the first 50 years of nuclear reaction studies, the lighter of the two partners was the projectile incident on a heavier target at rest. However, with the advent of modern heavy-ion accelerators, this situation can now be interchanged, permitting the study of systems in which a heavy projectile is used to bombard a lighter target (*reverse*

■ Fig. 3.5

Schematic description of the increasing density of nuclear levels as the excitation energy U increases above the minimum in the potential energy (ground state). The abscissa in this plot is a deformation coordinate that represents the “reaction coordinate” and shows the change in level density as the system follows a one-dimensional path toward one possible decay mode, i.e., fission. The lowest density of states along this path is indicated for the height of the fission barrier B_f . In this figure U is used for the excitation energy. This is consistent with the use of U in thermodynamics to indicate the internal energy. The excitation energy E^* is the energy above the ground-state energy (mass) and in this example is indicated by the horizontal arrow

kinematics). This situation provides a unique experimental environment in which the reaction products are focused forward. Most recently, it has become possible to create reactions between colliding beams of heavy nuclei (e.g., Au + Au), thereby retrieving the available energy lost to center-of-mass motion in conventional fixed-target collisions.

3.2.3 The Nuclear Potential Energy: Coulomb Barrier Effects

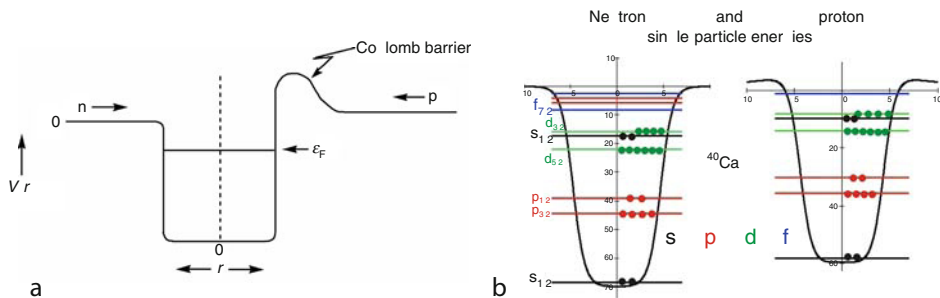

A second energetic factor, independent of the Q -value, is imposed by the *nuclear potential energy*, which summarizes the respective forces at play in atomic nuclei. As shown in ► Fig. 3.6, the potential energy for a complex nucleus is the sum of

1. A *central attractive well* created by the strong nuclear force acting at short range on the constituent neutrons and protons, and
2. A *repulsive Coulomb interaction* of long range acting between the positive charges of the target and projectile.

The saturated, short-ranged nature of the attractive nucleon-nucleon interaction creates an approximately uniform *mean field* inside the nucleus, giving rise to a nearly flat behavior of the nuclear potential. Near the nuclear periphery, the long-range Coulomb repulsive interaction overpowers the short-range nuclear attraction, giving rise to the *Coulomb barrier* and

■ Fig. 3.6

(a) A schematic representation of the nuclear potential energy as a function of the distance from the center of a complex nucleus is shown. Neutrons (*left*) do not experience Coulomb repulsion, as do protons (*right*). The Fermi energy level is indicated by ϵ_F . (b) A potential plot to scale for neutrons and protons in ^{40}Ca

a subsequent decrease in the potential at large distances according to the $1/r$ law. The actual nuclear potential energy will be multidimensional if spherical symmetry is broken by the ground state being deformed, as always happens at midshell, or when fission-like phenomena are being treated.

Using Gauss' Law and assuming that the charge is uniformly distributed within a sphere of radius R_C , the Coulomb potential (i.e., electric potential energy) has the following form:

$$V_C(r) = \frac{Z_p Z_t e^2}{r} = \frac{1.44 Z_p Z_t}{r} \text{ MeVfm}; \quad r \geq R_C$$

$$V_C(r) = \frac{Z_p Z_t e^2}{2R_C} \left(3 - \frac{r^2}{R_C^2} \right); \quad r < R_C. \quad (3.15)$$

Here Z_p and Z_t are the respective charges of the projectile and target nuclei and r is the separation distance between the centers of charge of the colliding nuclei.

The Coulomb barrier B_C^{cm} (in the center of mass) can be estimated as the interaction of nearly touching spheres, i.e., $B_C^{\text{cm}} = V_C(R_C)$, where $R_C = r_C(A_p^{1/3} + A_t^{1/3})$. Empirical studies suggest a value of $r_C \approx 1.4\text{--}1.6$ fm, also discussed in ▶ Sect. 2.2.3.1 of Chap. 2 in this volume. As with the Q -value, it is necessary to correct for center-of-mass motion, so that in the laboratory frame, the projectile energy required to surmount the Coulomb barrier is

$$B_C^{\text{lab}} = (A_{CN}/A_t) B_C^{\text{cm}}. \quad (3.16)$$

For charged particles with kinetic energies below the Coulomb barrier, the projectile usually elastically scatters from the target (discussion of Coulomb excitation below), leaving the reactants unchanged. Once the relative kinetic energy of the colliding pair becomes comparable to the Coulomb barrier, the projectile can classically penetrate into the attractive nuclear potential and produce a nuclear reaction. (Barrier penetration with lab energies below B_C^{lab} can occur but the probability is low.) This energy can be supplied by particle accelerators or in nature by either the high temperatures achieved in the core of a star or by the various cosmic accelerators that generate the high-energy nuclei found in cosmic rays. The Coulomb barrier is the energetic factor that determines the rate of reactions between charged nuclei at low energy.

This barrier also controls the decay rate for channels for which a charge separation is generated. Examples of the latter are all decay channels of an excited CN producing charged particles in the exit channel, ground-state (radioactive) decay via alpha-particle emission and fission.

Reactions between charged species first become probable when the projectile kinetic energy increases to values near the Coulomb barrier energy, permitting the tails of the nuclear matter distributions to overlap, ▶ Fig. 3.7. Because of the diffuse tail of the matter distribution and quantum penetration, it is possible for reactions to occur below the nominal Coulomb barrier. Most often, such reactions involve Coulomb excitation or the transfer of one or a few nucleons at the nuclear surface. However, more complex reactions can occur, including amalgamation of target and projectile, although with low probability. As the overlap between the two nuclear matter distributions increases, the probability for nuclear reactions involving many or all nucleons becomes increasingly probable.

3.2.4 Angular Momentum Effects: The Centrifugal Barrier

A second repulsive energetic factor is due to the orbital angular momentum associated with noncentral collisions. As shown in ▶ Fig. 3.8, initial projectile trajectories can be characterized semiclassically in terms of an *impact parameter* b , which is the distance between a given trajectory and one that passes through the center of the target.

The orbital angular momentum $\ell\hbar$ is quantized, so that for a projectile of mass m and velocity v ,

$$\ell\hbar = (mv)b, \quad (3.17)$$

For the case of two colliding spheres with sharp surfaces, the maximum value of the impact parameter is determined by the touching condition

$$b_{\max} = R_p + R_t, \quad (3.18)$$

where R_p and R_t are the respective radii of projectile and target nuclei as shown in the left panel of ▶ Fig. 3.9.

In a classical geometrical model, the maximum angular momentum for the collision of objects with a sharp surface is then,

$$\ell_{\max}\hbar = mvb_{\max} = mv(R_p + R_t) = mvr_0(A_p^{1/3} + A_t^{1/3}). \quad (3.19)$$

■ Fig. 3.7

Schematic picture of the increasing density overlap between projectile p and target t as two complex nuclei pass by one another

■ Fig. 3.8

Generation of angular momentum $\ell\hbar$ for projectiles with different impact parameters b . Each annular ring corresponds to the area defined by a given impact-parameter range and its associated ℓ -value. The indicated direction of rotation corresponds to “glancing” collisions represented by the two upper projectile trajectories. The middle trajectory leads to a “head-on” collision without angular momentum generation

■ Fig. 3.9

Left: Touching-spheres model of a nuclear collision. **Right:** Square-well nuclear potential, corresponding to a nucleus with a sharp surface

The amount of energy tied up in *rotational energy* E_{rot} depends on the impact parameter and constitutes a *centrifugal barrier*,

$$E_{\text{rot}}(\ell) = \frac{\hbar^2 \ell(\ell+1)}{2\mu r^2} = \frac{(\hbar c)^2 \ell(\ell+1)}{2 \left(\frac{A_p A_t}{A_p + A_t} \right) u r^2}; \quad \ell = 0, 1, 2 \dots \ell_{\text{max}}, \quad (3.20)$$

where μ is the reduced mass of the system, proportional to $A_p A_t / (A_p + A_t)$. (The constant $\hbar c = 197.3 \text{ MeV fm}$ simplifies calculations when combined with the numerical value of $u = 931.5 \text{ MeV}/c^2$).

Three additional points should be noted about this “barrier.” First, it drops off with distance much faster than the Coulomb barrier, i.e., $1/r^2$ versus $1/r$. Second, it is not the result of a real interaction. Rather, it can be viewed as removing that fraction of the energy from the

entrance channel that must be “spent” in angular momentum conservation and is thus not available for a reaction. In the standard language of chemistry, the relative separation is the reaction coordinate. The energy tied up in conserving angular momentum is not available to advance the reaction coordinate. Finally, it is this term in the expression for the energy that when put into the quantum mechanics (one-body) problem forces the wave functions to go to zero at the origin. The combined effects of the Coulomb and centrifugal barriers form independent constraints on the probability for a nuclear reaction.

The angular momentum involved in a reaction has important consequences, ranging from nuclear spectroscopic studies at low-angular momentum to the rotational instabilities that lead to fission, rotating dinuclear configurations (▶ Sect. 3.4.2), and for populating the highly deformed local minima responsible for fission isomers and super-deformed nuclei. For example, in a $^{238}\text{U} + ^{238}\text{U}$ collision, angular momenta up to $\ell_{\text{max}}\hbar \approx 1,000\hbar$ are possible. However, for values above $\ell\hbar \approx 80\text{--}100\hbar$ the composite system becomes rotationally unstable and cannot fuse. Thus all of the cross section associated with angular momentum above this stability limit is associated with reaction channels other than CN formation.

3.2.5 Summary of Energetic Factors in Nuclear Reactions and the Separation of Thermodynamic and Kinetic Factors

To form a composite nucleus, the threshold energy must be exceeded and the available energy must exceed the combined Coulomb and centrifugal barriers for the reaction probability to be appreciable. The threshold energy is imposed by mass-energy conservation and is important only for negative Q -values. The Coulomb barrier applies only to charged-particle reactions. The centrifugal barrier is not a fundamental constraint since $\ell = 0$ is always possible. (Also recall that ℓ is not a good quantum number if the potential is not spherically symmetric. This means that ℓ -waves can mix in such cases. However, as parity is a good quantum number, even values of ℓ mix with even and odd with odd.) As a general rule, the Coulomb barrier dominates for charged-particle-induced reactions, except for some cases where light nuclei are involved. For (n,γ) reactions on stable nuclei, the Q -value is always positive and the Coulomb barrier is zero, so only the centrifugal barrier constraint is relevant.

If the nuclei on either side of the reaction can exist only in one (i.e., the ground) or a few (as in the products of a direct reaction) states, the entropy of the participants is small as is the temperature T . Under these conditions, a thermodynamic discussion reduces to one of enthalpy (as the “ SdT ” term, i.e., the thermal term, in the free energies is tiny.) The Q -value represents the negative of the enthalpy, so a positive Q -value represents a spontaneous reaction. At $T = 0$, there are only two possible values of the degree of reaction: 0 (i.e., none) or 1 (all). So given enough time, something thermodynamics cannot give insight into, a positive Q -value will yield 100% products. (An energetically downhill reaction at equilibrium will yield 100% products at $T = 0$, a case realized in simple radioactive decay.) The barriers (both Coulomb and centrifugal) are kinetic factors. They do not influence ultimate equilibrium constants but they do determine rates (in the same way that the height of a chemical transition state determines the rate of a chemical reaction).

With the exception of the case of stars, or perhaps ultimately earth-bound fusion reactors, rates rather than true equilibrium are the concern. (As the reverse reactions required for true equilibrium do not occur.) Thus the description of the decay of a CN is a kinetic model.

3.2.6 Cross Sections: An Introduction

The compound nucleus scenario described in the previous section provides a useful framework for discussing the probability for a nuclear reaction as characterized by its *cross section*. As long as the excitation energy is not so high that internal thermal equilibration is short circuited, one can separate the formation process from the decay. When this is the case, the reaction probability can be factored into two terms: (1) the total probability for the projectile and target to fuse (entrance channel), and (2) the individual probabilities for formation of each product nucleus (exit channel). The total cross section can be defined more precisely in terms of the difference between the incoming and outgoing flux of beam particles. For specific exit channels, the production cross section is the fraction of the total cross section that yields a given product nucleus. Such a description fits equally well for direct reactions, which do not involve the intermediate composite-nucleus step.

In estimating the total reaction probability, a simple geometric touching-spheres model provides a useful benchmark calculation (► Fig. 3.9). In this model, a reaction will occur if the impact parameter b is less than or equal to the sum of the nuclear radii. For larger values of b there will be no reaction. The cross-sectional area defined by this geometry leads to a classical or *geometric cross section*,

$$\sigma^{\text{geo}} = \pi b_{\text{max}}^2 = \pi(R_p + R_t)^2 = \pi r_0^2 \left(A_p^{1/3} + A_t^{1/3} \right)^2; \quad r_0 \approx 1.40 - 1.60 \text{ fm}. \quad (3.21)$$

For medium-mass nuclei, this value has dimensions of order 10^{-24} cm^2 , which defines the unit for cross sections, the *barn* (b); i.e.,

$$1 \text{ barn} \equiv 1.0 \times 10^{-24} \text{ cm}^2 = 100 \text{ fm}^2. \quad (3.22)$$

For projectile energies well above the threshold and/or Coulomb barrier, ► Eq. (3.21) serves as a good approximation for the *total reaction cross-section*, $\sigma_R \approx \sigma^{\text{geo}}$.

For *neutron-capture* (n, γ) reactions at very low energies ($\ll 1 \text{ MeV}$), microscopic effects come into play, leading to significantly enhanced cross sections. Since (n, γ) reactions can proceed without threshold or Coulomb barrier limitations, reactions can occur at very low energies. More importantly, the wave nature of matter becomes the dominant factor. At very low energies (thermal, i.e., 300 K, energies correspond to an average kinetic energy of 0.025 eV) the neutron reduced *de Broglie wave length* ($\lambda = \hbar/p = 1/k$) is much larger than the nuclear radius; i.e., $\lambda > R$. The reduced de Broglie wave length is the reciprocal of the wave number $\lambda = 1/k$, where $k = (2mE)^{1/2}/\hbar$. Thus, for very low neutron energies, the values of σ_R can greatly exceed σ^{geo} .

Between the thermal and geometric extremes (i.e., between where the de Broglie wave length dominates and the width of the average state greatly exceeds the spacing between states) there is a resonance region where the cross section is characterized by sharp spikes at well-defined energies. All three of these regions are illustrated schematically in ► Fig. 3.10.

On the other hand, *charged-particle-induced reactions* at low energies are suppressed by the Coulomb barrier. To account for this effect, a simple modification of the form

$$\sigma_R = \sigma^{\text{geo}} (1 - B_C/E_p); \quad E_p \geq B_C \quad (3.23)$$

provides a good first approximation to the cross-section dependence on bombarding energy. By employing more sophisticated models that account for the diffuse nuclear surface and diffraction effects, a more quantitative description of the reaction cross section can be obtained.

■ Fig. 3.10

Left: Schematic representation of the excitation function for the capture of neutrons in a (n, γ) reaction. In this figure the velocity of the neutron is indicated by u_n . **Right:** Total cross section dependence on bombarding energy per nucleon for a charged-particle reaction

An important component of the reaction cross section is the relative distribution of angular momenta, or ℓ -wave distribution, generated in a collision. Angular momentum affects the population of quantum states of a given spin in direct reactions and is also a major factor in generating rotating nuclei that stretch axially into highly deformed nuclear shapes (Janssens and Khoo 1991). Angular momentum also destabilizes nuclei toward fission, much as a high-charge content does. In the geometric model the angular momentum is given by $\ell\hbar = mvb$ and $\ell_{\max}\hbar = mv(R_p + R_t)$, as shown in ► Fig. 3.8, and thus it is possible to partition the cross section by impact parameters,

$$\sigma_{\ell}^{\text{geo}} = \pi(b_{\ell+1}^2 - b_{\ell}^2) = \pi\lambda^2[(\ell+1)^2 - \ell^2] = \pi\lambda^2(2\ell+1). \quad (3.24)$$

By summing over all ℓ -waves the total reaction cross section, σ_R^{geo} , is then given by

$$\sigma_R^{\text{geo}} = \pi\lambda^2 \sum_{\ell=0}^{\ell_{\max}} (2\ell+1) = \pi\lambda^2(\ell_{\max}+1)^2. \quad (3.25)$$

In the simple black-disk model described above, nuclear effects of the diffuse nuclear surface and the discrete (i.e., quantum) nature of the allowed nuclear structure have been ignored and it is assumed that nuclear matter is perfectly opaque. The *optical model* addresses these omissions and is the subject of the next major section. One of the major results of this model is the introduction of ℓ -dependent *transmission coefficients*, T_{ℓ} , where $0 \leq T_{\ell} \leq 1$. The reaction cross section then becomes

$$\sigma_R = \sum_{\ell} \sigma_{\ell} \pi\lambda^2 \sum_{\ell} (2\ell+1) T_{\ell}. \quad (3.26)$$

These transmission coefficients are then the probability that the target-projectile collision will penetrate the interaction barrier and produce a nuclear reaction. Thus as ℓ increases, T_{ℓ} decreases; that is, $T_{\ell} = 1$ corresponds to complete absorption and $T_{\ell} = 0$ to pure elastic scattering.

3.2.7 Cross Sections, Excitation Functions, and Angular Distributions

Experimentally, evidence for a target-projectile interaction can be gained from measuring the probability for formation of the products that populate the various exit channels. This information then serves as the basis for interpretation of the reaction mechanism through which a nuclear collision proceeds. It may also provide essential data for nuclear astrophysics, as described in [Chap. 12](#) of Vol. 2, and for evaluating and implementing nuclear applications, discussed in [Chaps. 38](#) and [39](#) of Vol. 4).

The total reaction cross section is the sum of all possible reaction channels: $\sigma_R = \sum_b \sigma(a, b)$. Exit channels may involve only a single heavy nuclear product, as in the case of (n, γ) , reactions two fragments (as in fission) or even multiple fragments, as in multifragmentation. By measuring all possible exit channels, σ_R can be determined. Alternatively, σ_R can be measured with beam-attenuation measurements by measuring the rates [particle/s] of the beam reaching a detector with the target in and with it out (see the Addendum).

Measurements of production cross sections are performed with a wide range of both radiochemical and direct counter techniques. Historically, radiochemical techniques were particularly useful for measuring heavy residues, for which discrete Z and A identification are difficult to determine with nuclear particle detectors in reactions with normal kinematics. However, with the availability of very heavy-ion beams and the widespread use of reverse kinematics, the measurement of mass ($d\sigma_A/dA$), charge ($d\sigma_Z/dZ$), and isotope ($d\sigma_Z d\sigma_A/dAdZ$) distributions from direct counter techniques are now routinely done. For heavy residues, these values are frequently summarized graphically in terms of an *excitation function*, or cross section as a function of projectile energy, as in [Fig. 3.11](#). Extensive listings of production cross sections are maintained in several databases (IAEA 2010; NEA 2010; NNDC 2010; RNDC 2003).

In conducting direct counter experiments, the emission of reaction products over the full 4π of solid angle (θ, ϕ) must be taken into account, as well as the transformation of laboratory data into the center-of-mass system (Krane 1988). Thus, measurements of the *angular distribution*, i.e., differential cross section as a function of angle $d\sigma(\theta, \phi)/d\Omega$, must be made. In the absence of spin-polarized targets or projectiles, the cross section is independent of azimuthal angle ϕ . In this case, the angular distribution is characterized by the single differential cross section, $d\sigma(\theta)/d\Omega$, where Ω is the solid angle into which the particles are emitted. The production cross section is then given by

$$\sigma(a, b) = \int_0^{2\pi} \int_0^\pi \frac{d\sigma(\theta, \phi)}{d\Omega} d\Omega = 2\pi \int_0^\pi \frac{d\sigma(\theta)}{d\Omega} \sin\theta d\theta. \quad (3.27)$$

For statistical decay of a composite nucleus with no angular momentum, particles are emitted isotropically; that is, $d\sigma(\theta)/d\Omega$ is independent of angle in the center-of-mass system. Thus, $d\sigma(\theta)/d\Omega = \text{constant}$ or $d\sigma(\theta)/d\theta \propto \sin\theta$. If the composite nucleus is formed in a state of high angular momentum with the axis of rotation oriented perpendicular to the beam direction (i.e., from an ensemble of reactions, the angular momenta are uniformly distributed in a plane perpendicular to the beam), as in the approximate case in heavy-ion reactions, then one observes strong forward-backward peaking, reaching a limiting value of $d\sigma(\theta)/d\Omega$, $\propto 1/\sin\theta$ or $d\sigma(\theta)/d\theta = \text{constant}$. Schematic angular distributions for these two extremes are shown in [Fig. 3.12](#).

■ Fig. 3.11

Excitation function for the $^{197}\text{Au}(^4\text{He}, xn)^{201-x}\text{Tl}$ reaction (Lanzafame and Blann 1970)

■ Fig. 3.12

Schematic angular distributions for particle emission from an equilibrated hot nucleus. Solid line is for a system with no angular momentum and dashed line is an upper limit for very high angular momentum

On the other hand, for direct reactions, the projectile-like products tend to be focused in the direction of the incident beam momentum vector. Depending on the quantum state, collision energy and time scale, forward peaking or peaking at specific angles will be observed. Thus, angular distributions serve as key indicators of the degree of equilibration achieved in a reaction, as well as providing a means of evaluating the reaction mechanism and imparted angular momentum.

One of the most sensitive tests of any nuclear reaction model is its success in reproducing absolute doubly differential cross sections $d^2\sigma/d\Omega dE$. In order to obtain the differential cross section for a given exit channel, it is necessary to integrate over the full kinetic energy distribution of the emitted particles at a specific angle,

$$\frac{d\sigma(\theta)}{d\Omega} = \int_0^\infty \frac{d^2\sigma(\theta, E)}{d\Omega dE} dE. \quad (3.28)$$

It is the kinetic energy distribution as a function of angle that reveals the physics content of a nuclear reaction most transparently. For a fully equilibrated CN, the spectra of evaporated light particles are Maxwellian in shape and unchanging in angle in the center-of-mass system. The spectra of charged particles are suppressed at low energies by the Coulomb barrier. Two-body direct reactions exhibit discrete spectral lines or resonances, depending on the nuclear structure sampled in the collision. The two-body (simple momentum balance) scenario also produces a good first-order description of fission, yielding Gaussian-like fragment energy spectra resulting from highly stretched breakup configurations.

3.2.8 Cross-Section Measurements

Determination of the cross section for a nuclear reaction product requires measurement of the *reaction rate*, R = number of events/unit time. As in any two-body collision (second-order rate process), the rate is the product of a target-projectile collision factor $cn_p n_t$ and the “probability” σ that if a collision occurs, a specific product will be formed, i.e.,

$$\frac{dN(a, b)}{dt} = R(a, b) = cn_p n_t \sigma(a, b), \quad (3.29)$$

where c is a coefficient and the dimensions of $n_p n_t$ are defined by the geometry of the experiment. Three cases are of general interest:

1. Accelerator-based bombardments in which a beam of particles n_p is incident on a planar target.
2. Nuclear reactors, where a gas of neutrons permeates n_t target nuclei.
3. Stellar interiors, where the reactants act as two interacting gases.

Practical aspects of cross-section calculations are discussed in the Addendum at the end of the chapter.

3.3 Scattering Theory

The presentation in the preceding section is meant to give a general overview of relevant concepts needed to describe nuclear reactions. In this section a treatment of quantum scattering is presented. This presentation is meant to facilitate a comparison between various types of scattering and to link nuclear reactions to structure. Additional background on scattering theory can be found in (Bertulani 2009).

3.3.1 Preliminaries

Before dealing with the scattering problem, the quantum objects under study should be considered. If the neutron and proton constituents of the nucleus were noninteracting, self-bound nuclei would not exist. One might posit that the binding energy is the sum of attractive

two-body interactions, all $A(A - 1)/2$ of them. This amounts to making two assumptions: (1) that neutrons and protons are the only constituents in nuclei, i.e., nucleons are elementary particles and (2) that the interaction is *pair-wise additive*. The former assumption is formally incorrect, but not bad when the available energy is less than the mass of the pion, the lightest field particle that mediates the residual strong force (nuclear force). The second assumption is also likely wrong. Most nucleon-based descriptions of the residual strong force include 3-body forces between nucleons, but the origin of these – beyond *pair-wise additive* contributions – is unclear. Such interaction terms could come from the fact that nucleons are not truly elementary and the employed degrees of freedom (DoF), those of the nucleons, is an incomplete set. (Axilrod and Teller 1943 first introduced 3-body forces in an attempt to explain the crystal structure of solid Ar as a patch when they simplified the many-body problem by dropping all of the degrees of freedom associated with the electrons and retaining only those associated with the nuclear positions. Their assumption being that, if they could have solved the problem employing all degrees of freedom, a 3-body force would not be needed.) However, because the field-mediating bosons of Quantum Chromodynamics do interact with one another, while they do not in Quantum Electrodynamics, pair-wise additivity would not be expected in the former. Whatever the reason, nucleon-based theories require 3-body terms (see also [Chap. 2](#) in this Volume).

High-energy electron reaction studies measuring $(e,e'p)$ cross sections have shown that only 70–80% of the protons participate in independent-particle motion of the type imagined in one-body potential models. This low “occupancy” of one-body states is caused by strong correlations within the nucleus. These correlations are primarily between pairs of nucleons, but α -particle clustering, sometimes called “quarteting,” in any low-density region also suppresses one-body behavior. Nucleons are somewhat different objects inside and outside a nucleus, as they effectively lose 0.8% of their mass, i.e., the binding energy, when transported inside a nucleus. Often, the term “dressed” is used to describe nucleons in the nucleus.

Very recent electron scattering studies using two-nucleon knockout reactions $(e,e'pp)$ and $(e,e'pn)$, have shed considerable light on these in-medium correlations (Subedi et al. 2008). This work showed that the overwhelming strong pair correlations are between neutrons and protons with large relative momenta and small center-of-mass (CM) momenta ([Fig. 3.13](#)). Large relative momenta are expected due to the rather hard core of the nucleon-nucleon interaction, but the tensor force undoubtedly plays a role and helps distinguish like-nucleon versus different-nucleon correlations. The tensor force arises because the interaction between nucleons depends on the relative orientation of their spins with respect to their relative spatial vectors (see [Chap. 2](#) in this Volume).

Due to the Pauli principle, only n-p pairs can have their spins aligned and otherwise have the same quantum numbers. These pairs are referred to as short-range correlated (SRC) pairs and their presence strongly affects the properties of cold, dense nuclear matter, such as that found in neutron stars. This nucleon-nucleon interaction is also required to explain the fact that the n-p spin triplet is bound (i.e., the deuteron) while the n-n and p-p, required singlets, are not. Consideration of n-p interactions is also essential to understand the evolution of the phenomenological spin-orbit interaction as a function of n/p asymmetry (Otsuka 2005), one of the most discussed topics in nuclear structure research today.

A focus on like-nucleon singlet (spin zero, i.e., BCS-like) pairing is warranted in an effort to explain the slight variation in mass responsible for the overwhelming dominance of even-even nuclei as well as explaining their ground-state spins. On the other hand, this myopic focus near the Fermi energy misses the source of the bulk of nuclear binding.

■ Fig. 3.13

The initial nucleon correlations as seen from a two-nucleon knockout experiment (left) are summarized in a pie chart on the right (Subedi et al. 2008)

Descriptions of nuclei based on realistic nucleon-nucleon interactions that include the effects mentioned above have, as of this time (2010), only been able to deal with nuclei with $A < 12$ (Pieper et al. 2002). Above this mass number, various approximations are employed. Simplifying this many-body problem all the way down to independent particles moving in an overall potential is of great heuristic value and utility. (This utility does not extend to calculation of the total binding energy. For this, one needs to add a macroscopic correction to the total binding energy. In this macroscopic-microscopic approach, pioneered by Strutinsky (1967), it is the macroscopic part that captures the impact of nucleon-nucleon correlations far removed from the Fermi surface). The single-particle approximation leads to the one-body problem, i.e., the type solved for generating hydrogenic wave functions (in this case, a solitary e^- moving in a $1/r$ potential.) The greatly simplified (“one-body”) potentials (one for neutrons and one for protons) are separately adjusted to explain phenomena that occur *near* the Fermi surfaces for neutrons and protons. In fact, to explain behavior away from the Fermi surfaces, the potential depths have to be made both energy-dependent and complex.

Consider a nucleon interacting with a (one-body) potential well formed by, at least, the $A - 1$ interactions of this nucleon with the others. Now imagine that this potential is itself in a large box of dimensions much larger than the range of the nuclear force (► Fig. 3.14). Considering only the short-ranged nuclear force, outside the well the potential is zero. The box, while large relative to nuclear dimensions, presents a boundary condition, so the box contains (in the absence of the internal potential) all the “particle-in-a box” states. The wave function with the lowest energy has no internal nodes; the more nodes - the higher the energy (eigenvalue).

As the depth and width of the internal potential is “dialed up,” these particle-in-a-box wave functions are modified – increasing the frequency in the region of the potential well and can even localize some of them entirely within the potential well. The latter, having no probability far-removed from the potential well, are the “bound-states.”

The presence of the attractive potential produces a positive phase shift δ of the wave function at large distance, relative to the wave function without the potential (► Fig. 3.15).

■ Fig. 3.14

Nucleon potential in a box. As the potential is made either deeper or wider, states are moved from ones quantized only by the box boundary conditions, essential free waves, to those confined to the central potential. The latter correspond to bound nuclear states

This phase shift is a direct consequence of the higher frequency within the range of the potential. As the potential is made either wider or deeper, states are “sucked” in (from the box) and are localized in the potential well. In the case of a one-dimensional square well of depth V and width L , the number of bound states for a particle of mass m is $N = 1 + [(2mV)^{1/2}L/(\pi\hbar)]$ where the square brackets stand for the integer part. Every time the phase shift passes π , another one of the continuum (particle-in-a-box) states is “sucked” into the well. This phase shift, which plays a central role in scattering problems, records the asymptotic compression of the wave function, but the number of $(1/2)$ oscillations (each producing a bound state) is lost. However, the number of bound states for each ℓ , N_ℓ , can be recovered as it is encoded in the zero energy (i.e., threshold) phase shift, $\delta_\ell(0) = N_\ell \pi$. This is known as Levinson’s Theorem.

3.3.2 The Optical Model (OM)

The interaction of a nucleon with a nucleus can be modeled if the potential is made complex (Buck et al. 1960; Hodgson 1967; Messiah 1958). The common form is

$$\begin{aligned}
 U(r, E) &= V(r, E) + iW(r, E) \\
 &= [-V_v(E)f(r, r_v, a_v) + 4a_s V_s(E)f'(r, r_s, a_s) + V_{so}(E)h(r, r_{so}, a_{so})(\ell \mathbf{s}) + V_c(r, a_c)] \\
 &\quad + i\{-W_v(E)f(r, r_v, a_v) + 4a_s W_s(E)f'(r, r_s, a_s) + W_{so}(E)h(r, r_{so}, a_{so})(\ell \mathbf{s})\}.
 \end{aligned} \tag{3.30}$$

where $\ell\hbar$ and $s\hbar$ are angular momentum vectors and $(\ell \mathbf{s})$ is the scalar product of the vectors ℓ and \mathbf{s} .

■ Fig. 3.15

Illustration of the change in a wave function u , with an attractive potential and the associated phase shift

Note that the potential depends on the projectile center-of-mass energy E as well as radius r . The former accounts for the nonlocalities (and thus generates effective masses and spectroscopic factors, which are related to the occupancies of single-particle states). V and W are the real and imaginary parts of the potential, both of which have volume, surface, and spin-orbit-dependent components, V_v , V_s , and V_{so} , respectively. (The spin-dependent term given above is appropriate for the scattering of spin $\frac{1}{2}$ particles by spin 0 nuclei; for the scattering of particles of zero spin, there is no spin-dependent term, while for the scattering of particles of higher spin, more complex forms are required). V_c is the Coulomb potential, a term needed if the incident particle is charged. The refracting potential V elastically scatters the incident particles, and the absorbing potential W takes account of all the inelastic processes.

The unitless form factors (► Fig. 3.16) are most often taken as

$$f(r, r_i, a_i) = \frac{1}{1 + \exp\left(\frac{r - R_i}{a_i}\right)}, \quad (3.31)$$

and

$$h(r, r_i, a_i) = -\frac{1}{2} \left(\frac{\hbar c}{m_\pi c^2} \right)^2 \frac{f'(r, r_i, a_i)}{r}. \quad (3.32)$$

Here $f' = df/dr$.

The nuclear radii are $R_i = r_i A^{1/3}$ and the parameters a_i encode the diffuseness of the nuclear surface. The subscript (i) allows these constants to be different for the different terms in the potential. The spin-orbit form is analogous to the Thomas form for atoms. Relativistic treatments generate such a term, but do not provide insight into the strength or even its sign. The Coulomb potential can be taken to be that for uniformly charged spheres or calculated numerically assuming form factors for the density similar to that for the potential.

■ Fig. 3.16

Form factors of the OM for the real, $f(r)$, and imaginary, $g(r) = -af'(r)$, components

To calculate the observable cross sections for two particles interacting through the above potential, Schrödinger's equation must be solved,

$$\frac{\hbar^2}{2\mu} \nabla^2 \Psi + (E - V) \Psi = 0, \quad (3.33)$$

where the radial part of the kinetic energy operator is (in D -dimensions)

$$\nabla_r^2 = \frac{1}{r^{D-1}} \frac{\partial}{\partial r} r^{D-1} \frac{\partial}{\partial r}. \quad (3.34)$$

As the spin of the incident particle can couple in two ways to the orbital angular momentum ℓ (to give total angular momenta of either $j = \ell \pm 1/2$), there are two solutions for each ℓ to the one-body quantum problem posed above. These solutions are identified with “+” for the “stretched” (i.e., parallel) case and “−” for the “jack-knifed” case. In the solution of the radial problem, the kinetic operator can be reduced to a simple second derivative by solving for the product of r times the radial wave function, sometimes called the reduced radial wave function y . Employing y and defining $\rho = kr$, the resulting radial wave equations become,

$$\frac{d^2 y_\ell^+(\rho)}{d\rho^2} + \left[1 - \frac{V_c}{E} - \frac{(-V_v + iW_v)f(\rho) + 4a_s(V_s + iW)f'(\rho)}{E} - \frac{\ell(V_{so} + iW_{so})h(\rho)}{E} - \frac{\ell(\ell+1)}{\rho^2} \right] y_\ell^+(\rho) = 0 \text{ and} \quad (3.35)$$

$$\frac{d^2 y_\ell^-(\rho)}{d\rho^2} + \left[1 - \frac{V_c}{E} - \frac{(-V_v + iW_v)f(\rho) + 4a_s(V_s + iW)f'(\rho)}{E} + \frac{(\ell+1)(V_{so} + iW_{so})h(\rho)}{E} - \frac{\ell(\ell+1)}{\rho^2} \right] y_\ell^-(\rho) = 0. \quad (3.36)$$

The wave number is $k = (\lambda)^{-1} = \sqrt{(2\mu c^2 E)/\hbar c}$. These (reduced) radial wave functions are zero at the origin and beyond the nuclear field tend asymptotically to the form

$$\begin{aligned} y_\ell^\pm(\rho) &\propto [H_\ell^{\text{in}}(\rho)] - S_\ell^\pm [H_\ell^{\text{out}}(\rho)], \\ &\propto [G_\ell(\rho) - iF_\ell(\rho)] - S_\ell^\pm [G_\ell(\rho) + iF_\ell(\rho)], \end{aligned} \quad (3.37)$$

where the terms in square brackets can be thought of as the incoming and outgoing waves and the $S_\ell^\pm = \exp(2i\delta_\ell)$ are the elements of the so-called scattering matrix, where δ_ℓ are the phase shifts associated with the nuclear potential. (If the potential is spherical, ℓ is a good quantum number and one only needs to be concerned with the diagonal elements of this matrix, indexed by ℓ . If on the other hand, the potential is deformed, ℓ is not a good quantum number and a full matrix – introduced by J. Wheeler – is required). The regular (goes to zero at the origin) and irregular (finite at the origin) Coulomb functions $F_\ell(\rho)$ and $G_\ell(\rho)$ are solutions of [Eqs. 3.35](#) and [3.36](#) without the nuclear terms. These functions have the asymptotic forms

$$\begin{aligned} F_\ell(\rho) &\xrightarrow{\rho \rightarrow \infty} \sin \left[\rho - \eta \ln 2\rho - \frac{1}{2}\ell\pi + \sigma_\ell \right], \\ G_\ell(\rho) &\xrightarrow{\rho \rightarrow \infty} \cos \left[\rho - \eta \ln 2\rho - \frac{1}{2}\ell\pi + \sigma_\ell \right]. \end{aligned} \quad (3.38)$$

The incoming and outgoing waves have the asymptotic forms

$$\begin{aligned} H_\ell^{\text{in}}(\rho) &\xrightarrow{\rho \rightarrow \infty} \exp \left[-i \left(\rho - \eta \ln 2\rho - \frac{1}{2}\ell\pi + \sigma_\ell \right) \right], \\ H_\ell^{\text{out}}(\rho) &\xrightarrow{\rho \rightarrow \infty} \exp \left[+i \left(\rho - \eta \ln 2\rho - \frac{1}{2}\ell\pi + \sigma_\ell \right) \right]. \end{aligned} \quad (3.39)$$

The nonspin-flip $B(\theta)$ and spin-flip $A(\theta)$ scattering amplitudes are

$$A(\theta) = f_C(\theta) + \frac{1}{2ik} \sum_{\ell=0}^{\infty} \{(\ell+1)S_\ell^+ + \ell S_\ell^- - (2\ell+1)\} e^{2i\sigma_\ell} P_\ell(\cos\theta), \quad (3.40)$$

$$B(\theta) = \frac{1}{2ik} \sum_{\ell=0}^{\infty} \{S_\ell^+ - S_\ell^-\} e^{2i\sigma_\ell} P_\ell^1(\cos\theta), \quad (3.41)$$

where σ_ℓ is the (unitless) Coulomb phase shift for the ℓ th partial wave, $f_C(\theta)$ is the (unitless) Coulomb scattering amplitude, and η is the (unitless) Coulomb or Sommerfeld parameter. These are given by

$$\begin{aligned} \sigma_\ell &= \arg\Gamma(\ell+1+i\eta) = \sigma_0 + \sum_{s=0}^{\ell} \tan^{-1}\left(\frac{\eta}{s}\right), \\ f_C(\theta) &= -\frac{\eta}{2k} \csc^2\left(\frac{\theta}{2}\right) \exp \left[2i\sigma_0 - i\eta \ln \left(\sin^2 \frac{\theta}{2} \right) \right], \end{aligned} \quad (3.42)$$

and

$$\eta = \frac{Z_p Z_t e^2}{\hbar v} = \frac{\mu Z_p Z_t e^2}{k \hbar^2} = 0.1575 Z_p Z_t \sqrt{\frac{A_p}{E_{\text{lab}}/\text{MeV}}}. \quad (3.43)$$

(The gamma function Γ is used in the definition of the Coulomb phase shift.) There are three potential observables for elastic scattering. The first is the differential (elastic) scattering cross section,

$$\frac{d\sigma_E}{d\Omega}(\theta) = |A|^2 + |B|^2. \quad (3.44)$$

The above reduces to the famous Rutherford formula when the Coulomb amplitude f_C is all that contributes to the scattering amplitude

$$\frac{d\sigma_{\text{Ruth}}}{d\Omega} = |f_C|^2 = \left(\frac{1.44 Z_p Z_t}{4E/\text{MeV}} \right)^2 \text{fm}^2 = \frac{D_c^2}{16} \csc^4\left(\frac{\theta}{2}\right) \text{fm}^2, \quad (3.45)$$

where D_c is the distance of closest approach.

The second and the third observables are the polarization, $P(\theta)$, and spin rotation, $Q(\theta)$, (Glauber and Osland 1979),

$$P(\theta) = \frac{2 \text{Im}AB^*}{|A|^2 + |B|^2} \quad \text{and} \quad Q(\theta) = \frac{2 \text{Re}AB^*}{|A|^2 + |B|^2}. \quad (3.46)$$

If the incident particle is a neutron, the total elastic cross section is finite and integrates to

$$\sigma_E = \pi\lambda^2 \sum_{\ell=0}^{\infty} \left\{ (\ell+1) |1 - S_{\ell}^+|^2 + \ell |1 - S_{\ell}^-|^2 \right\}. \quad (3.47)$$

To deduce the total inelastic (sometimes called the reaction) cross section, all one needs to note is that for each ℓ -wave, the outgoing wave is reduced in intensity by $|S|^2$ relative to the ingoing wave, therefore

$$\sigma_R = \pi\lambda^2 \sum_{\ell=0}^{\infty} \left\{ (\ell+1) (1 - |S_{\ell}^+|^2) + \ell (1 - |S_{\ell}^-|^2) \right\}. \quad (3.48)$$

The transmission coefficients can be identified with

$$T_{\ell}^{\pm} = 1 - |S_{\ell}^{\pm}|^2 \quad (3.49)$$

and in so doing, one can see that the reaction cross section in the absence of intrinsic spin effects results in [Eq. \(3.26\)](#).

The total cross section, a quantity finite only for neutron scattering, comes from the sum of the elastic and reaction cross sections. Upon canceling terms for each pair of $|1 - S_{\ell}|^2 + 1 - |S_{\ell}|^2$ terms, one gets

$$\sigma_T = \sigma_E + \sigma_R = 2\pi\lambda^2 \sum_{\ell=0}^{\infty} \left\{ (\ell+1) (1 + \text{Re}S_{\ell}^+) + \ell (1 - \text{Re}S_{\ell}^-) \right\}. \quad (3.50)$$

There are several interesting benchmarks related to the results of [Eqs. \(3.47\)–\(3.50\)](#). The elastic scattering cross section (for neutrals) spans from where $S_{\ell} = 1$ (both elastic and inelastic cross sections are zero) to $S_{\ell} = -1$. Thus the cross section for each ℓ lies between

$$0 \leq \sigma_{E,\ell} \leq 4\pi\lambda^2(2\ell+1). \quad (3.51)$$

When $S_{\ell} = 0$,

$$\sigma_{E,\ell} = \sigma_{R,\ell} = \pi\lambda^2(2\ell+1) \quad \text{thus} \quad \sigma_{T,\ell} = 2\pi\lambda^2(2\ell+1). \quad (3.52)$$

► Equation (3.52) demonstrates that the presence of the inelastic scattering implies an elastic contribution. This explains the factor of 2 in ► Eq. (3.50), which indicates that the *total* cross section for neutrals, that is, the case for which the elastic scattering cross section is finite, is *twice* the geometric reaction value. Recalling the initial discussion of the geometric cross section, partial waves with ℓ greater than some value ℓ_{\max} do not contribute significantly to the summations in ► Eqs. (3.48)–(3.50), thus the sums may be truncated.

3.3.3 The Dispersive Optical Model (DOM)

In 1926 R. de L. Kronig noticed that the reflection and absorption of light were interrelated. The next year Hans Kramers explained this relation, essentially allowing for the calculation of *both* the absorption (extinction coefficient) and the index of refraction from the measurement of the 90° reflectance. The key concept is that the response of a system to the stimulus (in this case light and the response in question is called the dielectric response) is dictated by a *complex* quantity, for which the real and imaginary parts are “two-sides of the same coin.” The “sides” are related to one another by energy integrals over the complementary components. (That is, the real part at energy ε is related to an integral over all energies of the imaginary component with a pole at the energy of interest, and vice versa.) For example, in the case of the complex dielectric response (α in the equations below) of matter as a function of the frequency of the stimulus ω

$$\alpha = \alpha_1 + i\alpha_2$$

$$\alpha_1(\omega) = \frac{1}{2}P \int_{-\infty}^{\infty} \frac{\alpha_2(\omega')}{\omega' - \omega} d\omega' ; \quad \alpha_2(\omega) = -\frac{1}{2}P \int_{-\infty}^{\infty} \frac{\alpha_1(\omega')}{\omega' - \omega} d\omega', \quad (3.53)$$

where P stands for the “Cauchy principal value” of the integral whose integrand has a singularity. These relationships are the result of “causality”; that is, the system cannot respond before the stimulus arrives. From the earliest days of the nuclear optical model, it was appreciated that this relationship should be enforced, as it is in all careful optical spectroscopy.

The difficulty in imposing causality is that the interrelationships are in the form of “dispersion relations.” That is, one must know the real (imaginary) part of the response at *all* energies to deduce the imaginary (real) response at any energy. It is the “all” that provides the stumbling block. As a consequence, this dispersive form of the optical model, or dispersive optical model (DOM), has only limited applicability. However, recently, more effort has been directed at the dispersive optical model analyses of data, as they have been shown to be of great value in predicting the behavior of nuclei removed from stability. The utility of this generator is that in addition to using scattering data (at positive energy), structural data (at negative energy, i.e., the position of bound states) is used to fix the real part of the potential, making both parts more robust (via the dispersion interrelationship). A concise discussion of the Kramers–Kronig dispersion relations as applied to the dielectric response can be found in (Kittel 1986). A full presentation of the dispersive optical model can be found in (Mahaux and Sartor 1990) and its most recent application to nuclei as a function of n/p asymmetry can be found in (Charity et al. 2006, 2007). The most important implications of the DOM [based primarily on nucleon knockout reactions (e,e'p) and n and p elastic scattering] are presented below.

First, the connection between the full complex potential and that used in one-body structure models must be unmasked. The imaginary part of the potential vanishes at the Fermi surface. Thus the real one-body potential used as a basis for simple nuclear structure

models is *only* valid near the Fermi surface. Or conversely, if one is interested in phenomena that only involve excitations near the Fermi energy, working with a real potential is valid. On the other hand, at high excitation energies, which are likely to involve particles far above and holes far below the Fermi surface, the imaginary component must be dealt with.

The second feature of this model is that effective masses and spectroscopic factors can be extracted from the energy dependence of the potentials (the former from the real part and the latter, which are related to the occupancy of single-particle states, from the imaginary part). The most striking result of the optical model is that the potential must be made energy-dependent if either the position of the single-particle levels or elastic scattering over a broad range of energies are to be reproduced. While the positions of the levels near the Fermi surface can be extracted from single-nucleon transfer reactions, (e,e'p) reactions are needed to determine the strength functions below the Fermi surface. (These functions will exhibit sharp peaks for orbits slightly below the Fermi surface and broad distributions for deeply bound orbits.) This dependence is shown in [Fig. 3.17](#) for ^{208}Pb .

If the dependence is linear, an effective mass (m^*) can be introduced to allow the single-particle energy to be recast in terms of a fixed potential,

$$\varepsilon = \frac{(\hbar k)^2}{2m} + \left[V_0 + \frac{dV}{d\varepsilon} \varepsilon \right] = \frac{(\hbar k)^2}{2m} + [V_0 + \alpha \varepsilon], \quad (3.54)$$

$$\varepsilon = \frac{(\hbar k)^2}{2m(1-\alpha)} + V_0(r) \left(\frac{1}{1-\alpha} \right) = \frac{(\hbar k)^2}{2m^*} + V_0'(r), \quad (3.55)$$

with

$$\frac{m^*}{m} = 1 - \alpha = 1 - \frac{dV(r, \varepsilon)}{d\varepsilon} \approx 0.7 \quad (3.56)$$

Referring back to the harmonic oscillator, [Fig. 3.18](#) shows that an effective mass greater (less) than the nucleon mass will decrease (increase) the single-particle level spacing, making both the single-particle level density and many-body density of states larger (smaller).

The above discussion is associated with the finite range of the nucleon-nucleon interaction. This can also be viewed (via a Fourier transform) as a momentum dependence of the

■ **Fig. 3.17**

The energy dependence of the potential needed to reproduce the positions of the single-particle levels for ^{208}Pb (from Mahaux and Sartor 1990)

■ Fig. 3.18

How an effective mass affects the single-particle level spacing

interaction. As a consequence, the effective mass contribution mentioned above is often called the “ k -mass” or the momentum-dependent effective mass. This mass is relevant for matter (i.e., neutron-star calculations) and its dependence on neutron–proton asymmetry has attracted considerable attention (Li et al. 2008).

The description of real nuclei requires more than the k -mass. A second multiplicative effective-mass term, the “omega mass” or m_ω , arises from a time nonlocality of the interaction. (As the exchange involves mesons with mass, the “throwing” and “catching” are not simultaneous events.) This time nonlocality can be viewed as a fundamental energy (or frequency) effect. Following prescriptions developed by Mahaux and collaborators (Mahaux and Sartor 1990), the relative change of the effective mass from real nucleon masses can be represented by two unitless terms,

$$\frac{m^*}{m} = m_k m_\omega. \quad (3.57)$$

The “omega mass” is peaked at the nuclear surface, producing what solid-state scientists would call surface states. In the nuclear case, this just corresponds to low-lying (i.e., near the Fermi surface) collective excitations associated with the physical surface. The combined effective masses and the potentials from which they are derived are shown in ► Fig. 3.19. The k -mass suppresses the effective mass in the interior and the omega-mass produces a peak at the nuclear surface. Also extracted from this analysis are the occupation probabilities of single-particle levels, a subject that will be addressed in the next section when discussing single-particle knockout reactions from nuclei far-removed from stability.

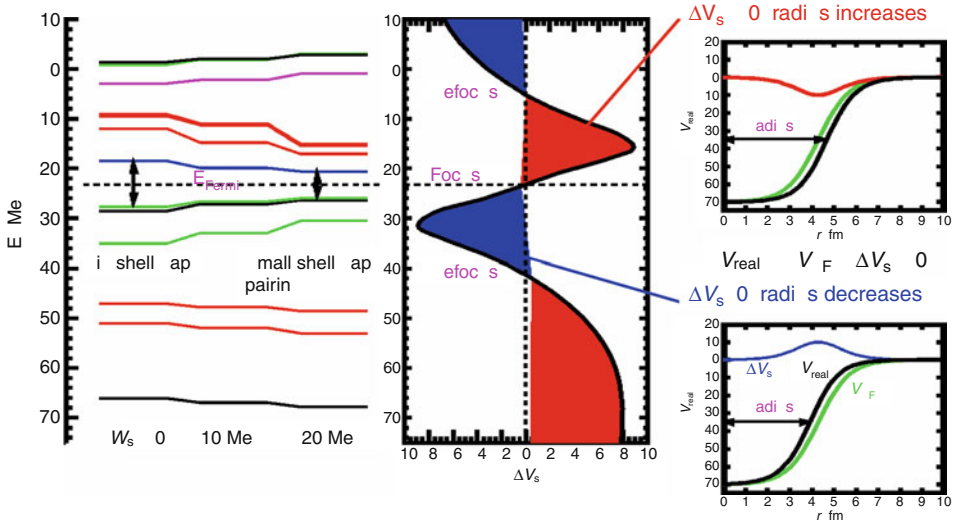

What must also be appreciated is that effective masses: (1) can be viewed as a compact repackaging of other physics, such as momentum dependent potentials, and (2) are required for discussing reactions as well as structure. Examples of the latter (for reactions) stem from the fact that the spacing of single-particle levels near the Fermi surface affects the many-body density of states (ω).

3.4 Near-Barrier Reaction Mechanisms

The study of nuclear reaction mechanisms has revealed a breadth of phenomena that have subsequently stimulated advances in related areas of nuclear research, as well as in nuclear

■ Fig. 3.19

Effect of the omega-mass on the refocusing of single-particle levels near the Fermi surface. This focusing is the result of the requirement that the potential be “pushed in” below the Fermi surface and “pulled out” above the Fermi surface in order to reproduce both the position of bound states and the scattering data (from Charity et al. 2007)

applications. The impetus to obtain a quantitative understanding of these phenomena has motivated the development of increasingly sophisticated measurement technologies, described elsewhere in this Handbook. Here, only an overview of the principal reactions of interest to, or being investigated by, nuclear chemists is provided. Additional references can be found in (Cerny 1974; Durand et al. 2001; Benenson et al. 2002).

Nuclear reaction mechanisms can be schematically separated into two general categories: low-energy reactions that are strongly influenced by structure around the Fermi energy and those at much higher energies where elementary nucleon-nucleon collisions become increasingly important. In either case, the correlations existing within the (ground-state) projectile and target can play determinative roles. This is true at low energy (alpha decay informs about alpha-clustering in the low-density surface of heavy nuclei) as well as high energy (where e^- -induced knockout reactions indicate an overwhelming dominance of high relative-momentum n-p pairs.)

As the model of nuclei composed of nucleons moving independently in a one-body potential is one that is roughly 75% correct, this mean-field approach often provides a rather good initial description of reactions. However, above energies commensurate with the depth of the one-body potential, this potential has little meaning and the best starting point is to consider collisions as sequences of individual nucleon-nucleon collisions. Often a distinction between the *mean-field* and *nucleon-nucleon* (N-N) regimes is made at bombarding energies of about 20 MeV per projectile nucleon (20 MeV/A). Below this energy, individual nucleon-nucleon (N-N) interactions lead to thermalization sufficiently quickly that no individual nucleon has sufficient energy to escape the mean-field potential well. When this has been achieved, a compound nucleus has been formed. As the relative collision energy increases, the

energy dissipation process produces harder N-N collisions with scattered nucleon energies in excess of the mean-field constraints, leading to prompt particle emission. The transition from mean-field to N-N dominance as the bombarding energy increases is a continuous one, mediated by the number of collisions that are not prohibited by the Pauli Principle (*Pauli blocking*). The blocking of 2-body collisions is strong below the Fermi energy, thus leading to surprisingly long mean-free paths at low energy, but weakens as the relative energy per nucleon approaches the Fermi energy.

However, it must also be appreciated that in either regime (mean-field or N-N), the correlations that exist in nuclei can be observed, sometimes as details in the extremes of distributions, other times as an essential ingredient required to explain gross observations, such as the α -particle emission in general.

This section is divided into several parts that focus on the near-barrier domain. The following section addresses N-N dominated reactions. One final comment must be made in an attempt to be forward looking. While the partition of reactions into low and high energy (mean-field dominated or not) has been common in the past, future work must move beyond this mental partition. As mentioned above, due to correlations in the nucleus, the ground state is replete with high-energy nucleons, well above what would be expected from the Fermi-gas model. It is actually this aspect, the correlations that exist in nuclei (for example as a function of n/p asymmetry), that will be the focus of many reaction studies in the future.

3.4.1 Neutron Capture

Recent work at the lowest energies has generated detailed data on (n,x) reactions on nuclei throughout the periodic table. Due to interest in advanced fuel cycles, as well as for possible transmutation of reactor waste, the attention has focused on the actinide elements. (All of these data can be found at the NNDC web site.)  [Figure 3.20](#) shows both fission and capture cross sections over six orders of magnitude in energy for ^{232}Th . The three regions shown schematically in  [Fig. 3.10](#) are clearly seen. The central region is dominated by pronounced resonances, bordered on each side by smoothly varying cross sections. The resonances for heavy nuclei have many-body wave functions, far too complicated to describe. (Only in the lightest nuclei can these resonances be described by simple single-particle excitations.) At higher energy, the number of these many-body resonances is so large per unit energy that they overlap and no experimental resolution would be sufficient to resolve them. At energies lower than the resonance region, one sees capture into the tail of the lowest-lying resonance, but with a probability that increases with the increasing de Broglie wavelength of the neutron (with decreasing energy).

In calculating the capture cross section for the lowest-energy neutrons, it is necessary to consider the energy level width Γ_i and the *natural lifetime* τ_i of resonances. The uncertainty principle gives

$$\Gamma_i = \hbar/\tau_i, \quad (3.58)$$

i.e., short lifetimes correspond to large level widths. For the general reaction $A + a \rightarrow [\text{CN}] \rightarrow B + b$, the resonance cross section is given by the *Breit–Wigner* form (Breit and Wigner 1936):

$$\sigma(a, b) = \frac{\pi \lambda^2 w(I) \Gamma_a \Gamma_b}{(E_a - E_0)^2 + (\Gamma/2)^2}, \quad (3.59)$$

■ Fig. 3.20

The Th n-capture and fission cross sections from 1 eV to 1 MeV (from Aerts 2006)

where $w(I)$ is a spin factor, a function of the spin of the CN (many-body) state,

$$w(I) = \frac{2I_{\text{CN}} + 1}{(2I_A + 1)(2I_a + 1)}, \quad (3.60)$$

and Γ is the total width composed of the sum of the partial widths $\Gamma = \sum_k \Gamma_k$ (the summation index k includes the exit channel b). E_a is the projectile center-of-mass energy and E_0 is the energy of the resonant state.

At very low energies, comparable to the average thermal energy $(3/2)k_B T \approx 0.025$ eV, (n, γ) is the only open channel. Thus the sum above has only one term, corresponding to gamma-ray emission ($b = \gamma$). These conditions, plus the realization that the neutron capture rate should depend on the velocity v (this is basically a detailed balance argument, more neutrons per unit time will impact the nucleus per unit time at high velocity than low), lead to the following approximations:

$$\begin{aligned} E_a = E_n \approx 0, \quad \text{so that} \quad E_n - E_0 \approx -E_0 \quad \text{and} \\ \Gamma_a = \Gamma_n \propto v_n \Gamma \quad \text{and} \quad \Gamma_b = \Gamma_\gamma = \Gamma. \end{aligned} \quad (3.61)$$

Furthermore, E_0 is a constant close to zero (as the resonance is close to zero energy). Thus the first term in the denominator is small compared to the second and, aside from terms that do not depend strongly on energy, the Breit-Wigner formula – [Eq. \(3.59\)](#) – reduces to a simple $1/v$ dependence,

$$\sigma(n, \gamma) \propto \pi \lambda^2 w(I) \left(\frac{v_n \Gamma \Gamma}{\Gamma^2} \right) \approx \frac{\pi \hbar^2 v_n}{(m v_n)^2} \propto \frac{1}{v_n}. \quad (3.62)$$

That is, for *thermal neutrons*, the lower the energy the higher the cross section.

As the neutron energy increases from thermal to higher energies, the cross section first falls monotonically according to the $1/v$ law. In the vicinity of each resonance state, where $E_n \approx E_0$, sharp spikes are observed in the cross section. When the state density (levels per unit energy) times the mean intrinsic width rises to order one, states are no longer resolved. At this point, the cross section is smoothly varying, of magnitude very roughly equal to the geometric value $\sigma^{\text{geo}} = \pi R^2$.

While the actinide region has achieved much recent attention, (n, γ) reactions throughout the periodic table are important for the analytic tool of neutron activation. Cd is also important for reactor control as the reaction $^{113}\text{Cd}(n, \gamma)$, with $\sigma = 2.0 \times 10^4$ b, is used to control the reactor neutron flux and hence the multiplication factor k in reactor design. The reaction $^{135}\text{Xe}(n, \gamma)$ with $\sigma = 2.6 \times 10^6$ b is a prominent fission-product poison that creates problems in the operation of nuclear reactors by consuming neutrons unproductively.

One of the most important features that can be gleaned from the (n, γ) data mentioned above is the density of states in the excitation energy region near the binding energy of the neutron. Upon capture, a neutron with thermal energy creates a nucleus with $A + 1$ nucleons and $E^* = B_N$. Collecting data from throughout the periodic table has validated the dependences expected for the many-body density of states from the *Fermi-Gas Model*. In this model, which is also needed to calculate the contribution to the heat capacity of the conduction electrons in metals (the component that becomes dominant at very low temperatures), the excitation energy (the thermodynamic internal energy often indicated by U) is proportional to the square of the temperature. The reason for the square rather than the linear dependence in classical gases is that not all the nucleons share in the excitation energy. The number of excited nucleons increases in proportion to T , as does the average energy of each of these (excited) nucleons. The same explanation holds for conduction electrons in metals at very low T .

$$E^* = aT^2. \quad (3.63)$$

As $dU = + SdT - PdV$ and $U = E^*$, the entropy is

$$S = \left(\frac{dE^*}{dT} \right) = 2aT, \quad (3.64)$$

and thus, using the Third Law, $S = k_B \ln \omega(E^*)$, one would expect the density of levels to be roughly

$$\omega^L(E^*) \approx Ce^{2aT} \approx Ce^{2\sqrt{aE^*}}. \quad (3.65)$$

Refer to Huizenga and Moretto (1972) for a general discussion of level densities. Note that the state density ω enumerates each projection of the angular momentum while the level density ω^L does not.

A more careful analysis of a two-component Fermi gas with spin and thermal energy ($U = E^* - E_{\text{rot}}$) yields (Bohr and Mottelson 1969)

$$\omega^L(U) = Ce^{2\sqrt{aU}} / U^2. \quad (3.66)$$

In practical usage the constants a and C are empirically-determined. Only experiments at low E^* , like resonance counting, are sensitive to the prefactor C . Experiments in the region of unresolved states are sensitive only to a relative change in the level density, i.e., $\omega^L(E^* + \Delta) / \omega^L(E^*)$, and thus only the *level density parameter* a can be extracted. It is the parameter a that

relates the excitation energy to the nuclear temperature. This parameter is roughly proportional to A but is reduced near closed shells. For near- ground-state nuclei away from closed shells, the average value is near $a \approx (A/8) \text{ MeV}^{-1}$ (► Fig. 3.21).

The mass number dependence is what one would expect from “particle-in-a-box logic,” i.e., the larger the box, the greater the number of single-particle levels per unit energy and the greater the number of ways to distribute particles among these levels with a fixed total available energy. However, independent-particle models predict that a should be closer to $(A/12) \text{ MeV}^{-1}$. There are both macroscopic and microscopic explanations for this discrepancy. From a macroscopic view, the nuclear surface, being less dense than the bulk, can accommodate more levels per nucleon. (Lower density, larger volume per particle, larger box, higher density of single-particle states.) This approach was pioneered by Töke and Swiatecki (1981).

These semiclassical formulations for the mass number A and deformation dependence of a are extensively used in statistical decay models. From the microscopic point of view, the augmentation of the density of states at low energy is explained as follows. In a single-particle picture the excitation is “carried” by exciting nucleons to single-particle states (solutions to the one-body potential problem). However, collective rotational bands can be built on any single-particle structure (excitation). Although these states are in principle described in the single-particle picture, they would lie at very high excitation energy in such a model rather than where they really are – low energy. Thus the enhancement in the level density at low energy – the $a \approx (A/8) \text{ MeV}^{-1}$ – can be viewed as a consequence of collective excitations that in a pure single-particle picture belong at very high energy. While the relocation of many-body states from high to low energy greatly increases the ω^L at low energy, it hardly affects the count at high energy as the number of states increases exponentially.

Thus one would expect a to decrease (ω increases, but the rate of increase slows) with excitation. In the last decade this has been confirmed (Shlomo and Natowitz 1990). Modern statistical model calculations (see ► Sect. 3.5) now employ an excitation-energy-dependent a that varies from about $a = (A/7) \text{ MeV}^{-1}$ at low energy to about $a = (A/13) \text{ MeV}^{-1}$ by the time the total excitation energy reaches 100 MeV.

Level-density parameter a as a function of mass number. The solid line shows an average fit for $a = (A/7.9) \text{ MeV}^{-1}$ (from Huizenga and Moretto 1972)

3.4.2 Nucleon and Heavy-Ion Elastic Scattering

3.4.2.1 Nucleon Elastic Scattering

Elastic scattering describes the simplest target-projectile interactions: specifically, those in which the colliding nuclei experience only an angular deflection, but do not change their Z or A composition or their energy state (► Fig. 3.22). For below-barrier projectile energies, the differential cross section for elastic scattering is governed by the Rutherford (Coulomb) scattering equation (► Eq. (3.45)). Rutherford employed this expression to deduce an upper limit to the size of nuclei and, from the angular distribution, the atomic number of the scatterer (Rutherford 1911). This same technique is in common use in analytical surface science work and was notably applied to analyze the elemental composition of lunar samples in situ by observing the scattering of alpha particles emitted from a radioactive source.

Below the Coulomb barrier only elastic and inelastic excitation by Coulomb excitation are likely. Moving above the Coulomb barrier, various inelastic reaction channels compete with each other and with elastic and Coulomb excitation for the partitioning of the income flux. These channels interfere with one another, as do elastic fluxes from near and far-side scattering. ► Figure 3.23 shows all the existing data for nucleon scattering from Ca isotopes. (Shown are the differential cross sections and the analyzing powers. The cited reference also contains spin-rotation data.) Also shown in this figure are the Dispersive Optical Model fits that define the potential, which in turn define the effective masses and occupancies of single-particle states.

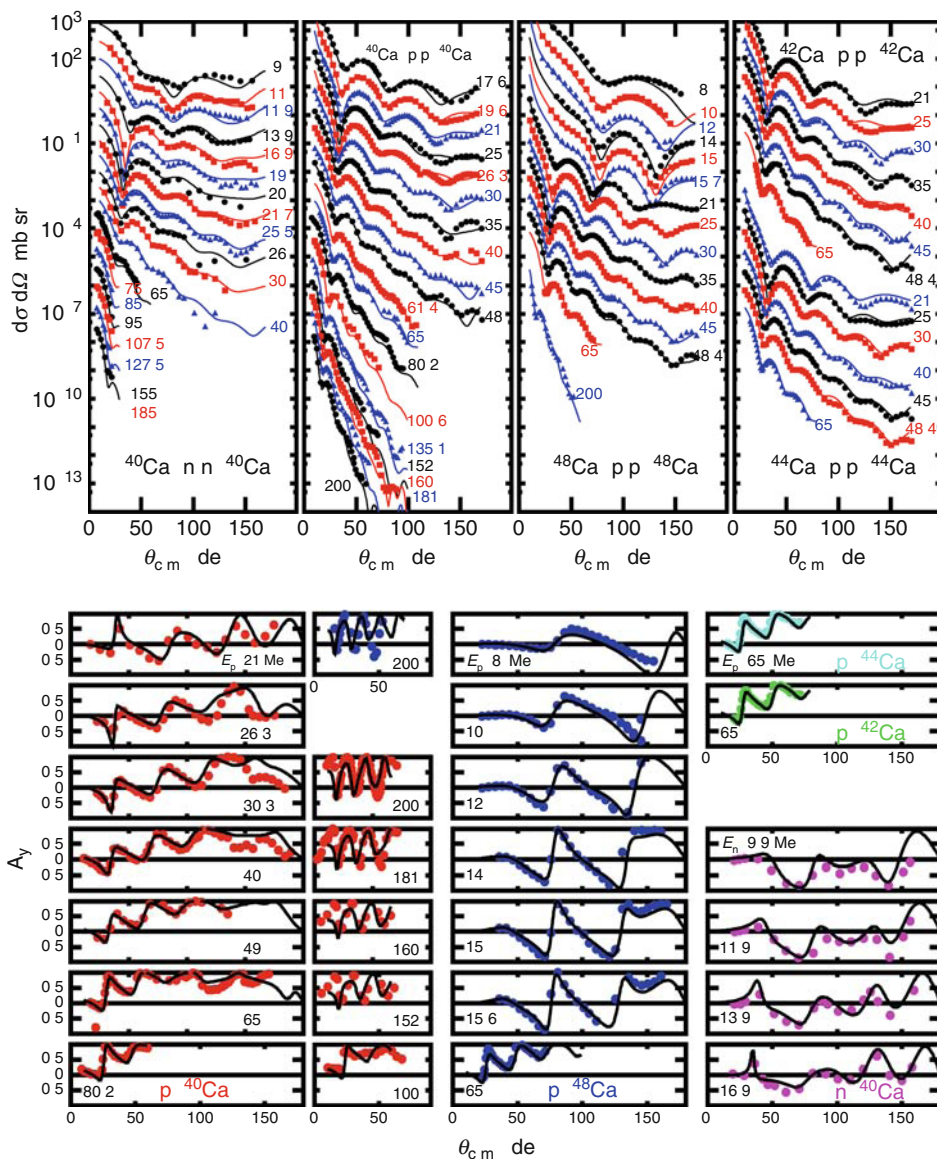

The occupancy of single-particle states was extracted in the 1980s for stable nuclei using $(e,e'p)$ for several nuclei on the line of beta stability. Much recent effort has been spent in attempting to do the same for nuclei off the line of stability and thus extract the asymmetry dependence of spectroscopic factors. Spectroscopic factors expose the deviation from a simple one-body description of the nuclear quantum problem. For example, if removal of a nucleon, from a system with A nucleons and associated quantum numbers, leaves the $A - 1$ system in the ground state, the spectroscopic factor would be unity. However, as the real A (and $A - 1$) systems are strongly correlated, removal of a particle requires a “reorganization” of the others. The spectroscopic factors can be roughly thought of as the fraction of the wave function (of valence particles) that can be described by occupancy of a mean-field quantum solution. Standard shell models predict spectroscopic strength less than one, but such calculations

■ Fig. 3.22

Trajectories of projectiles impinging on a target for reactions below the barrier (*left*), where only elastic scattering occurs and above the barrier (*right*), where the more central trajectories are absorbed. As is seen, nuclear reactions will necessarily decrease the large angle fraction of elastically scattered projectiles

World data set (below 200 MeV) of n and p elastic scattering on Ca isotopes along with DOM fits
(From Charity et al. [2007](#))

only capture that piece of the correlations contained in the space of the calculation. Particle correlations (for example multiparticle hole strength required to describe the ground state) beyond this very limited space would yield spectroscopic strength with even greater reductions than those predicted by standard shell-model calculations.

Three experimental lines of approach have been used to study the evolution of spectroscopic strength with asymmetry: the dispersive optical model, nucleon knockout reactions, and

■ Fig. 3.24

Proton single-particle occupation probabilities in ^{40}Ca (circles), ^{48}Ca (squares), and ^{60}Ca (triangles) as deduced from a Dispersive Optical Model fit (Charity et al. 2007)

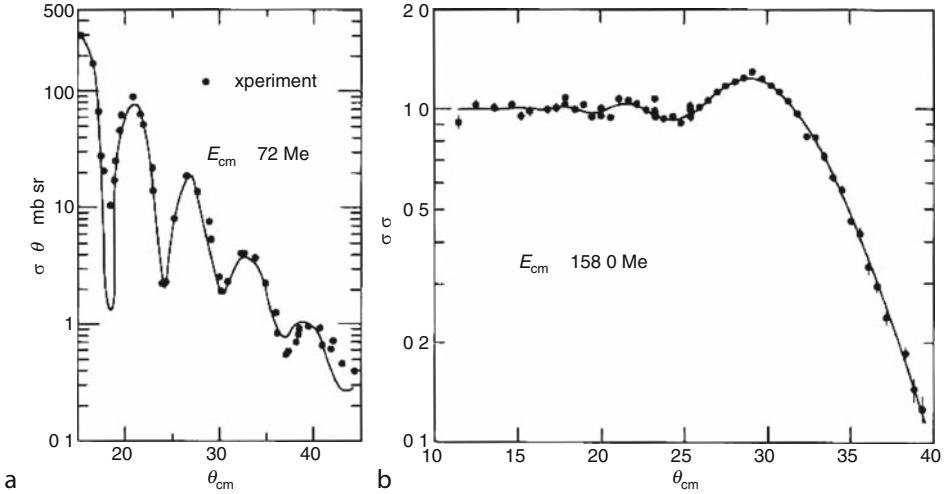

transfer reactions, the latter two projects using secondary beams. The results from these experiments are as follows: there is a general trend that the spectroscopic strength decreases (below the Fermi surface) for the minority (protons in this case) species. That is, for the analysis of the Ca isotopes presented in Fig. 3.23, the proton spectroscopic strength below the Fermi surface decreases in going from ^{40}Ca to ^{48}Ca to ^{60}Ca (^{60}Ca being an extrapolation from the fit), Fig. 3.24. This trend is likely the result of increasing p-n correlations mediated by the tensor force. The same trend is found in nucleon knockout reactions (Gade et al. 2004). However, here the effect mentioned above is found to be much stronger than that found in the DOM analysis. An additional difference is that the knockout work implies that this effect is a function of binding energy (the greater the binding, the greater the correlations), while in the dispersive optical model, the evolution is more subtle, depending on the parity of the levels (of both neutrons and protons) engaging in the correlations. For example, in the DOM case, while the occupancy of single-particle proton states decrease (increase) below (above) the Fermi surface in going from ^{40}Ca to ^{60}Ca ; there is little change in the neutron occupancy over this same range of asymmetry. This latter trend, while in contrast to the knockout results, is in agreement with the transfer studies (Lee et al. 2010). While the elucidation of this trend will be a major focus of research in the coming decade, the present DOM analysis suggests that nucleon correlations increase with the number of possible n-p pairs. (That is, protons become more strongly correlated with increasing neutron number, while neutron correlations do not increase with increasing neutron number.)

3.4.2.2 Heavy-Ion Elastic Scattering

Because of its diffractive nature (Fig. 3.25), elastic scattering measurements provide a useful probe of the nuclear potential near the nuclear surface, thus providing parameters for potential models such as the optical model. Reaction cross sections for reactions induced by heavy ions (HI) can also be determined from elastic scattering experiments (see superscript exp in the

■ Fig. 3.25

Left: Elastic scattering angular distribution for $^{12}\text{C} + ^{16}\text{O}$, illustrating *Fraunhofer scattering* (Hiebert and Garvey 1964). **Right:** ^{16}O ions incident on a ^{208}Pb target, showing a *Fresnel scattering* pattern (Baker and McIntyre 1967). The disappearance of elastic events at large angles is due to the absorption of lower ℓ -waves

following equation), since nuclear reactions preferentially remove elastic events at large scattering angles (low ℓ). Consequently, the ratio of the experimental elastic scattering cross section $d\sigma_{\text{E}}/d\Omega$ to the Rutherford scattering cross section as a function of angle will decrease strongly beyond some critical angle $\theta_{\text{crit}} \sim 30^\circ$ (► Fig. 3.25). The reaction cross section σ_{R} can be estimated from

$$\sigma_{\text{R}} = \int_{\theta_{\text{crit}}}^{\pi} \frac{d\sigma_{\text{Ruth}}}{d\Omega} d\Omega - \int_{\theta_{\text{crit}}}^{\pi} \frac{d\sigma_{\text{el}}^{\text{exp}}}{d\Omega} d\Omega. \quad (3.67)$$

More precise results can be obtained with diffractive models (Frahn 1978), which relate ℓ_{max} to the quarter point (or grazing) angle $\theta_{1/4}$, the angle at which $\sigma_{\text{el}}^{\text{exp}}(\theta)/\sigma_{\text{el}}(\theta) = 0.25$, $\ell_{\text{max}} = \eta \cot(\theta_{1/4}/2)$. The adherence of experiment to the Rutherford values for scattering angles well below $\theta_{1/4}$ makes elastic scattering a valuable technique for cross-section normalizations in heavy-ion reaction studies. The strong Coulomb field for heavy-ion collisions, proportional to $Z_p Z_t$, has important nuclear consequences. Among these are the Coulomb excitation of deformed nuclei to very high rotational levels and the fission of heavy nuclei at relativistic projectile energies.

3.4.3 Inelastic Excitation

Inelastic scattering refers to collisions in which there is a change in the energy state(s) of the target and/or projectile nuclei, but no change in Z and A . Such reactions are useful for

■ Fig. 3.26

Spectrum of protons observed in the $^{20}\text{Ne}(p,p')$ reaction. Elastically scattered protons appear in the 0^+ peak at 0.0 MeV near channel 1,100. Inelastic events populate the excited states of ^{20}Ne (Courtesy of E. J. Stephenson, IUCF)

investigating both the quantal and collective features of nuclear structure. Studies that employ (p,p') and (α,α') reactions are particularly useful for measuring the spins and parities of particle states in stable nuclei. In ▶ Fig. 3.26 the spectrum of protons observed in the $^{20}\text{Ne}(p,p')$ reaction is shown as an example.

Coulomb excitation is the process by which nuclear excitation occurs without a hard nuclear reaction. Basically, the energy for excitation is extracted from the time-varying Coulomb field as a target and projectile pass one another. This reaction has had a significant rebirth with the availability of fast (>50 MeV/A) heavy-ion beams. The basic process (▶ Fig. 3.27) is strongly energy-dependent (▶ Fig. 3.28) and allows for the extraction of the reduced matrix element for quadrupole excitation (from the probability of exciting the first 2^+ state) as well as studying collective giant resonances. The revival is due to the potential for making these measurements on fast (off β -stability) secondary radioactive beams (Glasmacher 1998).

In the case of the excitation of the first 2^+ state of even-even nuclei, in addition to determination of the energy of this low-lying state, one also measures the reduced matrix element $B(E2)$ from the yield of γ -rays depopulating this state. As the beam energy is increased, the probability for excitation of large-scale collective motion (giant resonances) increases (▶ Fig. 3.28). Fast-beam Coulomb excitation has been a fruitful area of research, because low-intensity secondary beams can be used since cross sections can be significant fractions of a barn. The focus here will be on just one of the interesting findings of this productive research area.

▶ Figure 3.29 shows the energy of the 2_1^+ state for silicon, sulfur, and argon isotopes, $Z = 14, 16, 18$, respectively. (The trailing subscript is used to indicate which level of a specific spin and parity to which one is referring. Thus 0_2^+ is the second 0^+ state in that nucleus.) First, focus on the behavior at $N = 20$. The relatively high energy of the 2_1^+ state in Si and S indicates that $N = 20$ is in fact magic for the corresponding proton numbers. Shifting the focus to the

■ Fig. 3.27

Schematic picture of the first-order Coulomb excitation of a nucleus from an initial state to a final bound state and its subsequent γ -decay

■ Fig. 3.28

Calculated cross sections for Coulomb excitation of ^{40}S in the first excited state (2^+), the giant dipole resonance (GDR), and the giant quadrupole resonance (GQR) in ^{40}S using a ^{40}S beam incident on Au, versus the beam energy. The calculation assumes a minimum impact parameter of 16 fm (From Glasmacher 1998)

region of $N = 28$, one finds that the same cannot be said, i.e., $N = 28$ is seemingly not magic for these very neutron-rich species. The $B(E2)$ values support this assertion. This loss of “magicity” to the “South-East” of stability on the chart of the nuclides is called the “island of inversion.” More generally, it has been appreciated that the values, or strengths, of the “magic” numbers can change with unusual n/p ratios. This shifting magicity can have universal consequences. For example, it has been postulated that the inversion region mentioned above determines the $^{48}\text{Ca}/^{46}\text{Ca}$ abundance ratio in Nature (Sorlin et al. 1993).

Inelastic excitation via α -particles (i.e., α, α') has provided the bulk of the data on the highly collective giant monopole resonance, often called the “breathing mode.” Data of this type (► Fig. 3.30) have been used to extract the nuclear incompressibility of finite nuclei, and with the aid of models, the incompressibility of symmetric matter (see ► Sect. 3.7).

With greater overlap of the two nuclear potentials, additional channels open up that permit transfer of one or more nucleons, or *direct reactions* (Austern 1970). Classic examples of direct reactions are one-nucleon transfer, or stripping, and pickup reactions. *Stripping* is the transfer of a single nucleon from the projectile to the target, for example a (d,p) reaction. *Pickup* is the

■ Fig. 3.29

Excitation energies of the first excited 2^+ states in argon, sulfur, and silicon plotted versus the neutron number N . Measured values (*solid circles*) are compared to shell-model calculations with a full and a truncated set basis states

reverse reaction, i.e., transfer of a nucleon from target to projectile, as in a (p,d) reaction. At low beam energies, the higher probability for neutron transfer relative to proton transfer demonstrates the charge polarizability that the colliding nuclei experience as they approach one another. This is shown schematically in [Fig. 3.31](#).

Direct reactions need not be simple one-step processes. The likelihood of a one-step process improves if the momentum transfer q is close to the angular momentum of the transferred nucleon divided by the nuclear radius at which the transfer occurs,

$$q \equiv |\mathbf{k}_{\text{in}} - \mathbf{k}_{\text{out}}| \approx \ell/R. \quad (3.68)$$

If this matching condition is satisfied, the cross sections can be compared to one-step reaction models, such as the Distorted-Wave Born Approximation (DWBA), from which spectroscopic information can be extracted. The common DWBA codes are DWUCK and PTOLEMY.

■ Fig. 3.30

■ Fig. 3.31

Schematic diagram of a (d, p) transfer reaction. Notice that the deuteron is polarized due to mutual Coulomb repulsion with the target. For a (p, d) pick-up reaction the arrows should be reversed

Stripping and pickup studies with heavy radioactive (secondary) beams on light targets are beginning to provide structure data on nuclei far-removed from stability. Furthermore, since the (d, p) reaction is the analog of neutron capture (n, γ) , it provides an important surrogate pathway for studying nuclear mass buildup in r -process nucleosynthesis (see ▶ Chap. 12 in Vol. 2). Using the $d({}^A_Z X, {}^{A+1}_Z X)p$ reaction, reverse kinematics reactions with beams of neutron-rich radioactive nuclei make it possible to study the structure and neutron-capture probabilities of nuclei nearer the *neutron-drip line* (neutron separation energy near zero).

A similar tool that is useful for studying mirror nuclei and isobaric analog states is the *charge-transfer reaction* of the type (p, n) or (n, p) , the nuclear reaction equivalent of beta-decay. *Mirror nuclei* are pairs of isobars that can be interconverted by exchanging a neutron and a proton, e.g., ${}^{15}_7\text{N}_8$ and ${}^{15}_8\text{O}_7$. An *isobaric analog state* of nucleus ${}^A_Z X_N$ is also a state in the

nucleus for which nucleonic wave functions are the same, as are the masses after correction for the Coulomb energy and the neutron-proton mass difference. One practical application of this process has been the measurement of the $^{37}\text{Cl}(p,n)^{37}\text{Ar}$ and $^{71}\text{Ga}(p,n)^{71}\text{Ge}$ cross sections that are related to understanding measurements of the *flux of solar neutrinos* (Bowles and Gavron 1993).

Numerous theoretical models have been employed in the analysis of direct reactions at low energies. Among the most prominent of these is the coupled-channels approach, which incorporates the quantum structure of the colliding nucleus and its product (Tamura 1965; Dasso and Landowne 1987). The coupled channels can be either inelastic or transfer modes. The coupled-channels model has proven to be among the most successful approaches for obtaining quantitative understanding of direct-reaction probabilities. In addition, it has served as a valuable guide in the interpretation of subbarrier fusion reactions (Broglia et al. 1983).

In heavy-ion reactions, the more general term *quasielastic scattering* is frequently applied to reactions at the nuclear surface. This more inclusive definition covers not only the above mechanisms, but also multiple-nucleon-transfer reactions. In these events, two or more nucleons may be transferred, producing a more diverse array of reaction products. The multiple-nucleon-transfer mechanism can produce nuclei relatively far away from the line of beta stability. Consider the example,

in which four neutrons are transferred from ^{48}Ca to ^{64}Zn and one proton is transferred in the reverse direction. While quantum and collective structure effects play an important role in inelastic scattering and few-nucleon transfer reactions, the primary products may also be formed with significant excitation energies. If the excitation energy exceeds particle binding energies, then secondary decay via statistical emission alters the primary exit channel nucleus.

3.4.4 Nucleon Knockout Reactions

Nucleon knockout reactions have also been the focus of considerable recent effort (both knockout and Coulomb excitation are dealt with in Gade et al. 2004 and Gade and Glasmacher 2008). One famous example of the power of nucleon knockout reactions using secondary beams is that of ^{11}Li , an extremely neutron-rich nucleus. It is thought to have a neutron halo, which would explain its large reaction cross section (Tanihata et al. 1985, [Fig. 3.32](#)). With a half-life of 8.7 ms, ^{11}Li can be produced by fragmentation of a heavier species (usually ^{18}O), separated in flight from other fragmentation products and made into an almost pure beam. Directing this beam toward a second target, a secondary reaction measurement can be performed. Neutron knockout from ^{11}Li forms ^{10}Li , which has no bound states so that the ultimate exit channel is $^9\text{Li} + 2n$. Detecting the ^9Li and a neutron allows for the reconstruction of the ^{10}Li momentum distribution after the knockout of the first neutron, [Fig. 3.33](#). If the target is a spectator, the ^{10}Li momentum distribution is the complement of the momentum distribution of the removed nucleon. Thus, with the caveats concerning the reaction mechanism, the knockout reaction is a measure of the momentum wave function (as opposed to the more standard position representation) of one of the loosely bound nucleons. These data suggest that these valence neutrons are a mixture of $2s_{1/2}$ and $1p_{1/2}$ components. Note that the higher the ℓ value, the broader the (linear) momentum distribution. The admixture of the second s state might seem surprising, as this level usually does not start filling until $N = 14$.

■ Fig. 3.32

Schematic view of the ^{11}Li nucleus, in which the two valence neutrons are in orbits much larger than the ^9Li core (Tanihata et al. 1985)

■ Fig. 3.33

Left: ^{10}Li residue momentum distributions measured following neutron removal from ^{11}Li on ^{12}C at 287 MeV/A. Right: Angular correlations of the decay neutrons measured relative to an axis defined by the ^{10}Li recoil direction as shown in the inset. The points are the experimental data and the histogram is a reconstruction corrected for experimental resolution and acceptance effects. Note the strong forward-backward asymmetry, which reflects interference of the $\ell = 0$ and 1 final states

Its contribution for $N = 8$ (in ^{11}Li) is thought to be a consequence of the tensor interaction between neutrons and protons (Myo et al. 2007).

Knockout reactions, such as (p, α) , (γ, α) , and $(e, e'\alpha)$ in even $N = Z$ (alpha particle) nuclei are also especially important as they provide evidence for *alpha particle clustering* in nuclei. At low energies, such reactions, for example, $^{19}\text{F}(p, \alpha)^{16}\text{O}$ and $^{28}\text{Si}(\gamma, \alpha)^{24}\text{Mg}$, which reduce the mass of the heavy partner, are important competitors to the synthesis pathways leading to the formation of elements just below ^{56}Fe in nova bursts.

3.4.5 Mean-Field-Dominated HI Reactions

3.4.5.1 Impact Parameter Dictates the Reaction Channel

Nuclear chemists have been particularly active in the study of reactions between heavy ions (HI) and heavy nuclei. The interest can be traced to the fact that all heavy elements with $Z > 101$ have been made with HI fusion–evaporation reactions (Loveland 2007). With increasing mass, the distinct quantal features become less important. Classical or quasiclassical reaction models become reasonable when the de Broglie wavelength becomes significantly smaller than nuclear dimensions. However, this condition is not satisfied in HI reactions with energies just exceeding the Coulomb barriers. Thus, quantal descriptions via a Time-Dependent Hartree-Fock (TDHF) approach (Bonche et al. 1976) or some form of quantum molecular dynamics (Feldmeier and Schnack 2000) are needed. In practice, semiclassical methods are usually invoked to describe the range of mechanisms observed at bombarding energies near the Coulomb barrier.

As the energy is increased well above the Coulomb barrier, classical concepts become more applicable and a partition of the impact-parameter space into different reaction types becomes reasonable. ▶ [Figures 3.34](#) and ▶ [3.35](#) illustrate the approximate relationship between reaction mechanism and impact parameter b , or ℓ -wave, for collisions between two complex nuclei at energies of more than a few MeV/A above the barrier.

The classification scheme in ▶ [Fig. 3.35](#) becomes simplified for lighter projectiles, for which fusion and simple surface reactions are the principal exit channels at low relative bombarding energies. For very heavy projectiles, the *damped-collision* (*deep-inelastic*)

■ [Fig. 3.34](#)

Reaction mechanisms classified schematically according to relative impact parameter b (ℓ -wave). Large values of b are classified as peripheral collisions and small values as central collisions

■ Fig. 3.35

Distribution of partial cross sections σ_ℓ as a function of angular momentum quantum number ℓ , decomposed according to reaction mechanism. Left panel is for light-ion-induced reactions (H, He) and right panel for heavy-ion reactions

■ Fig. 3.36

Illustration of a damped (deep inelastic) collision. The projectile trajectory is shown by the heavy curve and the extension of the original Coulomb-scattering trajectory by dashed lines. During the rotation angle of the dinuclear complex, $\Delta\theta = \theta_{el} - \theta_{exp}$, a neck is formed between the reacting species, through which nucleon exchange and energy dissipation proceed

mechanism is dominant as the mutual Coulomb field between the colliding particles becomes very large and inhibits fusion.

In the following subsections, the various mechanisms are discussed in order of decreasing impact parameter, beginning with elastic scattering and finishing with complete fusion.

3.4.5.2 Surface Reactions: Inelastic Scattering and Nucleon Transfer

For impact parameters with trajectories that scatter near the grazing angle, the separation between the colliding nuclei becomes sufficiently small that they begin to sample the attractive component of the nuclear potential. Reactions can then occur at the nuclear surface (leading to two-body final states) that proceed on a time scale comparable to the nuclear transit time. Interactions in this category usually involve excitation of low-lying modes in one or both of the colliding species and are particularly valuable for studying nuclear structure. Experimentally,

reactions at the nuclear surface are distinguished by: (1) angular distributions that peak in the forward direction or near the grazing angle, and (2) distinct spectral peaks, corresponding to energy states in the product nuclei.

3.4.5.3 Damped Collisions

At intermediate impact parameters, the nuclear overlap between target and projectile nuclei becomes sufficiently strong that the nuclear force may compete favorably with the repulsive Coulomb and centrifugal forces. When these competing forces approximately balance one another, it is possible to create short-lived dinuclear complexes, or “*nuclear molecules*” (► Fig. 3.36). These temporal species survive long enough to undergo a partial rotation and significant energy dissipation before undergoing binary breakup. Based on this behavior, these reactions are classified as *damped* or *dissipative* collisions, DC. The importance of the damped-collision mechanism relative to the total reaction cross section depends on the charge product $Z_p Z_t$. If the nuclear charge product is small, the DC cross section is also small. For collisions between very heavy nuclei, damped collisions may consume nearly the entire nuclear reaction cross section (Schröder and Huizenga 1977; Töke and Schröder 1992). While other processes become significant with increasing energy, for collisions between the heaviest nuclei, the bulk of the reaction cross section remains of this dissipative type up to several tens of MeV/A (Baldwin et al. 1995).

During the contact time, a neck forms between the reacting nuclei, through which statistical diffusion of neutrons and protons occurs in both directions (Planeta et al. 1990). It is this nucleon-exchange process that mediates the dissipation of radial kinetic energy into internal excitation energy. At the same time, extensive nucleon diffusion generates a broad distribution in both charge and mass around the projectile and target values. Thus the distinction between damped collisions and fission is that the product charge and mass distributions are concentrated near those of the projectile and target in the former case, but which for the latter are symmetric, near the total charge and mass divided by two (for all but the lowest excitation energies).

The angular and energy-damping features of the damped-collision mechanism are best illustrated by means of a Wilczynski plot (Wilczynski et al. 1973), shown in ► Fig. 3.37. This type of plot summarizes the probability for observing a projectile-like fragment in the $^{40}\text{Ar} + ^{232}\text{Th}$ reaction as a function of scattering angle and total kinetic energy. Here the most energetic nonelastic fragments form a peak near the grazing angle, as mentioned in ► Sect. 3.4.5.1. As the energy damping increases, a ridge of events develops near the grazing angle, corresponding to quasi-elastic surface reactions. The broad band that appears for the largest kinetic energies defines the damped collision events. The kinetic energies of the fully damped fragments are consistent with fission fragment kinetic energy systematics (Viola et al. 1985). However, the damped-collision angular distribution is peaked near the grazing angle, unlike fission, which is symmetric about 90° in the center-of-mass system.

Theoretical calculations indicate that the rotation angle $\Delta\theta$ (► Fig. 3.36) depends on the impact parameter. Smaller impact parameters lead to greater target and projectile overlap and thus longer rotation times, enhancing the degree of nucleon transfer and energy dissipation. Analysis of the data suggests that for fully damped events, the rotation time is about 10^{-22} s. The dissipated energy appears in the product nuclei as excitation energy. The frictional forces during contact also impart sizeable angular momenta to the primary fragments. These excited,

■ Fig. 3.37

Double-differential cross section (indicated on plot); contours $d\sigma^2/d\Omega dE$ for the 10MeV/A and $^{40}\text{Ar} + ^{232}\text{Th}$ reaction plotted versus scattering angle and kinetic energy of projectile-like fragment (Wilczynski et al. 1973). The grazing angle is near 40° in this reaction

high-spin product nuclei subsequently cool by secondary particle emission to form the observed fragment Z and A distributions.

Because of the statistical nature of nucleon exchange, the nuclide distribution of the products extends over a very broad range of projectile-like and target-like fragments. This has made possible the identification of a large number of exotic nuclei that have significantly expanded knowledge of nuclear properties. By utilizing similar reactions at higher projectile energies (► Fig. 3.38), it becomes possible to create beams of radioactive nuclei for further exploration of important problems in nuclear reactions, structure, and nuclear astrophysics.

In order to explain the dissipation of large amounts of relative kinetic energy into internal excitation and shape degrees of freedom, microscopic transport theories based on statistical nucleon exchange have proven to be of broadest utility. Based upon a master-equation approach (Nörenberg et al. 1974, 1976; Randrup 1978), the macroscopic variables are accounted for qualitatively via a Fokker–Planck equation in which a drift coefficient describes the net flow of nucleons across the target-projectile interface and a diffusion coefficient that accounts for nuclear friction effects.

3.4.5.4 Composite-Nucleus Formation

Total amalgamation of target and projectile corresponds to *complete fusion* (CF). If the composite completely samples the mononuclear phase space, a compound nucleus (CN) is formed.

If the barrier is robust, as it is for HI fusion, Wentzel–Kramers–Brillouin (WKB) logic can be used to generate the transmission coefficient (Gamow penetration factor) as a function of the energy of relative motion ε (as it is for spontaneous alpha-decay),

■ Fig. 3.38

Distribution of nuclides produced in the 75 MeV/A $^{78}\text{Kr} + ^{58}\text{Ni}$ reaction. Atomic number increases along the vertical axis and mass number along the horizontal axis (From Pfaff et al. 1996)

$$T_{\ell}(\varepsilon) = \exp \left\{ -\frac{2}{\hbar c} \int_{R_{\text{in}}}^{R_{\text{out}}} \sqrt{2\mu c^2 [V(r) - \varepsilon]} dr \right\} \approx \exp \left\{ -\frac{2\pi}{\hbar \omega} \left[V_C - \varepsilon + \frac{\ell(\ell+1)\hbar^2}{2\mu R_B^2} \right] \right\}. \quad (3.70)$$

Here ε is the energy of relative motion. In the first expression, the general WKB result is given in terms of the real potential $V(r)$ and the classical inner and outer turning points, R_{in} and R_{out} , respectively. The second quantity gives the result if the potential is approximated by an inverted harmonic-oscillator potential of frequency ω . R_B is the intranuclear separation distance at the peak of the barrier.)

From the expression for the transmission coefficient T_{ℓ} it is seen that for sufficiently high angular momenta, the Coulomb plus centrifugal terms may exceed the available beam energy, leading to an upper limit to the angular momentum, ℓ_{max} , that can contribute to fusion (Bass 1974). For slightly higher ℓ -waves this limitation may produce *incomplete fusion* reactions in which only a part of the projectile is captured by the target.

For heavy-ion reactions below the average ℓ -value, fusion saturates as the energy is lowered yielding a transmission coefficient T_{ℓ} and cross section nearly independent of ℓ (Vandenbosch 1992). In this case, the fusion cross section with a center-of-mass energy E , reduces to

$$\sigma_{\text{CF}} = \frac{R_B^2 \hbar \omega}{2E} \exp \left[-\frac{2\pi}{\hbar \omega} (V_C - E) \right]. \quad (3.71)$$

This expression, which predicts an asymptotic slope in energy of $\ln[E\sigma(E)] = 2\pi/\hbar\omega$, describes fusion excitation functions at low energy quite well. For deformed nuclei, R_B will depend on the relative orientation of the colliding pair, resulting in a distribution of effective fusion barriers. As a result, not only is it possible to observe fusion below the mean fusion barrier, but it is also possible to obtain information of the effective distribution of barriers contributing to fusion (Dasgupta et al. 1998). At subbarrier energies, coupling to inelastic channels can be considered as a “doorway” to fusion and thus coupling of such channels to the entrance channel can also be an important consideration (Brogia et al. 1983).

In some heavy-ion reactions a small fraction of the projectile mass may escape capture and proceed forward with the beam momentum. These reactions are called *incomplete fusion* (ICF) or *massive transfer*. The result of such incomplete fusion is, aside from the uncaptured fragment, an excited nucleus that is fully internally equilibrated and thus its decay is suitably treated by statistical models of compound nucleus decay, the subject dealt with in the next major section.

A special case of CN formation occurs when the capture proceeds through an isolated resonance reaction. Such reactions are also of fundamental importance to the nucleosynthesis pathways that form the elements beyond helium (see [Chap. 12](#) in Vol. 2). The classic example here is the $3\alpha \rightarrow {}^{12}\text{C}$ reaction

There are only three levels of ${}^{12}\text{C}$ below $E^* = 10 \text{ MeV}$. One of these levels occurs at 7.654 MeV, just above the Q -value for the ${}^8\text{Be}(\alpha, \gamma)$ reaction (also a resonance reaction). This level was predicted by F. Hoyle before it was observed, based on the fact that C (and life) exists. It is the resonance with this state that magnifies the $3\alpha \rightarrow {}^{12}\text{C}$ cross section and provides the gateway to synthesis of heavier elements. More detailed discussions of resonance and neutron-capture reactions in astrophysics can be found in (Rolfs and Rodney 1988).

The two major decay modes of CN are light-particle emission and fission. The modeling of these decay modes is treated in the next section. In closing this section, it is pointed out that the spectra of light particles (of energy ε and type τ emitted from a CN $P(\varepsilon_\tau)$) is Maxwell–Boltzmann (like) in form, up-shifted in energy by a Coulomb barrier height (B_C) if the ejectile is charged,

$$P(\varepsilon_\tau) \propto \varepsilon_\tau^x e^{-(\varepsilon_\tau - B_C)/T}. \quad (3.74)$$

The variable power x on the exponential prefactor (which determines the spectral rise at low energy) arises from: (a) statistical shape variations which affect the actual barriers, (b) a mixture of “volume” and “surface” emission, (c) the emission of more complex nuclei that subsequently decay into the channel of interest, and (d) quantum penetration. The first factor is the most important, and thus in fitting spectra, often a distribution of B_C values is required.

3.5 Statistical Decay

3.5.1 Preliminaries

Standard statistical-model treatments of compound nucleus decay are predicated on a time-scale separation between the formation of the CN and the time scales for simple (mostly single-particle) decay modes, as well as the massively collective decay process of fission. With

this decoupling of the entrance channel from the exit channel (except for conserved quantities), the CN decays statistically; that is, the decay samples all the phase space allowed by conservation laws (Ericson et al. 1963). The problem is always the identification and quantification of this phase space. As almost all reactions proceed through binary or sequences of binary steps, the rates of decays will be determined by the critical configurations of a binary nature. (The case of multifragmentation is thought to be an exception to this statement: see the end of this section and Sect. 3.7.5.)

There have been two successful approaches to this quantification: the Hauser–Feshbach (HF) and the transition-state (TS) treatments. The former was historically used to treat light-particle emission and the latter to treat fission. Modern codes have extended HF to treat ejectiles as heavy as carbon and with the aid of calculations of conditional barriers, transition-state theory has been used to treat binary divisions with mass asymmetry in the decay channel as a continuous variable.

3.5.2 The Hauser–Feshbach Treatment of Particle Emission

The logic employed in the HF treatment (Hauser and Feshbach 1952), as well as the earlier WE treatment (Weisskopf and Ewing 1940) the which lacks proper consideration of angular momentum coupling, is that the one-way decay rate would be equal to the reverse rate if true reactant-product equilibrium were attained. The one way, state-to-state probability for a fixed ℓ -value and energy is readily given by the transmission through the optical model potential, $T(\varepsilon)$. This rate would be equal, by microscopic reversibility (mechanics is time-reversal invariant), to the outgoing state-to-state probability. Thus an observable rate is simply the microscopic (state-to-state) rate times the density of final states. The latter reflects the number of possible final microstates within an experimental window. This window is naturally quantized by angular momentum and is quantized in energy either by the discrete structure of the quantum system or, at modest excitation energy, by the number of overlapping states in an energy bite determined by an experimental energy resolution, i.e., ωdE , where ω is the state density.

While the forward and backward rates would be equal and thus cancel, giving no net rate in an imagined equilibrium, in the kinetic process the net-rate (unconfined to a box and thus with no backward rate) is equal to the outgoing one-way rate. Thus the rate of emission of nucleons or clusters in any specified state from an initial parent level of excitation energy E_i and spin J_i is the result of a sum over the product intrinsic state-to-state rates and final-state level densities, where the sum is over: (a) the possible ℓ -values (inner sum Eq. (3.76)) and (b) the so called “channel spin” $S = j + s$, where j and s are the intrinsic spin of the residual and ejectile spin (outer sum). With consideration of the possible spin combinations, the HF equation for the emission rate $R_{i \rightarrow f}$ of a particle of type τ energy ε_τ and separation energy S_τ , in terms of the inverse cross section $\sigma_{f \rightarrow i}$ and the density of levels of the parent_{*i*} and the daughter_{*f*} is,

$$R_{i \rightarrow f}(E_i, J_i \rightarrow j, s) dE = \frac{2\lambda^2}{h} \sigma_{f \rightarrow i}(E_i, J_i) \left(\frac{(2s+1)(2j+1)}{(2J_i+1)} \right) \left(\frac{\omega_f^L(E_f, j)}{\omega_i^L(E_i, J_i)} \right), \quad (3.75)$$

with

$$\sigma_{f \rightarrow i}(E_i, J_i) = \pi \lambda^2 \sum_{S=|j-s|}^{S=j+s} \sum_{\ell=|J_i-S|}^{\ell=J_i+S} \left(\frac{2J_i+1}{(2s+1)(2j+1)} \right) T_\ell^\tau(\varepsilon), \quad (3.76)$$

and

$$E_f = E_i - S_\tau - \varepsilon_\tau. \quad (3.77)$$

In order to execute this logic, the following must be known: (1) the ejectile spin, mass, and separation energy and (2) the density of levels (as a function of excitation and angular momentum) of the parent (i) and daughter (f). As the latter has lower mass (and perhaps charge), as well as excitation energy, its level density will be smaller than that of the parent.

Monte Carlo codes are available that execute this logic event-wise, removing energy in each step until particle emission can no longer occur. Some codes seamlessly switch to gamma emission until all products are in their ground states. Since the HF equations treat ejectiles as objects with only one quantum option (there is no ejectile density of final levels), each level in a complex ejectile must be treated as a separate channel. Some modern codes (e.g., GEMINI) have used this logic to treat complex ejectiles (level by level) as heavy as C isotopes (Charity et al. 2001). Such codes are indispensable for calculating decays initiated by the low-energy accelerators located in hospitals for isotope production, for evaluating concepts for transmutation of nuclear reactor waste, and as afterburners for treating the statistical decay that invariably results after fast (nonstatistical) processes originating in high-energy collisions, including those initiated by cosmic rays.

3.5.3 The Transition-State Treatment of CN Decay

In the 1930s Eyring, Polanyi, and Wigner developed transition state (TS) theory, which is a computationally efficient way to compute *classical* reaction rates without integrating trajectories. The main idea is to define a dividing surface that partitions the configuration space into reactant and product sectors and compute the rate from the directional phase-space flux through this surface. One complication (below) is that the dividing surface must be such that it is not recrossed. The transition-state logic was almost immediately applied to fission by Bohr and Wheeler (1939). (See Vandenbosch and Huizenga (1973) or Wagemans (2000) for a detailed presentation of fission data and theory.) In this case, the absolute decay width (at an excitation energy above the ground state $E^* = E - V_{\text{gd.st.}}$) comes from an integral over the density of levels from the point where the energy in the decay channel ε is zero (i.e., maximal energy to be dispersed among the nondecay degrees of freedom and thus maximal level density) to the maximum channel energy (where there is a minimum of energy in the coordinates other than the decay channel),

$$\Gamma_f^{\text{BW}} = \left(\frac{1}{2\pi\omega_{\text{mn}}^{\text{L}}(E^*)} \right) \int_{\varepsilon=0}^{E^*-B_f} \omega_{\text{sp}}^{\text{L}}(E^* - B_f - \varepsilon) d\varepsilon. \quad (3.78)$$

The critical aspect in executing the TS logic is consideration of how the density of levels of the mononuclear (spherical or marginally deformed) parent ($\omega_{\text{mn}}^{\text{L}}$) grows with excitation energy as compared to growth of the density of levels of the highly deformed saddle-point shape ($\omega_{\text{sp}}^{\text{L}}$). The logic employed in statistical model codes is to calculate the level-density parameter via a physical expansion, increasing its value in proportion to the surface area. Following the prescription of Ignatyuk et al. (1975), Reisdorf (1981), and Töke and Swiatecki (1982), the level density parameter a (see Eq. (3.66)) can be written as a physical Liquid Drop Model-like expansion in terms of a deformation parameter q . In such an expansion, one has

constants for the volume c_v and surface c_s contributions, where the latter is multiplied by the surface area at deformation q relative to that of a sphere ($B_s(q)$),

$$a(q) \approx c_v + c_s A^{2/3} B_s(q). \quad (3.79)$$

The complication that the transition state cannot be recrossed was dealt with theoretically by Kramers (1940), where the fission width is reduced relative to the Bohr–Wheeler estimate by saddle recrossing. As the recrossing probability increases with friction, the reduced fission probability can be cast in terms of the friction coefficient γ ,

$$\Gamma_f^{\text{Kram}} = \left[(1 + \gamma^2)^{1/2} - \gamma \right] \Gamma_f^{\text{BW}} \quad (3.80)$$

The importance of this correction is still being debated (McCalla and Lestone 2008). However, it is included in most modern decay codes.

In the early 1980s data on so-called complex fragment (CF) statistical emission became available. Complex fragments are usually defined as those with atomic numbers from three to one half the total mass of the system. The first data, shown in ▶ Fig. 3.39, demonstrated the statistical nature of the emission and were used to extract conditional barriers; that is, barriers that correspond to the minimum energy required to pass from the CN system to an exit channel of fixed mass asymmetry. A general TS theory for treating CF emission was presented by Moretto (1975). This theory exchanges the problem of calculating transmission coefficients (needed for HF) with calculating the barrier and density of levels for the conditional barriers, i.e., barriers with frozen mass asymmetry. As mentioned above, the best modern codes allow for either scheme to be used.

3.5.4 The Density of States of Highly Excited Nuclei

A complete presentation of the issues related to the properties of what are often called “hot nuclei” is given in Shlomo and Kolomietz (2004). One of the assumptions underlying both of the standard treatments is that the reverse process can be considered as capture onto an object that bears significant resemblance to the ground state of the daughter. The macroscopic forward (decay rate) is then just the microscopic rate multiplied by the appropriate density of states. However, at high excitation energy nuclei will expand, with some reduction of the central density and the surface becoming far more extended. This poses two problems. First, the OM might not provide correct transmission coefficients, as the excited objects of relevance have different correlations than those of the ground state. The second problem is that even for uncorrelated fermion systems, the relevant density of states should be for the extended object.

From a schematic model the qualitative effects of expansion are shown in ▶ Fig. 3.40 (Sobotka et al. 2004). Calculations based on realistic effective Hamiltonians (Samaddar et al. 2007, 2008) yield similar results. With increasing excitation energy per nucleon, the equilibrium state (which for an isolated system is that with the maximum entropy) is one with reduced density. This effect increases the level-density parameter (see dotted line in ▶ Fig. 3.40, right hand side). Many-body theory (Prakash et al. 1983) has provided insight into how the effective mass terms evolve with density and excitation energy. In a local-density approximation (i.e., the level density parameter a can be calculated as the sum of contributions from different density regions of a nucleus), the k -mass (m_k , see ▶ Eq. (3.57)) increases from 0.7 to 1 with decreasing density and the peak of the ω -mass (m_ω), at the nuclear surface is removed with excitation energy (see ▶ Sect. 3.3.3). The effect of the k -mass is to suppress a at low excitation but to

■ Fig. 3.39

Left: Excitation functions for complex fragment evaporation from a ^3He -induced reaction (Mcmahan et al. 1987). **Right:** Mass distribution generated from the decay of $A \approx 110$ systems at both low and high angular momenta. The inset shows the finite-ranged Droplet Model conditional-barrier distributions (Sobotka et al. 1987)

increase it with increasing excitation. This evolution provides positive feedback to expansion, feedback that is active over several MeV/A of excitation. On the other hand, the collapse of the ω -mass at the nuclear surface (which was responsible for increasing a at low excitation) drives a down over the first few MeV/A of excitation energy. The collective effect is a variation of the density of states that yields a “Caloric Curve,” $E^*(T)$, with a pseudo plateau. While not a *phase* transition in the classical sense, these effects represent a transition from a correlated fermion system to one that more closely resembles a hot, but noninteracting Fermi gas.

3.5.5 Thermodynamic Models for Multifragmentation

Multifragmentation is thought to involve a nearly simultaneous breakup of the nucleus into many fragments. This image of the process suggests that the relevant phase space is that

■ Fig. 3.40

Left: The mononuclear excess entropy (above that for a nonexpanded system) as a function of a self-similar expansion coordinate (inverse of scaled radius parameter, i.e., $C = 1$ no expansion), for unit (MeV) steps in the excitation energy per nucleon ϵ . **Right:** The level density parameter with expansion but $m^*/m = 1$ (dotted), considering both expansion and the evolution of m_k (dashed) and expansion with both m_k and m_ω (solid) are shown (Sobotka et al. 2004)

corresponding to any number of fragments in the exit channel (rather than just two as in the HF and TS treatments). Statistical models of this phase space have been generated based on fixed energy and particle number – microcanonical ensemble, Gross (1990) and Bondorf et al. (1985); fixed temperature and particle number – canonical, Das et al. (2005), and fixed temperature and chemical potential – grand-canonical, Randrup and Koonin (1981). As would be expected, such models predict a liquid–gas phase transition for large, uncharged nuclear systems, as discussed in Sect. 3.7. These models do reproduce a considerable amount of data. Having done so, it has been the hope that manifestations of the infinite-system phase transition in a finite system is also represented. To give the flavor of these approaches, the canonical prescription (for one particle type) is presented here.

The first assumption is that the partition function Q is the product of the individual partition functions for the component parts, corrected for indistinguishability,

$$Q_A = \sum \prod_i \frac{1}{n_i!} \left(\frac{V_{\text{free}}}{\Lambda} \right)^{n_i} (q_i)^{n_i}, \quad (3.81)$$

where the sum is over all possible partitions, the product is over the fragments in that partition, n_i is the number of a given fragment type (i) in this partition, q_i is internal partition function for cluster type i , and the factor in parenthesis is the free volume measured in units of the thermal box size

$$\Lambda = \lambda_{\text{th}}^3 = \left[\frac{h}{(2\pi mT)^{1/2}} \right]^3. \quad (3.82)$$

The average number of clusters of type i is

$$\langle n_i \rangle = \left(\frac{V_{\text{free}}}{\Lambda_i} q_i \right) \frac{Q_{A-i}}{Q_A}. \quad (3.83)$$

The partition function (for A particles) can be readily calculated from a recursion relation (Das et al. 2005). The result of particle number conservation in each partition is,

$$Q_A = \frac{1}{A} \sum_{k=1}^A k \left(\frac{V_{\text{free}}}{A_k} q_k \right) Q_{A-k}. \quad (3.84)$$

The execution of this logic then comes down to specifying the internal partition function for each unit q . For nucleons, with no internal degrees of freedom, $q = 1$ (neglecting spin). For clusters, q is calculated from the Helmholtz free energy estimated using a liquid-drop model to calculate the internal energy and the Fermi-gas model to calculate for the entropic contribution to the Helmholtz free energy F , i.e.,

$$q_k = \exp[-F/T] = \exp[(W_0 k - \sigma(T)k^{2/3} + T^2 k/\varepsilon_0)/T]. \quad (3.85)$$

W_0 and ε_0 are constants, while $\sigma(T)$ models a surface free energy that goes to zero at a critical temperature.

This model is logically consistent and when extended to two particle types (for neutrons and protons, see Das et al. 2005) can reproduce many experimental observables. However, its main shortcoming is that it neglects interactions between the clusters. This leads to unphysical effects such as regions of negative heat capacity. This is inconsistent with thermodynamics and is well known to result from unphysical Hamiltonians. This has been made clear by both molecular (Lovett 2007) and mock nuclear systems, simulated with Lennard–Jones-type interactions (Campi et al. 2005). That is, if one considers the interactions that are active at the inter- (as well as intra-) cluster level, regions of negative heat capacity largely disappear as long as the system is truly ergodic. The later well-known qualification is demonstrated by the recent molecular dynamics work of Thirring et al. (2003).

3.6 Mechanisms in the Nucleon-Nucleon Domain

Once the projectile energy significantly exceeds the Coulomb barrier, nucleon-nucleon (N-N) scattering in the early stages of the target–projectile interaction may generate nucleons or clusters that are sufficiently energetic to escape the mean field of the composite system. These fast *nonequilibrium processes* begin to appear when the projectile energy per nucleon approaches the *Fermi energy* ε_F . In the Fermi Gas Model, the nucleus is treated as a degenerate gas of spin $\frac{1}{2}$ particles confined within the nuclear volume. The Fermi energy ε_F can be defined as the kinetic energy measured from the bottom of a one-body potential (a positive quantity) or the binding energy of the last nucleon (a negative quantity). By the former measure, ε_F is about +30 MeV for both neutrons and protons in nuclei near the valley of stability. By the latter measure, ε_F is equal in magnitude to the binding energy but opposite in sign. Thus, by the latter measure, $\varepsilon_F \approx -8$ MeV for both neutrons and protons in nuclei near beta stability but diverge from one another as the neutron/proton asymmetry deviates from stability, with ultimately the value of the nucleon type in excess decreasing to zero at the drip line. The kinetic energy view is a very useful concept for many reactions and is used below, but one has to appreciate that this approach views the nucleus as a collection of independent particles, i.e., no correlations. (The latter definition is more useful for nuclear structure and does not suffer from the one-body model assumption.)

Experimentally, nonequilibrium phenomena become apparent above projectile kinetic energies of about 20 MeV per projectile nucleon, which is comparable to the Fermi energy of nucleons in the nuclear potential well. These processes grow in both probability and complexity with increasing beam energy (Durand et al. 2001).

Nonequilibrium phenomena are distinguished by two principal features. First, they occur on a time scale much shorter than the typical equilibration time for statistical decay of a compound nucleus ($\tau \approx 10^{-21}$ s). Second, they produce multiparticle final states that are subsequently followed by statistical decay of the excited heavy product. In normal kinematics ($A_p < A_t$), the energetic light particles or clusters are forward-peaked and form a distinct exponential tail (area B in [Fig. 3.41](#)) on the Maxwellian spectra produced in later evaporation stages (area A in [Fig. 3.41](#)). The preequilibrium component for the nucleon channels is as in by early stage emissions of the multistep compound model, as in by the FKK model for example. At the extreme of nonequilibrium emissions are the discrete peaks (labeled C), which correspond to direct reactions, or the first step in a multistep compound model.

The same partition of the cross section seen in the light-particle emission is observed in the *linear momentum transfer* (LMT) to the heavy reaction partner, [Fig. 3.42](#). The folding angle between correlated binary fission fragments can be used as a gauge for measuring the degree of LMT in a reaction with a highly fissionable target, i.e., one for which $\sigma_R \approx \sigma_F$. In this context, $LMT = 1.0$ corresponds to a complete fusion (CF) reaction in which the total projectile momentum is transferred to the composite system, yielding the maximum excitation energy. $LMT = 0.0$ ($\theta_{\text{corr}} \approx 180^\circ$, [Fig. 3.42](#)) indicates a quasi-elastic mechanism that deposits only a small amount of momentum and excitation energy in the heavy product nucleus. At low bombarding energies, most of the reaction cross section goes into complete fusion reactions, with simple transfer events forming a peak near 180° . With increasing projectile energy, the high LMT peak broadens and shifts toward lower LMT due to the onset of nonequilibrium contributions in which incomplete fusion or prompt light particles carry off some of the projectile momentum, thus decreasing the deposited excitation energy. At the highest bombarding energies, the LMT distribution becomes nearly flat, indicating the deposition of a continuous spectrum of excitation energies, but with diminishing probability for complete fusion of target and projectile as the beam energy increases. Above beam energies of 100 MeV/A, the probability for complete fusion events is very low.

For nonfissionable systems, similar effects of the increase in nonequilibrium phenomena with increasing beam energy can be observed by measuring the velocity distribution of heavy residues relative to the expected velocity for complete fusion events. This approach is especially

Fig. 3.41

Kinetic energy spectrum at forward angles for emission of light particles. Region A corresponds to evaporation from an equilibrated compound nucleus; region B describes preequilibrium emission, and C indicates the excitation of discrete states in direct reactions

■ Fig. 3.42

Diagram of the evolution of nuclear reaction mechanisms from the mean-field to nucleon-nucleon regimes as a function of projectile kinetic energy per nucleon E/A , as measured by the angle between coincident fission fragments θ_{corr} . Correlation angles nearer 180° designate incomplete momentum transfer. The left frame shows the evolution for a proton-induced reaction on ^{232}Th ; arrows indicate θ_{corr} values for CF (Saint-Laurent et al. 1984). For the right-hand frame, the bar above each plot indicates the LMT scale (1.0 corresponds to CF) for the $^{14}\text{N} + ^{238}\text{U}$ reaction. The two peaks correspond to fusion-like and quasi-elastic processes (Tsang et al. 1984; Fatyga et al. 1985). In all cases, the correlations are broadened by neutron evaporation from the fission fragments

useful in reverse-kinematics studies, where the heavy residues have appreciable kinetic energies. Both the fission-fragment correlations and residue-velocity distributions demonstrate that energetic collisions produce a wide spectrum of nonequilibrium reaction mechanisms that vary with the projectile–target composition and bombarding energy.

The organization of this section proceeds as follows: Relatively simple nonequilibrium phenomena observed in reactions near the Fermi energy are initially discussed. The subsequent sections deal with: models designed to account for the complex reactions that occur at intermediate energies ($E/A > 20$ MeV), a simplified participant–spectator model to account for the reaction observables, and finally, reactions at sufficiently high energy to generate nuclear material with densities significantly in excess of normal nuclear density.

3.6.1 Reactions Near the Fermi Energy

The role of nonequilibrium emission as an intermediate mechanism, linking prompt one-step reactions to statistical particle evaporation from an equilibrated system, is most transparent in the proton spectra of light-ion-induced reactions on complex nuclei (Wu et al. 1979). The exponentially falling, or *preequilibrium*, component (B) in [Fig. 3.41](#) can be viewed as arising from a time-dependent process in which particles are emitted as the energy density in the initial target–projectile interaction zone randomizes throughout the nuclear volume: the lower the particle energy, the later in the process the particle was emitted. Two-component fits to the spectral shapes of components A and B yield slope temperatures consistent with an equilibrated Fermi gas for the statistical component, but slope temperatures are two-to-four times higher for the preequilibrium part, indicating emission from an earlier, hotter stage of the reaction.

Preequilibrium effects also appear in the excitation functions for heavy reaction products in this energy regime. The product yields shown in [Fig. 3.11](#) reach their peaks at bombarding energies consistent with compound nucleus formation; however, all excitation functions have appreciable cross-section tails that extend to higher bombarding energies. For example, in the reaction

the yield of ${}^{198}\text{Tl}$ ([Fig. 3.11](#)) persists to much higher energies than predicted by compound nucleus energetics, because at least one of the emitted neutrons is of preequilibrium origin and carries off more energy than an evaporated neutron. The lowering of the average excitation energy due to preequilibrium emission reduces the probability for sequential evaporative emission and thus serves to hinder attempts to produce nuclei far from stability by increasing the beam energy.

For bombarding energies well above the barrier, one also observes the preequilibrium emission of intermediate-mass fragments ($2 < Z < \sim 20$, or IMFs) in reactions on heavy nuclei. The reaction observables for IMF emission strongly resemble those for light particles and presumably occur on a comparable short time scale. Models based upon a coalescence concept (Bond et al. 1977) have met with some success for light clusters, but encounter more difficulties for IMFs.

The experimental observables ascribed to the preequilibrium mechanism have usually been interpreted in the context of the *exciton model* (Griffin et al. 1966; Blann et al. 1975). In the basic model, the nucleus is treated as a Fermi gas in which the projectile initiates a series of sequential N–N collisions, generating unstable particle-hole states, or excitons (*exciton* = a particle-hole pair). The number of excitons is thus proportional to the degree of thermalization.

Large exciton numbers imply multiple collisions for which the projectile energy is partitioned among many nucleons likely to be in bound (single-particle) states, yielding high

excitation energies. Conversely, when only a few excitons are involved (few collisions), much larger energy transfers must occur and particles are raised to unbound states that yield energetic particle emission, leaving the heavy partner in a low state of excitation. Refinements of the model now include numerous physical effects such as the treatment of the nuclear potential and N-N mean-free path, Pauli blocking, barrier penetration, and finite-state lifetimes (Gadioli and Hodgson 1992; Chadwick and Oblozinsky 1992).

3.6.2 Models of Collision Dynamics

While the exciton model and its derivatives have been relatively successful in describing light-ion-induced reactions near the Fermi energy, the reaction mechanism becomes more complex at higher energies or when heavy-ion projectiles are involved. A major complication is introduced when multiple nonequilibrium processes occur during the evolution from initial target-projectile contact to the internally equilibrated final state. This problem is frequently approximated by a two-step model that assumes a fast collision stage followed by statistical decay of the system at a much later time ($\tau > 10^{-21}$ s). The fast stage (time scale $\tau \approx 10^{-22}$ s) is described by models that attempt to account for mass and energy dissipation during the collision. The second stage is governed by statistical decay mechanisms such as particle evaporation and fission, as discussed in [Sect. 3.5](#).

For reactions well above the Fermi energy ($E/A > 100$ MeV), the *intranuclear cascade* (INC) model (Serber 1947) has been frequently employed. For projectiles with de Broglie wavelengths much smaller than the average internucleon separation distance in the nucleus, all nucleon-nucleon collisions can be treated as quasi-free N-N scatterings. The projectile is assumed to follow a semiclassical path and initiate an N-N interaction that generates a cascade of scatterings in three dimensions. The cascade is computed numerically until all available projectile energy is dissipated into either fast cascade particles that leave the system or into internal excitation energy of the target residue. [Figure 3.43](#) shows the schematic concept of the INC model.

The INC model is a phenomenological approach that employs experimental N-N scattering cross sections and angular distributions as a function of energy up to several GeV. Nuclear geometry is incorporated to deal with nuclear surface effects for large impact parameters and a Fermi-gas model with Coulomb barrier effects is used to evaluate the number of fast cascade particles that escape, as well as those that are thermalized and converted into excitation energy. Monte Carlo methods are used to select the impact parameter in each event as well as the scattering angles. For heavy-ion reactions, where multiple primary N-N collisions become possible in the initial contact stage, account must be taken of the vacancies created by these collisions. At energies for which meson production and excitation of the intrinsic resonance states of the nucleon (e.g., Δ , N^* etc.) become possible, the scattering cross section for these types of reactions must be included, as well as the reabsorption probability of the mesons and decay of the nucleon excited states. At proton energies of several GeV and above, the growing number of meson types and resonance states introduces an additional complication, since there is limited experimental guidance for estimating these scattering cross sections.

INC codes – e.g., ISABEL, Yariv and Fraenkel (1981), and QGSM, Toneev et al. (1990) – are relatively successful in reproducing the fast cascade component of the reaction observables for light-ion-induced reactions above 100 MeV. They also predict the qualitative result that a broad distribution of excitation energies will be produced due to impact-parameter-dependent

■ Fig. 3.43

Simplified schematic picture of an intranuclear cascade event for an energetic proton incident on a heavy nucleus. The number of scatterings increases as the impact parameter decreases

transparency effects, with the maximum usually being well below the maximum possible excitation energy. Quantitative predictions of the excitation energy are more problematical. This uncertainty stems from the simple approximations relative to the nuclear potential that became important in terminating the cascade in its latter stages.

For heavy-ion reactions, an additional complication with the INC model is that it ignores mean-field effects, which become relevant when there is extensive mixing of target and projectile nucleons. This shortcoming has been addressed via a microscopic theory based on the *Boltzmann–Uehling–Uhlenbeck* (BUU) formalism (Bertsch et al. 1984); and variations (Gregoire et al. 1985). In this formalism, the time evolution of the mean-field is described by a one-body density-distribution function that is solved simultaneously with a nucleon-nucleon collision integral, thus accounting for both the mean field and N-N collisions. The collision integral is calculated via an intranuclear cascade where only scattering into unoccupied phase space cells is allowed.

Models of this type have proven effective in describing the multiplicities and spectra for energetic nucleons (Durand et al. 2001), as well as small-angle particle-particle correlations and integrated spatial distributions (Bauer et al. 1992). In confronting theory with heavy residue data, BUU-type calculations encounter two principal shortcomings, both of which are also present in INC calculations: first, the time at which thermalization has been achieved and second, the lack of density fluctuations in the model that would provide a mechanism for the formation of nuclear clusters. In an effort to develop a full dynamical theory of fragment production, density fluctuations have been incorporated via the classical *molecular dynamics* (MD) approach (Schlagel and Pandharipande 1987), which has led to several quantal dynamical models (QMD) such as fermionic molecular dynamics (Feldmeier et al. 1995; Feldmeier and Schnack 2000), antisymmetrized molecular dynamics (Ono and Horiuchi 1996), and Brownian one-body dynamics (Chomaz et al. 1994).

Both BUU- and QMD-like models can be used to investigate the *nuclear equation of state* (EOS) and the phase diagram for nuclear matter shown schematically in ▶ Fig. 3.3. One parameter of particular concern is the nuclear incompressibility constant K (a subject dealt

with in the next section). From measurements of spatial flow distributions of emitted light ions, it has been possible to determine the bombarding energy at which the transition from the mean-field to nucleon-nucleon scattering dominance occurs; i.e., the “balance energy” where attractive mean-field scattering becomes equal to repulsive nucleon-nucleon scattering (Magestro et al. 2000).

The collision models also demonstrate how nuclear reactions can be used to explore variations from normal nuclear density ρ_0 , ranging from dilute ($\rho < \rho_0$) to compressed ($\rho > \rho_0$) states, by varying the bombarding energy and target–projectile asymmetry. For example, proton-induced reactions above about 5 GeV may leave the heavy partner in a state of depleted density due to the near-instantaneous knockout of several fast cascade particles. At the other extreme, in symmetric heavy-ion collisions, the large target–projectile overlap region in central collisions leads to significant compression and high energy density in the early stages of the reaction.

3.6.3 Participant–Spectator Reactions

For heavy-ion collisions well above the Fermi energy, models predict a low probability for composite-nucleus formation. Instead, most of the cross section is predicted to go into reactions that can be generalized as “*participant–spectator*” reactions (Fig. 3.44). In the participant–spectator scenario, the *participant* source is defined by those nucleons that occupy the geometrical overlap volume of the target and projectile, which is impact-parameter dependent.

■ Fig. 3.44

Schematic picture of the participant-spectator model. The hot participant region is formed from nucleons in the target-projectile overlap region. The target and projectile remnants on the periphery act as spectators, which then decay statistically

The number of participant nucleons and the energy-density of this localized source increase with decreasing impact parameter. The *spectators* are the target and projectile remnants outside the overlap volume and they decouple from the participant source on a time scale that decreases with increasing projectile energy and then decay statistically. The excitation energy of these spectators is a function of the overlap region.

Studies of the projectile spectator, or *projectile fragmentation*, permit investigation of nuclei at extremes of temperature and neutron–proton asymmetry (nuclei with large *isospin* components). By employing reverse kinematics, nuclei of all the elements can be studied. Because of the broad range of impact parameters that contribute to projectile-fragmentation events, the nuclidic yield distribution is very broad in N and Z , with the resultant formation of product nuclei far from stability. Exploitation of this result has led to the discovery of many new neutron- or proton-rich nuclei and provided access to a greatly expanded nuclear landscape for nuclear structure and nuclear astrophysics studies. One of the more intriguing byproducts of such studies has been the discovery of “*halo nuclei*” such as ${}^{11}_3\text{Li}$ (Fig. 3.32 and the discussion of knockout reactions) in which the nuclear radius is abnormally large, since the highest-lying pair of neutrons occupies an extended orbit (Hanson et al. 1995; Hanson and Tostevin 2003).

The participant zone constitutes a unique nuclear environment, analogous to a rapidly evolving plasma decoupled from the nuclear mean field. This zone is the source of energetic nonequilibrium light particles emitted from the neck region between the two separating spectator nuclei. Isospin effects in the overlap volume may subsequently modify the isotope yields. Because of the large multiplicities of particles that may be emitted from both spectator and participant sources, quantitative understanding of these reactions requires large detector arrays with excellent charge, mass, and spatial resolution (see Chap. 48 in Vol. 5).

The fact that the projectile fragments are emitted with velocities near that of the beam also has practical consequences. From the detection point of view, the identification of a fragment’s charge and mass is simplified by the strongly forward-focused kinematics. Projectile fragmentation is also the basis for one of the major radioactive-beam accelerator concepts. By magnetically separating specific fragmentation products, beams of nuclei far from stability can now be provided with intensities high enough to perform nuclear reaction and structure studies. This capability will greatly enhance future efforts to study the effects of neutron–proton asymmetry on the EOS that are predicted to be significant in several nuclear matter theories (Baran et al. 1998; Li 1997). Several accelerator facilities currently exist, or are in the construction/planning stages, for the study of nuclear isospin effects; for example, ATLAS at Argonne National Laboratory, USA (ATLAS 2010), ISAC at TRIUMF, Canada (TRIUMF 2010), CCL at Michigan State University, USA (CCL 2010), SIS at GSI, Germany (GSI 2010), GANIL, France (GANIL 2010), HRIBF at Oak Ridge National Laboratory, USA (HRIBF 2003), JINR in Dubna, Russia (JINR 2003), RARF at RIKEN, Japan (RIKEN 2010), Cyclotron Institute at Texas A&M, USA (TAMU 2010) and the recently approved FRIB facility at Michigan State University, USA (FRIB 2010).

3.6.4 Relativistic Heavy-Ion Collisions: Dense Nuclear Matter

In order to investigate the behavior of nuclear matter at still higher temperatures and densities, it is essential to rely on collisions between heavy ions at relativistic energies (Hermann et al. 1999; Reisdorf and Ritter 1997). At bombarding energies near 1 GeV/A and above, nuclear matter can be compressed to densities considerably higher than in normal nuclei, perhaps

approaching the conditions believed to be present when a neutron star is formed in the core of a collapsing supernova. From event-by-event analysis of the collective trajectories and the momenta of particles emitted during these collisions (► Fig. 3.45), vital tests of the nuclear equation of state can be performed. Two relevant terms often employed in relativistic heavy-ion research are rapidity and flow.

Rapidity is defined by the expression

$$y = \frac{1}{2} \ln \left(\frac{E + p_z c}{E - p_z c} \right), \quad (3.87)$$

where p_z is the momentum component parallel to the beam and E is the total energy (rest mass plus kinetic energy). Rapidity, which is a relativistic representation of the velocity parallel to the beam, provides a variable suitable for discussing the kinematical regions generated in collisions of relativistic heavy ions.

Depending on the axis of orientation, different types of flow can be defined by addition of vectors, such as in ► Fig. 3.45. *Transverse flow* (see F in ► Fig. 3.46) is a concept used to examine the emission patterns of spectator nucleons that are emitted transverse to the beam direction (z -axis in ► Fig. 3.45), presumably due to the anomalously large scatterings they undergo when they interact with the compressed region formed in an event. Target and projectile matter can be distinguished on the basis of their respective rapidities. The amount

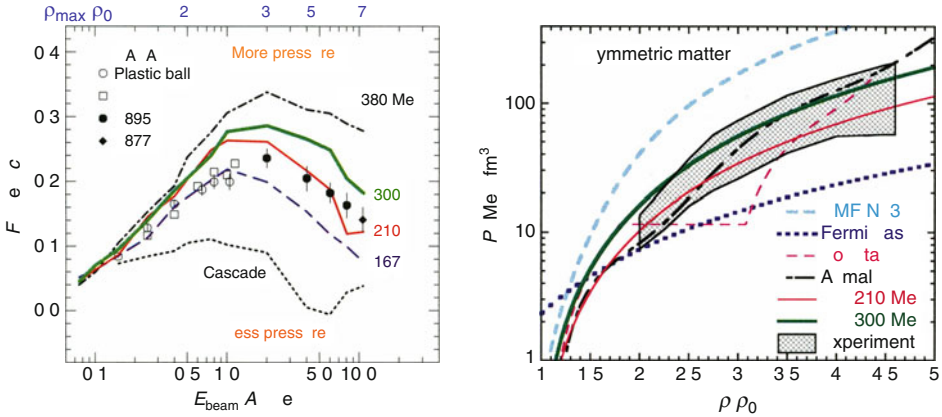

■ Fig. 3.45

Schematic view of a relativistic Au + Au collision with impact parameter $b = 6.0$ fm as a function of time (increasing from left to right as indicated in the cells of the top panel). The middle frame represents matter within a density greater than $0.1 \rho_0$, where ρ_0 is the ground-state density of nuclear matter. Bottom panel shows this projection in the reaction plane (x - z) with respect to the beam direction z . The top panel shows contours of constant pressure in the transverse plane (x - y) (From Danielewicz et al. 2002)

■ Fig. 3.46

Transverse flow F as a function of beam energy (left) and zero-temperature EoS for symmetric nuclear matter (right). Note that the larger the incompressibility coefficient, the larger the pressure P (From Danielewicz et al. 2002)

of flow (Danielewicz et al. 2002) is sensitive to the compressibility of the matter modeled by the transport model. By comparing flow data with the predictions of transport-theory calculations, it is then possible to evaluate the parameters of the EOS at high density (next section).

Flow can be used as a measure of the properties of the N-N interaction in the high density overlap volume, as well as evaluating the densities reached in such collisions. Densities up to $\rho/\rho_0 \approx 2-4$ (Danielewicz et al. 2002) have been estimated from such studies, providing new insights into the nuclear EOS and the related problem of neutron-star formation in supernovae. In addition, the spectra observed at bombarding energies above $E/A \approx 10$ GeV/nucleon reach spectral temperatures of up to $T \approx 150$ MeV. Such temperatures approach the value for deconfinement into a quark-gluon plasma, a plasma of a type not present since the primeval conditions of the Big Bang.

In recent years, the focus of this research has been at the Relativistic Heavy-Ion collider at Brookhaven National Laboratory (RHIC 2005, 2010). One of the most significant findings from the work at RHIC has been that the quark-gluon plasma generated has an ultralow viscosity-to-entropy ratio. The low viscosity implies that the degrees of freedom (quarks and gluons) have short mean-free paths and that the medium itself is still strongly correlated. While this implies that hydrodynamic reaction-model descriptions are valid, fundamental theory is yet to provide a clear insight into why the medium is so strongly coupled. Even higher energy work at the Large Hadron Collider at Conseil Européenne pour la Recherche Nucléaire (LHC, CERN 2010) will produce still higher temperatures and is likely to shed new light on this question.

3.7 The Nuclear Equation of State

3.7.1 Background and Connection to Classical Thermodynamics

In an introduction to thermodynamics, one studies large systems with the aid of “extensive” energy functions. These energy functions have two “sectors” for one-component systems, one

“mechanical” and the other “thermal.” For multicomponent systems another “chemical” sector must be added. The variables are: P and V (or its inverse, the number density ρ) for the “mechanical” sector and S and T for the “thermal” sector. The natural independent variable for the thermal sector is the entropy S for the pure energy functions while T is the independent variable in this sector for the free energies (corresponding to the energy available to do work). For macroscopic systems S and V are extensive, while T and P are intensive, meaning that one and only one of the variables in each set must be extensive.

Equations of state (EoS) are an attempt to capture the interrelationships between the variable set of thermodynamics for *infinite matter*, in the absence of long-range interactions. Thermodynamics itself is the enterprise of trying to describe matter with the absolute minimum number of macroscopic variables. One deduces the EoS from direct measurement of the macroscopic variables and from measureable derivatives such as the isothermal and adiabatic compressibilities for the “mechanical” sector and the constant pressure or volume heat capacities for the thermal sector.

For finite systems such as nuclei, a surface sector must be added. This sector is not extensive (i.e., while proportional to the surface area, it is not proportional to the amount of material). The study of systems where the energy functions are nonextensive has a long history starting with the work of Gibbs. Both small systems (due to surfaces) and systems with long-range interactions (where the interaction energy scales with the number of participants squared) fall into this category. Nuclei suffer from both of these extensivity-destroying features.

Recalling basic (extensive) thermodynamics, the internal energy E of an extensive one-component system is

$$dE^* = TdS - PdV \quad \text{or} \quad d\varepsilon = Tds - Pd v. \quad (3.88)$$

The lower case is employed in the second version to indicate the energy, entropy, and volume per particle. The pressure is no more than the dependence of energy on volume or number density,

$$P = -\left(\frac{\partial \varepsilon}{\partial v}\right)_s = \rho^2 \left(\frac{\partial \varepsilon}{\partial \rho}\right)_s = \rho^2 \left[\left(\frac{\partial \varepsilon_0}{\partial \rho}\right)_s \right] + \rho^2 \left\{ \left(\frac{\partial \varepsilon_{\text{asym}}}{\partial \rho}\right)_s \right\}. \quad (3.89)$$

The second equality makes use of the fact that the volume per unit and the number density are inversely related, $v = \rho^{-1} \rightarrow dv = -\rho^{-2}d\rho$. The final equality separates the isoscalar component of the pressure (the only term present for symmetric matter) from that originating from neutron/proton asymmetry. At large asymmetries, the second term dwarfs the first, so it is this term that is principally responsible for resisting the gravitational collapse of a neutron star.

The compressibility is defined as either the negative of the relative change in the volume with the application of pressure or the relative change in the density with the application of pressure under specified conditions. (The signs are such as to make the coefficient positive for any thermodynamically stable system.) Therefore, the adiabatic compressibility (the version which dictates the speed of sound) is

$$\kappa_s = -\frac{1}{v} \left(\frac{\partial v}{\partial P}\right)_s = \frac{1}{\rho} \left(\frac{\partial \rho}{\partial P}\right)_s. \quad (3.90)$$

Rather than dealing with κ , nuclear science has focused in its inverse, the “*incompressibility*” coefficient” K . Another minor change is that rather than dealing with a problem that is intrinsically 3-dimensional, the analysis is reduced to a one-dimensional problem of the stiffness with respect to harmonic vibrations of a uniform (albeit infinite) sphere of radius R .

(The conversion to a 1-D problem, with the independent variable being R , makes use of $d\rho/dR = -3\rho/R$ twice, yielding the factor of 9). In this case, from [Eq. \(3.89\)](#) one obtains the nuclear matter (nm) incompressibility K_{nm} (with the dimensions of energy):

$$K_{\text{nm}} [\text{MeV}] \equiv 9 \left(\frac{\partial P}{\partial \rho} \right)_s = 9 \rho_{\text{sat}}^2 \left(\frac{\partial^2 \varepsilon}{\partial^2 \rho} \right)_{s, \rho = \rho_{\text{sat}}} . \quad (3.91)$$

This is just the inverse of κ_s , with a slightly different coefficient. (Note that $1/\rho$ for saturated nuclear matter is $V/A = (4/3)\pi R^3/A = (4/3)\pi r_0^3 \approx 7.2 \text{ fm}^3/\text{nucleon}$).

The thermal properties of matter are captured by its ability to absorb energy. The quantum version of the relevant question is: at a given excitation energy, how many ways can a system sustain that energy? At constant volume, the energy-dependent answer to this question is captured in the heat capacity as a function of excitation energy

$$C_V(E^*) \equiv \left(\frac{\partial E^*}{\partial T} \right)_V = T \left(\frac{\partial S}{\partial T} \right)_V = k_B T \left(\frac{\partial \ln \omega(E^*)}{\partial T} \right)_V . \quad (3.92)$$

The effective mass, introduced in [Sect. 3.3](#) and discussed more in [Sect. 3.5](#), is the factor that corrects a single-particle logic for the many-body correlations. Thus, one can say that the study of the evolution in the level-density parameter a , is one of determination of how m^* changes with E^* . This thermal sector was discussed in [Sect. 3.5](#).

Description of the properties of matter is punctuated by phase transitions. While formally such transitions can occur only in the (extensive) matter limit, the manifestations of a matter phase transition in a finite system can profoundly affect the behavior of a finite “clump” of matter. In nuclear science, symmetric matter must undergo a liquid-to-gas-like transition as the matter is heated and the average density reduced, since it has an attractive interaction that can be saturated at short-range. Just as in the case of standard fluids, there will be a coexistence region that self-partitions into low- and high-density phases. Just how this transition is manifest in real charged and finite nuclear (i.e., in the real nonextensive) systems has been the focus of considerable effort.

3.7.2 The Perspective from Energy-Density-Functional Theory

Extraction of an EoS from a fundamental theory is of course desirable, and while there has been progress along this line, presently one must work with functionals of relevant properties such as the density and asymmetry that depend on free parameters that must be determined by some fitting procedure (Bender et al. 2003).

The task is to generate a functional for the energy of a finite system as a function of density and other variables that might be relevant. In fact, this procedure just generates a more rigorous alternative to the Liquid-Drop Model (LDM). This version of developing an expression for the mass of a drop involves an integral over space. The surface term comes from the gradients (inspired by van der Waals) and the asymmetry terms by the dependence on both of the individual densities. The Coulomb term, not included in the expression provided in the text, comes from an integral over the nuclear volume, the same way as it does in the LDM.

Let the energy as a function of density $E(\rho)$ be this function, which in the nuclear case must be a function of the local neutron and proton densities and their derivatives. (Van der Waals appreciated that nature must “pay” for producing nonuniform densities.) The binding energy

for a drop must come from an integral of the nuclear energy density ξ , with corrections for density gradients over the nuclear density,

$$E = \int \left\{ \xi(\rho_n, \rho_p) + \eta(\nabla\rho)^2 + \eta_{\text{asym}}(\nabla\rho_n - \nabla\rho_p)^2 + \dots \right\} d^3r + E_{\text{Coul}}, \quad (3.93)$$

where, in this case, the η 's (one isoscalar and one for the asymmetry) are coefficients to be determined by fitting data in exactly the same fashion as the surface and asymmetry coefficients are fit in the liquid-drop model.

This approach works well for classical fluids, although its convergence has never been proved. The connection to infinite uncharged nuclear matter is that the gradient expansion vanishes and the Coulomb term (which blows up in the infinite limit) is dropped. In that case, the nuclear energy density ξ or the energy per nucleon ε (see [Eq. \(3.94\)](#)) can be viewed as an isoscalar part (with only a density dependence) and an asymmetry component with both a density and an asymmetry dependence as a function of the deviation of the density from saturation and of the asymmetry from symmetry,

$$\xi \equiv \frac{E}{V} = \rho \left\{ \frac{E}{A} \right\} = \rho \varepsilon, \quad (3.94)$$

where

$$\varepsilon(\alpha, \delta) \approx [\varepsilon_0(\alpha)] + \{\varepsilon_{\text{asym}}(\alpha, \delta)\} \approx [\varepsilon_0(\alpha)] + \{S(\alpha)\delta^2\},$$

$$\alpha \equiv \frac{\rho_n + \rho_p}{\rho_0}, \quad \delta \equiv \frac{\rho_n - \rho_p}{\rho_n + \rho_p}. \quad (3.95)$$

The term in square brackets is the energy (per nucleon) of symmetric nuclear matter, while the term in curly brackets captures the change in the energy with asymmetry. Note that the coefficient of the asymmetry term is density-dependent.

Development of the first and second terms (isoscalar and isovector, respectively) in [Eq. 3.94](#) leads to several other coefficients that in principle can be phenomenologically determined. As symmetric matter represents an equilibrium point, an expansion in the density (from the saturation value) cannot have a linear term. The same cannot be said of the asymmetry term. Therefore, an expansion for both the isoscalar and asymmetry terms can be written,

$$\varepsilon(\alpha, \delta) = \left[\varepsilon_0 + \frac{K}{18}(\alpha - \alpha_0)^2 + \dots \right] + \left\{ \left(S_0 + \frac{L}{3}(\alpha - \alpha_0) + \frac{K_{\text{asym}}}{18}(\alpha - \alpha_0)^2 \dots \right) \delta^2 \right\} + \dots, \quad (3.96)$$

where the term in curly parenthesis is the asymmetry contribution is the $S(\alpha)$ in [Eq. 3.94](#). The constants in the coefficients are chosen so that the constants (K , L , and K_{asym}) are consistent with other formulations (Danielewicz and Lee [2009](#)).

3.7.3 The Incompressibility from the Physical LDM-Like Expansion

The incompressibility can also be expressed in a Liquid-Drop Model-like expansion, that is, an expansion where the terms are associated with *physical corrections*, rather than the result of

a Taylor expansion. Doing so provides an expression for the incompressibility of a *finite* charged drop (Youngblood et al. 1999),

$$K_A = K_{\text{nm}} + K_{\text{surf}} A^{-1/3} + K_{\text{asym}} \left(\frac{N-Z}{A} \right)^2 + K_{\text{coul}} \frac{Z^2}{A^{4/3}}. \quad (3.97)$$

The first term K_{nm} is the incompressibility of infinite uncharged nuclear matter (the extensive quantity), the second corrects the matter incompressibility for the presence of the surface, the third term corrects for the neutron–proton asymmetry of the matter and the fourth term (one that blows up for infinite matter) corrects for the charge on the finite drop.

The left-hand side of the physical expansion can be determined from the (mean) energy of the giant-monopole resonance (GMR), and root-mean-square size of the nuclear drop (Colò et al. 2004),

$$E_{\text{GMR}} = \hbar \sqrt{\frac{K_A}{m \langle r^2 \rangle}}. \quad (3.98)$$

Fitting the physical expansion leads to a value of $K_{\text{nm}} = (240 \pm 10)$ MeV (Colò et al. 2004).

Unfortunately, the GMR data address only tiny variations of the mean density about saturation. The extrapolation to densities far different than saturation is questionable. To gain insight into density variations of more relevance to neutron-star structure, HI “flow” analyses of the type shown in Fig. 3.45 have been used. The momenta transverse to the beam (as a function of the beam energy) are shown in Fig. 3.46 along with a comparison to model (BUU) simulations. The more incompressible the fluid, the greater the momentum “extruded” perpendicular to the beam axis. The constraints on the symmetric matter incompressibility are summarized on the right-hand side of the same figure (Danielewicz et al. 2002). Two statements can be made about the flow results. First, these data are inconsistent with the strongly repulsive nuclear equations of state derived from relativistic mean field theories and weakly repulsive equations of state, which would result from a phase transition at densities less than three times the saturation density. Second, while the uncertainties grow with density, the flow results are consistent with those from the GMR studies.

It is the asymmetry term that has been the focus of much recent effort, as it is this term that provides the internal pressure, holding back the gravitational collapse of a (cold) neutron star. First, results are presented from the perspective of the physical (LDM-like) expansion. As K_{surf} is close in magnitude (but opposite in sign) to K_{nm} , and the Coulomb constant (-5.2 MeV) is essentially model-independent, for sufficiently heavy isotopes, the difference $K_A - K_{\text{Coul}} Z^2 A^{-4/3}$ from Eq. 3.97 can be approximated by the analytic form $y = K_{\text{asym}} \delta^2 + b$, where $\delta = (N - Z)/A$. This approximate relationship has been employed for a series of even- A Sn isotopes for which the giant monopole resonance (GMR) was excited with inelastic alpha-particle scattering at small angles (Li et al. 2007). This work (Fig. 3.47) provided a value $K_{\text{asym}} = (-550 \pm 100)$ MeV. Data on the GMR from isotopes with asymmetries greater or less than those of the natural Sn isotopes would greatly reduce the uncertainty on K_{asym} . This will be one of the focus activities at FRIB in the coming decade. Nevertheless, this result is consistent with the value $K_{\text{asym}} = (-500 \pm 50)$ MeV obtained from analysis of the isotopic transport ratios in medium-energy heavy-ion reactions (Li et al. 2008).

Viewed from the energy-density expansion perspective, the analysis described above will scramble the constant (S_0), linear (L), and quadratic (K_{asym}) terms in Eq. 3.96. Separating the dependences is an active research area, about which several comments can be made.

■ Fig. 3.47

Systematics of the difference $K_A - K_{\text{Coul}} Z^2/A^{4/3}$ in the Sn isotopes as a function of $\delta = (N-Z)/A$; $K_{\text{Coul}} = -5.2$ MeV. The solid line represents least-squares quadratic fit to the data (When plotted in this fashion, the value of K_{asym} comes from the curvature of the best fit) (From Li et al. 2007)

First, there is a cross-correlation (shown in Fig. 3.48) between the constant term (S_0) and the linear term (L) (Tsang et al. 2009). Second, an overall constraint on the density dependence of the asymmetry energy is deduced from HI-reaction data (Danielewicz and Lee 2009; Shetty et al. 2007),

$$S(\rho) \propto \rho^x(1 + c\rho); \quad \frac{2}{3} \leq x \leq 1. \quad (3.99)$$

Again, in an effort to be forward looking, experiments on parity-violating electron scattering on ^{208}Pb (a project called PREX) will be done in the next few years. If successful, this experiment will produce data directly sensitive to the linear term in the dependence of the asymmetry energy on density (Horowitz and Piekarewicz 2002).

3.7.4 Cluster Formation at Very Low Density

At very low density and temperature, alpha clusters become a significant component of symmetric nuclear matter (Friedman and Pandharipande 1981). The contribution of such clusters is determined by an interplay between the translational phase space (which favors free nucleons with increasing temperature) and binding energy (which favors alpha-particle formation by allowing more energy to be available for translation). One only needs to consider alpha decay of heavy nuclei to appreciate that clustering in the matter tails of heavy (cold) nuclei is significant. As is the case in water, one can consider such clusters as transitory, an existence that increases as the density and temperature decrease.

There have been significant advances on both the theoretical and experimental fronts in elucidating the behavior of nuclear material at very low densities, densities less than 0.1 of saturation. On the theoretical front, a virial (density expansion) EoS has been formulated by

■ Fig. 3.48

Representation of the constraints on parameters S_0 and L in ▶ Eq. 3.96. The right axis corresponds to the neutron-matter-symmetry pressure at saturation density. The region bounded by the *diagonal lines* represents the constraints obtained from analysis of HI collisions. The vertical lines near $S_0 = 31$ MeV are obtained from LDM-like analyses (i.e., masses). The lower and upper boxes are formed by the constraints from the so-called Pigmy Dipole resonances (neutron-rich skin vs. core) and from symmetry-energy analysis on nuclei, respectively. The inset shows the density dependence of the symmetry energy in the shaded region. The symbol in the inset represents the GDR. Note the greatly offset scales on the abscissa and ordinate (From Tsang et al. 2009)

explicitly considering the (N-N), N-alpha and alpha-alpha scattering phase shifts (Horowitz and Schwenk 2006). One of the values of this work has been to quantify the pressure reduction and asymmetry energy enhancement (relative to a nucleon gas), due to alpha-particle clustering. Confirmation of this enhancement at densities of 0.01–0.05 times the ground-state density of symmetric nuclear matter has been observed in an analysis of HI reaction data (Kowalski et al. 2007, Natowitz et al. 2010). This limiting behavior is one aspect of clustering in nuclear systems. The next section deals with perhaps the most significant aspect of this behavior.

3.7.5 Multifragmentation: The Low-Density Regime and the Manifestation of the Liquid–Gas Phase Transition in Nuclear Collisions

When the first high-energy accelerators became available in the 1950s, radiochemical and emulsion studies indicated the existence of a reaction mechanism in which a heavy nucleus is disintegrated into multiple neutrons, H and He ions, and IMFs (▶ Fig. 3.1), a process now called multifragmentation (Lynch 1987; Trautmann 2001; Chomaz 2001). The connection of this phenomenon to the nuclear liquid–gas phase transition in matter was made after construction of a “caloric curve,” i.e., $T(E^*)$, shown in ▶ Fig. 3.49 (Pochodzalla et al. 1995). The ordinate was constructed using isotope ratio “thermometers.” Such thermometers use the

■ Fig. 3.49

Caloric curve (temperature vs. heat) derived from peripheral collisions in $^{197}\text{Au} + ^{197}\text{Au}$ reactions. Temperatures are derived from yield ratios of $^3\text{He}/^4\text{He}$ and $^6\text{Li}/^7\text{Li}$ isotopes and heat (E^*/A) from event-by-event calorimetry. The **solid line** describes the expected behavior for nuclear evaporation. The dashed line is that expected for a hot nuclear gas. The plateau region in between has been interpreted as evidence for a “boiling-like” phase transition in nuclei (Pochodzalla et al. 1995)

difference in the ground-state masses of different isotopes in a Boltzmann expression for the relative yield of the isotopes (Albergo 1985). The experimental isotope ratios are fit by adjusting the temperature.

The only way to have a halt in the increase in T with increasing E^* is for additional degrees of freedom to become available. In the case of the macroscopic liquid–gas transition, it is the access to the full 3-D translational degrees of freedom that halts the increase in the average energy in any one degree of freedom (as energy is poured into the newly accessed ones.)

The observables in high-energy light-ion or intermediate-energy HI collisions all relate to the above-mentioned multifragmentation exit channel. In order to create multifragmentation events, it is necessary to deposit excitation energies in a nucleus in excess of $E^*/A \approx 4\text{--}5$ MeV, i.e., about 1 GeV in a heavy nucleus. Transport codes predict that such events are rare, comprising less than $\sim 5\%$ of the nuclear reaction cross section. Among the methods used to prepare such systems have been light-ion reactions (ISiS, FASA), reverse-kinematics reactions (EOS), peripheral reactions (ALADIN), and near-symmetric heavy-ion ($A + A$) reactions (INDRA, ALADIN and Miniball). The various detector systems (given in square brackets) and earlier devices are referred to in Durand et al. (2001).

The plateau in the caloric curve is only indicative of access to additional degrees of freedom, not necessarily access to prompt multifragment decay. For example, expansion or greatly increasing the surface diffuseness, or an increase in the level-density parameter all would decrease the rate of increase of T with E^* , as discussed in ► Sect. 3.5. However, numerous

observables do in fact indicate that multifragmentation is the result of a near-instantaneous phenomenon rather than the result of sequential binary decays. Among these observables are evidence for a breakup density of only 20–30% of normal nuclear density ($\rho/\rho_0 \approx 0.2\text{--}0.3$), compression–decompression effects in $A + A$ reactions, and most important, time-scale measurements based on spatial correlations among the clusters. The latter work demonstrates that the breakup time scale is nearly simultaneous ($\tau \approx 10^{-22}$ s), much shorter than expected for a drawn-out sequential evaporative sequence (see [Fig. 3.50](#) and Viola et al. 2006).

Nuclear models based upon both statistical concepts and those for a generalized liquid–gas phase transition dependent on fragment size distribution are in general accord with the phase transition interpretation as long as the models assume expansion to a given breakup volume. In these models, the decay can be that expected from a statistical sampling of the cluster phase space (Bondorf et al. 1985; Gross 1990; Das et al. 2005), that is, without any dynamics, or a time-dependent approach in which emission occurs as the system expands to the breakup volume (Friedman 1990). However, it must be mentioned that as recent fragment–fragment correlation data could not be reproduced by prompt fragmentation models, Gentil et al. (2008), the interpretation of these complex decays is still not fully understood.

Fig. 3.50

Top: Evolution of a multifragmentation reaction as a function of heat E^*/A for the number of $Z \geq 3$ fragments (probability $P(N_{\text{imf}})$, IMF multiplicity N_{imf}). **Bottom:** Breakup time τ in fm/c (1 fm/c $= 3.3 \times 10^{-24}$ s). The growing multiplicity and rapid decrease in the breakup time are consistent with a “boiling-like” phase transition in nuclei (Beaulieu et al. 2000)

Analyses based on the finite-scaling model proposed by Fisher for classical drops (Elliott et al. 2002), percolation theory (Bauer et al. 1992), and a statistical multifragmentation model (Botvina et al. 1999) show generally good agreement with the concept that the transition (halt in the increase in the T with E^*) is associated with accessing the multifragment phase space. The opening of this most complex decay channel in finite nuclei at $T \approx 4\text{--}6$ MeV implies that infinite, uncharged matter cannot exist above $T_{\text{crit}} \approx 17$ MeV (Natowitz et al. 2002).

Perhaps, the most insightful result employing the fragmentation data comes from employing Fisher's model (Elliott et al. 2002). The critical exponents associated with the transition that occurs in the finite system's analog to the infinite matter liquid–gas phase transition are extracted. In addition, using the ubiquitous coexistence behavior for classical fluids, the nuclear phase transition data were added to what are known as “Guggenheim plots” (T/T_{crit} vs. both the low and high reduced densities $\rho_v/\rho_{\text{crit}}$ and $\rho_l/\rho_{\text{crit}}$). However, it should be kept in mind that unlike the macroscopic cases employed by Guggenheim and others to prove reducibility, actual measurements of the two coexisting densities as a function of temperature is not done. Nevertheless, this work shows how nature's systems, while seeming quite different, are often interrelated. The careful reader would have noted a few such cases of this unity of natural systems in this chapter.

3.8 Addendum: Cross-Section Calculations

For the case of a beam of charged particles incident on a thin target of thickness x , as illustrated in Fig. 3.51, the projectile flux can be expressed as $n_p = I/(qe)$. Here I is the electric current in amperes, as measured in a Faraday cup that collects the total charge deposited by projectiles of charge qe . For light ions, the projectile ion is usually fully stripped of its atomic electrons so that $q = Z$, the atomic number of the ion. However, for very low energy or very heavy ions, complete stripping of the atomic electrons may not occur, so that the ionic state of the projectile must be accounted for. The number density of target atoms n_t is given by

$$n_t = (\rho_M/M)N_A, \quad (3.100)$$

where ρ_M is the mass density, M is the molar mass of the target atoms, and N_A is Avogadro's number ($6.022 \times 10^{23} \text{ mol}^{-1}$). For reactions induced by a beam of particles (two dimensional geometry), the surface number density of target nuclei (N_t/area) is the relevant target collision factor, assuming that the beam cross section is smaller than the target area. For a given thickness x the surface number density (usually measured in cm^{-2}) is

$$N_t/S = n_t x. \quad (3.101)$$

where S is the surface area of the target.

With these definitions the production rate $R(a,k)$ for a given exit channel k becomes

$$R(a,k) = n_p n_t x \sigma(a,k). \quad (3.102)$$

where the quantities are most commonly given in the following units: R (s^{-1}), n_p (s^{-1}), n_t (cm^{-3}), x (cm), and σ (cm^2). For thick targets the above linear behavior does not hold anymore. However, an arbitrarily thick sample can be viewed as being composed of thin slices of thickness dx . The rate of product nucleus formation is then given by the rate of particle removal from the beam as it passes through the slice of the target of thickness dx ,

■ Fig. 3.51

Beam of projectile nuclei impinging on a circular disk of thickness x

$$-dn_p = n_p n_t \sigma(a, k) dx. \quad (3.103)$$

Here $\sigma(a, k)$ stands for the total cross section. Integration over the thickness x of the target gives

$$-\int_i^f \frac{dn_p}{n_p} = \sigma n_t \int_0^x dx, \quad (3.104)$$

where i (initial) and f (final) are to indicate the particle flux entering and leaving the target, respectively, and

$$\frac{n_p(f)}{n_p(i)} = \exp(-n_t \sigma x). \quad (3.105)$$

The production rate then becomes

$$R = n_p(i) - n_p(f) = n_p(i)[1 - \exp(-n_t \sigma x)]. \quad (3.106)$$

If σ is the total reaction cross section, this expression predicts the attenuation of the beam due to all nuclear reactions in a target of thickness x . This expression assumes that the beam intensity and cross section are constants. In reality, this is not necessarily the case and corrections may be required due to time variations in the projectile current and dependence of the cross section on beam energy (► Fig. 3.51).

For an infinitely thin target, that is, one in which there is no appreciable attenuation of the beam due to target thickness, the above expression can be simplified by expanding the exponential term, $\exp(-n_t \sigma x) \approx 1 - n_t \sigma x$. This leads to a commonly-used expression for the rate

$$R(a, b) = \frac{I_0}{z_p e} \sigma(a, b) \frac{N_t}{S}, \quad (3.107)$$

where S is the area of the target containing N_t atoms of weight w and $N_t = (w/M)N_A$. The surface number density (measured, for example, in atoms cm^{-2}) – or its alternative, the surface density (given, for instance, in g cm^{-2}), to which it is proportional – is ordinarily a more accurate and easily determined quantity for thin targets than is the actual thickness. The basic assumption here is that the beam diameter is smaller than that of the target.

In the geometry of a nuclear reactor, the target can be considered to be immersed in a neutron gas, so that all target atoms N_t are exposed to the flux of neutrons. In such cases, target thickness usually does not matter and one can write

$$R = \sigma(a, b)N_t\phi, \quad (3.108)$$

where ϕ is the *neutron flux* (which is usually given in neutrons $\text{cm}^{-2} \text{s}^{-1}$), a parameter of the reactor and the position of the irradiation within it. The same is true for reactions in stars, except that this expression must be modified for the flux of both reactants.

Finally, in the production of radionuclides, it is necessary to include the effects of radioactive decay during bombardment in the rate equation as discussed in [Chap. 7](#) of this volume. The net production rate (dN/dt) will be the difference between the production (R) and decay (λN) rates

$$dN/dt = R - \lambda N. \quad (3.109)$$

The solution to this differential equation gives the number of atoms N produced as a function of time,

$$N = (1/\lambda)R(1 - e^{-\lambda t}), \quad (3.110)$$

where λ is the decay constant of a given radioactive product nucleus and t is the bombardment time. The factor $(1 - e^{-\lambda t})$ is called the *saturation factor*. This factor is an important consideration in production of short-lived medical radionuclides for diagnosis and therapy, and for efficient use of accelerator or reactor time. For bombardment times greater than one half-life, this factor illustrates the *law of diminishing returns*; i.e., half the maximum activity is formed after one half-life, 3/4 after two half-lives, etc.

Abstract: This chapter first gives a survey on the history of the discovery of nuclear fission. It briefly presents the liquid-drop and shell models and their application to the fission process. The most important quantities accessible to experimental determination such as mass yields, nuclear charge distribution, prompt neutron emission, kinetic energy distribution, ternary fragment yields, angular distributions, and properties of fission isomers are presented as well as the instrumentation and techniques used for their measurement. The contribution concentrates on the fundamental aspects of nuclear fission. The practical aspects of nuclear fission are discussed in [Chap. 57](#) of Vol. 6.

4.1 Introduction

Nuclear fission has had a large impact on human life, probably greater than any other field of radiochemistry. It has truly changed the world for good or for bad. Nuclear power stations are producing electricity for billions of dollars every year, and nuclear weapons changed the military and political equilibrium between nations. Research reactors used as intense sources of neutrons through neutron diffraction have contributed immensely to the knowledge of the structure of biological molecules or to the development of new materials. Nuclear reactors are used for the mass production of radioisotopes required in medical diagnosis and therapy and in modern technology.

The study of the process of nuclear fission as such has also contributed to the fundamental knowledge of matter. A nucleus that undergoes fission has to change its shape from a round-shaped or somewhat deformed ground state to some elongated dumbbell-like configuration, which finally divides into two fragments. Such a large-scale collective motion cannot be observed in other processes at low nuclear temperature. It gives very valuable information on the existence and the survival of shells and nucleon pairs in nuclear matter. This way, it carries information on the viscosity of nuclear matter. The distribution of protons and neutrons between the two fragments formed is informative of the electrical polarizability of nuclear matter. The fission process cannot be understood without taking into account the two complementary aspects of matter: particles and waves.

This chapter, which has been elaborated through giving lectures to students of chemistry, concentrates on these latter fundamental aspects of nuclear fission. The presentation is sometimes more qualitative than quantitative in order to address also the nonspecialist. Due to the large volume of research accomplished in the 7 decades since its discovery and also because of the complexity of the matter, this chapter cannot be exhaustive. Many references have to be made to some more specialized literature. To start with, an early work (Vandenbosch and Huizenga 1973) and a more recent comprehensive volume (Wagemans 1991b) should be mentioned, which will give access to many further references. Partly for didactical reasons, this chapter will more or less follow the historical evolution of experimental techniques used and the knowledge gained. A first point of discussion will be the highly interesting sequence of events that led to the discovery of the process.

4.2 History of the Discovery of Nuclear Fission

4.2.1 The Discovery of the Neutron

The way to nuclear fission was paved by the discovery of the neutron (Chadwick 1932a, b). This discovery was made relatively late compared to the discovery and characterization of the two

other basic (charged) constituents of the atom, the electron (Thomson 1897) and the proton whose fundamental character was probably first recognized by E. Rutherford (Rutherford 1914) (“the suggestion that the hydrogen nucleus is the positive electron”) following some earlier work on electric discharges in gasses (e.g., Goldstein 1886; see Glasstone 1967).

Already in 1920, Rutherford predicted the existence of a sort of neutral particle within the nucleus on the following grounds (Rutherford 1920): From his earlier experiments on the straggling of α particles passing through thin metal foils (Rutherford 1914) it was known that the atom consisted of a small positively charged nucleus surrounded by a cloud of electrons. The charge of the nuclei of the individual elements became known through the pioneering work of Moseley (Moseley 1913, 1914). If one made the reasonable assumption that the nuclear charge of an atomic nucleus was due to a corresponding number of protons, it turned out that the mass of this atom (or atomic nucleus) was generally about twice the value calculated from the number of protons. This observation led Rutherford to predict the presence of electrons besides protons within the nucleus (Rutherford 1920). He viewed these intranuclear electrons as forming “a very close and powerful combination with the charged positive units.” In 1927, after the formulation of the uncertainty principle by Heisenberg (Heisenberg 1927) the proposed existence of electrons as a separate entity within the nucleus even in the form postulated above had to be given up because an electron confined to the small volume of a nucleus would have an energy too high to be stable within the nucleus.

As a consequence, one was searching for a neutral particle. More by chance, Bothe and Becker (Bothe and Becker 1930a, b) found an unusually hard (energetic) “ γ ” radiation emitted when light elements like lithium and beryllium were exposed to α radiation. From the absorption in lead, they calculated an energy of 10 MeV. This radiation was also studied by Curie and Joliot (Curie and Joliot 1932). These authors found that protons were ejected from paraffin and calculated a “ γ ”-ray energy of even 50 MeV – a large discrepancy from the results of Bothe and Becker.

Finally, Chadwick studied the radiation emitted when beryllium was exposed to α particles from ^{210}Po by measuring the energy of recoil protons from paraffin and recoil nitrogen atoms in gaseous nitrogen. His results led to inconsistencies when he assumed that the unknown radiation was γ radiation and that the scattering mechanism was following the law of Compton scattering taking place with the corresponding nuclei (proton or nitrogen) rather than with electrons. The observed recoil energies led however to conclusive results when he assumed that the unknown radiation was composed of particles (of mass one and no charge) rather than photons (Chadwick 1932a, b). The nuclear reaction producing neutrons was

The neutron provided the nuclear physicist (or chemist) for the first time with a simple means to carry out artificial nuclear reactions. The production of neutrons did not require large and expensive accelerators. A mixture of beryllium powder with an α emitter in a little tube was sufficient to produce a neutron source of 10^6 neutrons per second. Neutrons possess no charge. Consequently, they do not have to overcome a Coulomb barrier and therefore do not have to be accelerated to enter an atomic nucleus. On the contrary, “capture cross sections” are usually larger for neutrons of smaller energy (thermal neutrons) because due to their lower velocity their residence time near a particular nucleus is larger.

The capture of a neutron by a nucleus produces an isotope with a mass number one unit higher:

The nucleus formed is often unstable and undergoes a β^- decay in which a neutron within the nucleus is transformed into a proton, an electron, and an antineutrino:

The net result of neutron capture is thus normally a radioactive isotope of the element exposed to neutrons, which, at its decay, will form an isotope of the element with the next higher atomic number. The isotope formed may be stable or may again be radioactive and undergo another nuclear transformation to finally reach stability.

The availability of neutron sources opened the way to the production of radioactive isotopes of most elements and, in fact, practically all the elements of the periodic system were exposed to neutrons within the following years. This was mainly done in three locations: Rome by Fermi and coworkers, Paris by the Curies and coworkers and, a little later in Berlin by Hahn, Meitner, and Strassmann.

4.2.2 Search for Transuranium Elements

A particularly interesting element for these studies was uranium, the heaviest and last element of the periodic system known at that time with the atomic number $Z = 92$. Neutron capture and subsequent β^- decay in this case should lead to a new, hitherto unknown, element (“transuranium element”). What would the chemical properties of element 93 be?

There was a problem: The chemical properties of element 93 were evidently unknown; on the other hand, a certain knowledge of its chemical properties would be required in order to isolate and identify the element or elements formed.

To predict the chemical properties, the periodic system of the elements was resorted to. At the time, however, the last part of the periodic system, including the elements Ac, Th, Pa, and U, was not known correctly. In particular, it was not recognized that these elements belong to the group of the actinides. Due to the most stable oxidation states of the four elements [Ac (III), Th (IV), Pa (V), and U (VI)], they were thought to belong to the group of the transition elements and, hence, were considered homologues of the elements La, Hf, Ta, and W. The elements beyond U were expected to be homologues of Re, Os, Ir, and Pt. Therefore, it was expected that they would form insoluble sulfides and that they could be separated in this way from the uranium and identified. Today it is known that the elements beyond actinium form the group of actinides with different chemical properties and in particular do not form insoluble sulfides.

Nevertheless, when, e.g., Fermi and coworkers were irradiating uranium with neutrons and made a precipitation of sulfides from the solution, radioactive products were indeed found. Now it is known that these products were fission products, different isotopes of lighter elements, like tellurium and antimony. The scientists involved in this work assumed, however, for reasons to be discussed later, that elements much lighter than uranium could not be formed in a process induced by slow neutrons. As a consequence, they came to the conclusion that transuranium elements were formed.

The combined results on the “transuranium” elements formed by the irradiation of uranium by neutrons as obtained by the different groups involved and as generally accepted at the time (Meitner et al. 1937) are shown in  Fig. 4.1. The results were, however, surprising (and somewhat suspicious) in two respects.

■ Fig. 4.1

Transuranium elements as believed to be established by 1937; after (Meitner et al. 1937).

The prefix Eka (= one from Sanskrit) indicates a heavy homologue of the corresponding element. Eka is a designation chosen by Mendeleev for unknown elements expected for empty places in his early periodic system

- Whereas in the simple (n, γ) -reactions taking place in other (lighter) elements normally one β transition or at most two β transitions lead to a stable nuclide, here long chains of up to six radioactive isotopes could be identified.
- A second surprise was the observation of more than one such chain. Since ^{238}U represents 99.3% of natural uranium, the contribution of the other isotopes of uranium should be negligible. Consequently, one was expecting one and only one decay chain starting with ^{239}U . Certainly, isomers, i.e., nuclides with the same mass number and nuclear charge but different half-lives were known. Such isomers, if undergoing a β decay, would however decay to the same daughter nucleus and not form a completely separate chain of radionuclides.

Today one understands the above results as due to fission products, i.e., different elements and different isotopes of single elements, as will be discussed later.

In the year 1938, Enrico Fermi received the Nobel Prize among others for the results shown in  Fig. 4.1. Half a year later it was clear that all the information given there was incorrect.

4.2.3 Discovery of Alkaline Earth Metals: Identification of Barium

The situation became seemingly more complicated by an observation of Curie and Savitch (Curie and Savitch 1938a, b), of an activation product (half-life of about 3.5 h “that behaved like lanthanum.” Today it is known, the authors had observed the fission products ^{141}La (3.9 h) with an admixture of ^{142}La (92 min). This observation led however to the resolution of all the problems, namely to the discovery of nuclear fission.

Hahn, Meitner, and Strassmann put forward the hypothesis that this nuclide could be an isotope of actinium, the heavy homologue of lanthanum. Actinium could have been formed by the β decay of radium and radium could have been originated from uranium by an $(n, 2\alpha)$ -reaction – actually an unlikely reaction for energetic reasons.

The hypothesis got some support from the fact that the activity coprecipitated from the solution of irradiated uranium with a precipitate of salts of added barium – the lighter homologue of radium. Hahn and coworkers used a coprecipitation with barium chloride from a solution of concentrated hydrochloric acid. Under these conditions, the BaCl_2 precipitate is very clean and one could conclude that a radioactive species coprecipitated would have to be an element belonging to the group of alkaline earths, namely Sr, Ba, or Ra. Since barium

■ Fig. 4.2

Radioisotopes identified after coprecipitation with barium chloride and initially attributed to radium; after (Hahn and Strassmann 1939)

and its lighter homologues were excluded on grounds to be discussed later, the conclusion was that indeed radium was formed. In further studies, again four chains of “isomers” were identified (Hahn and Strassmann 1939) (► Fig. 4.2).

The activity of 3.5 h half-life behaving like lanthanum as claimed by Curie and Savitch was indeed found (Ac II with 2.5 h). In reality, as discussed above, this activity originated from a mixture of 3.93 h ^{141}La and 92.5 min ^{142}La .

In further experiments, Hahn and Strassmann tried to separate the radium from the barium (that was added to carry out the coprecipitation procedure). Such a separation between barium and radium is not easy because of the similar chemical properties of homologues. The chemist uses a procedure of fractionated crystallization in which only “fractions” of the total mixture are precipitated. In the first fractions of the precipitate, the element with a lower solubility is enriched. If a series of such precipitations is carried out in a systematic way, one eventually comes to a clean separation even between elements of similar properties.

Hahn and Strassmann used different salts (bromides, chromates) trying to separate radium from barium. (Lise Meitner had to leave the team in 1938 due to the political situation in Germany. She found a position in the Physical Institute of the Academy of Sciences, Stockholm. She remained, however, in close contact by letters with O. Hahn and F. Strassmann.) Surprisingly no enrichment of the less soluble radium was found in the first fractions. As these chemical procedures are difficult and may not always be successful, they tested the procedure by adding ^{226}Ra , a natural α -emitting isotope of radium. The result of this crucial experiment performed on December 17, 1938 was a big surprise: The natural radium did show enrichment in the first fractions but the radioactive species produced in the neutron irradiation of uranium did not. For a chemist the conclusion could only be that this species was not radium but barium, an element with roughly half the mass of uranium – a conclusion which, with only light-particle emission being known, seemed to disagree with one of the basic laws of physics, namely, energy conservation.

4.2.4 Arguments of Nuclear Physicists and Publication

This argument of the nuclear physicists is perhaps best illustrated by a sketch presented in a popular talk by N. Bohr referred in (Bohr 1936) and shown in ► Fig. 4.3.

The shallow basin filled with billiard balls shown represents a nucleus filled with protons and neutrons. An incoming slow or thermal neutron would share its liberated binding energy (represented here by the difference in height between rim and basin) with other nucleons. This

■ Fig. 4.3

Sketch of a shallow basin with billiard balls shown by N. Bohr in 1936 to illustrate the concept of a nucleus capturing a neutron (Bohr 1936)

would normally lead to an excited state that would return to the ground state by emission of γ rays. In a few cases, it could be that by chance after many collisions the total energy would concentrate on a single neutron again. In that case this neutron would have enough energy to leave the nucleus, a so-called (n,n') -process. If the incoming neutron had a kinetic energy higher than the separation energy of a neutron or of an α particle (a few MeV), the process could lead to the emission of two neutrons in a so-called $(n,2n)$ -process or to the emission of an α particle called (n,α) -process, respectively.

From this picture it is, however, obvious that an incoming thermal neutron could not lead to the loss of nearly half the nucleons. Such a process would indeed violate the basic law of conservation of energy. The qualitative picture presented here was actually backed by some sound theory on α decay (Gamov 1928; Gurney and Condon 1928, 1929).

The physics community was therefore convinced that nuclear reactions induced by thermal neutrons or neutrons with a few MeV of energy could not produce reaction products further away from the original (“target”) nucleus than a few mass units.

Therefore, Hahn and Strassmann were reluctant to accept the consequences of their own discovery. In a letter to Lise Meitner, Hahn wrote on December 19:

- ▶ *Es ist (nämlich) etwas bei den “Radium Isotopen”, was so merkwürdig ist, dass wir es vorerst nur Dir sagen..... Unsere Ra-isotope verhalten sich wie Ba.... Wir wissen dabei selbst, dass es nicht in Ba zerplatzen kann (There is something so strange with the “radium isotopes” that for the moment we tell it only to you. ... Our radium isotopes behave like barium... We know, however, ourselves that it cannot burst into barium...).*

Even though Hahn and Strassmann did not realize fully at this moment the consequences of their discovery, they knew that their results would change fundamental aspects of nuclear physics. They also knew that Curie and Savitch (with their discovery of a β emitter of 3.5 h half-life “that behaved like lanthanum”) were extremely close to the same discovery. Therefore, they wanted to publish their results quickly. They selected the journal *Naturwissenschaften* for its rapidity.

It seemed too time consuming to both to write a new publication. They had a manuscript describing the decay properties of the supposed radium isotopes: “Über den Nachweis und das Verhalten der bei der Bestrahlung des Urans mittels Neutronen entstehenden Radium-Isotope” (On the detection and the properties of the radium isotopes formed in the irradiation of

uranium with neutrons). This manuscript was changed in a few points: In the title, Radium Isotope was changed in Erdalkalimetalle (alkaline earth metals). The article (Hahn and Strassmann 1939) describes the measurements of the radium isotopes as formulated in the original draft. At the end, a few paragraphs were added:

- *Nun müssen wir aber noch auf einige neuere Untersuchungen zu sprechen kommen, die wir der seltsamen Ergebnisse wegen nur zögernd veröffentlichen...* (Now we have to discuss some more recent studies, which we publish with a certain hesitation because of their strange results.)

After the description of the fractionated crystallization it follows:

- *Wir kommen zu dem Schluss: Unsere "Radiumisotope" haben die Eigenschaften des Bariums; Als Chemiker müssten wir eigentlich sagen, bei den neuen Körpern handelt es sich um Barium... Als der Physik in gewisser Weise nahestehende Kernchemiker können wir uns zu diesem, allen bisherigen Erfahrungen der Kernphysik widersprechenden, Sprung noch nicht entschließen...* (We come to the conclusion: our "radium isotopes" behave like barium; as chemists we ought to say the new substances are barium... As nuclear chemists that are in a certain way close to physics, we cannot yet decide to make this leap, which would contradict all the previous knowledge on nuclear physics).

The rapidity of the publication of the results was impressive: After the decisive experiment on December 17 (counting of the samples continued until December 21), the revised manuscript was finished on December 22 (just before Christmas). Otto Hahn called up his friend Paul Rosbaud, a freelance of Die Naturwissenschaften practically in charge of natural science. He came over, got the article, brought it to the printing shop, and replaced another article in press by the one of Hahn and Strassmann. The galley proofs were finished by December 27 and the article was out by January 6, 1939.

4.2.5 Interpretation of the Fission Process by L. Meitner and O. R. Frisch

Besides the letters, Hahn and Strassmann had sent a preprint of the article to Lise Meitner. She took along the news to Kungälv near Göteborg in Sweden, where she spent the Christmas holidays with her nephew Otto R. Frisch. During an extended walk through the wood, they discussed it and suddenly came to the conclusion that indeed fission of a heavy nucleus into two fragments of similar size was certainly possible – and even to be expected. The mechanism of such a reaction would have to be very different from the emission of small particles (neutrons, protons, α particles) and different from what was in a way suggested by a simple picture as shown in ► Fig. 4.3.

Unlike what is suggested by ► Fig. 4.3, a nucleus can get deformed, and actually a quantitative model describing a nucleus as a liquid drop was already existing, 4 years before (Weizsäcker 1935)! This model describes the nucleus as held together by short-range forces. The total binding energy is influenced, among other terms, by the surface energy and by the Coulomb repulsion between the protons. Even while walking through the wood, Meitner and Frisch could estimate that for nuclei with around 92 protons (uranium, with $Z = 92$) the cost of surface energy at deformation could be balanced by a gain in Coulomb energy. Thus, with the excitation energy due to the capture of a neutron, such a nucleus would become unstable against deformation, could evolve into an elongated form, and be driven apart into two fragments. They could estimate that an amount of about 200 MeV would be set free by such

a “fission” reaction, as they chose to call it and that this energy would appear to be about 80% in the form of kinetic energy of the fragments.

In agreement with Hahn and Strassmann, they sent a corresponding manuscript to Nature (on January 16, 1939) (Meitner and Frisch 1939), where, for the first time, the word fission was used. From the estimate that the kinetic energy of the two fragments is about 160 MeV, one could derive that such fragments would make huge signals (of about 80 MeV for each fragment) in an ionization chamber. On his return home, Frisch irradiated a uranium-coated ionization chamber and observed the corresponding pulses with an energy of at least 70 MeV (Frisch 1939).

Lack of space restricts the presentation of details on the history of the discovery of nuclear fission. Detailed accounts of this history and of the scientists involved are published in a number of monographs and journal articles (e.g., Hahn 1962; Frisch 1979; Krafft 1981; Kramish 1986; Lemmerich 1989; Herrmann 1990a, b; Herrmann 1995; Sime 1996).

4.2.6 Missed Opportunities

Three times at least before, one missed the discovery of fission by an inch:

1. Ida Noddack (Noddack 1934) criticized the claim of the discovery of element 93 by “*Es wäre denkbar, dass bei der Beschießung schwerer Kerne mit Neutronen diese Kerne in mehrere größere Bruchstücke zerfallen, die zwar Isotope bekannter Elemente, aber nicht Nachbarn der bestrahlten Elemente sind*” (It would be conceivable that in the bombardment of heavy nuclei with neutrons these nuclei disintegrate into several larger fragments, which are isotopes of known elements but not necessarily neighbors of the irradiated elements). If Noddack had made a pertinent experiment, she would certainly have found the truth 4 or 5 years earlier than Hahn and Strassmann.
2. Experiments using thin layers of uranium or thorium in an ionization chamber like the one made by Frisch to confirm the occurrence of fission were made by many scientists (see, e.g., Herrmann 1995) to study the β decay of radioisotopes produced or to search for high-energy α particles. In these cases, normally the uranium or thorium layer was covered by a thin foil to absorb the high α background of the natural α decay. In some cases, reportedly, the foils were inadvertently omitted and the large fission pulses were observed. They were however interpreted as artifacts of electronics and ignored (see Walton 1961; Flügge 1989).
3. In another case the fission pulses were attributed to high-energy α particles searched for (Braun et al. 1937).

A few months after the discovery of fission, it was clear that neutrons were set free in the process (von Halban jun et al. 1939). This initiation opened the way to speculations for a self-propagating chain reaction that would produce almost unlimited amounts of energy for peaceful and military uses (Flügge 1939). With the beginning of World War II, this had the consequence that from 1940 to the end of the war results on the fission process were kept secret and could not be published. Meanwhile, enormous efforts and money were invested in the development of nuclear reactors and nuclear weapons, particularly in the USA and somewhat later also in the Soviet Union, in Great Britain, France, China, and in other countries. These developments will not be covered here. Further information may be found in [Chap. 1](#) of this Volume. The rest of this chapter will be dedicated to the physics of the fission process, i.e., to the experimental methods used, to the results, and their implications on the structure and behavior of nuclear matter.

4.3 Model Considerations

4.3.1 The Liquid Drop Model (LDM)

The liquid drop model of Weizsäcker (Weizsäcker 1935), which allowed Meitner and Frisch to understand the most important features of fission during the hour of their walk through the woods of Kungälv shall be discussed in the following. Actually, this model, published 4 years before the discovery of nuclear fission, has the inescapable consequence that nuclei with a sufficiently high atomic number must be unstable and ought to undergo fission into fragments of similar sizes. It is astounding that this consequence had not been seen before.

An example for various slightly differing mathematical formulas for the binding energy (E_B) of a nucleus as given in textbooks is (Mayer-Kuckuck 1970)

$$E_B = aA - bA^{2/3} - c \frac{Z^2}{A^{1/3}} - d \frac{(Z - A/2)^2}{A} \pm \frac{p}{A^{1/2}} \quad (4.4)$$

(cf. ► Eq. (2.3) in Chap. 2). The model views an atomic nucleus as a drop of a liquid. A drop of normal liquid is held together by the van der Waals forces well known to the chemist as attractive forces of short range. In the atomic nucleus, these short-ranged forces are the “nuclear forces.” The terms appearing in ► Eq. (4.4) will be discussed briefly.

Term 1 (Volume energy = aA)

The consequence of the short range of nuclear forces is that the total binding of a nucleus (in analogy to a drop) is, to a first approximation, proportional to the number of nucleons. Each nucleon feels only its direct neighbors. As a consequence, the first term in ► Eq. (4.4) is given by a force constant (a) times the number of nucleons (A).

Term 2 (Surface energy = $bA^{2/3}$)

Nucleons on the surface feel an attractive force only from inside, so that their binding energy is smaller. The missing contribution has to be subtracted from term (1). The contribution is proportional to the surface ($S = 4\pi R^2$, for a sphere of radius R). Since nuclear matter is incompressible, the volume (V) of a nucleus is proportional to the number of nucleons, i.e., to the mass number (A). As, generally, the volume of a sphere is given by $V = (4/3)\pi R^3$, the radius is proportional to $V^{1/3} \propto A^{1/3}$. Hence, the surface of a spherical nucleus is proportional to $A^{2/3}$. In term (2) of ► Eq. (4.4), $A^{2/3}$ appears with the constant b .

Term 3 (Coulomb energy = $cZ^2/A^{1/3}$)

The protons all have positive charges and, hence, are repelled by each other. This repulsion diminishes the binding force and the term representing Coulomb repulsion has a negative sign in ► Eq. (4.4). The electrostatic repulsion energy in a uniformly charged spherical drop with radius R and a total electric charge q is

$$\frac{3q^2}{5R} \frac{1}{4\pi\epsilon_0}.$$

Since $q = Ze$ (Z = number of protons) and $R = r_0 A^{1/3}$, one can write $cZ^2/A^{1/3}$.

Term 4 (Asymmetry energy = $d(Z - A/2)^2/A$)

This term is beyond the analogy of a liquid drop and results from the fact that there are two constituents of the atomic nucleus (neutrons and protons) that can occupy two different sets of quantum states. The term becomes zero when the number of protons in a nucleus equals that of neutrons ($Z = A/2$).

Term 5 (Pairing energy = $\pm p/A^{1/2}$)

This term (abbreviated frequently with δ) takes care of the fact that nuclei with even numbers of protons and neutrons are more stable. The constant p has a positive sign for nuclei with even numbers of protons and of neutrons (even–even nuclei) and a negative sign for nuclei with odd numbers of protons and of neutrons (odd–odd nuclei). It is set equal to zero for odd–even and even–odd nuclei. The pairing energy is responsible for the fact that in low energy fission, products with even numbers of nucleons generally dominate. This “odd–even effect” allows theoreticians to study the internal excitation energy (temperature) of a fissioning nucleus at scission.

The following quantitative discussions will be based on a modified version of [Eq. \(4.4\)](#) (Myers and Swiatecki 1966; Friedlander et al. 1981): [Eq. \(4.5\)](#) differs from [Eq. \(4.4\)](#) by the fact that the asymmetry energy is not only subtracted from the volume energy (term 1) but also from the surface energy (term 2). This is consistent and follows from the definition of the surface energy. In addition, a further term, ($f Z^2/A$), is added, which takes into account that nuclear surface is somewhat diffuse.

$$E_B = (aA - bA^{2/3}) \left[1 - d \frac{(Z - A/2)^2}{A} \right] - c \frac{Z^2}{A^{1/3}} + f \frac{Z^2}{A} \pm \frac{p}{A^{1/2}} \quad (4.5)$$

with $a = 15.677$ MeV; $b = 18.56$ MeV; $c = 0.717$ MeV; $d = 1.79$; $p = \pm 11$ MeV or 0 as has been discussed in the context of [Eq. \(4.4\)](#); $f = 1.211$ MeV.

Evidently the liquid drop model can be used to calculate the mass ($M(Z, A)$ in atomic mass units) of any atom as a function of its number of protons (Z) and neutrons (N):

$$M(Z, A) = Z M(1, 1) + (A - Z) M(0, 1) - E_B/c^2. \quad (4.6)$$

Here $M(1, 1)$ and $M(0, 1)$ are the mass of a hydrogen atom (proton and pertinent electron) and neutron, respectively; c is the speed of light in vacuum and E_B is defined by [Eq. \(4.4\)](#) or [Eq. \(4.5\)](#).

4.3.2 Fission Barrier in the Liquid Drop Model

The liquid drop model is a very versatile instrument, which explains not only fission as a process in which the Coulomb energy driving a nucleus apart would overcome the surface energy holding it together but also gives an estimate for the amount of energy set free in the process. Actually, it is very easy to write a little program for [Eqs. \(4.4\)](#), [Eq. \(4.5\)](#) or [Eq. \(4.6\)](#) and study its implications for the stability of matter as a function of A and Z . Some of the implications for the understanding of the fission process shall be discussed in the following.

The first question concerns the region of instability toward fission. A plot of the binding energy of nuclei versus mass derived from experimental masses of stable elements or calculated from [Eq. \(4.4\)](#) or [Eq. \(4.5\)](#) for the optimum neutron to proton ratio shows a maximum of stability around mass $A = 60$. Nevertheless, stable nuclei are found up to a mass number of $A = 209$. This is due to the fact that a barrier exists that prevents these nuclei from decaying into the most stable nuclei around $A = 60$. This barrier is due to the repulsive Coulomb force that a charged particle undergoes when emerging from a heavier nucleus. In order to estimate this barrier height for a heavy nucleus fissioning into two fragments of equal size one can proceed in the following way. One calculates the binding energy of a nucleus, $E_B(Z_f, A_f)$, with mass number

A_f and atomic number Z_f and the binding energy of two fission products of half the mass ($2E_B(Z_f/2, A_f/2)$). The total energy (Q_f) set free in this fission process is then given by

$$Q_f = 2E_B(Z_f/2, A_f/2) - E_B(Z_f, A_f) \quad (4.7)$$

For $A_f = 238$ and $Z_f = 92$ (^{238}U) this gives a value of $Q_f = 193$ MeV. This value is valid for the ground states of the two fission products in infinite distance from each other. In order to obtain a limit for the barrier height, the two fission products will be imagined to approach each other until they touch and then the Coulomb energy that is required to be overcome will be calculated. Mathematically the Coulomb potential V_C (actually: potential energy) between two uniformly charged spheres is given by

$$V_C = \frac{Z_1 Z_2 e^2}{4\pi\epsilon_0(R_1 + R_2)} \quad (4.8)$$

with $e = 1.602 \times 10^{-19}$ As and $\epsilon_0 = 8.854 \times 10^{-12}$ As/(Vm). Setting $Z_1 = Z_2 = Z_f/2$, $R_1 = R_2 = R$ (for two fission fragments of equal size, i.e., symmetric fission), $R = r_0(A_f/2)^{1/3}$, one obtains

$$V_C = \frac{(Z_f/2)^2 e^2}{2(A_f/2)^{1/3} 4\pi\epsilon_0 r_0}. \quad (4.9)$$

Introducing the numerical values of the constants e and ϵ_0 and choosing a value of 1.5×10^{-15} m for r_0 one obtains

$$V_C = 0.151 \frac{Z_f^2}{A_f^{1/3}} (\text{MeV}). \quad (4.10)$$

For the (symmetric) fission of ^{238}U ($Z_f = 92$) one gets $V_C = 206$ MeV. An estimate for the height of the fission barrier (H_B) for the symmetric fission of ^{238}U is obtained according to

$$H_B = V_C - Q_f, \quad (4.11)$$

hence, $H_B = 206 - 193 = 13$ MeV. This value is an upper limit because the picture of two touching spheres is not realistic. In a situation of two touching nuclei, the nuclear force would set in, lowering the total energy. In fact, the experimental barrier height for the specific case is about 7 MeV. This energy corresponds roughly to the binding energy of a neutron. As a consequence, one can imagine that the capture of a (thermal) neutron can induce fission in such a nucleus. Actually in the case of uranium, a thermal neutron will induce fission only in the isotope 235. To induce fission in ^{238}U a neutron has to bring in an additional amount of 1 MeV of kinetic energy.

In order to illustrate the dependence of the fission barrier on the mass of nuclei, [Table 4.1](#) gives values calculated according to [Eq. \(4.11\)](#) for a few selected nuclei.

The results presented confirm the expectation that the fission barrier decreases with increasing mass of the nuclei. Physically this is due to the fact that the Coulomb repulsion driving apart a nucleus increases with $Z^2/A^{1/3}$ and that the surface force holding it together varies only with $A^{2/3}$.

4.3.3 The Fissility Parameter

From a general consideration of [Eq. \(4.11\)](#) a parameter can be extracted, which describes the instability of a nucleus toward fission ("fissility"). For this purpose, one defines a situation where the height of the barrier H_B approaches zero, i.e., according to [Eq. \(4.11\)](#) $Q_f \geq V_C$. Q_f

■ **Table 4.1**

Height of fission barriers in MeV calculated according to the liquid drop model

Nuclide	Atomic number (Z)	Fission barrier H_B (MeV)
^{140}Ce	58	50
^{174}Hf	72	37
^{232}Th	90	16
^{236}U	92	11
^{238}U	92	13
^{250}Cf	98	2

and V_C are defined according to [Eqs. \(4.7\)](#) and [\(4.9\)](#), respectively. E_B in [Eq. \(4.7\)](#) is defined by [Eq. \(4.5\)](#). Writing down [Eq. \(4.7\)](#) again

$$Q_f = 2E_B(Z_f/2, A_f/2) - E_B(Z_f, A_f) \quad (4.12)$$

and replacing E_B by the explicit terms of [Eq. \(4.5\)](#):

$$\begin{aligned} Q_f = 2 & \left[(a(A_f/2) - b(A_f/2)^{2/3}) \times \left(1 - d \frac{(Z_f/2 - A_f/4)^2}{A_f/2} \right) \right. \\ & \left. - c \frac{(Z_f/2)^2}{(A_f/2)^{1/3}} + f \frac{(Z_f/2)^2}{A_f/2} \pm \frac{p}{(A_f/2)^{1/2}} \right] - \left[(aA_f - bA_f^{2/3}) \right. \\ & \left. \times \left(1 - d \frac{(Z_f - A_f/2)^2}{A_f} \right) - c \frac{Z_f^2}{A_f^{1/3}} + f \frac{Z_f^2}{A_f} \pm \frac{p}{A_f^{1/2}} \right]. \end{aligned} \quad (4.13)$$

Inserting the numbers of the constants and rearranging the terms, one comes to the relation:

$$Q_f = 0.265 \frac{Z_f^2}{A_f^{1/3}} - 34.54 \frac{Z_f}{A_f^{1/3}} (1 - Z_f/A_f) + 3.81 A_f^{2/3}. \quad (4.14)$$

Now one can write for $V_C < Q_f$ using [Eqs. \(4.10\)](#) and [\(4.14\)](#):

$$0.151 \frac{Z_f^2}{A_f^{1/3}} < 0.265 \frac{Z_f^2}{A_f^{1/3}} - 34.54 \frac{Z_f}{A_f^{1/3}} (1 - Z_f/A_f) + 3.81 A_f^{2/3}. \quad (4.15)$$

Multiplication of the equation with $A^{-2/3}$ and isolation of the terms with Z^2/A on the left side gives

$$\frac{Z_f^2}{A_f} > 303 \frac{Z_f}{A_f} (1 - Z_f/A_f) - 33.4. \quad (4.16)$$

Since Z/A varies only between 0.38 and 0.42 throughout the periodic system, it is set equal to $Z/A = 0.40 \pm 0.02$. As a consequence, [Eq. \(4.16\)](#) can be rewritten as

$$\frac{Z_f^2}{A_f} > 39.3 \pm 1.2 \quad \text{or} \quad Z > 98.3. \quad (4.17)$$

Z_f^2/A_f (or more simply Z^2/A) appears as a factor that determines the “willingness” of nuclei to fission. Therefore, it is called the fissility parameter. A value of Z^2/A larger than 39 indicates that the nucleus should be unstable toward (spontaneous) fission. Values of Z^2/A larger

than 39 are found for nuclei with $Z \geq 100$. These nuclei should undergo spontaneous fission rapidly. The fact that such nuclei have a certain stability is explained by a stabilization due to shell effects. Actually, the number 39 calculated as the critical value depends on the value of r_0 assumed. Choosing $r_0 = 1.4$ fm rather than 1.5 fm changes the critical value of $Z^2/A = (Z^2/A)_{\text{krit}}$ from 39 to 43.

4.3.3.1 Second Derivation of the Fissility Parameter

Another derivation of the fissility parameter goes back to Bohr and Wheeler (Bohr and Wheeler 1939) and (independently) to Frenkel (Frenkel 1939): Oscillations of a nucleus will be unstable if the gain in Coulomb energy surpasses the loss of surface energy. The volume (V) of a sphere is given by

$$V = \frac{4}{3} \pi R^3 \quad (4.18)$$

If the sphere (drop) is incompressible, a deformation will not change the volume. An ellipsoidal deformation may be described by

$$V = \frac{4}{3} \pi ab^2 \quad (4.19)$$

with a being the long half-axis and b the two short half-axes of the ellipsoid. The half-axes may be described by

$$a = R(1 + \varepsilon) \quad (4.20)$$

and

$$b = R(1 + \varepsilon)^{-1/2} \quad (4.21)$$

with ε a measure for the eccentricity of the ellipsoid. The surface (S) of an ellipsoid can then be approximated by a series (which will be cut after the second term):

$$S = 4\pi R^2 \left[1 + \frac{2}{5} \varepsilon^2 + \dots \right] \quad (4.22)$$

Correspondingly, the surface energy (E_S) will be given by

$$E_S = b' A^{2/3} \left[1 + \frac{2}{5} \varepsilon^2 + \dots \right] \quad (4.23)$$

with

$$b' = b \left[1 - d \frac{(Z - A/2)^2}{A} \right] \quad (4.24)$$

(see [Eq. \(4.5\)](#)). Generally, the Coulomb energy of an ellipsoidal body with charge q is given by

$$E_C = \frac{3q^2}{20\pi e R \varepsilon_0} \left[1 - \frac{1}{5} \varepsilon^2 + \dots \right] \quad (4.25)$$

For the present case of a charged nucleus with atomic number Z and mass number A this results in

$$E_C = c \frac{Z^2}{A^{1/3}} \left[1 - \frac{1}{5} \varepsilon^2 + \dots \right] \quad (4.26)$$

(see [Eq. \(4.5\)](#)). As a consequence, when ε (the deformation) increases, the surface energy E_S will increase and E_C will decrease. Obviously, the decrease of Coulomb energy is due to the increase of the mean distance between the protons. The condition of $|\Delta E_C| > |\Delta E_S|$ results in a nucleus that is unstable to deformation, i.e., the spherical configuration cannot be restored once it gets deformed. As a consequence, one can write for the condition that will lead to spontaneous fission:

$$c \frac{Z^2}{A^{1/3}} \frac{1}{5} \varepsilon^2 > b' A^{2/3} \frac{2}{5} \varepsilon^2 \quad (4.27)$$

or

$$\frac{Z^2}{A} > 2 \frac{b'}{c} = 47 \quad (4.28)$$

Like in the derivation based on the height of the fission barrier, Z^2/A appears as the parameter determining fissility. The minimum values obtained for Z^2/A (39 or 47) should not be taken too strictly, as they are based on rather arbitrary assumptions for nuclear constants.

The role of the fissility parameter in the stability of nuclei against fission is documented in [Fig. 4.4](#) where the half-lives of heavy nuclei toward spontaneous fission are plotted. As a general trend, one can observe a gradual decrease over 35 orders of magnitude with increasing Z^2/A in the semilogarithmic plot. At closer look, one can see however that most elements (characterized by their atomic numbers) show a bell-shaped behavior. This deviation from

Fig. 4.4

Half-lives for spontaneous fission of heavy elements (characterized by their atomic numbers Z) as a function of their fissility parameters (Z^2/A). (Data from Wagemans [1991a](#), p 37). The data represent even–even nuclei only

■ Fig. 4.5

Half-lives for spontaneous fission of even–even nuclei (as shown in ▶ Fig. 4.4) (open circles) and of odd- A and odd–odd nuclei (full circles) versus the corresponding fissility parameter (Wagemans 1991a)

a simple log-linear dependence has been explained by shell effects in the ground state masses (Swiatecki 1955; Vandenbosch and Huizenga 1973).

In ▶ Fig. 4.4 only even–even nuclei are plotted. Nuclei with an odd number of either neutrons or protons or both, generally, have longer half-lives, as will be discussed later in the context of the influence of nuclear shell structure on fission. For comparison, the half-lives of odd (i.e., odd- A and odd–odd) and even–even nuclei for spontaneous fission as a function of the fissility parameter are shown in ▶ Fig. 4.5. It is obvious that in general the half-lives of odd nuclei are several orders of magnitude longer.

Fission induced by neutrons, charged particles or photons is preceded by an excitation step. This step will allow the nucleus to overcome the barrier. On the other hand, there is a competing process, which allows the nucleus to get rid of the excitation energy by γ -ray emission. The timescale of this competing process does not allow a slow tunneling through the fission barrier. As a consequence, induced fission takes place only if the excitation energy is at least as high as the fission barrier. (Tunneling is only possible in the direct neighborhood of the top of the fission barrier (= sub-barrier fission)).

4.3.4 LDM and Fission-Critical Evaluation

In summary, the liquid drop model explains

1. The existence of a fission barrier as a result of the opposing action of Coulomb and surface forces. It predicts that the barrier diminishes with increasing atomic number of the elements and approaches zero around $Z = 100$.
2. The liberation of about 200 MeV per fission event.

3. The formation of fission products, which are neutron rich and which stabilize by a sequence of several β -decay processes and/or by the emission of prompt neutrons. This is due to the fact that the valley of stability is bent toward the neutron-rich region from the initial $N = Z$ direction due to the Coulomb term.
4. The formation of a compound nucleus in which the excitation energy is redistributed many times between different degrees of freedom (single-particle states of the nucleons and collective degrees of freedom, like deformations and vibrations) before fission occurs (timescale 10^{-14} s).

The liquid drop model does, however, *not* explain some important observations of the fission process:

1. Even though the formation of two fission products of equal mass (half the mass of the fissioning nucleus, “symmetric fission”) would be most exoenergetic, experimentally (as will be shown later) the mass ratio of the two fission products is normally found to be approximately 1/3 to 2/3 (“asymmetric fission”).
2. The deviation from a smooth straight-line behavior and the difference between even–even and odd nuclei, as discussed in the context of [Figs. 4.4](#) and [4.5](#).
3. The existence of elements with atomic number $Z > 100$.
4. Phenomena, like the existence of “fission isomers,” to be discussed later.

The key for the understanding of these observations is the “shell model” (Haxel et al. 1950; Mayer 1950). The shell model is presented in the textbooks of nuclear- and radiochemistry and nuclear physics. Nevertheless, for the reader’s convenience, the basic concept shall be repeated here. A more detailed treatment and other basic information on the physics of nuclei can be found within this volume (see [Chap. 2](#) in this Volume).

4.3.5 The Shell Model

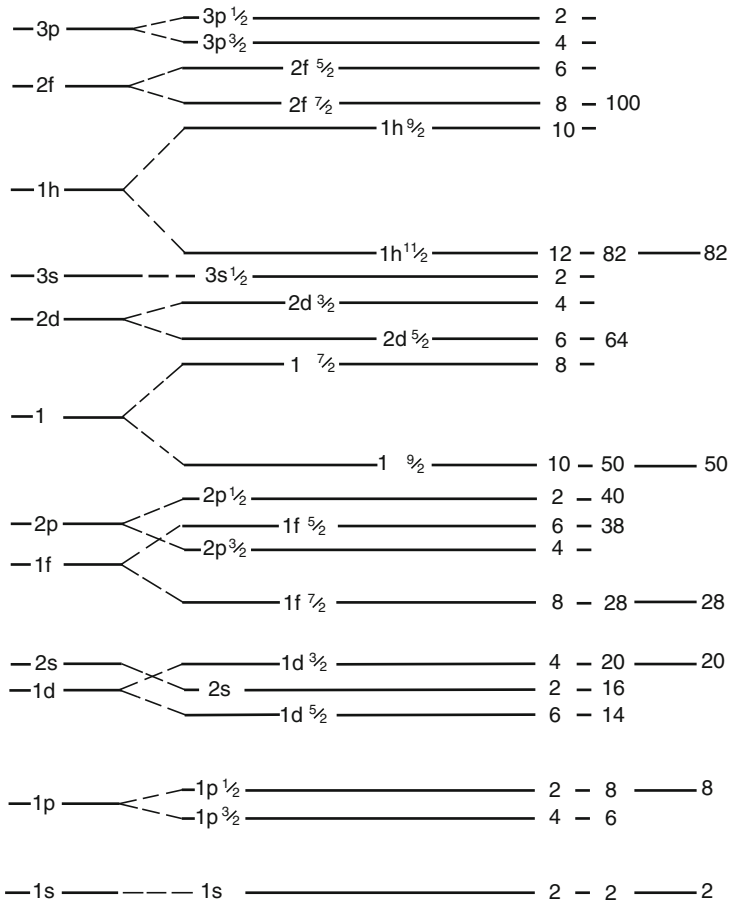

The viewpoint of the shell model is very different from that of the liquid drop model. The nucleons are looked at as standing waves occupying well-defined quantum states in a potential that is formed by the other nucleons. The chemist knows such a system from the behavior of the electrons in the atomic shell. Whereas in the atomic shell the potential and the forces acting are known, this is not the case for nuclei. The form of the nuclear potential well is not known exactly. The form of the nuclear potential well can be parameterized by a harmonic oscillator, by a square well potential or – more realistically – by a Woods–Saxon potential (see [Fig. 2.2](#) in [Chap. 2](#)).

In the nucleus, like in the atom, one has principal quantum numbers (1, 2, 3, ...) and angular momentum quantum numbers (s, p, d, f, ... with $l = 0, 1, 2, 3, \dots$). The latter ones, like in the atom, may be occupied by 2, 6, 10, 14 ... (in general $2(2l + 1)$) nucleons of a particular kind. The numbering is different though. In the atom the nodes pertaining to a p ($l = 1$), d ($l = 2$), f ($l = 3$)-state are added to the main quantum number. In the nucleus this is not so. As a consequence, a sequence of levels of 1s, 2p, 3d, 4f ... in the electron shell corresponds to 1s, 1p, 1d, 1f ... for the nucleus. A level scheme for a spherical nucleus is given in [Fig. 4.6](#).

Another difference between the atomic shell and the nuclear shell is that in the latter spin–orbit coupling has an important energetic effect. This effect changes the energetic sequence of levels. For instance, the $1d_{5/2}$ -level in [Fig. 4.6](#) ends up underneath the 2s-level. The gap due to

■ Fig. 4.6

Level scheme calculated for a Woods–Saxon like potential well (*left*) and the effect of spin–orbit coupling (*middle*). The numbers in parenthesis give the maximum number of neutrons or protons that can occupy the subshell. The numbers in square brackets are the sums of the former from the lowest level up through the level concerned. Proton or neutron numbers that produce particular stability “magic numbers” are given further right

spin–orbit coupling increases with increasing angular momentum quantum number (l) (see levels $1p_{1/2}$ and $1p_{3/2}$ or $1h_{9/2}$ and $1h_{11/2}$ in ▶ Fig. 4.6). Generally, nuclei with fully occupied shells are highly stable. In nuclear physics, a shell is defined by large gaps in the energies of single-particle states. In the electron shell, shell closures occur in the rare gasses, where the p-shell is occupied and the s-shell of the next higher principal quantum number is at a considerably higher level. The numbers of electrons in these shells of particular stability are 2 (He), 10 (Ne), 18 (Ar), 36 (Kr), 54 (Xe), and 86 (Rn). In the nuclear case these “magic numbers” may be read from ▶ Fig. 4.6: 2, 8, 20, 28, 50, 82, etc. One can also see further below that the shell closures at 28 and, especially at 50, have an important influence on the fission process.

The atomic subshells host a number of $(2l + 1)$ pairs of electrons. So the p subshell hosts three pairs of electrons designated by the quantum numbers $m_l = +1, 0, -1$. These states differ in their orientation within the electron shell and possess normally identical energy. Physicists, for some obscure reason, call such levels “degenerate.” When, however, an external electric field or magnetic field is applied, the orientation of the magnetic moment of the p-, d-electrons, etc., makes a difference, and the three levels of the p term mentioned above ($m_l = +1, 0, -1$) will differ in energy (Stark effect, Zeeman effect).

The situation is analogous in the nucleus: The $p_{1/2}$ and $p_{3/2}$ -levels (created from the p-level by the spin–orbit coupling) host six nucleons of the same kind ($p_{1/2}$: $+1/2, -1/2$ and $p_{3/2}$: $+3/2, +1/2, -1/2, -3/2$). Their energies are the same as long as the nucleus is spherical, but when the nucleus is deformed the degenerate levels split up.

Apparently, in a nonspherical nucleus, the orientation of a wave within the nucleus influences the energies of single-particle states. Obviously, deformation is important for a nucleus on the way to fission and important aspects of fission can be explained by the effect of deformation on nuclear levels. The effect of deformation on nuclear levels is shown schematically in [Fig. 4.7](#) in the case of an $f_{7/2}$ -state. A realistic situation for a nucleus with its different principal and angular momentum quantum states is shown in [Fig. 2.11 of Chap. 2](#).

The splitting of levels leads to an increased level density. Energetic gaps (“closed shells”) found in a spherical nucleus may disappear in a deformed nucleus. New gaps may be formed at different nuclide numbers at specific deformations. The sum of the energetic effects of all the occupied quantum states in a nucleus shows an oscillating behavior, i.e., the stability of a nucleus (as far as shells are concerned) as a function of deformation shows maxima and minima.

The true behavior of a fissioning nucleus can be described only by combining the liquid drop model and the shell model.

Fig. 4.7

Schematic diagram of the energy of an $f_{7/2}$ -state with deformation (oblate = pancake-shaped, prolate = cigar-shaped)

4.3.6 The Combination of the Liquid Drop Model and the Shell Model According to Strutinsky

For the case of fission, Strutinsky (1967) chose a simple but very successful way to describe the energy of a nucleus by combining liquid drop energy (E_{LDM}) with local shell (δU) and pairing (δP) corrections:

$$E = E_{\text{LDM}} + \sum_{p,n} (\delta U + \delta P). \quad (4.29)$$

The result of his approach for the potential energy as a function of deformation is shown in [Fig. 4.8](#). These calculations result in a two-humped, double fission barrier ([Fig. 4.8](#)), which is confirmed by multiple experimental evidence, such as the asymmetry of fission, the existence of elements with $Z > 100$ and of fission isomers as will be discussed further below.

A quasi-three-dimensional presentation of the potential energy surface of a fissioning nucleus as a function of deformation and asymmetry is shown in [Fig. 4.9](#).

The way to fission starts at symmetry with a neck radius of 7 fm and a potential energy of $E_{\text{pot}} = 0$ MeV. The nucleus has to pass a first saddle at 6.5 fm ($E_{\text{pot}} = 4.3$ MeV). Beyond the subsequent valley ($E_{\text{pot}} = 1$ MeV) a second barrier appears at 5 fm neck radius. The height of this barrier depends on the degree of asymmetry of the fragments formed. It is 8 MeV for symmetric fission and 5.7 MeV for the saddle at a fragment mass ratio of 88:148. This barrier is responsible for the asymmetric character of low energy fission. As will be shown later, this is due to the shell closures for protons at $Z = 50$ and 28 and for neutrons at $N = 82$. Beyond the second barrier, the fissioning nucleus finds a smooth descent toward scission (at 0 fm neck radius). A return to symmetry on this way is hindered by a mountain ridge of several MeV.

Fig. 4.8

Illustration of the method of Strutinsky to merge shell model and liquid drop model as a function of deformation. Upper full curve shows energetic oscillations due to shell effects around a mean (upper dashed curve). The upper dashed curve has been “adjusted” to the low-deformation part of the lower dashed curve, which is calculated using the liquid drop model; from (Vandenbosch and Huizenga 1973)

■ Fig. 4.9

Potential energy surface of the compound nucleus $^{236}\text{U}^*$ on its way to fission. The path to fission is given in terms of the neck radius. (Fission is achieved when the neck radius drops to zero). The degree of asymmetry is given by the mass ratio of light and heavy fragments formed. The potential energy is shown in the form of contour lines as in geographical maps; after (Mustafa et al. 1973)

4.3.7 Further Model Considerations

Many attempts have been made to understand the fission process and to calculate the measurable quantities (yields, kinetic energies of fragments, etc.). These attempts have not been fully successful yet. Nevertheless, important progress has been made in recent years and new insight has been gained. Due to limitation in space, only two approaches will be mentioned here.

A model, based on the construction of a potential energy surface from a combination of liquid drop terms for protons and neutrons as a function of deformation and shell corrections, has been published by Wilkins, Steinberg, and Chasman (Wilkins et al. 1976). In the model, a specific excitation energy (nuclear temperature) is assumed at scission and the probability to reach this specific state is calculated. The general trends of mass–yield curves in the fission of very different nuclides from ^{211}Po to ^{258}Fm and for different excitation energies of the fissioning nucleus from 0 MeV (spontaneous fission) to highly excited fission reactions are reproduced correctly. In particular, the transition from the symmetric fission of (the compound nuclei) ^{212}Po to a triple-humped mass–yield curve for ^{227}Ra to double-humped yield curves for ^{236}U , ^{246}Cm , and ^{252}Cf and, finally, a partial return to symmetry for ^{258}Fm is reproduced correctly. However all the yield curves are by far too narrow, so that a quantitative prediction of fission yields is not possible.

The latter problem has been solved by Brosa et al. (1990) by introducing fluid dynamics. One may imagine the scission configuration as a dumbbell-like structure with two spheres connected by a neck. When this neck elongates, its diameter becomes increasingly smaller. In this case, fluid dynamics reveals that the location of rupture of the neck is not well defined and this leads to broader mass distributions. In addition, Brosa et al. discovered in their calculations the coexistence of different paths to fission. These paths depend on the mass of the fragments formed. A path leading to a fragment with mass number near the double shell closure of $Z = 50$ and $N = 82$ will be influenced by the rigidity of magic nuclei. The consequence is that the scission configuration will be less deformed. The path to fission will be shorter and the fragments will have a higher kinetic energy. On the other hand, a path leading to well-deformed fragments will be long and will produce fission fragments with less kinetic energy.

4.4 Experimental Facts and Interpretation

4.4.1 Sequence of Events Leading to Fission

In order to understand how the fission process can be accessed experimentally, i.e., to have an overview on the different quantities that can be measured, the sequence of events occurring during the fission process will be briefly described.

For induced fission, the first step is the transfer of sufficient excitation energy to overcome the fission barrier. This excitation energy is most frequently provided by the binding energy of a thermal neutron. It can, however, be due to the absorption of a sufficiently energetic photon. Higher excitation energies can be induced by fast neutrons or charged particles.

In the case of low energy fission, the excited nucleus forms a vibrationally excited compound nucleus, which can return to its ground state by emission of γ rays. In competition with this de-excitation process, the nucleus may find a configuration (saddle point), which is unstable toward fission. This configuration, according to the present understanding, has the shape of two spheres

connected with a neck in a dumbbell-like manner. From this saddle point on, the Coulomb force will drive the nucleus apart. The neck will become gradually thinner and finally snap forming two more or less deformed fragments. In rare cases (1 out of 400 events), a small third fragment will also be formed from the snapping neck (“ternary fission”). The deformed fragments will be accelerated due to the Coulomb repulsion and simultaneously will relax into spherical shapes. In this process, the deformation energy will transform into internal excitation energy allowing the boil-off (emission) of a few neutrons within about 10^{-14} s (“prompt neutrons”). The nuclei formed after prompt neutron emission are usually called “fission products” rather than “fission fragments” as they are referred prior to prompt neutron emission.

The fission products are neutron-rich unstable nuclei, which stabilize by a sequence of β decays. Each β decay will transform a nuclide into its neighbor with the next higher atomic number and the same mass number. (In rare cases, the β decay of a fission product is accompanied by the emission of a neutron, called delayed neutron – as opposed to the prompt neutrons discussed above. In these cases, the mass number of the fission product decreases by one. The delayed neutrons are important for the control of nuclear reactors and will be discussed later.)

Historically, the first quantities measured were the yields of the longest-lived members (near-end products) of the β -decay chains. These yields are called chain yields or mass yields.

With the development of fast chemical separation techniques and physical techniques that allows one to differentiate between different elements of an isobaric decay chain, information could be obtained on the fission product distribution prior to β decay. The corresponding yields are called “independent” or “primary” product yields.

A fission product is hence normally produced in two ways: Directly from the fissioning nucleus and indirectly by the β decay of a precursor. Correspondingly, one can distinguish between independent (primary) and secondary yields. The sum of primary and secondary yields is called cumulative yield. The cumulative yield of the last chain member is normally identical to the chain yield. “Fractional” (independent, cumulative, etc.) yields show what fraction of the total chain yield comes from a particular formation path.

In addition to the yields of the fission products, the yields of the fission fragments (prior to prompt neutron emission), as well as the number of prompt neutrons (and γ rays) emitted are of interest. The yields of ternary fragments and their angular distribution with respect to the direction of the two main fragments give some information on the neck. The kinetic energy of the two fragments gives information on the distance of the two charge centers, i.e., on the deformation of the fissioning system at scission.

In the following, the experimental techniques used to measure the quantities mentioned above will be discussed.

4.4.2 Chain Yields

4.4.2.1 Methods of Measurement

Radiochemical methods. Chain yields are obtained by isolating different elements chemically from a fission product mixture and determining the absolute activities of the isotopes found. Since chemical separation is normally rather time consuming, by the end of the separation, the precursors have decayed into the long-lived isotopes whose cumulative yields then represent the corresponding chain yields.

Radiochemical separations and subsequent counting are supposed to be the domain of radiochemists but, motivated by the interest in fission and its possible applications, even physicists were compelled in the early days to do chemical separations as is described about Fermi by A. v. Grosse (1965). (*"It was fascinating to see Fermi disappear in dense fumes of sulfuric acid as he was carrying out some chemical separation in the corner room of the basement of the Pupin Laboratories at Columbia University (1939). His voice could be clearly heard out of the 'London fog' giving instructions as to what should be done next."*) Large laboratories were set up during World War II for this work first in the USA ("Manhattan Project") and later in the Soviet Union and other countries. The results of the US scientists were kept secret during the war and were published in comprehensive form later (Coryell and Sugarman 1951).

In order to obtain fission yields, the number of atoms of a specific nuclide formed (N_X) must be compared to the number of fission events (N_f) in the corresponding target. The yield is then defined as $Y_X = N_X/N_f$. The number N_f could be determined using a fission counter (Engelkemeir et al. 1951). A thin foil of the fissile material placed in a proportional counting tube is irradiated under the same conditions as the target. The fission products leaving the foil and projected into the counting volume produce large pulses that can be counted. Correcting for the different amounts of fissile material in the foil and in the target, the fission rate (or the number of fissions) in the target can be calculated. The absolute fission yield is then given as

$$Y_X = \frac{A_X}{R_f f_X F_T} \quad (4.30)$$

where A_X is the absolute activity (number of disintegrations per second of X in the chemically separated sample), R_f is the fission rate (number of fission events per second) in the target, f_X is the yield of chemical separation of X (expressed as fraction), and F_T is the fraction of saturation activity of X in the chemically separated sample.

The latter can be expressed as

$$F_T = (1 - e^{-\lambda t_b}) e^{-\lambda t_a} \quad (4.31)$$

where λ is the decay constant of X, t_b is the irradiation time and t_a is the time between end of irradiation and start of measurement.

The yield of the chemical isolation (f) of a particular element can be determined, e.g., by adding a known amount of this element before the chemical separation and determining the amount present in the sample after the chemical separation.

Once the absolute fission yield of a nuclide has been determined accurately in a particular fission reaction, this nuclide could serve as a monitor if it is isolated and counted simultaneously with the nuclide of interest.

Mass spectroscopy. In addition to radiochemical separations, in which the different isotopes of one element were isolated, mass separations can be carried out (De Laeter 1988). A sample is introduced into the ion source of a mass separator; it is heated, vaporized, ionized, accelerated, separated, intercepted on a catcher foil, and counted. In some cases, the separated ions can be counted directly when the accelerated ions impinge on a detector. In mass separation one has the problem that the separation yield is not known, but one knows that this yield is identical for all isotopes of one element (as long as the precursors have decayed completely). Therefore, if one knows the fission yield of one nuclide, one can determine the fission yields of the other isotopes of this element. It is often possible to determine the same chain yield by identifying more than one isotope. These cases may be used to interrelate the separation yields of different elements. Finally, when sufficient yields are known, one

has the possibility to check whether the sum of all chain yields equals 200% (as it should be in the case of a “binary” fission).

Measurements based on momentum conservation. Purely physical methods to determine mass yields are based on the laws of the conservation of energy and momentum. They became possible when the technique of the measurement of the kinetic energy (or the velocity) of the fission fragments became precise enough. The most convenient detectors for this purpose are surface barrier detectors, but proportional counters can also be used. In principle, the masses m_1 and m_2 and the velocities u_1 and u_2 of two fission fragments, produced by a fissioning nucleus at rest, obey the following equation:

$$m_1 u_1 = m_2 u_2. \quad (4.32)$$

In addition, one has the relation

$$u = \sqrt{\frac{2E}{m}}, \quad (4.33)$$

where E is the kinetic energy of either of the fission fragments. As a consequence, one can also write

$$m_1 E_1 = m_2 E_2. \quad (4.34)$$

One can set $m_1 + m_2 = m_f$, the mass of the compound nucleus, which is known. By measuring the kinetic energy of both fragments, one can calculate the mass of each fragment according to

$$m_1 = m_f \frac{E_2}{E_1 + E_2}. \quad (4.35)$$

A great number of such measurements have been performed. A few typical examples are given in the following publications (Schmitt et al. 1966; Pleasonton 1968; Derengowski and Melkonian 1970; Unik et al. 1973; Asghar et al. 1981; Thierens et al. 1981; Thierens et al. 1984; Barreau et al. 1985; Wagemans et al. 1996).

Alternatively, the velocity (u) of the fission fragments can be measured. This is normally done by determining the time of flight across a known distance. Such measurements have been performed quite early for the spontaneous fission of ^{252}Cf (Whetstone 1963). The formula used for mass determination is now

$$m_1 = m_f \frac{u_2}{u_1 + u_2}. \quad (4.36)$$

Finally, the simultaneous measurement of the energy and the velocity of the same fragment also make it possible to calculate its mass as has been shown by Schmitt et al. (1965), Derengowski and Melkonian (1970), and Schillebeeckx et al. (1994). The calculation is based on [Eq. \(4.33\)](#).

The problem with the above methods is that [Eqs. \(4.35\)](#) and [\(4.36\)](#) are only valid for fission *fragments* (prior to prompt neutron emission). As shown above, the formation of fission fragments is followed within about 10^{-14} s by the emission of up to about three prompt neutrons. This neutron emission affects the measured quantities (E or u) to a different extent.

The *velocity* of the fission fragments is changed due to the recoil of the neutrons, which are emitted with an energy of about 1 MeV. This effect is small (about 0.01 MeV) and since the emission of neutrons is isotropic from the fragments in flight, it does not change the mean velocity but widens the distribution and leads to a loss in mass resolution.

The energy of the fragments in flight is changed by two factors: (1) by the change of velocity as discussed above and (2) by the loss of mass due to neutron emission of the fragment in flight. This loss of mass decreases the kinetic energy according to the relation $E = mv^2/2$. As can be estimated easily, the second effect amounts to about 1 MeV per neutron emitted.

As a consequence, mass yields based on a double velocity measurement are in principle more accurate than those based on energy measurements. However, in practice, a velocity measurement (based on the flight time of a fragment through a defined distance) is generally less accurate than an energy measurement.

Examples of sophisticated instruments are “Cosí fan tutte” at the Institute Laue-Langevin (ILL) (Grenoble) (Oed et al. 1984) and a similar one attached to the reactor of the Moscow Engineering and Physics Institute (Alexandrov et al. 1991).

The physical measurements of mass yields based on momentum conservation (double energy, double velocity or energy, and velocity determination) – as opposed to the radiochemical measurements discussed further above – have the advantage of producing a more or less complete mass–yield curve in one experiment using up only small amounts of the possibly exotic fissile material (in one thin target). The mass resolution in the yield curves obtained is, however, not quite as good as that of the radiochemical methods, so that fine details of the mass–yield curve cannot be observed.

In addition, the physical measurements (after some corrections for prompt neutron emission) allow one to obtain fragment mass distributions (prior to prompt neutron emission). A comparison of these fission fragment yield curves with fission product yield curves makes it possible to extract information on prompt neutron emission. This will be discussed in the next subsection.

A very interesting instrument based on the measurement of the energy and the velocity of one fission fragment is Hiawatha (Diiorio and Wehring 1977). In this instrument, the measurement of the kinetic energy of the fission fragments is done by an electrostatic analyzer with an energy resolution of 0.3% unaffected by prompt neutron emission. As a consequence, the mass resolution, in contrast to the instrumentation discussed above, is sufficiently good to measure product yields without disturbance by neighboring masses.

Mass separation of unslowed fission products (Lohengrin). The most successful instrument for the study of fission yields, as will be shown below, is the mass separator Lohengrin (Moll et al. 1975, 1977) (ILL, Grenoble). In contrast to the instruments discussed above (including Hiawatha), which provide mass identification event by event, it provides a true spatial separation of fragments of different masses. Lohengrin achieves the mass separation of fission products by using magnetic and electric sector fields. As a consequence, fission products of one mass can be collected with Lohengrin and may be studied online or off-line, e.g., by γ -ray spectroscopy.

Thin targets of nuclei that are fissile by thermal neutrons are irradiated at the European High Flux Reactor at Institute Laue-Langevin, Grenoble, France. The fission fragments escaping from the target possess almost the whole kinetic energy (60–110 MeV) that they obtained in the fission process. A narrow beam of fission products enters the magnetic and electric sector fields. The separation takes place according to the ratio (A/q) of mass number to ionic charge state and to E/q the ratio of kinetic energy to ionic charge state of the fragments. The ionic charge states range from about $15e$ to $30e$ as a result of the dynamical equilibrium established when fission fragments with their full kinetic energy move through the thin targets. The resolution of the separator is sufficiently good to separate generally single mass numbers in spite of the multiplicity of the q values.

Lohengrin is, in principle, not able to separate identical A/q -ratios (e.g., $100/25 = 96/24 = 92/23 = 4.0$) thus delivering multiplets. Such a multiplet can be resolved using a surface barrier

detector or ionization chamber attached to the collector side and measuring the kinetic energies of the fragments because the members of the multiplet possess the same velocity and different masses and, hence, different kinetic energies.

One problem with Lohengrin is a less efficient use of beam time compared with the measurements based on momentum conservation: whereas in the latter case the information on the total mass and energy distribution is obtained in one shot, Lohengrin requires a measurement for each mass and kinetic energy setting. In addition, measurements of several ionic charge states have to be performed in order to exclude an influence of this parameter on the results.

The advantage of Lohengrin and the reason for its success in contributing more complete data sets on mass, charge, and energy distributions than any other method is its good resolution due to the fact that it is not influenced by prompt neutron emission. Another great advantage of Lohengrin is the almost complete absence of background, which allows the measurement of very low yields (under certain conditions down to about $10^{-7}\%$).

All the physical measurements discussed above have the general advantage to give some information on the kinetic energy of the fission fragments (and, hence, on the deformation of the scission configuration).

4.4.2.2 Experimental Results and Interpretation

Fission products (post-neutron emission). Chain yields as a function of the mass number of the fission product are given in ▶ Fig. 4.10 for different fission reactions. There are several remarkable points in ▶ Fig. 4.10. They will be discussed in the following.

■ Fig. 4.10

Mass-yield distributions for thermal-neutron-induced fission of the following nuclides: ^{235}U , ^{239}Pu , ^{241}Pu , ^{242}Am , ^{245}Cm , and ^{249}Cf . The labels in the figure refer to the respective compound nuclei; after (Tsekhanovich et al. 2001)

First, the curves show two maxima, thus providing the experimental proof of asymmetric fission that has already been referred to. The observation of the mass asymmetry in fission was surprising because the liquid drop model predicts that the formation of two fragments with about equal size would be preferred on energetic grounds. The asymmetry of fission really remained a puzzle from the time of its discovery in 1939 (Jentschke and Prankl 1939a, b) until 1976 (i.e., for 37 years) when the problem was understood in the sense that qualitatively correct predictions could be made (Wilkins et al. 1976). The suspicion that asymmetric fission had to do with nuclear shells was however put forward already in 1948 by M. Goeppert-Mayer together with the formulation of the shell model itself (Goeppert-Mayer 1948) and in 1950 by Lise Meitner (Meitner 1950). These authors argued that fission would occur in such a way that one fragment has at least 82 neutrons and the other one at least 50 neutrons. It turned out subsequently that it is the proton shells (at $Z = 50$ and $Z = 28$) that play the decisive role. This point will be discussed later.

The dip between the two peaks is most pronounced for the fission of ^{235}U and decreases with increasing mass or rather with increasing fissility parameter (Z^2/A) of the fissioning nucleus. This is in agreement with the expectation that shell effects will become less important with increasing excitation energy of the nucleus at the scission point.

The yield curves are shifted along the mass axis according to the mass of the compound nucleus. However, there are two regions where all the curves coincide: one region is around mass number 132 and the other one around mass number 80.

The results shown in Fig. 4.10 and a number of additional experimental findings to be discussed further below can be interpreted in terms of a picture (see Fig. 4.11), which illustrates – with some simplifications – the theoretical findings discussed above.

The configuration of the fissioning nucleus just before scission is understood as a dumbbell-like configuration with a larger sphere and a smaller sphere connected by a neck. The following assumption will explain the experimental yield curves: In the vast majority of the cases, the configuration will break (undergo scission) at the neck and to a first approximation the neck diameter at a specific location will determine the probability of scission at this location.

Fig. 4.11
Dumbbell configuration of a fissioning nucleus ($^{236}\text{U}^*$) just before scission. The numbers refer to the number of nucleons (A), protons (Z), and neutrons (N) contained by the large sphere, the neck, and the small sphere, respectively. (The numbers in parenthesis for the small sphere represent a subunit, the experimental evidence of which will be discussed later)

Assuming the numbers of nucleons as shown in ▶ Fig. 4.11 for the two spheres and the neck, one would predict a mass–yield curve, which starts essentially with a low yield at mass 80 (scission point between the small sphere and the neck), hence producing fragments with mass 80 and (e.g., for ^{236}U) the corresponding complementary fragment with mass 156. When the scission point moves away from the small sphere toward the large one, fragments heavier than $A = 80$ and lighter than $A = 156$ will be formed in increasing yields reaching a plateau in the mass range around 144/92 ($132 + 12$ and $80 + 12$). Further on, when the breaking point approaches the sphere with $A = 132$ (and the complementary mass 104 (for ^{236}U)), the yield curve will show a steep decrease. This is exactly what is shown in ▶ Fig. 4.10.

As appears from ▶ Fig. 4.10, the area of steep descent around mass 132 and mass 80 is found not only for the fission of $^{236}\text{U}^*$ but also for the other compound nuclei shown: $^{240}\text{Pu}^*$, $^{242}\text{Pu}^*$, $^{243}\text{Am}^*$, $^{246}\text{Cm}^*$, and $^{250}\text{Cf}^*$. This can be interpreted as follows. The two spheres in the dumbbell configuration do not change with the mass of the compound nucleus but rather the change in mass of the compound nucleus only affects the size of the neck connecting the two spheres. Surprisingly enough, the steep areas mentioned coincide not only on the mass axis but also on the yield axis, i.e., the different compound nuclei show nearly identical yields around $A = 132$ and 80. This inference may indicate that the two onsets of the neck (toward heavy and light spheres, respectively) are also more or less independent of the mass of the compound nucleus. A comparison of the very light nucleus ^{227}Th with the very heavy nucleus ^{249}Cf (▶ Fig. 4.12) confirms the stability of the mass range around $A = 132$ in an even more spectacular way: The mass–yield curves agree around $A = 132$ (and – not shown in the figure – basically around $A = 80$ as well). The rest of the curve is shifted according to the mass of the compound nucleus.

The middle of the valley (▶ Figs. 4.10 and ▶ 4.12) represents symmetric fission. It has a different (symmetric) shape at scission that is connected with a path over the symmetric barrier indicated in ▶ Fig. 4.9. Since this path crosses a region with higher potential energy, the fraction of symmetric fission depends on the excitation energy available for the nucleus at scission. It appears from ▶ Fig. 4.10 that the depth of the valley decreases with increasing mass (or more precisely increasing fissility parameter, Z^2/A) of the compound nucleus. This is due to the decreasing fission barrier and increasing exoenergetic character of fission with increasing fissility.

▶ Figure 4.13 shows yield curves for various nuclei undergoing spontaneous fission. In the case of spontaneous fission, the barrier is crossed by tunneling. As a consequence, the excitation energy at scission is very small. The figure shows that the yield of symmetric fission is extremely low (below the limit of detection), as one would expect.

On the other hand, when more excitation energy is put into the system the peak-to-valley ratio decreases. This can be observed for fission reactions induced by reactor neutrons having about 2 MeV of energy (▶ Fig. 4.14) and by 14 MeV neutrons (▶ Fig. 4.15).

The importance of the shell closures at $Z = 50$ and, to a lesser extent, $N \approx 82$ is demonstrated again in the mass–yield curves of very heavy spontaneously fissioning nuclides. ▶ Figure 4.16 shows the fission yield curves for different isotopes of the elements Cf ($Z = 98$) to Rf ($Z = 104$). Starting with element Fm ($Z = 100$, which allows the formation of two fragments with $Z = 50$), one can observe the occurrence of symmetric fission, whenever the neutron number permits it. The minimum neutron number is 158 (i.e., 2×79) for $Z = 100$ and 154 (2×77) for $Z = 104$. More evidence for the fact that the effect of closed neutron shells can be observed already in the direct neighborhood of the magic number will be presented further on. This fact has certainly to do with the other fact that forming fragments is not the same as

■ Fig. 4.12

Mass–yield curves for the thermal-neutron-induced fission of ^{227}Th and ^{249}Cf ; from (von Gunten 1969)

forming isolated nuclei. It shows the limitations of the simple picture shown in ▶ Fig. 4.11 and the requirement of a more fundamental treatment as presented by (Brosa et al. 1990) and others and as mentioned above.

Fission fragments (pre-neutron emission). The yield curves discussed above refer to fission product yields after emission of prompt neutrons. As discussed above, the physical methods based on momentum conservation at scission (double energy, double velocity, or energy and velocity measurements) allow the measurement of the yield distribution of fission fragments (prior to prompt neutron emission). In these cases, simultaneous information is obtained on the kinetic energy of the fragments detected.

▶ Figure 4.17 shows the mass–yield curves determined for the fission fragments as well as for the fission products of ^{235}U for comparison (Schmitt et al. 1966). The two curves are slightly shifted relative to each other along the mass axis due to the emission of neutrons. Accordingly, the number of neutrons emitted can be obtained from a comparison.

Prompt neutron yields and kinetic energy distribution. The evaluation of prompt neutron emission from fission fragment and product yields is based on a method proposed by Terrell (1962). The yields of the single (light) fragments (and products) are plotted cumulatively starting with the lightest mass. This way symmetry is reached at a cumulative yield of 100% (▶ Fig. 4.18). For the heavy fragments (products), one starts from the heaviest fragment and proceeds toward symmetrical fission.

■ Fig. 4.13

Mass–yield curves for the spontaneous fission of ^{238}U , ^{240}Pu , ^{242}Cm , and ^{252}Cf ; from (von Gunten 1969)

For the fission products, two S-shaped lines are obtained that are separated on the mass axis by the total number of neutrons emitted. For the fission fragments, the two lines naturally coincide. As a consequence, the number of prompt neutrons emitted from light and heavy fragments, respectively (ν_L and ν_H), can be read from the figure, as a function of the mass combination. It is observed that the emission of neutrons varies along the curve. At the location $A = 84/152$ most of the neutrons emitted stem from the heavy fragment whereas at the mass combination with $A = 104/132$ most of the neutrons emitted stem from the light fragment.

➤ Figure 4.19 shows the number of prompt neutrons emitted for various fissioning systems. Within the error margins, these curves follow the same pattern. They show a “sawtooth” shape presenting a minimum around masses 82 and 130 and a linear increase with increasing mass beyond 82 and 132, respectively.

The interpretation is as follows. Prompt neutron emission is due to the excitation energy of the fragments. The excitation arises when fragments deformed at scission relax into their stable nearly spherical configuration. Taking the scission configuration in ➤ Fig. 4.11 seriously, breaking the neck near the heavy sphere ($A = 132$), for instance, would mean that the fragment with $A = 132$ would be practically spherical, but the complementary fragment with $A = 236 - 132 = 104$ (for $^{236}\text{U}^*$) would be composed of a spherical part ($A = 80$) and the entire neck, hence, it would be very deformed. As a consequence, the fragment with $A = 132$ would emit practically no neutrons and all the neutrons would come from the complementary

■ Fig. 4.14

Mass–yield curves in the reactor-neutron-induced fission of ^{227}Ac , ^{232}Th , ^{231}Pa , ^{235}U , ^{238}U , and ^{241}Am ; from (von Gunten 1969)

fragment. As the breaking point is shifted along the neck toward the small sphere, neutron emission from the heavy fragment would gradually increase until a maximum is reached at $A = 156$ ($= 236 - 80$). Correspondingly, the neutron emission from the light fragment will show a minimum around $A = 80$ and will increase with increasing mass. The sawtooth-like curve observed in [Fig. 4.19](#) is in exact agreement with these expectations.

The fact that the lines have the same slope for various fissioning nuclei (from ^{233}U to ^{252}Cf) shows that not only the two spherical parts of the dumb-bell configuration are unchanged but also the neck diameter remains the same. Certainly, the neck for the heavier system (^{252}Cf) will be slightly longer and neutron emission will reach further into the mass region near $A = 120$ and 160 (see [Fig. 4.19](#)).

On these grounds, one would expect that the total number of prompt neutrons emitted will increase with the mass of the compound nucleus. This is found indeed as is documented in [Fig. 4.20](#).

There is, however, an interesting exception in the figure, namely ^{260}Md , which shows a neutron yield of about 2 rather than an extrapolated value of 4. The nucleus of ^{260}Md is the only nucleus among those shown in [Fig. 4.20](#) with a symmetric yield distribution as seen in [Fig. 4.16](#). (The fermium isotopes with $A = 254$, 256 , and 257 ($N = 154$, 156 , and 157) shown also in [Fig. 4.20](#) have an asymmetric mass distribution (see [Fig. 4.16](#))). Unfortunately, no values of prompt neutron emission are known for the other isotopes with $Z \geq 100$ that show a symmetric mass distribution ([Fig. 4.16](#)).

■ Fig. 4.15

Mass–yield curves in the 14 MeV-neutron-induced fission of, ^{232}Th , ^{235}U , ^{238}U , and ^{237}Np ; from (von Gunten 1969)

Apparently, the sharp transition from asymmetric fission to symmetric fission (► Fig. 4.16) is accompanied by a sudden change in the scission configuration. When Z and N of the fissioning nucleus allow a scission configuration with two spheres with $Z = 50$ and N sufficiently close to 82, a configuration with two such spheres and nearly no neck is realized. As a consequence, the arising symmetrical fragments show only a small amount of deformation, which may turn into excitation energy and later into neutron emission.

Such a compact configuration with two magic nearly spherical structures at short distance will necessarily lead to a high kinetic energy of the fragments (super-short fission path of Brosa). In fact, the kinetic energy of the fragments has been measured using the methods based on momentum conservation (double energy, double velocity, or energy/velocity techniques discussed above). The results are shown in ► Fig. 4.21.

In ► Fig. 4.21, one can observe the expected steady increase in kinetic energy of the fission products with increasing mass/atomic number of the compound system (or more precisely with the increase in the parameter $Z^2/A^{1/3}$ describing the Coulomb repulsive energy between the two fragments formed). However, one can see that a number of nuclei with $Z \geq 100$ ($^{258,259}\text{Fm}$, $^{259,260}\text{Md}$, and $^{258,262}\text{No}$) show a higher kinetic energy. These are the nuclei that are undergoing symmetric fission as demonstrated in ► Fig. 4.16. For most of these nuclei (^{258}Fm , $^{259,260}\text{Md}$, and $^{258,262}\text{No}$) the kinetic energy distribution can be resolved into two components, a component with low (i.e., normal) kinetic energy (labeled “l” in ► Fig. 4.21) and another

■ Fig. 4.16

Schematic representation of the known mass–yield curves for the spontaneously fissioning isotopes of the elements with $Z = 98$ to $Z = 104$ (Hoffman and Lane 1995)

component with high kinetic energy ("h"). Presumably, in these cases there is a coexistence of symmetric and asymmetric fission with the respective scission configurations.

In summary, for compound nuclei with $Z < 100$ one has a scission configuration as shown in ► Fig. 4.11 with two spheres stabilized by the shell closures at $Z = 50/N = 82$ (heavy sphere) and, as it will be shown later, $Z = 28/N \approx 50$ (light sphere). For compound nuclei with $Z \geq 100$ (and $N > 152$) one observes a transition to another scission configuration with two spheres of about $Z = 50$ and N close to 82. The neck between these spheres is small. Therefore,

■ Fig. 4.17

Pre-neutron emission mass distribution, $N(m^*)$, corrected for resolution and post-neutron emission mass distribution, $N(m)$, for the thermal-neutron-induced fission of ^{235}U ; from (Schmitt et al. 1966)

the configuration is compact. This brings about fragments with high kinetic energy and low excitation energy – hence a small number of prompt neutrons are emitted.

The assumption that the emission of prompt neutrons is due to an evaporation of neutrons from excited fragments whose excitation energy comes from the relaxation of potential energy of deformation implies that the neutrons are emitted from flying fragments accelerated by the repulsive Coulomb force between the two positively charged nuclei. As a consequence, the vector addition of the velocity of the fragments and the velocity of the neutrons (emitted isotropically from the flying fragments) should lead to a preferential emission of neutrons in the direction of the flying fragments. The angular distribution of the neutrons with respect to the axis of the fragments has been measured and is shown in ▶ Fig. 4.22.

The neutrons are clearly peaked at 0° with respect to the light fragment and at 180° , i.e., along the flight path of the heavy fragment. The peaking in the direction of the heavy fragment is less pronounced because, due to momentum conservation, the velocity of the heavy fragment is smaller than the one of the light fragment.

In addition to the emission of *prompt* neutrons discussed here, there is also an emission of *delayed* neutrons. The delayed neutrons arise from some fission fragments when they undergo β decay. Normally, β decay can lead not only to the ground state of the daughter nucleus but also to some excited states. Such excited states, normally, go over to the ground state by the emission of γ rays. In some fission products, the excited level fed by the β decay of its precursor is higher than the binding energy of the last neutron. In such a case, the nucleus can emit a neutron rather than γ rays.

The longest-lived example of such a delayed neutron emitter (or delayed neutron precursor) is the nuclide ^{86}Br . It undergoes β decay with a half-life of 55 s. The daughter nucleus is the

■ Fig. 4.18

Cumulative plot of the mass yields for thermal-neutron-induced fission of ^{235}U obtained by summing the yields from very asymmetric fission to symmetric fission for fission products (+) and fission fragments (●). The numbers of prompt neutrons emitted (ν_L and ν_H) for light and heavy fragments, respectively, can be obtained from the horizontal distances between the curves using slight corrections for curvature; from (Terrell 1962)

stable ^{86}Kr . The majority of the decays (70%) lead to an excited state in ^{86}Kr , which emits a neutron turning into ^{85}Kr . The neutrons from this process appear with a half-life of 55 s. Among the fission products there are more than 250 such delayed neutron precursors (frequently abbreviated dnp) with half-lives ranging typically between 25 s and 0.2 s. A total number of 17 nuclides out of the above 250 – mainly neutron-rich isotopes of As, Br, Rb, and I – contribute more than 85% of the delayed neutron yield. A list of the delayed neutron precursors and of their properties can be found in (Wahl 1988; England and Rider 1994). The fraction of delayed neutrons among the total amount of neutrons set free is small (e.g., 0.65% and 0.21% for thermal-neutron-induced fission of ^{235}U and ^{239}Pu , respectively). Delayed

Average or most probable total kinetic energy of fission products versus ($Z^2/A^{1/3}$), a parameter describing the Coulomb repulsive energy between the two arising fragments. The dashed line is the linear fit of Viola et al. (1985) and the dotted line is the linear fit of Unik et al. (1973); from (Hoffman and Lane 1995)

neutrons are very important for the control of nuclear reactors. Their role is to be discussed in another chapter in this handbook (see [▶ Chap. 57](#) of Vol. 6).

Chain yields in very asymmetric mass distribution. Recently, using the mass separator Lohengrin briefly presented above, it has become possible to measure yields of the light fission fragments down to very low values. Four fission reactions studied are shown in ► Fig. 4.23.

The remarkable observation is a small peak or at least a hump at mass 70. Beyond this hump, the yields are dropping practically to zero. Anticipating some information to be discussed later, it may be said here that the elemental composition is such that the yield of mass 70 consists almost exclusively of nickel with the magic number of 28 protons.

It is concluded therefore that the hump at mass 70 is an effect of the closed shell of 28 protons. At mass 80 in [Fig. 4.23](#), one may vaguely discern another deviation from the general trend. This deviation can be seen more clearly in [Fig. 4.24](#). This figure includes data of additional fission reactions that could be measured down to mass numbers below 80 but not yet down to mass number 70.

A line has been fitted through the data points for masses $A \geq 80$. This is reasonable since the slopes of a Gaussian distribution in a logarithmic display and sufficiently far from the maximum can be approximated very well by a linear relationship. The figure shows that all the curves are broken at mass 80. The yields decrease more rapidly than extrapolated. The effect appears more pronounced if the strongly compressed logarithmic scale is taken into account. The region around $A = 80$ is the region where the mass-yield curves of nearly all low energy

■ Fig. 4.22

Number of prompt neutrons emitted versus the angle with respect to the light fragment direction in spontaneous fission of ^{252}Cf ; from (Bowman et al. 1962), referred to in (Vandenbosch and Huizenga 1973)

fission reactions agree (see Fig. 4.10) and where the neck and the small sphere touch. The tendency to preserve intact the small sphere with $A = 80$ ($Z = 32$ and $N = 48$, near $N = 50$) seems to be at the origin of the more rapid decrease of the yield at masses $A < 80$.

The fact that not $N = 50$ (the magic number for isolated nuclei) but $N = 48$ is the critical number has to do with the fact that the forming fragment is not an isolated nucleus but is part of a scissioning system. In this context, it is worth remembering that in the transition from asymmetric fission to symmetric fission the limiting neutron number is 158 for Fm ($Z = 100$) and 154 for Rf ($Z = 104$) (Fig. 4.16), i.e., a few neutrons less than 164, which would represent twice the magic number of 82.

In contrast to this observation, the shell closures for protons ($Z = 28$, and $Z = 50$) are practically not influenced by the rest of the scissioning nucleus: The transition from asymmetric fission to symmetric fission takes place exactly at Fm $Z = 100$ (2×50) (Fig. 4.16) and the hump at mass 70 (Fig. 4.23) also occurs exactly at $Z = 28$. In this context, it is worth mentioning that – in the framework of astrophysical studies of the r-process (see Chap. 12 in Vol. 2) – it has been revealed that the energetic effect of closed neutron shells is quenched in extremely neutron-rich nuclei (Pfeiffer et al. 2001).

In summary, the light sphere of the dumbbell-like scission configuration possesses an onion-like structure with two shells that are progressively difficult to break into: the total mass

■ Fig. 4.23

Absolute mass yields in the reactions $^{235}\text{U}(n_{\text{th}},f)$ (Sida et al. 1989), $^{239}\text{Pu}(n_{\text{th}},f)$ (Ditz 1991), $^{242\text{m}}\text{Am}(n_{\text{th}},f)$ (Tsekhanovich et al. 1999), and $^{249}\text{Cf}(n_{\text{th}},f)$ (Hentzschel et al. 1994). For clarity of display, the curves have been displaced on the yield axis by dividing the yields labeled Pu-239 by 10, Am-242m by 100, and Cf-249 by 1,000)

of 80 consisting of 32 protons and 48 (nearly 50) neutrons. Inside this structure, a sub-unit of 28 protons and 42 neutrons is found.

For the nuclear physicist it is interesting to learn from this behavior that nuclear shells document themselves not only as structural elements of nuclei but also as structural elements of subsystems of nuclei.

4.4.3 Nuclear Charge Distribution

So far, essentially mass–yield curves were dealt with. Each point of such a curve represents the formation cross section of isobaric nuclei of mass number A , composed of different combinations of protons and neutrons. Because heavy, fissile nuclei are generally more neutron rich than stable nuclides with about half their mass, fission products are generally also more neutron rich than stable nuclides of the same mass, even after the loss of a few prompt neutrons. (Example: The symmetric fission of the compound nucleus ^{236}U ($Z = 92$, $N = 144$) would form two *fragment* nuclei of ^{118}Pd ($Z = 46$, $N = 72$). Assuming the emission of one prompt neutron, the corresponding primary fission product would be ^{117}Pd . The stable isobar in mass chain with $A = 117$ is, however, ^{117}Sn ($Z = 50$, $N = 67$). As a consequence, the nucleus ^{117}Pd would have to undergo a sequence of four β decays to reach stability.) Thus, the products

■ Fig. 4.24

Mass yields of various thermal-neutron-induced fission reactions characterized by their compound nuclei ($^{236}\text{U}^*$ (Sida et al. 1989), $^{240}\text{Pu}^*$ (Ditz 1991), $^{242}\text{Pu}^*$ (Friedrichs et al. 1998, Friedrichs 1998), $^{239}\text{Np}^*$ (Tsekhanovich et al. 2001), $^{243}\text{Am}^*$ (Tsekhanovich et al. 1999), $^{246}\text{Cm}^*$ (Friedrichs et al. 1998, Friedrichs 1998), and $^{250}\text{Cf}^*$ (Hentzschel et al. 1994)). For clarity of display the single yield curves have been shifted by a factor of 10 among each other. The (logarithmic) yield values at $A \geq 80$ have been fitted to a linear relationship

of the fission process are generally radioactive and decay (by β decay) into some less neutron-rich daughter products until stability is reached. The yields of the primary fission products show a distribution along these β -decay chains. Primary fission yields generally comprise nuclides one to six charge units away from stability with correspondingly different half-lives ranging from less than 1 s to days or, in a few cases, even years. As a consequence, these chain members are generally produced directly in fission and via the β decay of precursors.

The question whether, e.g., the primary products in chain with $A = 70$ are mainly nickel ($Z = 28$, $N = 42$) or cobalt ($Z = 27$, $N = 43$) is decisive for the question whether the closed shell with $Z = 28$ plays a role. The lengths of the β -decay chains are important for the safety of reactors, as β decay produces heat even after the shutdown of a reactor and this heat has to be carried off even in case of an accident. An emergency cooling system has to be designed accordingly. Prompt neutron emission competes with β decay. The number of prompt neutrons emitted determines the possibility for a chain reaction.

Due to these reasons, attempts were made very early to determine the distribution of “primary” or “independent” yields of single nuclides within the isobaric mass chains. The different approaches will be described in the following.

4.4.3.1 Methods of Measurement of Independent Yields

Radiochemical techniques. The first attempts were based on radiochemical techniques. From the preceding discussion, it is clear that, for the measurements of independent yields, time is an important factor. Therefore, the determination of the primary (or “independent”) yield of a nuclide, which is being formed directly and by the decay of precursors, requires a chemical separation from these precursors before they could decay into it in a disturbing amount. Therefore, the determinations of independent yields require short irradiation times and fast chemical separations. In the early years, there were hardly any such procedures available. The first independent yields were obtained for a few exceptional cases where a neutron-rich stable or long-lived nuclide was interrupting the decay chain, producing a “shielded nuclide.” (Example: ^{136}Cs shielded by the stable ^{136}Xe .) Wherever independent yields could be measured, they concerned generally the part of the decay chains near stability, where half-lives were longer than in the very neutron-rich part of the decay chains.

Later, many fast radiochemical separations and ingenious automatic chemical separation methods were developed (Herrmann and Denschlag 1969, 1982; Rengan and Meyer 1993) and were applied to the determination of independent fission yields (Denschlag 1986, 1997). Summarily, one can say that the methods developed allow isolating any element formed from the complex mixture of fission products within the time span of a few seconds (exception: rare earth elements that require a time span of minutes).

γ -ray spectroscopy of unseparated mixtures. The development of γ -ray detectors with high resolution (Ge detectors) led to attempts to use the selectivity of γ rays to identify single isotopes in an unseparated mixture of fission products and to measure their independent yields. Unfortunately, γ -ray spectra of short-lived fission product mixtures are so complicated that they are very difficult to analyze. As a consequence, the results are of limited accuracy and have been restricted mostly to measuring chain yields and a few independent yields of nuclides with favorable γ -decay properties. Moreover, the absolute line intensities required to convert count rates into yields that are often not known accurately. This problem can be partly overcome by the analysis of growth and decay curves of parent/daughter systems. The method has been applied to the thermal-neutron-induced fission of a number of fissile nuclides like ^{229}Th (Dickens and McConnell 1983), ^{239}Pu (Dickens and McConnell 1980, Dickens et al. 1981), ^{241}Pu (Dickens 1979), ^{245}Cm (Dickens and McConnell 1981a), and ^{249}Cf (Dickens and McConnell 1981b).

Conventional fast mass separation with γ -ray spectroscopy. The combination of online mass separation (of fission products stopped in the target, volatilized, ionized, and separated) with γ -ray spectroscopy would be an ideal tool to determine both independent and cumulative yields, because mass separation of nuclides diffusing out of a target under irradiation can be performed within seconds. The selection of a single mass chain would simplify the γ -ray spectra dramatically, so that even short-lived nuclides could be measured. Unfortunately, problems arise with the volatilization from the targets and ionization in the ion source that show different yield and time characteristics for different elements (“chemical selectivity”). Therefore, yields obtained with this technique have frequently been considered unreliable.

Later, high-temperature ion sources were developed (Münzel et al. 1981; Jacobsson et al. 1987) ($T = 2500^\circ\text{C}$), which show a faster release of fission products and less chemical selectivity. Also careful studies of the release and ionization mechanisms (Rudstam 1987; Kirchner 1992) of the elements involved indicate that the previous problems may be overcome.

The technique has been used by Rudstam and coworkers to measure systematically a large part of the independent yield distribution in the fission of ^{235}U , including many isomeric pairs and the region of symmetry (Rudstam et al. 1990), and in the fission of ^{233}U (Galy et al. 2000).

Information on both the distribution of independent yields among different isomeric states and the charge distribution in the region of symmetry is still scarce, as these values are practically inaccessible to most other techniques.

Z-identification by specific energy loss. A more recently developed technique has been adapted from heavy ion research, which consists in identifying the atomic number Z of unslowed fission fragments, i.e., fission fragments with kinetic energies of 60–100 MeV. This Z -identification is based on the fact that the stopping power of matter for fast heavy ions depends (among others) on their atomic number Z , since a higher Z of the ion causes stronger interaction with the electronic shells of the atoms of the stopping material.

The method can be employed in principle in combination with any of the instruments that have been discussed above in the context of the measurement of mass yields provided that they use mass separation or mass identification of unslowed fission fragments; i.e., with instruments like Lohengrin, Hiawatha, and the equipment using momentum conservation to identify fragment masses (energy and/or velocity correlation experiments). Unfortunately, only Lohengrin and Hiawatha possess sufficiently good mass resolutions to produce unbiased yields. In addition, the Z -resolution of the method at the typical kinetic energies of fission fragments is only good enough to distinguish single isotopes up to $Z = 47$, i.e., for the light mass peak. This is, however, not a real problem. As the Z -distributions of light and heavy mass peaks are complementary around Z_f the atomic number of the compound nucleus, a measurement of the light mass peak gives the information on the heavy mass peak as well.

The fact that the technique operates with unslowed fission fragments allows the study of the yield distribution as a function of the kinetic energy of the fragments, i.e., as a function of different degrees of deformation of the fissioning system at scission. Another important advantage is the rapidity of the method. The separation or identification of fragment mass, atomic number, and kinetic energy takes only a time in the order of microseconds. This time is short relative to the time of β decay (>100 ms). Therefore, an undisturbed primary distribution is obtained automatically.

In practice, Z -identification has been added to the mass-separator Lohengrin (Clerc et al. 1975; Bocquet et al. 1988), to Hiawatha (Strittmatter and Wehring 1978; Strittmatter and Wehring 1979) and to the mass identification system Cosí fan tutte (Oed et al. 1983; Boucheneb et al. 1989). It is possible to combine such measurements of Z -identification with a simple double-energy coincidence technique if the analysis is limited to high kinetic energy events not disturbed by prompt neutron emission (Butz-Jørgensen et al. 1987). Finally, at the expense of the mass information, Mariolopoulos et al. were able to measure the plain nuclear charge distribution by combining a measurement of specific energy loss dE/dx , rest-energy, and (for calibration purposes) X-rays (Mariolopoulos et al. 1981).

The actual techniques of Z -identification are based on measuring the specific energy loss (dE/dx) of the fast fragments when they pass through a thin layer of matter (solid or gaseous) in which the fission fragments deposit about half their kinetic energy. Different variants of this technique are given in review articles (e.g., in Denschlag 1997).

The Z -resolutions of these variants are fairly similar. Differences are due to the properties of the detectors and the resolution also depends on the nuclear charge and kinetic energy of the fragments. A typical example of a spectrum of different members of a nuclear decay chain is given in  Fig. 4.25.

■ Fig. 4.25

Pulse height spectrum of the residual energy (kinetic energy of the fragments minus energy loss in the absorber) of fission products after passing through an absorber. The experimental data are shown in histogram form. The smooth curve is the result of a computer fit to four Gaussian curves. The area under each Gaussian is proportional to the relative independent yield of the particular nuclide indicated; after (Quade et al. 1979)

As it appears from ► Fig. 4.25, the most important elements contributing to the total mass chain can be well separated. A fit with equidistant Gaussians provides the contributions. However, the figure demonstrates that contributions of fractional yields smaller than 5% are difficult to ascertain with this method and should be treated with caution.

4.4.3.2 Experimental Results and Systematic Description (Z_p -Model)

The number of independent fission yield values obtained so far is enormous. Because of their multitude and theoretical and practical importance, these values have been compiled in special data banks, e.g., (James et al. 1991; England and Rider 1994). The latter data bank, which is accessible on the Internet, includes 132,000 values from 60 fission reactions (fission of different nuclei induced by different particles of varying energy). The work of collecting, evaluating, and compiling fission yields is coordinated by the International Atomic Energy Agency, Vienna (IAEA 2000).

The best way to deal with the enormous body of data is using a systematic description, which has been developed by A.C. Wahl first for the fission of ^{233}U , ^{235}U , and ^{239}Pu induced by thermal neutrons and for the spontaneous fission of ^{252}Cf (Wahl 1988). This method has been extended to other fission reactions with varying excitation energies later (Wahl 1989; IAEA 2000). The model comes in two variants (Z_p - and A_p '-model). The following discussion will be limited to the Z_p -model.

In this model the fractional independent yields in an isobaric chain (mass chain) are described by a Gaussian curve with a maximum (most probable charge, Z_p) and a width

parameter (standard deviation, $\sigma(Z)$). Both parameters may be obtained by a fit of a Gaussian to the experimental fractional yield values. Z_p may be compared to Z_{UCD} , which represents the nuclear charge of a fission product calculated assuming unchanged charge density of this fragment with respect to the compound nucleus. Z_{UCD} is calculated according to

$$Z_{UCD} = (A + \nu) \frac{Z_f}{A_f} \quad (4.37)$$

with A = the mass number of the fission product, ν = the (average) number of prompt neutrons emitted in producing this fission product, and Z_f and A_f the nuclear charge and mass of the fissioning (compound) nucleus, respectively. The difference of the two values:

$$\Delta Z = Z_p - Z_{UCD} \quad (4.38)$$

represents a charge polarization between the two fragments formed.

At a direct inspection of experimental fractional independent yields and their fits by Gaussian curves one can observe that yield values with even proton and/or neutron numbers tend to lie above the curve and those with odd numbers tend to lie below it. This is taken into account by two factors EOZ and EON, the even–odd (or odd–even) factors for protons and neutrons, respectively. These values may be given in percentage. In this way, an EOZ-value of, e.g., 15% corresponds to a factor 1.15 by which a value read from the Gaussian curve has to be multiplied (even- Z nuclide) or divided (odd- Z nuclide) in order to obtain the predicted yield.

As a consequence, the Z_p model allows one to describe the nuclear charge distribution of a specific fission reaction by four parameters:

$$\Delta Z, \sigma(Z), \text{EOZ, and EON.}$$

In general, these parameters depend on the mass number of the isobaric chain considered. In the region of “normal asymmetric fission” (>99% of the fission yields), e.g., ΔZ can be given as a linear function of the mass of the heavier fragment:

$$\Delta Z(A_H) = \Delta Z(140) + s(A_H - 140). \quad (4.39)$$

Here A_H is the mass of the heavy primary fragment, s a parameter for the slope, and $\Delta Z(140)$, the ΔZ -value for mass $A_H = 140$, arbitrarily taken as a reference (Fig. 4.26). The value of s is generally small and comparable to its error margins.

In this mass region of “normal asymmetric fission,” the parameters $\sigma(Z)$, EOZ, and EON can be generally assumed to be constant and independent of the mass ratio of heavy and light fragments.

In the region of symmetric fission or in the neighborhood of shell closures, the four parameters behave differently and show some abrupt changes. The behavior of the four parameters mentioned, as a function of the fission fragment mass and also as a function of the mass, charge, and excitation energy of the fissioning nuclide, is the subject of the fission yield systematics mentioned (Wahl 1988, 1989; IAEA 2000). A version (YCALC) of the model calculations is attached to ref. IAEA 2000, and it is also available for downloading (YCALC 2003).

The program YCALC allows the calculation of the independent yields of any fission product for 12 different fission reactions (i.e., the spontaneous fission of ^{252}Cf , the thermal-neutron-induced fission of ^{229}Th , ^{233}U , ^{235}U , ^{238}Np , ^{239}Pu , ^{241}Pu , ^{242}Am , and ^{249}Cf , the reactor-neutron-induced fission of ^{232}Th , and ^{238}U , and the 14 MeV-neutron-induced fission of ^{238}U).

Numerical values of the parameters mentioned (for the yield range of “normal asymmetric fission”) are given in Table 4.2.

Fig. 4.26

Illustration of the systematic description of nuclear charge distribution. The outer frame shows a part of a chart of nuclides with a plot of the atomic number (Z) versus the neutron number (N). The location of stable nuclides is shown by the "Line of Stability." Products formed by the fission of a heavy neutron-rich nucleus (^{235}U) with an "Unchanged Charge Density" of both fragments would be located on or around the line labeled "UCD." The maximum of the experimental distribution of fractional yields (shown as protruding from the paper plane) (Z_p) is shifted by ΔZ to even more neutron-rich nuclei for heavy fission fragments and, correspondingly, toward less neutron-rich nuclei for light fission fragments. The amount of charge polarization at the arbitrarily chosen reference mass $A = 140$ is given by $\Delta Z^{140} = Z_p^{140} - Z_{\text{UCD}}^{140}$ for mass $A = 140$ or, generally, for $\Delta Z(A) = Z_p^A - Z_{\text{UCD}}^A = \Delta Z(140) + s(A - 140)$. The insert shows a cut through the three-dimensional yield distribution and allows to illustrate the significance of the parameters ΔZ , σ , EOZ, and EON. The open circles in the insert represent experimental yields (of isobaric nuclides) serving as a basis for the determination of Z_p and σ

Table 4.2

Numerical values for the parameters of the Z_p -model (asymmetric region) for the thermal-neutron-induced fission of ^{233}U , ^{235}U , ^{239}Pu , and the spontaneous fission of ^{252}Cf (from (Wahl 1988))

Fissile nucleus	σ	ΔZ^{140}	s	EOZ	EON
^{233}U	0.52	-0.47	-0.010	1.27	1.08
^{235}U	0.54	-0.50	-0.015	1.26	1.05
^{239}Pu	0.55	-0.48	-0.015	1.06	1.00
^{252}Cf	0.61	-0.47	-0.005	1.00	1.00
(Estimated uncertainty)	(± 0.02)	(± 0.02)	(± 0.005)	(± 0.03)	(± 0.03)

4.4.3.3 Physical Implications of the Nuclear Charge Distribution in Fission

The fact that ΔZ^{140} is different from zero shows that polarization occurs in the fissioning nucleus. As appears from the negative sign for ΔZ^{140} and as is also visible from [Fig. 4.26](#), heavy fission fragments are more neutron rich than would correspond to an unchanged charge density. Correspondingly, light fission fragments are less neutron rich. This is due to the Coulomb force between protons that favors neutron-rich structures for heavier nuclei.

The width of the distribution (characterized by standard deviation σ) is nearly constant between 0.5 and 0.6, which indicates that within a β -decay chain the direct formation from fission is concentrated to 3–4 nuclides (see insert in [Fig. 4.26](#) and the experimental yield distribution in chain 97 in [Fig. 4.25](#)). The width of this nuclear charge dispersion (σ) is a rough indication of the excitation energy of the nucleus at scission. Surprisingly, σ is not really larger in fission reactions induced by fast particles and, hence, with a larger initial excitation energy. The conclusion supported by other experimental observations is that in these cases particle emission takes place prior to fission, cooling down the compound nucleus.

The even–odd factors for protons (EOZ) and for neutrons (EON) are also indicators of the nuclear temperature before scission. [Table 4.2](#) shows that EOZ approaches one with increasing mass (or fissility Z^2/A) of the fissile nucleus. It is a general observation that even–odd effects tend to decrease or even disappear with increasing fissility parameter. This is probably due to the fact that fission reactions with higher fissility set free more energy leading to higher excitation energy of the nuclei at scission. The observation that the selection of fragments of high kinetic energy (which is possible, e.g., in Lohengrin) shows increased values of EOZ (Denschlag 1986; Gönnerwein 1991) is in agreement with this statement, as the selection of fragments with high kinetic energy leaves correspondingly less excitation energy in the system.

The even–odd effect for neutrons (EON) shows a similar decrease with increasing fissility ([Table 4.2](#)). The absolute values of EON are however smaller than for EOZ. This observation was initially attributed to the fact that neutrons are emitted from the fission fragments smearing out an initially stronger effect. It was however observed that EON was smaller than EOZ even for fragments of sufficiently high kinetic energy to exclude an emission of neutrons (Armbruster et al. 1981; Knitter et al. 1992). This discrepancy, which remained a puzzle until recently, will be discussed below.

In general, the odd–even effects were interpreted for a long time to indicate the survival of the pairing of protons and neutrons on the way of the nucleus from saddle point to scission (Bjornholm 1974; Nifenecker et al. 1980). The preservation of pairing would mean that nuclear matter would remain in a state of superfluidity on the way to scission. This explanation would imply no odd–even effect (i.e., $\text{EOZ} = 1.00$) for the fission of odd Z nuclei (like Np with $Z = 93$ or Am with $Z = 95$). The recent discovery that these odd fissile nuclei also show an odd–even effect (of a slightly different character and in very asymmetric fission) (Stumpf et al. 1992; Davi et al. 1998; Tsekhanovich et al. 1999; Tsekhanovich et al. 2001) demonstrates that preservation of pairing cannot be the only reason for the effect. (The odd–even effect for protons in even fissile nuclei as discussed above means that all fission fragments (light or heavy) with even numbers of protons are formed EOZ times the value expected without odd–even factor (for EOZ, see [Table 4.2](#)). For odd nuclei (which necessarily always form one even and one odd fission fragment), the odd–even effect means that **light** fission fragments with even numbers of protons are formed EOZ times the value expected without odd–even factor and that correspondingly **heavy** fission fragments with odd numbers of protons are formed EOZ times the

value expected without odd–even factor. The situation for neutrons is analogous; it is however complicated by the fact that, after fission, neutrons are emitted obscuring the initial situation.)

The discovery of an odd–even effect in the (again, very asymmetric) fission of lighter odd- Z fissioning systems studied in “inverse kinematics” (Steinhäuser et al. 1998) has confirmed the findings obtained in thermal-neutron-induced fission.

Based on these experimental findings, Nifenecker’s theory (Nifenecker et al. 1982) of the odd–even effect should be modified. The argument is that the level density at a certain excitation energy (phase space) has to be taken into account (Steinhäuser et al. 1998; Rejmund et al. 2000). The level density in a larger nucleus is higher than in a smaller one. Therefore, at scission of an odd- Z nucleus the last unpaired proton will see a larger phase space in the larger fragment and will more likely be attached to it. As a consequence, the heavy fragment will preferably be odd and the light fragment correspondingly even, and that is the observed odd–even effect.

The model also explains the old puzzle mentioned above, i.e., that the odd–even effect for protons is higher than for neutrons even if a high kinetic energy of the fragments excludes the emission of neutrons from the fragments. The argument is as follows (Rejmund et al. 2000). In the mass range considered the number of neutrons exceeds that of protons. Accordingly, the single-particle level density of the neutrons exceeds that of the protons. As a consequence, for a given amount of excitation energy, neutron pairs are broken up more frequently than proton pairs. Thus, the odd–even effect will be smaller for neutrons than for protons.

The limitation in space does not allow a more detailed discussion of nuclear charge distribution in fission. The interested reader should be referred to special literature like (Gönnenwein 1991; Wagemans 1991a; Denschlag 1997). A few specific points have already been presented above. The fact that the fine structure at $A = 70$ shown in ▶ Fig. 4.23 consists practically only of nickel ($Z = 28$) has already been used as an argument for the role of the 28-proton shell in fission. In addition, it has been mentioned in the context of ◀ Fig. 4.24 that the fission products with $A = 80$ are predominantly $Z = 32$ and $N = 48$ (not exactly $N = 50$), in agreement with other observations showing that closed shells of neutrons may be influenced more by nuclear surroundings than proton shells.

4.4.4 Ternary Fission

So far only binary fission was considered, i.e., the fission into two fragments (plus a few neutrons). In about one fission event out of 400 the nucleus splits, however, into three charged particles. In most cases the third particle is an α particle. It is assumed that these third particles stem from the neck of the scission configuration (see ▶ Fig. 4.11). The experimental evidence for this assumption is provided by the angular distribution of the fragments. This was measured, e.g., by “Diogenes” (Heeg et al. 1983) a cylindrical, position sensitive detector surrounding a source of fissile material. The detector registers heavy, light, and ternary fragments and their directions in space. Results of an (earlier) measurement (Fluss et al. 1973) are presented in ▶ Fig. 4.27.

The configuration assumed to be responsible for the observed angular distribution is shown in ▶ Fig. 4.28. The α particles are focused to a direction of about 90° with respect to the axis formed by the two fission fragments. The focusing is not exactly 90° but somewhat more inclined toward the light fragment because the Coulomb repulsion of the larger fragment is stronger.

■ Fig. 4.27

Angular distribution of the α particles (with energy greater than 11 MeV) in coincidence with heavy (squares) and light (circles) fission fragments; from (Fluss et al. 1973). The angle θ is defined with respect to the flight direction of the heavy/light fragment as indicated in the figure

■ Fig. 4.28

Diagram illustrating the focusing of the ternary fragment by the two heavier fragments to an angle θ of about 90° with respect to the axis formed by the two heavier fission fragments. Due to the stronger Coulomb interaction with the heavy fragment, the angle of the third particle is around 80° with respect to the light fragment and around 100° with respect to the heavy fragment; from (Vandenbosch and Huizenga 1973)

Alpha particles are by far the most prominent ternary fragments. Other lighter and heavier fragments are, however, also emitted. The extreme sensitivity of the mass separator Lohengrin has allowed to measure yields of ternary fragments down to values of $10^{-7}\%$. A survey of yields of ternary products as a function of their atomic number (Z) is given in [Fig. 4.29](#) for the thermal-neutron-induced fission of ^{233}U and ^{249}Cf .

It is interesting to note that the spectra of ternary particles extend to different atomic numbers, which coincide nearly with the size of the neck that results from the postulate extracted from the mass yield and nuclear charge distributions. To correlate the data, it has been postulated that the two spheres of the dumbbell configuration shown in [Fig. 4.11](#) for the fission of $^{236}\text{U}^*$ are practically the same for all asymmetrically fissioning nuclei from $Z = 90$ to about 99 and, consequently, that the variation in the neutron/proton numbers of the different compound nuclei must be connected with the size of the neck. [Fig. 4.29](#) is the direct experimental proof for this assumption: in the fission of uranium, the neck size is $(92 - 82 =) 10$ protons; in the fission of californium, the neck size is $(98 - 82 =) 16$ protons. The situation is similar for neutrons and for the total mass. This is, however, less convincing due to prompt neutron emission.

4.4.5 Fission Isomers

4.4.5.1 Detection and Measurement of Half-Lives

Considering the minimum in the potential energy barrier as shown in [Figs. 4.8](#) and [4.9](#), one cannot exclude that a nucleus may be trapped in this minimum.

This is indeed the case, and such a short-lived state is called a fission isomer. Actually, it was the discovery of a spontaneously fissioning nucleus with an abnormally short period that led Polikanov et al. to postulate the existence of shape isomers and brought Strutinsky to formulate his theory (Strutinsky 1967). Polikanov's experimental setup is shown in [Fig. 4.30](#).

A beam of ^{22}Ne or ^{16}O was directed on a target of ^{238}U . By the impact, the fission isomers formed were projected onto a rotating collector wheel and transported in front of two ionization chambers. Any fission fragments formed from a spontaneously fissioning nuclide on the wheel were to be detected by the ionization chambers. The beam of ^{22}Ne or ^{16}O ions was stopped in a Ta-collector connected to a current meter for monitoring the beam intensity. The apparatus was equipped to allow a calibration of the chambers using fission fragments from the reaction $^{238}\text{U}(n_{\text{th}}, f)$.

The ratio of count rates in the two ionization chambers at a known rotational speed of the wheel (800–1,400 rpm) allowed to calculate the half-life of the spontaneously fissioning nuclides. The value obtained was 0.02 s – about 10^{10} times shorter than expected for a normal spontaneously fissioning nuclide of this fissility parameter (see [Fig. 4.4](#)). (The shortest-lived normal spontaneously fissioning nuclide that could be considered is ^{252}Fm formed in the reaction $^{238}\text{U}(^{16}\text{O}, 2n)^{252}\text{Fm}$. Its fissility parameter would be $Z^2/A = 39.7$. The half-life extrapolated from the systematics ([Fig. 4.4](#)) would be of the order of 10^8 – 10^9 s. The species observed here was later identified to be a shape isomer of ^{242}Am (fissility parameter of 37.3). The ground state of ^{242}Am decays by β^- decay and electron capture with a half-life of 16 h.)

Soon after this discovery, fission isomers were observed in a multitude of other fission reactions (Michaudon 1973; Wagemans 1991a) ([Fig. 4.31](#)). Most of these fission isomers are

■ Fig. 4.29

Yields of light charged particles (ternary products) emitted in the reactions $^{233}\text{U}(n_{\text{th}},f)$ (Wöstheinrich et al. 1998) and $^{249}\text{Cf}(n_{\text{th}},f)$ (Davi 1997) relative to the yield of ^4He in these reactions (set arbitrarily to 10,000). Data points with arrows represent upper limits

■ Fig. 4.30

Setup used to detect the first fission isomer (Polikanov et al. 1962). (1) Target (^{238}U , 1 mg/cm² on a foil of Al, 5.8 μm thick) exposed to the beam of ^{22}Ne - or ^{16}O -ions (energy 80–139 MeV). (2) Rotating collector wheel intercepting the reaction products (fission isomers) and assuring the transport in front of two ionization chambers. (3) Where any fission fragments originating from nuclei on the wheel were detected. (4) Thin nylon windows of the ionization chambers. (5) Fitting permitting the calibration of the chambers using fragments from the reaction $^{238}\text{U}(n_{\text{th}},f)$. (6) Beam stop connected to a current meter for monitoring the beam intensity

■ Fig. 4.31

Half-lives for spontaneous fission from the second minimum of the potential energy curve as shown schematically in Fig. 4.8 (fission isomers) (*full points*) as a function of the fissility parameter compared to the corresponding half-lives from the ground states (*open points*). The latter points are identical to those in Fig. 4.4. All data are from the compilation of (Wagemans 1991a)

considerably shorter-lived than the isomer of 0.02 s (later identified as ^{242m}Am with its half-life determined more accurately to be 0.014 s).

It was a lucky circumstance for Polikanov et al. that they chose a reaction leading to the longest-lived of the fission isomers; their experimental setup would not have been able to detect any other fission isomer.

For the detection of these shorter-lived isomers a different instrumentation had to be developed. This method is also based on the transfer of momentum from the incoming beam of heavy fragments to the compound nuclei, which will then have sufficient energy to escape from the thin target. Whereas prompt fission will occur in or very near the target, any shape isomers will undergo fission while in flight along a detector plate (Michaudon 1973). The geometrical arrangement is such that prompt fission events are not allowed to enter the detector. The detector plate may be a solid-state track detector such as a foil of Makrofol or another position sensitive detector for fission fragments. (Makrofol KG is a 2,2 bis (4-hydroxy-phenyl) propane polycarbonate available in thin foils. The impact of a fission fragment produces local radiation damage. Such an event, magnified by etching, is visible under a microscope.) The number of fission events per cm^2 can be counted as a function of distance from the target and, since the velocity of the fission isomers is known from momentum conservation, the distance can be converted into time, hence obtaining the half-life of the fissioning isomers. The method in different variants is applicable to half-lives in the range of microseconds to nanoseconds and even below (Metag et al. 1974).

4.4.5.2 Deformation (Charge Plunger Experiment)

A particularly interesting variant of the measurements described above is the “charge plunger experiment.” It allows one to obtain some direct experimental information on the spectroscopic transitions in the second minimum and from this on the degree of deformation of the fission isomers. The experimental setup is shown in ► Fig. 4.32.

A beam of α particles of 33 MeV is impinging on the target (a thin layer of ^{238}U). Due to the impact, the reaction products (ions of $^{239\text{m}}\text{Pu}$, which have escaped prompt fission) are knocked out of the target, pass through a thin carbon foil and a collimator tube into a volume with a strong magnetic field (B), where they are separated according to their ionic charge (2+ to 40+). The volume is surrounded by a detector foil. The nuclei of $^{239\text{m}}\text{Pu}$ (half-life 8 μs) are intercepted on the foil and undergo fission there leaving an etchable mark at the location of their interception.

The ions of $^{239\text{m}}\text{Pu}$ are produced with high angular momentum and decay by conversion electrons to the “isomeric ground state.” The corresponding Auger cascades produce ionic charges in $^{239\text{m}}\text{Pu}$ up to 40+. These charges can be reset to the equilibrium values (1+ and 2+) by the passage through the thin carbon foil. As a consequence, Auger cascades taking place before the ions have reached the carbon foil are reset to low ionic charges. Auger cascades taking place later are not reset. Since the velocity of the ions can be calculated assuming momentum conservation from the known energy of the α particles and the distance of the target to the carbon foil can be measured, the time difference between the formation of $^{239\text{m}}\text{Pu}$ and the passage through the carbon foil can be calculated. The overall timescale of the rotational de-excitation in the fission isomer $^{239\text{m}}\text{Pu}$ can be determined by varying the distance of the carbon foil to the target. The half-life resulting in the present case is about 20 ps.

The lifetime information of the rotational excitations can be converted to the quadrupole moments of the corresponding nuclei using the rotational model. If the shape of the nucleus for

► Fig. 4.32

Setup of the “charge plunger experiment” (Habs et al. 1977; Metag et al. 1980). See text for details

the isomeric state is described by a prolate spheroid, the quadrupole moments obtained correspond to an axis ratio of about 2:1 for the isomers. The 2:1 ratio of the axes is sometimes called the superdeformed shape (Thirolf and Habs 2002). This ratio is in very good agreement with the calculations of Strutinsky (Strutinsky 1967) discussed in the context of Fig. 4.8. A thorough discussion of the double-humped fission barrier (including its experimental and theoretical implications) is given in (Bjornholm and Lynn 1980).

It is interesting to note that in some fissioning nuclei, like ^{234}U , the potential energy surface has been shown to have a third minimum, and the fissioning system may stay in the states supported by this third pocket (Blons et al. 1978; Krasznahorkay et al. 1998; Thirolf and Habs 2002). The length of the system in such an elongated transient state is three times as large as its breadth, thus the state fulfills the definition of a hyperdeformed state.

4.4.5.3 Level Densities in the Isomers

Besides the information on the deformation of the fission isomers based on rotational excitations described above, some information can also be obtained on the level density of vibrational and single-particle excitations in fission isomers.

Back in 1968, a grouping of resonances was observed when the fission cross section was measured as a function of the energy of the neutrons for the neutron-induced (sub-barrier)

Fig. 4.33

The neutron total (Kolar and Böckhoff 1968) and sub-barrier (Migneco and Theobald 1968) fission cross sections of ^{240}Pu as a function of neutron energy between 0.5 and 3 keV; from (Weigmann 1991)

fission of ^{240}Pu (Migneco and Theobald 1968) and for ^{237}Np (Fubini et al. 1968). The behavior for the example of the reaction $^{240}\text{Pu}(n,f)$ can be studied in ► Fig. 4.33.

Whereas the resonances observed for the total cross section (upper part of ► Fig. 4.33) show a spacing of about 14 eV, characteristic of a usual compound nucleus, the fission cross section shows groups of resonances interrupted by larger empty spaces of about 450 eV. The interpretation of this behavior is that, in this region of sub-barrier fission, the fissioning system goes over to the isomeric state in the second well by tunneling. The tunneling is facilitated by the existence of two levels (of identical energy, spin, and parity) in the first and second minimum of the potential barrier. As a consequence, the grouped resonances are a measure of the level density in the first and second well of the potential barrier. The distance between the groups reflects the level density in the isomeric state (second well), and the splitting within each group results from mixing with states in the first well.

Abstract: This chapter gives a survey of the latest results obtained for the fission process that takes place when the energy of the compound system is smaller than the energy of the fission barrier. The tunneling and resonant tunneling processes play a role in this energy region. The transmission resonances were studied in high-energy-resolution experiments and the excitation energies, J^π and K values of the states were determined. Rotational bands were constructed, from which the moment of inertia and the degree of the deformation were determined. The implications of these results to the present knowledge of the fission potential extracted from experiments are discussed.

5.1 Introduction

Nuclear fission is quite a complicated large-scale collective motion. In spite of several decades of intense work, the experimental information on nuclear fission is still rather limited. Knowledge of the nuclear fission phenomenon acquired up to 1972 was summarized by Vandenbosch and Huizenga (1973) and in a comprehensive volume by Wagemans (1991). In [Chap. 4](#) of this Volume, Denschlag has given an overview concentrating mostly on the fundamental aspects of nuclear fission.

In the last decades, studying nuclei with exotic shapes became one of the liveliest fields in modern nuclear structure physics. Especially, studying superdeformed shapes with an axis ratio of 2:1 and hyperdeformed shapes with an axis ratio of 3:1 in the actinide region belong to the frontiers of this field.

The fission of nuclei of this region presents a very rich variety of nuclear shapes. The fissioning nucleus undergoes a continuous sequence of nuclear surface shapes from more or less spherical to elongated, followed by super- and/or hyperdeformed shapes, then neck and split into two fission fragments. The fission potential, which holds the two fragments together, is very complicated and has a lot of structure (minima, maxima, and saddle points) as a function of its parameters. If the energy of the system is lower than the fission barrier, then the system can spend more time in the different potential minima and one can study the cold nuclear system under such extreme conditions.

The focus of this chapter is to review the latest results obtained for the excited states in the second and third minima of the potential barrier. In addition to these exotic shapes, it is also an interesting and longstanding question, at which points of the fission path the mass and energy distributions of the fission fragments are determined. Can one get different mass distributions after the fission of the super- and hyperdeformed states as suggested by Cwiok et al. (1994)? What kind of clusterization is expected in these exotic nuclear states? Does the predicted cold valley exist in the fission barrier? These are very interesting questions but the presently available experimental information is still not sufficient to answer them.

In the seven decades since the discovery of nuclear fission, experimental studies on low-energy fission have been restricted to about 80 fissionable nuclei. They represent only about 15% of all known nuclei with $Z \geq 82$. However, recently a novel experimental technique has been introduced. The fission of relativistic secondary projectiles has now been studied in flight. The benefit of the radioactive beams for studying the fission process is clear, but no fission probabilities below the fission barrier have been determined so far (Schmidt et al. 1994).

Starting with a brief discussion of the theoretical model predictions for the fission potential as a function of the deformation of the nucleus, the consequences of the multiple-humped potential barrier on the fission probabilities will be discussed. During the last decade

a considerable amount of high-resolution experimental data were collected for the fission resonances. These data will be reviewed and their implications for the present experimental knowledge of the fission potential will be discussed.

Such fission potentials might also have practical relevance. The possibility of transmutation of nuclear waste and the production of energy by accelerator-driven systems is under consideration. Accurate fission potentials are needed, particularly in the actinide region, to predict the fission cross sections for these applications.

5.2 Theoretical Predictions for the Fission Potential

5.2.1 The Liquid Drop Model (LDM)

Immediately after the discovery of fission (Hahn and Strassmann 1939), Meitner and Frisch (1939) gave a quantitative explanation of the process using the picture of the LDM. Bohr and Wheeler (1939) developed this picture into their classical theory, which remained the basis for the description of the nuclear fission process for many years to come.

The liquid drop model introduced by von Weizsäcker (1935) treats the nucleus macroscopically similarly to a uniformly charged liquid drop. The total energy is expressed as a sum of a volume energy E_v proportional to the volume (and, consequently, to the mass number) of the nucleus, a surface energy E_s proportional to the surface of the drop, the Coulomb energy E_C , the symmetry energy E_{sy} , and the pairing energy E_p :

$$E = E_v + E_s + E_C + E_{sy} + E_p. \quad (5.1)$$

In application to the fission process, in which the dependence on the deformation is relevant, only the surface and Coulomb terms come into play.

The deformation of the nucleus can be described by a multipole expansion of the nuclear surface

$$R(\theta, \vartheta) = R_0 \left[1 + \sum_{\lambda\mu} a_{\lambda\mu} Y_{\lambda\mu}(\theta, \vartheta) \right] \quad (5.2)$$

For small deformations, if limited to quadrupole deformations (only $a_{20} \neq 0$), the surface and Coulomb energies are given by

$$E_s = E_s(0) \left(1 + \frac{2}{5} a_{20}^2 \right), \quad (5.3)$$

$$E_C = E_C(0) \left(1 - \frac{1}{5} a_{20}^2 \right). \quad (5.4)$$

Consequently, the condition for stability of a spherical nucleus is $E_C(0) < 2E_s(0)$. According to Bohr and Wheeler (1939), one can define the fissility parameter

$$x = \frac{E_C(0)}{2E_s(0)} = \frac{0.71Z^2/A^{1/3}}{2 \times 17.5A^{2/3}} \approx \frac{1}{50} \frac{Z^2}{A}. \quad (5.5)$$

Hence, according to the liquid drop model, nuclei with $x > 1$ or $Z^2/A > 50$ are unstable against spontaneous fission.

For $x < 1$, the deformation energy has a local minimum at the spherical shape. For the common actinide nuclei ($0.68 < x < 0.76$) the deformation energy also has a maximum with positive energy relative to the ground state at positive values of the deformation parameter (a_{20}). That defines the fission barrier. Numerical calculations including multipoles up to $\lambda \approx 16$ led to fission barrier heights

$$E_B = 0.83 E_s(0)(1 - x)^3 \quad (5.6)$$

relative to the ground state.

In spite of several refinements of the LDM, see, e.g., (Myers and Swiatecki 1969; Krappe et al. 1979; Möller and Nix 1981), it seemed to be clearly inadequate to explain some of the basic properties of the actinide nuclei (Wagemans 1991).

When the fission isomeric states were discovered (Polikhanov et al. 1962), it became clear that the fission potential should have a second minimum as a function of the deformation and the observed fission isomers are shape isomers in such a second minimum. Strutinsky's proposal (see [Chap. 2](#) in this Volume) was to combine the virtues of both the LDM and shell models to describe such a second minimum of the fission potential.

5.2.2 The Shell Correction Method

In the nuclear shell model, the mutual interaction between the nucleons adds up to a single-particle average potential consisting of a (spherical) central potential and a spin–orbit interaction. The nucleons are assumed to move independently in this potential. The solutions of the Schrödinger equation yield single-particle energy levels and wave functions for the individual nucleons (Haxel et al. 1949; Goepfert-Mayer 1949).

Nilsson (1955) extended the single-particle shell model to deformed potentials. The solutions of the Schrödinger equation then depend on deformation also. In the independent-particle model (Wagemans 1991) the sum of the single-particle energies of an even–even nucleus is given by

$$U = \sum_{\mu} 2n_{\mu} \varepsilon_{\mu}, \quad (5.7)$$

where the n_{μ} are the occupation numbers of the energy levels ε_{μ} . Unfortunately, in the above expression the errors due to the approximate nature of the shell model potential and the neglect of residual interactions will tend to accumulate. Thus, the final result will be much less accurate than the total energy obtained from the LDM.

The LDM is thus a suitable starting point for an accurate calculation of the total energy, but it has to be corrected for the fluctuations due to the shell structure. Such a combined macroscopic–microscopic method should then hopefully reproduce both the smooth trends and the local fluctuations.

The method in its present form was developed in 1967 (Strutinsky 1967) and has since revolutionized the calculation of fission barriers. There had been a number of studies that employed very similar techniques before Strutinsky's work as well. Swiatecki (1964) had introduced the idea of a macroscopic–microscopic method, but the simplified procedure that he used to calculate the microscopic fluctuations worked only for small deformations. However, even in this form, the method correctly predicted many features of nuclear ground-state masses and deformations, fission-barrier heights, and the probable existence of

superheavy nuclei. Somewhat similar approaches had been used even earlier by Hill and Wheeler (1953). The importance of single-particle effects on the nuclear potential energy, particularly on nuclear ground-state masses, had been recognized and discussed frequently since the early days of nuclear physics.

Strutinsky's "macroscopic-microscopic" or "shell correction" method (SCM) amounts to correcting the LDM energy according to

$$E = E_{\text{LDM}} + U - \langle U \rangle = E_{\text{LDM}} + \delta U. \quad (5.8)$$

Here $\langle U \rangle$ means a smoothed deformation dependence of the shell model energy as defined in Wagemans (1991) and δU means the so-called shell correction energy. The qualitative behavior of the shell correction δU with deformation is easily understood. See [Fig. 5.1](#).

The liquid drop energy contains the contributions of both the kinetic energy and of the potential energy, and the right-hand side of [Eq. \(5.8\)](#) contains a correction for the shell effects as well. The quantity E is not an operator, but a value, which depends on various parameters, and it is usually considered a function of the deformation parameters. It is referred to as the energy curve or energy surface depending on the number of parameters that are allowed to vary. The deformation parameters express the properties of the system that are most important in fission, and are considered dynamical variables, just as in the collective model ([Chap. 2](#) in this Volume). That is an intuitive step guided by the success of the collective model. The collective variables are actually expressible in terms of the single-particle

Fig. 5.1

Illustration of the method of Strutinsky to merge the liquid drop model (LDM) and the shell model as a function of deformation. The upper curve shows the oscillations due to shell effects around a mean (upper dashed curve). The difference of the two (δU) was used to correct the LDM energy (lower dashed curve)

coordinates (Buck et al. 1979), and thus it is justifiable to regard them as dynamical variables. (Then, of course, E should be evaluated in terms of intrinsic coordinates from which the collective coordinates have been removed, but that distinction is disregarded.) It is plausible that the dynamics of the system is determined by the energy surface just as that of a particle by the potential, and that it should be complemented by a kinetic energy dependent on the same coordinates. The role of the energy surface as a potential justifies its calling a potential energy surface or a potential energy curve. The energy surface shows a varied landscape of valleys and mountain ridges called (fission) barriers, with peaks and saddle points. In principle, the kinetic energy of the motion of the surface could also be expressed in terms of the single-particle kinetic energies, but that is also beyond the scope of the model. This treatment is fully consistent with that of the potential energy. Overall, in the model of the fission adopted in this report, the Hamiltonian is the sum of the kinetic energy and of the (potential) energy surface/curve, both expressed in terms of the deformation parameters.

Whenever the density of states as a function of deformation is comparatively low (high), the shell correction is negative (positive). Such gaps in the single-particle energy levels occur not only at zero deformation (magic numbers) but also at nonzero deformation. Particularly, strong negative shell corrections are found for nuclear shapes corresponding to a ratio of major and minor axes of the deformed nuclear shape of 2:1, which is now called the superdeformed shape.

Theoretical progress later on also enabled purely microscopic calculations for the fission potential. Self-consistent mean-field calculations within the Hartree–Fock–Bogolyubov (HFB) approach (Berger 1989) for the fission potential in ^{230}Th clearly exhibit even a third minimum at large quadrupole deformations. In recent years, fission potentials have also been calculated within the relativistic mean-field model (Blum 1994), approximately reproducing the double-humped fission barrier of ^{240}Pu . Even the triple-humped fission barrier of ^{232}Th was described by the relativistic calculations with a quality comparable to the nonrelativistic models (Rutz et al. 1995). While early shell-correction calculations (Howard and Möller 1980) as well as HFB (Berger et al. 1989) and relativistic mean-field calculations predicted rather shallow third minima ($\sim 0.2\text{--}0.5$ MeV), shell-correction calculations by Cwiok et al. (1994) predicted much deeper hyperdeformed third minima ($\sim 1\text{--}3$ MeV), in better agreement with experimental findings, which will be discussed in [Sect. 5.5](#).

Cwiok et al. (1994) performed systematic calculations of potential energy surfaces for even–even Rn, Ra, Th, and U isotopes using the shell correction approach with the axially deformed average Woods–Saxon potential (Cwiok et al. 1987), while for the macroscopic part the Yukawa-plus-exponential liquid-drop mass formula of Möller and Nix (1988) was used. The energies of the local minima in the potential energy surface were obtained by performing a multiparameter minimization of the total energy with respect to the deformation parameters $\beta_3\text{--}\beta_7$. According to these calculations third minima appear in many actinide nuclei, characterized by very large elongations ($\beta_2 \approx 0.9$) and significant reflection asymmetry, $0.35 < \beta_3 < 0.65$. This model does not contain any free parameter adjusted to the properties of these hyperdeformed configurations. In the nuclei around ^{234}U the hyperdeformed minimum splits into two distinct minima with very different values of β_λ ($\lambda = 3\text{--}7$). [Figure 5.2](#) shows the resulting fission potentials for Th, U, and Pu isotopes as a function of the quadrupole deformation β_2 .

The deepest third minima are predicted for the thorium isotopes, while the lowering of the outer barrier with increasing proton number prevents the formation of pronounced third minima beyond uranium.

■ Fig. 5.2

Potential energy as a function of the quadrupole deformation parameter for Th, U, and Pu isotopes. The energy and location of the saddle points and minima (except for the third one) were taken from Howard and Möller (1980), while the energy of the third minimum for the less reflection asymmetric hyperdeformed minimum ($\beta_3 \approx 0.4$) was taken from Cwiok et al. (1994). The energy scale was slightly shifted in order to reproduce the energy of the ground states in the first well (Krasznahorkay et al. 1998b). The best energy regions for studying the super- and hyperdeformed states are marked by green and red shadowed regions, respectively. See ▶ Sect. 5.3.1 for more details. Based on Krasznahorkay (1998a)

The analysis of experimental data for thorium isotopes resulted in values for the moment of inertia $2\Theta/\hbar^2$ close to 500 MeV^{-1} . For comparison, moments of inertia have been calculated using Nilsson and Woods–Saxon potentials as a function of deformation (Boldeman and Walsch 1985). For large deformations ($\beta_2 \approx 0.9$) the results are close to the rigid-body value.

■ Fig. 5.3

Schematic illustration of class I, class II, and class III compound states

5.2.3 Shape Classification of Excited States

For energies of the system below the inner maxima of the fission barrier, the model wave functions are normally concentrated within one of the minima of the deformation potential. This process leads to a classification of the wave functions as class I (with major amplitude within the first well), class II (centered in the second well), and class III (centered in the third well). A schematic illustration of this classification of vibrational states is shown in [Fig. 5.3](#).

Obviously, the tails of these wave functions penetrate the intermediate barriers, and, consequently, there is a certain degree of mixing of idealized pure class I, class II, and class III excitations. The main factors determining the amount of mixing are the penetrability factors of the internal barriers, which can be small below the barriers.

5.3 Excited States Related to the Fission Barrier

It has been known for a long time that the fission barrier can be studied by measuring the fission probability as a function of the excitation energy. If the energy is well below the fission barrier, then one is dealing with a classical tunneling process via the barrier. The fission probability increases exponentially with the energy. In the WKB approximation, the probability of tunneling through the barrier can be calculated (Hill and Wheeler 1953).

Assuming a parabolic fission barrier with a height of V_0 and curvature of $\hbar\omega$, then one can get the well-known Hill–Wheeler transmission coefficient

$$T_{\text{HW}} = \frac{1}{1 + \exp\left(2\pi \frac{V_0 - E}{\hbar\omega}\right)}. \quad (5.9)$$

The experimentally determined fission probabilities can then be compared to the results obtained with the expression above and the height and the curvature of the barrier can be determined. If the fission barrier is more complicated, then this simple formula cannot be used. More sophisticated calculations – including double- and triple-humped fission barriers – have been published recently by Sin et al. (2006, 2008). The situation is complicated by the presence

of the transitional states introduced already by Bohr (1956), which are expected to give more structure in the fission probability above the top of the fission barrier.

5.3.1 Resonances in the Fission Probability

Bohr suggested that in a saddle-point configuration a nucleus is in a very cold state and that the spectrum of **transition states** resembles the spectra near the ground states of stably deformed nuclei. These transition states could cause resonances in the fission probability. Therefore, first the low-lying excited states of even–even nuclei shall be discussed briefly.

Two-particle states in these nuclei have $\sim 1\text{--}2$ MeV of excitation energy, and the excited states lying lower than those states correspond to collective motions. These collective motions are expected to form a sequence of collective vibrational and rotational states.

When developing the analogy of the transition state spectra to these excited state spectra of stably deformed nuclei, the following points must be taken into consideration:

- β -vibration cannot exist at the saddle-point configuration of the outermost barrier, since it is a vibration in the fission direction, and is unstable.
- The energy of a two-particle excitation is higher at the saddle point than that in the stably deformed configuration. Thus, it is sufficient to consider only collective excited states as transition states.

Several experiments support the existence of transition states, and give their spectra (Kikuchi and An 1970). However, there are also many misidentified resonances in the literature, which are actually below the fission barrier and can best be described as resulting from class II and class III states of the multiple-humped fission barrier.

Thanks to the resonant tunneling effect, such excited states (class-II and class-III) can be mapped by measuring the fission probability as a function of the excitation energy (see [Fig. 5.4](#)). If one measures also the angular distribution of the fragments arising from fission induced by some reaction, then one can get information on the spin and K values of such excited states as well.

If the excitation energy is higher than the inner barrier of the second well, but lower than the barriers of the third well then the transmission resonances corresponding to class II and class III states could in principle be distinguished by their widths. The widths of class II

■ Fig. 5.4

Schematic illustration of the resonant tunneling process through the fission potential

resonances should be much broader due to the strong coupling to class I states, while the damping of class III resonances is hindered by the higher barriers of the third well. Therefore, the best energy region for studying the hyperdeformed states by measuring the transmission resonances in the actinides is indicated in [Fig. 5.2](#), illustrating the potential barriers for the Th, U, and Pu isotopes.

5.3.2 Description of the Fission Probability Without Damping

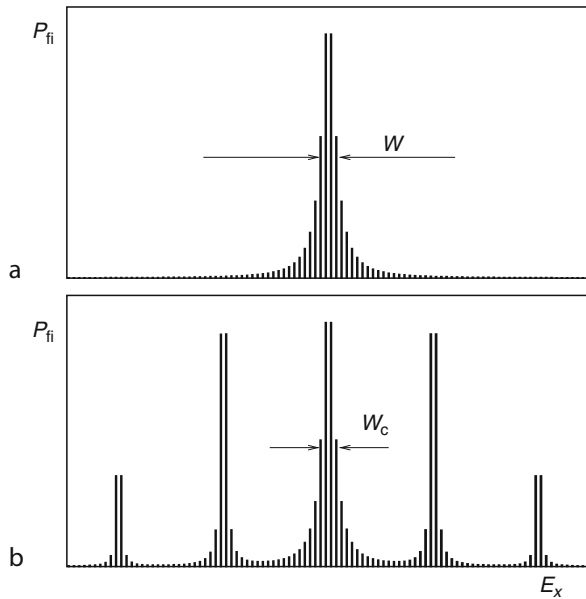

For double-humped potential barriers, detailed calculations were performed by Glässel, Röser, and Specht (Glässel 1974; Glässel et al. 1976). The results of the calculations were summarized by Thierolf and Habs (2002). A schematic illustration of the character of an undamped transmission resonance and a damped (i.e., not fragmented and fragmented) transmission resonance is shown in [Fig. 5.5](#).

For a pure and undamped transmission resonance, where the strength of the β -vibrational state is not distributed over the neighboring intrinsic states in the second minimum, the fission probability P_{fi} of a class-I state can be described as (Glässel et al. 1976)

$$P_{fi} = \frac{D_I}{2\pi} \frac{\Gamma_A \Gamma_B / \Gamma_{\gamma I}}{(E - E_\beta)^2 + W^2/4}, \quad (5.10)$$

Fig. 5.5

Undamped and damped transmission resonances. Panel (a) shows the Lorentzian of the fission probability for class-I states. Panel (b) displays the strength function of the β -vibration in the case of damping into class-II states. Constant level distances D_I for states in the first and D_{II} for states in the second minimum were assumed

where the width W of the resonance is given by

$$W = \left\{ (\Gamma_A + \Gamma_B + \Gamma_{\gamma I})^2 + \frac{2}{\pi} \Gamma_A \Gamma_B \frac{D_I}{\Gamma_{\gamma I}} \right\}^{1/2}. \quad (5.11)$$

Here $\Gamma_{\gamma I}$ ($\Gamma_{\gamma II}$) represents the γ -decay width in the first (second) minimum. D_I describes the level distance between class-I states and E_β stands for the excitation energy of the β -vibrational state. The widths Γ_A and Γ_B caused by the tunneling of a state through the inner and outer fission barrier, respectively, can be determined using the transmission probabilities $P_{A,B}$ through a single barrier with height E_A and E_B , respectively, calculated by Hill and Wheeler (1953):

$$\Gamma_{A,B} = P_{A,B} \frac{\hbar\omega_{II}}{2\pi} = \{1 + \exp(2\pi(E_{A,B} - E)/\hbar\omega_{A,B})\}^{-1} \frac{\hbar\omega_{II}}{2\pi}. \quad (5.12)$$

The $\hbar\omega_{II}$ corresponds to the β -phonon energy in the second minimum, while $\hbar\omega_{A,B}$ denotes the curvature of the parabolic parameterization of the fission barrier. The experimentally accessible fission cross section σ can be obtained from the cross section σ_{cl} for the formation of a compound state $|cl\rangle$ in the first minimum and the fission probability

$$\sigma = \sigma_{cl} P_{II}. \quad (5.13)$$

As shown in  Fig. 5.5, the fission probability is distributed among the class-I states. The width of the distribution is determined by barrier penetration probabilities (P_A and P_B). If one wants to observe sharp transmission resonances in the fission probability, then one should go well below the fission barriers. A more detailed analysis of the transmission resonances will be given in  Sect. 5.4 for ^{240}Pu .

5.4 High-Resolution Study of the Transmission Resonances in ^{240}Pu

After the discovery of fission isomerism in the actinide region, great efforts were directed toward the spectroscopic studies of excited states in superdeformed (SD) nuclei (Strutinsky 1967; Wagemans 1991; Bjornholm and Lynn 1980). The appearance of such elongated shapes with an axis ratio of 2:1 in the actinides is the consequence of a second minimum in the shell-corrected potential energy surface. Low-lying SD excitations were mostly observed in conversion electron experiments, which resulted in the successful identification of rotational bands upon the fission isomeric ground states (Specht et al. 1972; Metag et al. 1980).

In contrast to the first minimum, β -vibrations at higher excitation energies can be investigated in the second minimum as transmission resonances in the prompt fission probability, since the β -vibrations manifest themselves as doorway states to fission. A few members of the vibrational series were systematically observed in actinide isotopes just below the fission barrier (Bjornholm and Lynn 1980). Due to the damping of the vibrational motion, their large fission widths are distributed over many compound states in their vicinity. The fine structure due to compound levels in the first minimum (class I states) cannot be resolved, but the gross structure of the β -vibrational transmission resonances, the intermediate structure due to SD class II compound states can be resolved due to their lower level density. High-energy-resolution studies of fission resonances can therefore give spectroscopic information on SD compound states with specific spin J^π and spin projection K at excitation energies below the fission barrier.

The more one can probe with efficient detector systems, the subbarrier regions of vibrational damping, the better one should be able to observe isolated levels with small widths in the fission channel. The transmission resonances observed in ^{240}Pu at excitation energies, with respect to the ground state in the first minimum, $E^* = 5.1$ MeV (Specht et al. 1969; Specht 1970; Pedersen and Kuzminov 1969) and at $E^* = 4.6$ MeV (Goldstone et al. 1978; Goerlach 1978; Goerlach 1980; Goerlach et al. 1982; Just 1978; Just et al. 1979) were repeatedly interpreted as best examples for damped vibrational resonances. In the experiment of Glässel et al. (1976) on ^{240}Pu , the $E^* = 5.1$ MeV resonance group was investigated with a high-energy resolution of 3 keV. With the aid of a detailed model description (Glässel et al. 1976), all experimentally resolved class-II states that are predominantly populated in the (d,p) reaction were identified as $(K^\pi, J^\pi) = (0^+, 2^+)$ states, but the two states were not resolved due to their fission widths. The $E^* = 4.6$ MeV resonance group was studied by Goldstone et al. (1978), Just (1978) with modest resolution. With good statistics and high-energy resolution, however, individual $K^\pi = 0^+$ SD rotational band members were identified with spin and parity of $J^\pi = 0^+, 2^+, 4^+$.

The high-energy-resolution experiment on ^{240}Pu was carried out at the Munich Accelerator Laboratory employing the $^{239}\text{Pu}(\text{d},\text{pf})^{240}\text{Pu}$ reaction ($Q = 4.309$ MeV) with a deuteron beam of $E_d = 12.5$ MeV, and using an enriched (99.9%) ~ 30 $\mu\text{g}/\text{cm}^2$ thick target of ^{239}Pu on a 30 $\mu\text{g}/\text{cm}^2$ thick carbon backing (Krasznahorkay et al. 2001c; Hunyadi et al. 2001). Protons were detected in coincidence with the fission fragments. The excitation energy E^* of the ^{240}Pu compound nucleus was directly deduced from the kinetic energy of the protons, which was analyzed by a Q3D magnetic spectrograph (Enge and Kowalsky 1970) (see ► Fig. 5.6) set at $\Theta_{\text{Lab}} = 130^\circ$ relative to the incoming beam ($\Omega = 10$ msr).

The spectrograph is equipped with two position-sensitive parallel-plate avalanche counters for the detection of fission fragments in coincidence with proton ejectiles registered by a light-ion focal plane detector (Zanotti et al. 1991).

■ Fig. 5.6

Experimental setup for the transmission resonance experiments performed at the Munich Q3D magnetic spectrograph

■ Fig. 5.7

(a) Proton coincidence spectrum of the $^{239}\text{Pu}(\text{d},\text{pf})$ reaction measured by Hunyadi et al. (2001). (b) Proton coincidence spectrum at $E_d = 12.5$ MeV and $\theta = 140^\circ$ from Specht et al. (1969). For comparison the spectra folded with a resolution of 17 keV from Hunyadi et al. (2001) (solid line) and Glässel et al. (1976) (dashed line) are also shown. Based on Hunyadi et al. (2001)

The measured proton energy spectrum from the (d,p) reaction in coincidence with the fission fragments (after subtraction of random coincidences) is shown in ▶ Fig. 5.7a in terms of the excitation energy of the compound nucleus ^{240}Pu . The spectrum is proportional to the product of the fission probability and the known smoothly varying (d,p) cross section, which shows no fine structure (Specht et al. 1969).

In ▶ Fig. 5.7b, the Munich measurement is compared with previous high-resolution measurements of the same reaction: The (d,pf)-spectrum of ▶ Fig. 5.7b was measured with a resolution of 17 keV by Specht et al. (1969). It is nicely reproduced in all fine structures after folding the spectrum from Hunyadi et al. (2001) with the reduced resolution and applying a global shift of 120 keV to higher energies on the experimental data of Specht et al. (1969) to correct partially for the proper Q-value. When folding the measurement by Glässel (1974), which was performed at $E_d = 12.5$ MeV and $\theta = 125^\circ$ with an experimental resolution of 3 keV, only a small overall shift of 12 keV was necessary.

5.4.1 Experimentally Resolved Intermediate Structure

The overall features of ▶ Fig. 5.8a (Hunyadi et al. 2001) show gross structures with a damping width of about 200 keV in the region of the two transmission resonances at 4.6 MeV and 5.1 MeV.

Besides these features, the proton spectrum exhibits a rich structure of individual transitions. The resolved intermediate structure of the lower resonance shows a regular pattern of well-resolved triplets, with weaker lower and upper peaks, which are separated by 19 keV and

■ Fig. 5.8

Panel (a) Proton spectrum of the reaction $^{239}\text{Pu}(\text{d},\text{pf})$ measured with 7 keV resolution (Hunyadi et al. 2001). Also shown is a fit of the data with rotational $K^\pi = 0^+$ bands. The $0^+, 2^+, 4^+$ picket fences show the rotational bands used in the fit. In the upper part of the 5.1 MeV resonance, the fit (thin line), is based on the positions of the rotational bands extracted from panel (d). Panels (b), (c) The full dots represent the a_2 (a_4) fission angular distribution coefficients determined in the same measurement, while the open symbols are the a_2 (a_4) coefficients taken from Glässel et al. (1976). The thick full line results from the fit to spectrum (a). The thin lines correspond to the theoretical a_2 (a_4) coefficients for different angular momentum values j of the transferred neutron. Panel (d) Proton spectrum of the reaction $^{239}\text{Pu}(\text{d},\text{pf})$ from Glässel et al. (1976) measured at 3 keV resolution together with a fit of the spectrum using rotational bands as indicated. Based on Hunyadi et al. (2001)

43 keV, respectively, from the stronger central peak. These separations are very close to the 0^+-2^+ and 2^+-4^+ separation energies (20 keV, 46.6 keV) of the $K^\pi = 0^+$ ground-state rotational band in the second minimum, strongly suggesting that these structures are due to excited $K^\pi = 0^+$ rotational bands in the superdeformed minimum of ^{240}Pu . Thus, at the lower resonance at 4.6 MeV, a series of “pure” resonance states have been observed with $K^\pi = 0^+$ and spins $0^+, 2^+, 4^+$ with rotational energy spacings as known from the ground-state band in the second minimum (Specht 1970; Specht et al. 1972). This is in contrast to the excitation-energy region above 5 MeV, where Hunyadi et al. (2001) confirmed the bunching of peaks “without any systematic trend” observed earlier (Specht et al. 1969; Glässel 1974).

The part of the 5.1 MeV resonance region in the spectrum of Glässel et al. (1976), which sufficiently overlaps with the spectrum of Hunyadi et al. (2001) was fitted with $K^\pi = 0^+$ rotational bands assuming a Lorentzian line shape for the band members. The position and amplitude of each band were treated as individual parameters, and a common moment of inertia (Θ) was used. For the intensity ratio of the band members, the value of Glässel et al. (1976) was accepted as a starting value for the fitting procedure. The fit nicely reproduced the experimental data with 13 rotational bands (see [Fig. 5.8d](#) and Hunyadi et al. 2001). Satisfactory description of the experimental data was achieved again by fitting the line width and the relative amplitudes of the bands, as shown in [Fig. 5.8a](#) with a thin curve. The 4.6 MeV group and the lower part of the 5.1 MeV group obtained in the experiment of Hunyadi et al. was also fitted by the same procedure; however, the rotational parameters $\hbar^2/2\Theta$ and the intensity ratios I_{2+}/I_{0+} and I_{4+}/I_{0+} were determined separately for the bands with prominent band heads at $E^* = 4,434, 4,526, 4,625, 4,685, 4,703$ and $4,733$ keV.

In order to confirm the spin and K -assignments of the observed compound levels in the second minimum, the corresponding fission fragment angular correlations with respect to the recoil axis were analyzed, describing them in the usual way with coefficients a_2 and a_4 of Legendre polynomials (LPs). In [Fig. 5.8](#), the measured proton coincidence spectrum ([Fig. 5.8a](#)) is shown together with the coefficients a_2 ([Fig. 5.8b](#)) and a_4 ([Fig. 5.8c](#)). For comparison, the spectrum of Glässel et al. (1976) is also shown in [Fig. 5.8](#) together with their a_2 and a_4 coefficients marked by open circles in [Fig. 5.8b, c](#). The horizontal lines in [Fig. 5.8b, c](#) show the theoretical a_2 and a_4 coefficients for different values of the angular momentum j of the neutron transferred in the (d,p) reaction, leading to ^{240}Pu states with $K = 0$ and $J = |1/2 \pm j|$. Due to the low ground-state spin ($J_i^\pi = 1/2^+$) of ^{239}Pu , in ^{240}Pu only low total angular momenta J are populated. 0^+ states can easily be identified in the fission-fragment angular correlations through their isotropic emission characteristics. The large and positive a_2 and a_4 coefficients point to a dominant $K = 0$ character of both resonances. From $^{240}\text{Pu}(\gamma, f)$ data (Rabotnov et al. 1970) a “suppression of the $K^\pi = 0^-$ – channel by more than two orders of magnitude relative to the $K^\pi = 0^+$ channel” was deduced (Glässel et al. 1976). For the lower 4.6 MeV resonance a $K^\pi = 0^-$ contribution was discussed as well, however, as will be described below, a reasonable description of the fission probability was achieved assuming a $K^\pi = 0^+$ channel (Goerlach 1978; Just 1978; Just et al. 1979).

5.4.2 Excitation Energy of the Ground State in the Second Minimum

From the experimental findings discussed in [Sect. 5.4.1](#), it seems that a complete spectroscopy of $K^\pi = 0^+$ bands is possible in the regions of vibrational damping. In order to check this completeness and the consistency of the observed level density with the excitation energy in

the second minimum, a statistical analysis of the level distances was performed using the band head energies. The statistical distribution of the ratio of experimental and calculated average 0^+ level distances, using the back-shifted Fermi-gas formula by Rauscher et al. (1995), was generated. The shape of the resulting distribution was successfully approximated by a Wigner-type distribution (Brody et al. 1981), as expected for repelling states with the same angular momentum and parity.

In [Fig. 5.9](#) the experimentally observed 0^+ level distances in the transmission resonance groups of ^{240}Pu (full circles) are compared to calculations of the level density in the first minimum according to different models. The solid line on the left side of the figure corresponds to the level distances in the first minimum calculated in the framework of the back-shifted Fermi gas model in the parameterization by Rauscher et al. (1997). In order to reproduce the experimentally observed 0^+ level distances, this curve has had to be shifted by 2.25 MeV, corresponding to the ground-state energy in the second minimum of ^{240}Pu . For comparison, also shown are the level distances in the first minimum calculated with the Bethe formula and within the “constant temperature” formalism in a parameterization by von Egidy et al. (1988).

The value of $E_{\text{II}} = (2.25 \pm 0.20)$ MeV – extracted for the excitation energy of the ground state in the second minimum of ^{240}Pu – is in good agreement with the fission isomer energy obtained from the well-known method of extrapolated excitation functions of various experiments (see, e.g., Wagemans 1991 and references therein). Thus having proven the reliability of this method, an excellent tool has been obtained to address the question of the depth of the (hyperdeformed) third minimum of the potential surface. This tool will be discussed in

[Sect. 5.5](#).

(1997). Based on Hunyadi (1999)

5.5 Experimental Evidence for Hyperdeformed States in U Isotopes

5.5.1 Hyperdeformed States in ^{236}U

Subbarrier resonances, at about 5-MeV excitation energy, have been observed previously in many actinide nuclei (Back et al. 1972; Blons et al. 1978, 1984; Bjornholm and Lynn 1980). Based on the modest energy-resolution measurements, these subbarrier resonances were believed to arise from the coupling of compound nuclear states in the first potential well to vibrations of the fission degree of freedom in the second potential well. Goldstone et al. (1978) proposed that the observed transmission resonances in ^{234}U and in ^{236}U might be due to states in the second well, which consist of a fission vibration coupled to low-lying states in the second well such as rotations and $K^\pi = 0^+, 0^-, 2^+, 1^- \dots$ collective vibrations. Blons et al. (1988) were able to resolve the fine structure of the resonances in ^{234}U , and they measured also the angular distribution of the fission fragments, but their results were not consistent with the angular distributions calculated with the assumption of single pure J resonances.

The first high-resolution study of the transmission resonances in ^{236}U was carried out at $E_d = 9.73$ MeV at the Debrecen 103-cm isochronous cyclotron and at $E_d = 13.0$ MeV at the Munich Tandem accelerator. Enriched (97.6–99.89%) 88–250 $\mu\text{g}/\text{cm}^2$ thick targets of ^{235}U were used.

The energy of the outgoing protons was analyzed in Debrecen by a split-pole magnetic spectrograph (Spencer and Enge 1967), which had a solid angle of 2 msr and was set at $\Theta_{\text{Lab}} = 140^\circ$ with respect to the incoming beam (see in [Fig. 5.10](#)). The position and energy

Fig. 5.10

Experimental setup for the transmission resonance experiments performed at the Debrecen split-pole magnetic spectrograph

of the protons were analyzed by two Si solid-state, position-sensitive, focal-plane detectors. The overall proton energy resolution of the system, including the effects of target thickness and long-term stability, was estimated to be less than 20 keV.

In Munich, the energy of the outgoing protons was analyzed by a Q3D magnetic spectrograph (Enge and Kowalsky 1970), which was set at $\Theta_{\text{Lab}} = 130^\circ$ relative to the incoming beam and the solid angle amounted to 10 msr. The position in the focal plane was measured by a light-ion, focal-plane detector of 1.8-m active length. Using that detector with the spectrograph, a line-width of <3 keV has been observed for elastic scattering of 20 MeV deuterons.

Fission fragments were detected in both experiments by two position-sensitive avalanche detectors (PSAD) (Crouzen 1988) having two wire planes (with delay-line read-out) corresponding to horizontal and vertical directions. Protons were measured in coincidence with fission fragments. Typical proton energy spectra are shown in [Fig. 5.11](#) as a function of excitation energy.

A highly damped superdeformed (SD) vibrational resonance, which is very close to the top of the first barrier, is clearly seen at 5.1 MeV (Goldstone et al. 1978). Above this resonance, one observes some sharper peaks (FWHM ≈ 30 keV) similar to the modest energy-resolution work (FWHM = 60–70 keV) of Goldstone et al. (1978) and to previous results (Krasznahorkay et al. 1996, 1998a). These resonances do not appear to be appreciably damped although they are above the top of the inner barrier, so these sharp resonances cannot be associated with SD states lying in the second well. These results support the presence of a deep HD minimum as predicted by Cwiok et al. (1994).

In the third well of the potential, the reflection asymmetry permits almost degenerate levels of both parities in the rotational spectrum. These kinds of rotational levels have been nicely observed in the experimental fission probability of ^{231}Th (Blons et al. 1975). Assuming that each of the observed resonances also contains a whole rotational band, the experimental results

Fig. 5.11

Proton spectra in coincidence with the fission fragments measured in Debrecen (ATOMKI) and in Munich (LMU). Based on Krasznahorkay et al. (1998b)

were fitted by simple Gaussian functions for describing the different members of the band following the procedure of Blons et al. (1975).

The relative excitation probabilities for members of the rotational band were taken from the work of Back et al. (1972) who performed Distorted Wave Born Approximation (DWBA) calculations for the (d,p) reaction at the same bombarding energy. The width of the Gaussians was set by the experimental resolution.

The following free parameters were introduced: (1) energy of the band head, (2) absolute intensity of the band, and (3) rotational parameter of the band. The last parameter was kept identical for all of the groups, i.e., the 5.28, 5.37 and 5.47 MeV groups. A fit to the measured spectrum was performed with the above parameters using the least squares method. The nonresonant part of the fission probability was taken into account as an exponential “background.”

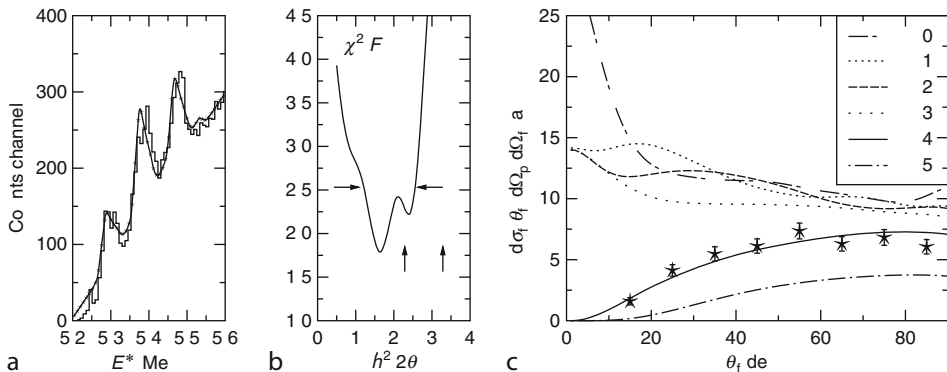

The best fit was obtained with $K = 4$ as shown in Fig. 5.12a. The K value of the target was $K = 7/2$. At the low bombarding energy (9.73 MeV) the $\ell = 0$ transfer is the most probable, which implies the excitation of mainly $K = 3$ and 4 states.

The calculated χ^2 values as a function of $\hbar^2/2\Theta$ are plotted in Fig. 5.12b. The predicted values of $\hbar^2/2\Theta$ for the hyperdeformed and superdeformed states are indicated by HD and SD, respectively. The best fit results in $\hbar^2/2\Theta = 1.6^{+1.0}_{-0.4}$ keV is in good agreement with the value predicted for the hyperdeformed state $(\hbar^2/2\Theta)_{\text{Theo.}} = 2.0$ keV (Bengtsson et al. 1987).

Fission-fragment angular distributions were generated for the 5.47 MeV line as well as for the continuous nonresonant part of the fission probability and normalized to the known (d,f) angular distribution (George et al. 1963). The angular distribution is shown in Fig. 5.12c. All distributions were fitted with even Legendre polynomials (LPs) up to fourth order. For the nonresonant region, the LP coefficients are in good agreement with the previously published data (Britt et al. 1968; Specht et al. 1966; Vandebosch et al. 1967). The measured angular

Fig. 5.12

(a) Proton spectrum measured for ^{236}U in coincidence with the fission fragments as a function of excitation energy, compared to the fitted rotational bands; (b) the results of the χ^2 analysis (F is the number of degrees of freedom of the fit); the theoretical predictions for the HD and SD rotational parameters are indicated by arrows; (c) experimental fission-fragment angular distribution for the 5.47 MeV resonance with respect to the recoil axis (z-axis) compared to the calculated ones. Based on Krasznahorkay et al. (1998b)

distribution was compared to the calculated ones assuming different K values, in order to get information on the K value of the hyperdeformed rotational band. From the comparison, the most probable K value of the band is $K = 4$ (see ► Fig. 5.12c), which is in perfect agreement with the analysis of the proton spectrum.

5.5.2 Reinvestigation of the Fission Resonances in ^{236}U

In the experiment discussed in ► Sect. 5.5.1, the resonances observed at 5.27, 5.34 and 5.43 MeV have been identified as hyperdeformed resonances (Krasznahorkay et al. 1998a, b), however without resolving their rotational structure.

A second experiment aiming at a better energy resolution and a more convincing statistics was carried out at the Munich Accelerator Laboratory to investigate the $^{235}\text{U}(\text{d}, \text{pf})$ reaction with a deuteron beam of $E_d = 9.75$ MeV. The energy of the proton ejectiles was analyzed with a Q3D magnetic spectrograph. The Q3D spectrometer was placed at $\Theta_L = 125^\circ$ relative to the incident beam and the solid angle was 10 msr. The energy resolution obtained from the $^{208}\text{Pb}(\text{d}, \text{p})$ reaction was 3 keV at 8.7 MeV proton energy. Furthermore, this reaction was used for the energy calibration. Fission fragments were detected by two position-sensitive avalanche detectors (PSAD) (Hunyadi et al. 2001). An active area of $16 \times 16 \text{ cm}^2$ resulted in a relatively large solid-angle coverage of the detectors. The measured high-resolution fission probability as a function of the excitation energy of the compound nucleus ^{236}U is shown in ► Fig. 5.13. It was obtained by dividing the proton energy spectrum measured in coincidence with fission fragments by the smoothly varying proton spectrum from the (d,p) reaction.

The structures of the previously identified resonances at 5.27, 5.34, and 5.43 MeV have been nicely resolved as shown in ► Fig. 5.14. The resonance structure around 5.1-MeV excitation energy was formerly interpreted by Goldstone et al. (1978), Just et al. (1979) and Just et al. (1980) as a vibrational resonance in the second minimum.

In the first step of the analysis, the resonance structure between 5.2 and 5.5 MeV was analyzed. In order to describe the rotational structure, overlapping rotational bands were assumed with the same moment of inertia, inversion-splitting parameter and intensity ratio for the band members. Simple Gaussians were used for describing the different band members.

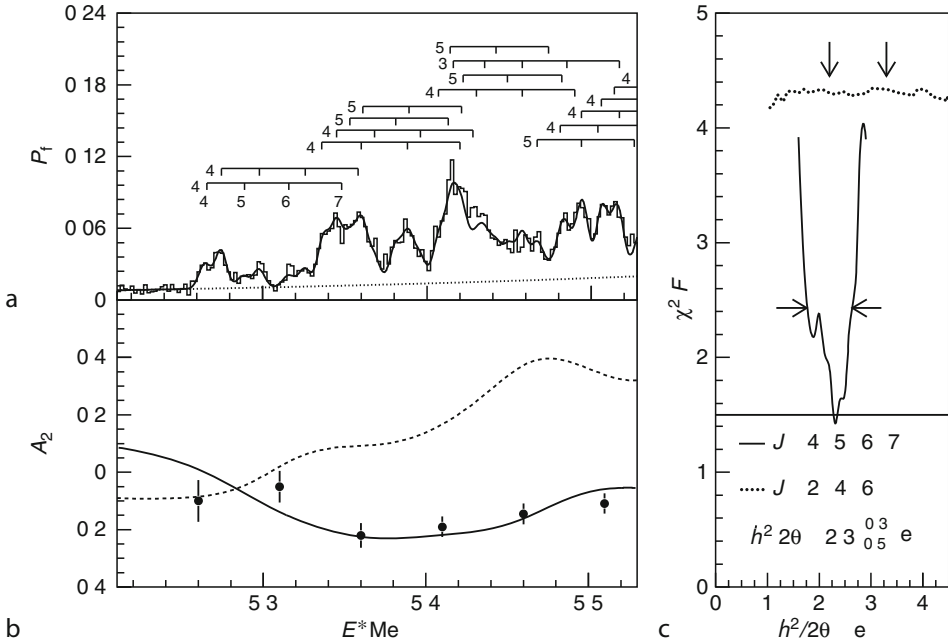

■ Fig. 5.13

Proton spectrum in coincidence with the fission fragments measured in Munich. Based on Csátlós et al. (2005)

■ Fig. 5.14

(a) Fission probability P_f for the $^{235}\text{U}(\text{d},\text{p})^{236}\text{U}$ in the excitation-energy region above 5.2 MeV. The solid line shows a fit to the data assuming rotational bands. The tick marks indicate the positions of the band heads with K values as indicated by the numbers. (b) Consistent description of the angular correlation coefficient A_2 from Just et al. (1979) (data points) with the fit function from panel (a) based on the distribution of K values as indicated there. (c) Normalized χ^2 values for the fit to the spectrum of panel (a). The best fit has been obtained by hyperdeformed rotational bands with $\hbar^2/2\Theta = 2.3 \pm 0.4$ keV. Based on Csátlós et al. (2005)

The width of the Gaussians was fixed by the experimental resolution. The relative excitation probabilities for the members of the rotational bands were taken from DWBA calculations for the (d,p) reaction by Back et al. (1971), calculated around 5.4 MeV excitation energy. During the fitting procedure, three free parameters were used for each band, the first two parameters being the energy of the band head and the absolute intensity of the band. A common rotational parameter ($\hbar^2/2\Theta$) and inversion-splitting parameter (ΔE^\pm) were adopted for all bands. Since the ground-state spin and parity of the target is $7/2^-$, and because at the relatively low bombarding energy the $\ell = 0$ transfer is the most probable one, mainly $J^\pi = 3^-$ and $J^\pi = 4^-$ states were excited. For the reproduction of the angular correlation coefficients, the K value of each rotational band was an additional free parameter.

The HD states are characterized by the presence of alternating parity bands with very large moments of inertia because of the very large quadrupole and octopole moments (Blons et al. 1988). Assuming alternating parity bands with $K = 3, 4$, and 5 band heads, the fission probability between 5.2 and 5.5 MeV was fitted, resulting in the fit curve superimposed on the data in Fig. 5.14a. The corresponding normalized χ^2 values are presented in Fig. 5.14c as a function of $\hbar^2/2\Theta$. The horizontal line represents the 99.9% (3σ) confidence level for the

χ^2 test. The deduced rotational parameter is $\hbar^2/2\Theta = (2.3 \pm 0.4)$ keV, which is consistent with the small inversion parameters, obtained by Blons et al. (1988).

Fitting the fission probability with rotational bands with opposite parity assignments resulted in a fit of similar quality as the one shown in [Fig. 5.14a](#), thus indicating that the analysis is not sensitive to parity. With the series of 15 rotational bands shown in [Fig. 5.14a](#) not only the fission probability, but also the angular correlation coefficient A_2 measured by Just et al. (1979) could be reproduced (data points in [Fig. 5.14b](#)). The extracted rotational parameter corresponds to a value characterizing HD rotational resonances. The moment of inertia $\Theta = (217 \pm 38) \hbar^2/\text{MeV}$ is in good agreement with the values (Shneidman et al. 2000) for ^{234}U and ^{232}Th , with assumed exotic heavy clustering as predicted by Cwiok et al. (1994).

In the second step of the analysis, the proton energy spectrum below 5.2 MeV was analyzed. In the $^{234}\text{U}(t, \text{pf})$ reaction, Back et al. (1974) observed a weak, narrow resonance at 5.0 MeV and a distinct shoulder (or resonance) around 5.15 MeV. Goldstone et al. (1975) and Just et al. (1979) reported the first clear observation of a series of narrow subbarrier fission resonances in ^{236}U produced in the (d, pf) reaction. In their analysis, the underlying states of these resonances were assumed to originate from the second well, close to the top of the inner barrier.

The result of the analysis in the excitation-energy region between 5.05 and 5.2 MeV is shown in [Fig. 5.15](#), where the prompt fission probability is displayed (panel a) together with the results of a fit by rotational bands similar to the procedure described above for the upper resonance region. Again the spin-dependent excitation probabilities of the rotational band members were based on DWBA calculations by Back et al. (1971) for $E^* = 5.1$ MeV.

Fig. 5.15

Fission probability P_f for the $^{235}\text{U}(d, p)^{236}\text{U}$ in the excitation-energy region below 5.2 MeV. Based on Csatlós et al. (2005). The panels are similar to those of [Fig. 5.14](#)

The optimized fit curve shown in [Fig. 5.15a](#) required modifications of the DWBA calculations by Back et al. (1971). However, it is apparent already from the work of Back et al. (1971) that variations of the excitation energy by only a few hundred keV result in variations of the excitation probabilities of up to a factor of 3. Moreover, it should be kept in mind that the Nilsson single-particle structure underlying the DWBA calculations – see also Andersen et al. (1970) – inherently carries large uncertainties in the region of heavy nuclei and high excitation energies in question here. Thus, modifications of the spin-dependent excitation probabilities can very well be justified. In order to allow for a consistent description of the fission probability and the angular correlation coefficient A_2 from Just et al. (1979), a distribution of K values rising from $K = 1$ to $K = 4$ between 5.05 MeV and 5.2 MeV had to be chosen.

The tick marks in [Fig. 5.15a](#) indicate the positions of the band heads with their respective K values marked as numbers. The sign change of the A_2 coefficient already indicates the tendency toward lower K values with decreasing excitation energy. The resulting curve for the A_2 angular-correlation coefficient calculated based on the fit function derived from the fission probability in panel (a) is displayed in panel (b) of [Fig. 5.15](#). The quality of the fit can be judged from [Fig. 5.15c](#), where the normalized χ^2 values are displayed with the horizontal solid line representing the 99.9% confidence level.

The rotational parameter derived from the best fit is $\hbar^2/2\Theta = (2.4 \pm 0.7)$ keV, corresponding to a hyperdeformed configuration. This result is in contrast to the old assumption that the decaying vibrational excitations originate from the superdeformed second minimum. It is impossible to reproduce the data with overlapping rotational bands in the second well with a spin sequence of $J^\pi = 2^+ - 4^+ - 6^+ - 8^+$ and a typical rotational parameter for superdeformed bands $\hbar^2/2\Theta \approx 3.3$ keV.

5.5.2.1 The Depth of the Third Minimum in ^{236}U

The depth of the third well (as shown in [Fig. 5.16](#)) was determined by comparing the experimentally obtained average level distances of the $J = 5$ members of the rotational bands with $K = 4, 5$ of [Fig. 5.15a](#) with calculated ones using the back-shifted Fermi-gas description (Rauscher et al. 1997) as described in [Sect. 5.4.2](#).

The theoretical prediction for the depth of the third minimum in ^{236}U according to Cwiok et al. (1994) is 3.8 MeV. This experimental result is in a good agreement with that prediction and is also consistent with another experimentally determined value of $E_{\text{III}} = (3.1 \pm 0.4)$ MeV for ^{234}U (see in [Sect. 5.5.3.1](#)).

5.5.2.2 The Innermost Barrier of Uranium Isotopes

The new interpretation of the 5.1 MeV transmission resonance group in ^{236}U as a resonance in the third and not in the second minimum leads to a determination of the parameters of the innermost barrier. Previously the interpretation as a resonance in the second minimum led to the requirement that the inner barrier height E_A was approximately equal to the outer barrier E_B , because a strong resonance requires penetrabilities of both barriers with comparable values. Based on the present interpretation, the innermost barrier has to be reduced to the excitation energy of the lowest transmission resonance in order to achieve a good mixing between the first and second minima.

■ Fig. 5.16

Average distances of the $J = 5$ spin states in the third minimum of ^{236}U as a function of excitation energy. The solid, dotted, and dash-dotted curves show calculated values by different formulas (explained in Krasznahorkay et al. 1999), the full points correspond to experimental values. The dark dotted curve is shifted from curve labeled “Rauscher 1” to fit the data. In this way the value for the ground-state energy is estimated to be $E_{\text{III}} = (3.30 \pm 0.40)$ MeV. Based on Csatlós et al. (2005)

With a back-shifted Fermi-gas formula, the level spacing for 0^+ compound states in the second minimum at a total excitation energy of 5.1 MeV is calculated to be about 80 keV. The damping width of these states due to tunneling through the inner barrier $\Gamma = \hbar\omega_{\text{II}}/2\pi \cdot P_A$ is about 100 keV at the top of the barrier with $P_A \approx 1$. Therefore, the occurrence of a transmission resonance in the third well at 5.1 MeV requires a rather complete damping and an inner-barrier height E_A lower than 5.2 MeV.

On the other hand, one can obtain a lower limit for the inner-barrier height E_A from the previously measured isomer population probability. This is shown in Fig. 5.17 with data from Goerlach (1978). For excitation energies between ~ 4.4 and ~ 4.9 MeV, the weak coupling limit is valid, and the isomer population probability is proportional to the square root of the penetrability P_A of the inner barrier (Goerlach 1978). The data show a clear exponential increase. At an excitation energy of 5.1 MeV, the isomer population probability starts to saturate because the compound states of the first and second minima become largely mixed. Above 6 MeV, one observes a drop of the isomer population probability because the competing fission and neutron channels open up. From the exponential rise of the isomer population probability, for low energies it can be inferred that the inner barrier E_A has to be larger than 4.9 MeV.

■ Fig. 5.17

Isomer population probability from Goerlach et al. (1978)

From these two limits, one obtains $E_A = (5.05 \pm 0.20)$ MeV. Furthermore, from the exponential rise and the estimate of the penetrability from the γ back-decay one obtains $\hbar\omega_A = 1.2$ MeV.

In summary, study of the prompt fission probability of ^{236}U reveals the shape of the fission barrier. The rotational parameter extracted is $\hbar^2/2\Theta = (2.3 \pm 0.4)$ keV. The corresponding moment of inertia ($\Theta = (217 \pm 38) \hbar^2/\text{MeV}$) agrees with a theoretical value (Shneidman et al. 2000). The hyperdeformed rotational-band structure in the excitation-energy region around 5.1 MeV supports that there is a rather deep third minimum in ^{236}U . The lowest transmission resonance in the third well sets limits on the height of the inner barrier E_A .

An extrapolation of the height of the inner barrier indicates that for Th isotopes it should be about 4.5 MeV, which is different from a former interpretation (Bjornholm and Lynn 1980), but agrees with a theoretical prediction (Howard and Möller 1980).

5.5.2.3 Clustering in the Actinide Region

The clustering phenomenon is a dramatic manifestation of the shell structure at very large deformations. From such a di-nuclear system one may expect strong fission decay to the components, similarly to the case of the enhanced α decay of light α + core nuclei above the α + core threshold.

The HD states lying in the third well of the fission barrier may play the role of a doorway-like state before fission, from which the fission can only occur through a limited number of fission paths, resulting in a sharper mass distribution (Krasznahorkay et al. 2000, 2001a, b, 2003, 2004).

5.5.3 Hyperdeformed Rotational Bands in ^{234}U

The experimental results of Blons et al. (1988) concerning ^{234}U were reanalyzed similarly. Each of the resonances observed (see Fig. 5.18) was assumed to consist of a complete rotational band.

■ Fig. 5.18

(a) Fission probability of ^{234}U as a function of excitation energy. The full curve is a result of the fit with $\hbar^2/2\Theta = 1.8$ keV according to the deepest χ^2 minimum; (b) the results of the χ^2 analysis. Based on Krasznahorkay et al. (1998b)

The energies of the band heads, the absolute intensities of the bands, and an inertia parameter ($\hbar^2/2\Theta$) were fitted to the experimental data. The obtained inertia parameter is $\hbar^2/2\Theta = 1.8_{-0.7}^{+0.5}$ keV, which is the average of the values of the equivalent χ^2 minima, and again agrees well with the predicted value for the HD states.

The angular distribution of the fission fragments was also calculated and compared to the experimental data (see Fig. 5.19). Good agreement has been obtained, which also supports that each of the peaks observed contains a complete rotational band with $K = 1$ or 2, instead of one definite state with a well-defined J^π as assumed by Blons et al. (1988). The K value of the target was 5/2, which implies the excitation of $K = 2$ or 3 states with $\ell = 0$ transfer.

5.5.3.1 High-Resolution Study of the Fission Resonances in ^{234}U

The $^{233}\text{U}(\text{d,pf})^{234}\text{U}$ reaction was also studied with better energy resolution, to resolve the HD rotational bands and, from the level densities, to estimate the depth of the third minimum.

In order to investigate the HD bands, the excitation energy was chosen between the energy of the inner and outer barriers of the second well, i.e., between 4.5 MeV and 5.2 MeV (Krasznahorkay et al. 1998a). In this energy range, the SD resonances in the second well should be much broader than the HD states due to the strong coupling to the normal deformed states. The widths of the HD states due to the higher outer barriers of the third well remain below the actual experimental resolution of ~ 5 keV.

The experiment was carried out with an $E_d = 12.5$ MeV deuteron beam of the Munich Tandem accelerator. The energy of the outgoing protons was analyzed by a Q3D magnetic spectrograph, in coincidence with the fission fragments.

Fig. 5.19 Fission fragment angular distributions for the 4.86, 4.91, and 4.97 resonances in ^{234}U compared to the theoretically calculated curves assuming different K values for the rotational bands. Based on Krasznahorkay et al. (1998)

■ Fig. 5.20

Part of the proton spectrum measured in coincidence with the fission fragments and compared to the result of Blons et al. (1988). Based on Krasznahorkay et al. (1999)

The obtained widths of the peaks show the experimental energy resolution up to about 5.3 MeV. Above this excitation energy, the peaks get increasingly broader due to the increasing fission width when one approaches the top of the fission barrier. The low-energy part of the spectrum, which was analyzed before (Krasznahorkay et al. 1998b), is compared to the one published by Blons et al. (1988) in ▶ Fig. 5.20.

The energy resolution has been considerably improved and one can clearly see the fine structure of the peaks. Experimentally, the very large quadrupole and octopole moments of the HD states should manifest themselves by the presence of alternating parity bands with very large moments of inertia (Blons et al. 1988). Assuming overlapping rotational bands with the same moment of inertia, inversion parameter (Ackermann et al. 1993) and intensity ratio for the members in a band, the spectrum was fitted in the same way as in the previous work (Krasznahorkay et al. 1998b). The result of the fit is shown in ▶ Fig. 5.21a.

The relative intensities of the members of the rotational bands have been taken from Back et al. (1971). These values have been calculated by DWBA for $^{235}\text{U}(\text{d},\text{p})$. These relative intensities depend sensitively on the distribution and widths of the single-particle states involved in the (d,p) process at the given excitation energy. These relative intensities have been adopted as initial parameters for the fitting procedure.

The jump in the relative intensities going from $J = 2^+$ to 3^- , as predicted by Back et al. (1971) might be a consequence of the alternating parities within the rotational bands, although the fit was actually not very sensitive to the relative intensity of the 2^+ state. Increasing this intensity by a factor of two worsens the χ^2 by less than 8%. After fixing the relative intensities of

■ Fig. 5.21

(a) Part of the measured proton energy spectrum fitted with 24 rotational bands of the same rotational parameter. The spectrum was divided into two parts at $E^* = 5,150$ keV for the fitting; (b) Experimental fission-fragment angular-distribution coefficients as a function of excitation energy compared to the calculated ones using $K = 1$ (upper curve) and $K = 3$ (lower curve) for all of the bands. The $K = 0$ curve is very close to the $K = 1$ curve while that with $K = 2$ is between those with $K = 1$ and $K = 3$. The latter are not shown. Based on Krasznahorkay et al. (1999)

the band members, two specific parameters for each band were used during the fitting procedure: the energy of the band head and the absolute intensity of the band. A common rotational ($\hbar^2/2\Theta$) parameter was adopted for all bands.

Although the statistics in the second part of the spectrum is better, the density of the states is about twice as large, making the determination of the rotational parameter more uncertain. The rotational parameter was therefore determined for both parts separately and the weighted average was calculated. The result is $\hbar^2/2\Theta = (2.2 \pm 0.2)$ keV.

The low-lying rotational bands have been investigated in the $^{233}\text{U}(\text{d},\text{pf})$ reaction at 13 MeV by Bjornholm et al. (1968). They obtained intensity distributions, which peak around $J = 2$, distinctly lower than those found by Back et al. (1971). Although Bjornholm et al. (1968) only investigated rotational bands consisting of states of the same parity, and it is known that the intensities depend strongly on parity; the relative intensities were also used to fit the data as an alternative scenario. Using alternatively the relative intensities of Bjornholm et al. (1968) almost as good a fit was obtained as above with $\hbar^2/2\Theta = (1.5 \pm 0.5)$ keV. The somewhat different value obtained by assuming these two very different sets of relative intensities indicates the sensitivity of the rotational parameter to the assumed relative intensities.

Fission-fragment angular distributions were generated as functions of the excitation energy, normalized to the known (d,f) angular distribution (George et al. 1963) and fitted with even Legendre polynomials (LPs) up to fourth order. The a_2 angular distribution coefficient is shown in [Fig. 5.3b](#) as a function of the excitation energy. In order to get information on the spins and K values of the observed rotational bands, or to check the assumptions made for fitting the energy spectrum, the angular distribution coefficients of the fission fragments have been calculated and compared with experiment.

The $a_2(E^*)$ shown in [Fig. 5.21b](#) has been calculated by using the parameters obtained from a fit of the energy spectrum. The amplitudes of the different band members obtained from the fit were then multiplied by the corresponding theoretical Legendre coefficients $A_\lambda(J_f, K_f)$. The final distribution was then obtained by normalizing it with a similar function calculated with the $A_0(J_f, K_f)$ values (Krasznahorkay et al. 1999).

Since the spins J_f of the excited states are already fixed by the energy spacings of the peaks as shown in [Fig. 5.21a](#), in the next step only the K values of the bands were varied between 0 and 3. The measured angular distribution coefficients were compared to the calculated values in [Fig. 5.21b](#).

With the assumption of quadrupole rotational bands with intensities peaking at $J^\pi = 2^+$ it was impossible to explain even the gross structure of the measured angular distribution. The calculated a_2 coefficients were always too low compared to the experimental ones. In order to explain the experimentally measured $a_2 \approx 0.5$ values, one should assume an intensity distribution, which peaks at higher J values than 2, most probably at $J = 3$ as assumed before.

5.5.3.2 The Depth of the Third Minimum in ^{234}U

The density of the $J = 3$ states determined from the experimental data (Krasznahorkay et al. 1999) is close to a Wigner quasi-probability distribution (Brody et al. 1981) but the mixing-in of some Poisson type distribution is also visible. The density of $J = 3$ states has also been calculated using the back-shifted Fermi-gas description with parameters determined by Rauscher et al. (1997). The calculated curve had to be shifted by 2.7 MeV to reproduce the experimental values (Krasznahorkay et al. 1999). The energy of the ground state in the third well is obtained to be $E_{\text{III}} = (3.1 \pm 0.4)$ MeV.

Two different HD minima were predicted (Cwiok et al. 1994) for ^{234}U with very different β_λ ($\lambda = 3-7$) values. One of them has an octopole deformation parameter of $\beta_3 \approx 0.4$ and a minimum of $E_{\text{III}} = 3.5$ MeV, while the other is more reflection-asymmetric and has an octopole deformation parameter of $\beta_3 \approx 0.6$ and a minimum of $E_{\text{III}} = 2.7$ MeV. The experimental value of $E_{\text{III}} = (3.1 \pm 0.4)$ MeV is in between the two predicted values with an error bar, which overlaps with both theoretical values.

In summary, the fission probability of ^{234}U has been measured as a function of excitation energy with high energy resolution using the (d,pf) reaction. The rotational parameter obtained from fitting the energy spectrum around $E^* \approx 5$ MeV is found to be $\hbar^2/2\Theta = (2.1 \pm 0.2)$ keV, which is characteristic of the hyperdeformed nuclear shape. The level density of the most strongly excited $J = 3$ states has been compared to the prediction of the back-shifted Fermi-gas formula, and the energy of the ground state in the third minimum has been estimated to be $E_{\text{III}} = (3.1 \pm 0.4)$ MeV, which agrees well with the predicted value (Cwiok et al. 1994).

5.5.4 Subbarrier Fission Resonances and Transitional States Observed in ^{232}U

In contrast to the $^{234,236}\text{U}$ isotopes, where sharp HD fission resonances have been identified (Blons et al. 1988; Krasznahorkay et al. 1998b, 1999; Csatlós et al. 2005), in ^{232}U no clear resonance structures have been observed so far, but rather a broad shoulder around $E^* = 5.0$ MeV, which was assumed to consist of resonances with $K^\pi = 0^+$ and $K^\pi = 2^+$ (Back et al. 1974). However, according to the calculations on the height of the fission barriers and on the depth of the third potential well (Cwiok et al. 1994; Möller et al. 1972), the appearance of fission resonances representing HD states is expected also in the case of ^{232}U .

The most recent experiment was carried out at the tandem accelerator of the Munich Accelerator Laboratory (now called Maier-Leibnitz Laboratory, MLL) at Garching employing the $^{231}\text{Pa}(^3\text{He},\text{df})$ reaction with a ^3He beam of $E = 38.1$ MeV to investigate the fission probability of ^{232}U in the excitation-energy region of $E^* = 4.0$ –6.5 MeV. An enriched (99%) $70\text{ }\mu\text{g}/\text{cm}^2$ thick radioactive target of ^{231}Pa was used. The excitation energy of ^{232}U was determined from the kinetic energy of the deuteron ejectiles.

The kinetic energy of the outgoing deuterons was analyzed by the Q3D magnetic spectrograph (see in Fig. 5.6.) set at $\Theta_{\text{lab}} = 35^\circ$ relative to the beam direction. The experimental energy resolution was deduced to be $\Delta E = 11$ keV (FWHM) in the energy region of interest. Fission fragments were detected in coincidence with the outgoing deuterons by two position-sensitive avalanche detectors (PSAD), allowing for a detection of the fission fragment angular correlation with respect to the recoil axis ($30^\circ \leq \Theta_R \leq 90^\circ$) and solid-angle coverage of 10% of 4π .

The measured high-resolution excitation-energy spectrum of ^{232}U is shown in Fig. 5.22 as a function of the excitation energy of the compound nucleus in the region of $E^* = 4.0$ –4.8 MeV together with the contribution of the random coincidence events (dashed line).

A number of sharp transmission resonances have been observed in the excitation-energy region of $E^* = 4.0$ –4.8 MeV with widths of $\Delta E \approx 30$ keV. Considering their narrow width, these resonances do not appear to be considerably damped; thus, they cannot be associated with states in the second minimum. The damping width of class II (SD) resonances should be much

■ Fig. 5.22

Excitation-energy spectrum of ^{232}U between $E^* = 4.0$ MeV and $E^* = 4.8$ MeV. Based on Csige et al. (2009)

broadener (~ 200 keV (Bjornholm and Lynn 1980) due to the strong coupling to class I states, while the damping of class III (HD) resonances is hindered by the higher barriers of the third well.

The angular distribution of the fragments was measured by gating on the energies of all observed resonances with respect to the recoil axis and the values were normalized to the value at 90° as can be seen in [Fig. 5.23](#). Angular data for random coincidence events were subtracted, while the efficiency of the PSADs was taken into account by dividing the angular distribution spectrum with the spectrum of random events gated by excitation energies above the fission barrier, where numerous fission channels are open. Errors are caused not only by the statistical contribution but also by the uncertainty coming from the small continuous nonresonant part of the fission probability.

The measured angular distribution was compared to calculated ones in order to derive information on the K value of the rotational bands. The results of these calculations based on different K values are displayed in [Fig. 5.23](#) as continuous lines. These rather high K values ($K = 4, 5$), indicated by the comparison of theoretical and experimental results, can be understood by considering the most probable angular momentum transfer of $L = 3$ and $L = 4$ in the ($^3\text{He}, d$) reaction (Back et al. 1974) and the spin of the ^{231}Pa target nucleus ($J^\pi = 3/2^+$).

Gaussians were used for describing the different band members, as explained before, while the nonresonant part of the fission probability, which is caused by simple tunneling through the fission barrier, was treated as an exponential background. The relative excitation probabilities $\alpha(E, J^\pi)$ for the members of the rotational band were taken from Back et al. (1974). The rotational parameter has been determined to be $\hbar^2/2\Theta = (1.96 \pm 0.11)$ keV, which is far smaller than the corresponding values characterizing SD shapes ($\hbar^2/2\Theta \approx 3.3$ keV) as described in Krasznahorkay et al. (1999); Csatlós et al. (2005). The results have been obtained assuming $K = 4, 4, 4, 4, 5$, and 4 for the seven rotational bands at band head energies $E^* = 4,080(5)$, $4,160(7)$, $4,345(6)$, $4,402(4)$, $4,468(3)$, $4,651(4)$, and $4,678(3)$ keV, respectively. In [Fig. 5.23](#),

Fig. 5.23

Comparison of theoretical and experimental fission fragment angular distributions $W(\theta)/W(90^\circ)$ with respect to the recoil axis. The theoretical curves were obtained by assuming different K values for the rotational bands. The thick line was calculated using K values that were assigned to the experimentally identified rotational bands during the fitting procedure. Based on Csige et al. (2009)

the thick line represents the resulting angular distribution obtained with these assignments. The experimental and calculated values are in very good agreement, supporting the validity of the analysis (► Fig. 5.23).

For the determination of the fission-barrier parameters an analytical expression for the fission probability was used, which was fitted to the experimental values. The details of the fitting procedure are described elsewhere (Csige et al. 2009). The result of the fitting procedure is presented in ► Fig. 5.25.

Considering the results for the fission-barrier parameters of ^{232}U , the discrepancy from the fitted function around $E^* = 5.0$ MeV seems to be a nice signature of the existence of transition states, which are assigned to states built on the second barrier.

According to Bohr's transition state concept (Bohr 1956), at excitation energies near the barrier, when the nucleus is passing over a saddle point, most of its energy is expended into deformation energy. Therefore, at this highly deformed configuration, the system should be thermodynamically rather "cold" and exhibit a discrete spectrum of low-lying collective excitations, similar to the ground-state deformation. Within Bohr's concept, it is assumed that near-barrier fission proceeds through these discrete transition states. The fragment angular distributions are then determined by the quantum numbers of the transition states involved. The consequences of such transition states are found to be important in describing both the fission probabilities and the angular distribution of the fission fragments. However, these states usually have large damping widths, which usually prevents their observation separately.

► Figure 5.26 shows the fission probability spectrum $E^* = 4.0$ MeV and $E^* = 4.8$ MeV. In order to describe the rotational structure of these resonances, overlapping rotational bands were assumed again with the same moment of inertia (Θ) and intensity ratio for the band members as described previously for the HD-bands. The angular distribution of the fission fragments showed a $K = 0$ character of the band, but the statistics was insufficient to determine

■ Fig. 5.24

the spins of the individual states. The energies and intensities of the resonances could best be described with quadrupole rotational bands, whose members are indicated in Fig. 5.26 for the ground-state band. The energy of the band head was found to be $E^* = (4,970 \pm 3)$ keV. Two other similar bands located at $(5,085 \pm 5)$ keV and $(5,285 \pm 5)$ keV were also included in the fitting procedure. The rotational parameter obtained from the fit was $\hbar^2/2\Theta = (3.38 \pm 0.10)$

keV, which is characteristic of superdeformed nuclear shape in this mass region (Hunyadi et al. 2001). This result implies that the fission potential might be somewhat distorted.

5.6 The Fission-Barrier Landscape

All presently available information on fission-barrier parameters in the actinide mass region is shown in [Fig. 5.27](#).

Fig. 5.27

Fission-barrier parameters of actinide isotopes. Red symbols indicate the outermost fission barrier E_B , while blue symbols stand for the innermost barrier E_A . The experimental data points from the compilation by Bjornholm and Lynn (1980) are given by the full circles, indicating the centroid of the barrier parameters for a given Z with the error bars denoting the respective range of barrier heights. Open circles indicate the average value of the two outer barriers for the triple-humped barrier in Ra and Th. Open squares show calculated barrier heights taken from Howard and Möller (1980), while open triangles contain, in addition to the calculations by Howard, information on the depth of the third potential well according to Cwiok et al. (1994)

Solid blue and red squares display the barrier heights for ^{236}U as derived in ▶ Sect. 5.5 as well as an estimate for the inner barrier in ^{232}Th . The solid lines visualize the trends visible in the data. While previous publications favored the increase of E_A with decreasing Z (Bjornholm and Lynn 1980) as shown by the dashed blue line, the more recent experimental information, in agreement with earlier calculations, indicates a lowering of E_A as illustrated by the solid blue line below Pu. This discrepancy is explained by the fact that at the time of Bjornholm and Lynn (1980) the existence of a deep third minimum was not known. In the paper of Britt et al. (1973), unease about the obvious discrepancy to the theoretical expectations for E_A in ^{228}Th is explicitly expressed; however, the interpretation of the experimental data was misguided by the assumption of a double-humped fission barrier. In view of the present knowledge, the theoretical trend of a drastic lowering of the inner barrier height with decreasing Z is clearly confirmed. ▶ Figure 5.27 impressively locates the occurrence of the island of fission isomers in the mass region of the light actinides. With the continuous decrease of the outer barrier height E_B with increasing Z , the corresponding half-life of isomeric fission drops below the pico-second region for $Z > 98$. Quite similarly, the decrease of the inner barrier height E_A with decreasing Z results in sub-picosecond half-lives for the γ back-decay in the region of $Z < 88$ thus marks the lower limit for the island of shape isomers.

▶ Figure 5.28 shows the experimentally determined fission-barrier parameters for U isotopes as a function of mass number. The innermost barrier heights and the depths of the third well are marked by full circles and triangles, respectively.

■ Fig. 5.28

The heights of the innermost barrier (E_A) and the depths of the third well (E_{III}) for even-even uranium isotopes. The experimental data for ^{232}U , ^{234}U , ^{236}U , and ^{238}U indicated by full circles and full triangles were taken from Csige et al. (2009); Krasznahorkay et al. (1999); Csatlós et al. (2005); Krasznahorkay (2006); Royer and Bonilla (2007), while the experimental data represented by open circles were taken from Back et al. (1974). Data points marked by (C) are results of calculation taken from Royer and Bonilla (2007). The upper full curve represents theoretical results for the height of the inner barrier (Howard and Möller 1980), while the lower full curve shows the theoretical E_{III} values (Cwiok et al. 1994)

The value for the third minimum of the fission barrier of ^{238}U results from a theoretical calculation, taken from Royer and Bonilla (2007). In [Fig. 5.28](#), the fission-barrier parameters (assuming double-humped fission barrier) obtained by Back et al. (1974) are indicated by open circles. The data for the inner barrier heights E_A (full circles) reveal a clear trend within the isotopic chain. [Figure 5.28](#) also shows a nice agreement between the latest experimental and theoretical results for the fission-barrier parameters supporting strongly the claim that a third minimum exists. The findings presented in this chapter assemble into a firm evidence for the existence of a deep third minimum of the fission potential.

6.5	<i>Nuclear Reactions and Reaction Rates in the Sun</i>	330

Abstract: This chapter is devoted to the fundamental concepts of nuclear fusion. To be more precise, it is devoted to the theoretical basics of fusion reactions between light nuclei such as hydrogen, helium, boron, and lithium. The discussion is limited because our purpose is to focus on laboratory-scale fusion experiments that aim at gaining energy from the fusion process. After discussing the methods of calculating the fusion cross section, it will be shown that sustained fusion reactions with energy gain must happen in a thermal medium because, in beam-target experiments, the energy of the beam is randomized faster than the fusion rate. Following a brief introduction to the elements of plasma physics, the chapter is concluded with the introduction of the most prominent fusion reactions ongoing in the Sun.

6.1 Introduction

Since the times of ancient civilizations, it has been known that the Sun plays a crucial role in sustaining life on Earth. The inevitable question regarding the source of the Sun's energy also arose very long ago.

Until the birth of nuclear science, only chemical reactions seemed to be available as candidates for the production of the heat that comes from the Sun. While this explanation was held correct, the age of the Earth was believed to be only a few thousand years, as chemical reactions alone would be capable of powering the Sun for only a few thousand years.

Einstein's theory about the equivalence of mass and energy opened the way for finding the real source of the Sun's power, namely nuclear reaction, or – more precisely – nuclear fusion.

The phenomenon called *nuclear fusion* (the merging of nuclei and/or nucleons) is a very broad and complex subject on its own and covers all physical and technological aspects of fusion between nuclei and/or nucleons regardless of whether it happens on the Earth, in a laboratory, or in distant stellar objects. Those aspects of fusion that are relevant to laboratory experiments are covered in this chapter. The processes going on in stellar objects are considered here if they are also relevant to terrestrial experiments.

At the present stage of controlled nuclear fusion experiments, exclusively light elements (isotopes of hydrogen, helium, boron, and lithium) are considered as possible fuel candidates for a future fusion power station; this chapter, therefore, deals only with fusion reactions between light elements. Moreover, this chapter is devoted only to the basics of physics, the technological aspects of the field being covered by [▶ Chap. 60 of Vol. 5](#).

One should emphasize that in stellar media, fusion between heavier elements is also of primary importance. The reader is advised to consult textbooks on astrophysics.

The basic structure of this chapter is as follows.

After a brief introduction to the nuclear physics of fusion (reaction types, cross sections, reaction rates), it is shown first that sustained nuclear fusion reactions with positive energy balance must also be thermonuclear, i.e., they should take place in a thermal medium. To be precise, the thermal medium where sustained fusion can and should take place is a special medium called *high temperature plasma*.

After an introduction to the elements of plasma physics, the chapter is concluded with the introduction of the most prominent fusion reactions going on in the Sun. After studying those reaction channels, one will be able to better understand the choice of the reactions to be used for terrestrial energy production.

Throughout the chapter, ε_0 denotes the permittivity of vacuum and k_B , the Boltzmann constant, and, of course, the SI system of units is used.

6.2 Basics of Nuclear Physics

As already shown in [Chap. 2](#) of this Volume, the average binding energy of a nucleon in a nucleus as a function of mass number has – for β -stable nuclei – a maximum at around the element iron. Consequently, unification (*fusion*) of two light nuclei can release energy. The energy released in the form of the kinetic energy of the particles in this process is exactly the mass difference between the initial nuclei and the final nucleus. Eventually, other particles (e.g., protons, neutrons, electrons, positrons, etc.) may also be borne in the reaction and thus influence the energy balance of the reaction.

It is obvious that many different reactions are possible between light nuclei. The list below summarizes only those possible combinations that are (or might be) relevant in terrestrial fusion applications. For the reactions that occur in the interior of stars (and so in the Sun), see [Sect. 6.5](#).

The following list summarizes the most prominent fusion reactions between light nuclei and the energies released in the reactions. The percentages represent branching ratios. Note that (as throughout this chapter) the element symbols below refer to bare nuclei without the electron shell – a special notation common in the field of fusion.

1. $D + t \rightarrow {}^4\text{He} + n + 17.6 \text{ MeV}$
2. $D + d \rightarrow T + p + 4.03 \text{ MeV}$ 50%
3. $\rightarrow {}^3\text{He} + n + 3.27 \text{ MeV}$ 50%
4. $D + {}^3\text{He} \rightarrow {}^4\text{He} + p + 18.5 \text{ MeV}$
5. $T + t \rightarrow {}^4\text{He} + 2n + 11.3 \text{ MeV}$
6. ${}^3\text{He} + {}^3\text{He} \rightarrow {}^4\text{He} + 2p + 12.9 \text{ MeV}$
7. ${}^3\text{He} + t \rightarrow {}^4\text{He} + p + n + 12.1 \text{ MeV}$ 51%
8. $\rightarrow {}^4\text{He} + D + 14.3 \text{ MeV}$ 43%
9. $\rightarrow {}^4\text{He} + n + p + 14.3 \text{ MeV}$ 6%
10. $D + {}^6\text{Li} \rightarrow 2 {}^4\text{He} + 22.4 \text{ MeV}$
11. $p + {}^6\text{Li} \rightarrow {}^4\text{He} + {}^3\text{He} + 4.0 \text{ MeV}$
12. ${}^3\text{He} + {}^6\text{Li} \rightarrow 2 {}^4\text{He} + p + 16.9 \text{ MeV}$
13. $p + {}^{11}\text{B} \rightarrow 3 {}^4\text{He} + 8.7 \text{ MeV}$

D refers to deuteron (${}^2\text{H}$) and T to triton (${}^3\text{H}$) in target or residual nucleus position, while d and t are the same, respectively, in projectile or ejectile position.

Without going into the details of the *nuclear interaction*, which governs the interaction of two colliding nuclei, the rather simple, qualitative picture given below is adequate to understand the most important points of the fusion process.

The two colliding nuclei have charges of identical (positive) sign, and so they experience a repelling Coulomb force when the distance between them is larger than some distance r_0 . At distances smaller than this r_0 , the nuclear interaction starts to come into play, and the force between the two nuclei gradually becomes attractive. The exact value of r_0 is dependent on the type of the fusing particles, but is approximately of the order of the nuclear radius, i.e., of a few femtometers.

[Figure 6.1](#) depicts the potential energy between two fusing nuclei as a function of the distance between them. The exact behavior of the potential is unknown near the nucleus but, at larger distances, it is Coulomb-like and decreases as the inverse of the distance. The potential barrier resulting from the two interactions is called the *Coulomb barrier*.

In his celebrated paper, George Gamow (Gamow 1928) had investigated the dynamics of the α -decay of heavy elements. Based on general quantum mechanical considerations, he had

■ Fig. 6.1

The qualitative behavior of the potential energy between two colliding nuclei as a function of the internuclear distance

derived an empirical formula that described the dependence of the decay constant on the energy of the α -particle.

Based on Gamow's investigations and the results of cross-section measurements done in the early 1940s mainly for the four most important reactions, $D(d, n)^3\text{He}$, $D(d, p)\text{T}$, $D(t, n)^4\text{He}$ and $^3\text{He}(d, p)^4\text{He}$, two approximate representations of the fusion cross sections have been proposed and widely used ever since. One of these representations, which is also listed in the NRL Plasma formulary (Huba 2009), was derived by Duane (1972) and the other by Peres (1979). Duane's cross sections pose particular difficulties if they are extrapolated to energies below about 20 keV because of the unphysical parameterization of the penetrabilities that was used. In general, both approximations as well as the corresponding parameterizations for the Maxwellian reactivity $\langle\sigma v\rangle$ (where σ is the cross section and v is the speed) calculated by Hively (1977, 1983) (on the basis of Duane's cross-section formula) and by Peres (1979) need to be improved (Bosch and Halle 1992) mainly for two reasons:

1. While in the past the detection of fusion reaction products was used as a qualitative measure for the success of the thermonuclear fusion experiment, modern fusion experiments use the measured fusion rates as plasma diagnostic tools. If people want to draw reliable conclusions about the plasma parameters from these measurements, detailed knowledge of the fusion cross sections becomes more important than ever.
2. As the experimental devices become larger from one generation to the next, it becomes increasingly more important for the design to predict their behavior reliably. Among other parameters, the fusion rate in these plasmas must be determined accurately. In addition, for reactor design and blanket studies, it is necessary to know the energy dependence of the fusion cross sections with the greatest possible precision.

The proposed improvements, however, did not alter the very basics of how the cross sections are parameterized, and therefore, for the sake of simplicity, the analysis of Peres is followed here.

As said earlier, when a nucleus approaches another one, at large distances they feel each other's Coulomb force, and at short distances they also feel the nuclear force. If the energy of

the collision is not enough to overcome the Coulomb barrier (most collisions are such), quantum mechanical tunneling is the only available channel for fusion. It is thus expected that the nature and energy dependence of fusion cross sections will be influenced by both phenomena: electrostatics and nuclear physics.

Quantum mechanics shows that the fusion reaction probability is also proportional to a geometrical factor $\pi\lambda^2 \propto 1/E$, where λ in this context is the de Broglie wavelength. The strong energy dependence of this factor and the barrier penetrability have prompted the introduction of the astrophysical S -function (Burbidge et al. 1957), defined by writing the cross section as a product of three factors:

$$\sigma(E) = S(E) \frac{1}{E} \exp\left(-\frac{B_G}{\sqrt{E}}\right). \quad (6.1)$$

The motivation for this definition is that the two well-known, strongly energy-dependent factors (which describe the Coulomb and velocity space parts of the incident channel) are separated, leaving the S -function to represent mainly the presumably slowly varying nuclear part of the fusion reaction probability.

This form of the cross section is the extrapolation of the original Gamow formula,

$$\sigma(E) = \frac{A(E)}{E[\exp(B_G/\sqrt{E}) - 1]} \quad (6.2)$$

to low energies, where $A(E) \equiv S(E)$ is a slowly varying function of the center-of-mass energy E and

$$B_G = \pi\alpha Z_1 Z_2 (2m_{\text{cm}} c^2)^{1/2} \quad (6.3)$$

is the *Gamow factor* for nuclei of charges Z_1 and Z_2 and reduced mass m_{cm} , expressed in terms of the fine structure constant $\alpha = e^2/\hbar c$.

The S -functions for the four reactions – $\text{D}(\text{d}, \text{n})^3\text{He}$, $\text{D}(\text{d}, \text{p})\text{T}$, $\text{D}(\text{t}, \text{n})^4\text{He}$, and $^3\text{He}(\text{d}, \text{p})^4\text{He}$ – shown in [Fig. 6.2b](#) demonstrate very clearly the advantages of using the S -functions instead of the cross sections themselves ([Fig. 6.2a](#)):

1. The S -function describes mainly the intrinsic nuclear physics of the reaction and therefore shows clearly the difference between the reactions considered here. The $\text{D} + \text{d}$ reactions do not have resonances close to the threshold, resulting in weak energy dependence, while the other two reactions involve a near-threshold resonance. This is very evident in the S -function, while in the cross section it is masked by the strong energy dependence of the penetrability of the Coulomb barrier.
2. In all cases, the S -functions only vary by a factor of 20 over the whole energy range shown here, rather than by several orders of magnitude as the cross sections do. Therefore, it is much easier to calculate a fit to the experimental data.

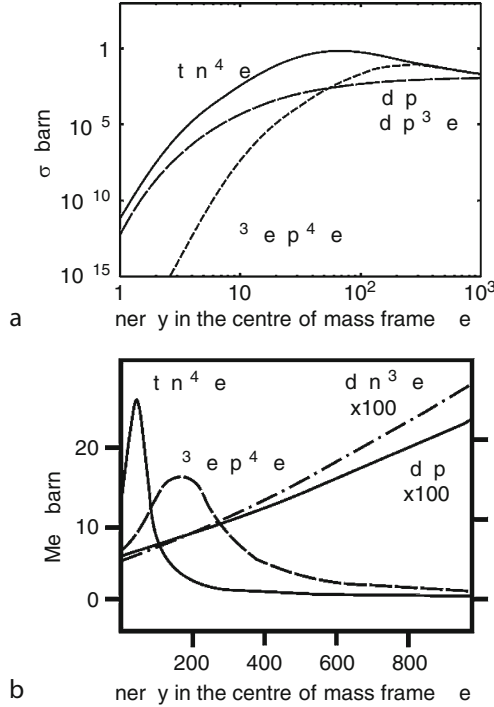

If an analytic fit to the measured cross-section data is available, the reaction rates $\langle\sigma v\rangle$ (Maxwellian averages) can easily be calculated for *weak plasma coupling* approximation as

$$\langle\sigma v\rangle = \text{Const.} \times T^{-\frac{3}{2}} \int_0^\infty E \sigma(E) \exp(-E/k_B T) dE. \quad (6.4)$$

For *strongly coupled plasmas*, an appropriate enhancement factor must be introduced. [Figure 6.3](#) shows, again, for the most important fusion reactions, the energy dependence of the Maxwellian averaged fusion reaction rate.

■ Fig. 6.2

(a) Fusion cross sections for the most important fusion reactions as a function of the center-of-mass energy of the reacting particles. The curves are calculated from the Peres formula (Peres 1979). (b) The S -functions for these reactions as derived from Eq. (6.1). For the $D + d$ reactions, the ordinate values have been multiplied by 100 to improve visibility

6.3 The Cross Section of the Coulomb (Rutherford) Scattering

In nuclear physics, the low-energy collision of two nuclei with positive charges, governed by the Coulomb interaction, is called Rutherford scattering. In this chapter, the identical term *Coulomb scattering* is used, which is more common in plasma physics.

As has already been pointed out in the Introduction, self-sustained fusion reactions with positive energy balance must happen in a thermal medium. This statement can be justified by comparing the effective cross section of individual Coulomb scattering to the fusion cross section.

Due to the long range of the Coulomb interaction, the definition of the collision cross section requires some attention. By solving coupled equations for the conservation of energy and momentum for two colliding particles of identical charge, the deflection angle φ can be obtained as a function of the collision parameter b as follows:

$$\tan \frac{\varphi}{2} = \frac{q_T q_P}{4\pi\epsilon_0 b m v_0^2}. \quad (6.5)$$

Here q_T and q_P are charges of the target and the projectile, m is the reduced mass, and v_0 is the relative velocity in the center-of-mass frame. It is clear that small collision parameters

■ Fig. 6.3

The dependence of the fusion reaction rate on the plasma temperature

correspond to large deflection angles, and large collision parameters to small deflection angles. Collision parameter zero corresponds to *central collision*, and there is a well-defined collision parameter called $b_{\pi/2}$ that corresponds to $\pi/2$ deflection angle. It is a bit arbitrary, but collisions with collision parameters smaller than $b_{\pi/2}$ are called *large-angle collisions*, and collisions with collision parameters larger than $b_{\pi/2}$ are called *small-angle collisions*.

A large angle collision event resulting in 90° deflection can happen not only in a single large-angle collision with $b < b_{\pi/2}$ but also as a consequence of a series of small-angle scattering events. The cross section corresponding to a single large-angle scattering is simply $\sigma_{\text{large}} \approx \pi b_{\pi/2}^2$. It is easy to show (Bellan 2006) that the σ^* cumulative cross section corresponding to the series of small-angle scattering events that result in the same 90° deflection as in a single large-angle event is:

$$\sigma^* = 8 \ln \left(\frac{\lambda_{\text{De}}}{b_{\pi/2}} \right) \sigma_{\text{large}} = 8 \ln(\Lambda) \sigma_{\text{large}}. \quad (6.6)$$

Here λ_{De} is the electron Debye length – a distance at which the diverging integral for the Coulomb cross section must be cut off – and Λ is the plasma parameter. For the physical meaning of the Debye length and an explanation of the plasma parameter, see the next section. In a solid, a liquid, or a gas, the cut-off length for the integral (λ_{De}) is the size of the atom, at which the electron cloud shields the Coulomb potential. In plasmas, this distance can be considerably larger, but as this parameter is included logarithmically, the effect is not dramatically different.

The name of the expression $\ln(\Lambda)$ is *Coulomb logarithm*. Depending on the values of the parameters in Eq. (6.6), the cumulative small-angle cross section can be much larger than the cross section that corresponds to a single large-angle scattering.

The cross section in the center-of-mass frame of the Coulomb scattering (cumulative or large angle) is inversely proportional to the fourth power of the relative velocity of the two colliding particles.

The Coulomb scattering cross section at the energy where the fusion cross section has its maximum is estimated as follows. The maximum cross section of the $D(t, n)^4\text{He}$ reaction (see ► Fig. 6.2) is at around 100 keV and has a value of the order of 1 barn = 10^{-28} m^2 . At 100-keV center-of-mass energies, the large-angle Coulomb scattering cross section (see ► Eq. (6.6)) is around 10 barns. Depending on the value of the Coulomb logarithm – that varies from neutral atoms to plasmas between 10 and 20 – the total Coulomb scattering cross section exceeds the fusion cross section by at least a factor of 1,000.

In principle, if the energy released in a single fusion event were 1,000 times the beam energy, one could make an energy multiplication of the order of unity, even if the Coulomb scattering cross section was so large. However, since the energy released per fusion event is only 100–200 times the beam energy, the beam-target scheme cannot be used for energy production.

There is only one way to overcome this problem. Since it is not possible to increase the released energy per fusion event, the effect of the Coulomb scattering must be mitigated. This happens when the energy distribution of the colliding particles is thermal, in which case collisions do not represent an energy loss. For the energies required for fusion, this means plasma state as the binding energy of electrons on the nuclei is several orders of magnitude lower than the energies required for fusion. In these high-temperature plasmas, Coulomb scattering only redistributes the energy between the particles, and any particle can take part in a fusion event, unlike in a beam-target experiment, where only beam particles have enough energy to react with the target particles.

Before proceeding further, some elements of plasma physics must be introduced along with a few figures of merit that describe a high-temperature ensemble of charged particles (plasma). Readers interested in more details than given below may refer to textbooks on the subject (Bellan 2006; Freidberg 2007; Fitzpatrick 2008).

6.4 The Elements of Plasma Physics

Plasma is an ensemble of charged (and possibly neutral) particles. For a medium to qualify to be plasma, it is of crucial importance that the coupled interactions of its charged constituents dominate the behavior of the whole system. In plasmas, the particles move freely around, in a sense that their motion is only influenced by electromagnetic fields – both external and generated by the plasma particles themselves – and the species are not bound to any special place in the space, unlike the atoms in a solid lattice or the electrons bound to a molecule. This is because the temperature of plasmas is sufficiently high, so that the thermal motion of the particles is so intense that atoms can leave their fixed positions and electrons can be stripped off (fully or partly) from the atoms.

In *fully ionized plasmas*, there are only electrons and ions, but not all the electrons are necessarily stripped off the atoms – ions of different states of ionization may be present in the plasma at the same time. In *partially ionized plasmas* electrons, ions, and neutral atoms coexist. In this chapter, the different particles (atoms, electrons, and ions of different types and charges) are denoted by σ .

Plasmas are macroscopically neutral, and since the particles are free to move in the plasma, any excess charge is screened at some spatial distance via the modification of charge densities. This eventually means that the vacuum Coulomb potential of charged particles is modified,

namely the fall-off of the potential changes from $\sim 1/r$ in a vacuum to $\sim (1/r) \times \exp(-r/\lambda_D)$, where

$$\lambda_D = \left(\sum_{\sigma} \frac{1}{\lambda_{\sigma}^2} \right)^{-1/2} \quad (6.7)$$

is the so-called *Debye length*, which is a function of the individual Debye lengths of particles σ :

$$\lambda_{\sigma} = \left(\frac{\epsilon_0 k_B T_{\sigma}}{n_{\sigma} q_{\sigma}^2} \right)^{1/2}. \quad (6.8)$$

Here, n_{σ} is the number density (number of particles per unit volume), T_{σ} is the temperature, and q_{σ} is the charge of species σ . The decrease with the distance of the actual potential in plasmas is much faster than in a vacuum, such that

$$\varphi(\mathbf{r}) = \frac{q_T}{4\pi\epsilon_0 r} \exp(-r/\lambda_D). \quad (6.9)$$

Here, q_T is the charge of a test particle, and r is the distance measured from it. This expression essentially means that outside the distance given by the Debye length (i.e., outside the *Debye sphere*), any excess electric charge is completely screened, and internal as well as external electrostatic fields must vanish. Although hidden in the derivation of the Debye length, it is still very important that the test particles are much slower than the plasma particles, and so even the heaviest and slowest plasma particles have enough time to contribute to the screening.

The Debye length is one of the most important figures of merit that characterizes plasmas.

Another important quantity is the *plasma parameter*. This parameter virtually quantifies the intensity of electrostatic interaction between the plasma particles relative to their kinetic energy.

The average distance between the particles of type σ is defined as:

$$r_D \equiv n_{\sigma}^{-1/3}. \quad (6.10)$$

The distance of closest approach between two particles of the same kind can be obtained as:

$$r_C \equiv \frac{q_{\sigma}^2}{2\pi\epsilon_0 k_B T_{\sigma}}. \quad (6.11)$$

This relationship is derived from the fact that, at the distance of the closest approach, all energy of the two-particle system is potential energy.

The ratio r_C/r_D plays a crucial role in the description of plasmas. When this ratio is small, charged particles are dominated by one another's electrostatic influence more or less continuously, because many particles are inside the virtual sphere available for a particle, and their kinetic energies are small compared to the interaction potential energies. Such plasmas are termed *strongly coupled*. On the other hand, when this ratio is large, strong electrostatic interactions between individual particles are occasional and relatively rare events. A typical particle is electrostatically influenced by all of the other particles within its Debye sphere, but this interaction very rarely causes any sudden change in its motion. Such plasmas are termed *weakly coupled*.

Based on the concepts of these two special distances for the electrons (r_C and r_D), the following definition of the plasma parameter is straightforward:

$$\Lambda = 4\pi n_e \lambda_e^3. \quad (6.12)$$

Here, n_e and λ_e refer to the electron number density and electron Debye length, respectively. The meaning of the plasma parameter is clear: if it is large, then the Debye sphere is heavily populated (this is the case of the weakly coupled plasma), whereas if it is small, then the Debye sphere is only sparsely populated and the plasma is strongly coupled. Some authors define the plasma parameter as 1/3 of the value in [Eq. \(6.12\)](#). In this case, the plasma parameter is exactly the number of particles inside the Debye sphere, whereas in the definition given by [Eq. \(6.12\)](#), it is only proportional to it. The plasma parameter is defined for the electrons only. One could, in principle, define a plasma parameter for the ions also, but that is not common.

After recasting [Eq. \(6.12\)](#) one obtains:

$$A = \frac{1}{\sqrt{4\pi}} \left(\frac{r_D}{r_C} \right)^{3/2} = \frac{\sqrt{2\pi}\epsilon_0^{3/2} (k_B T_e)^{3/2}}{q_e^3 n_e^{1/2}}. \quad (6.13)$$

It can be inferred from [Eq. \(6.13\)](#) that strongly coupled plasmas tend to be cold and dense, whereas weakly coupled plasmas are diffuse and hot. Examples of strongly coupled plasmas include solid-density laser ablation plasmas, the very “cold” (i.e., with kinetic temperatures similar to the ionization energy) plasmas found in “high pressure” arc discharges, and the plasmas which constitute the atmospheres of collapsed objects such as white dwarfs and neutron stars. On the other hand, the hot diffuse plasmas – typically encountered in ionospheric physics, astrophysics, nuclear fusion, and space plasma physics – are invariably weakly coupled.

Another expression that shows the meaning of the plasma parameter very clearly is:

$$\frac{k_B T}{E_{\text{Coulomb}}} = 4\pi (n_\sigma \lambda_D^3)^{2/3}. \quad (6.14)$$

In strongly coupled plasmas (small $n_\sigma \lambda_D^3$), the Coulomb energy dominates, whereas in weakly coupled plasmas (large $n_\sigma \lambda_D^3$), the kinetic energy of the particles dominates.

A subtle but important point in the above introduction of the plasma parameter is that its expression with the Debye radius is only valid as long as the Debye radius has a meaning at all. The above introduction of the Debye radius is valid if the number of particles inside the Debye sphere is “statistically significant,” and this number does not fluctuate “too much.” If there are very few particles inside the Debye sphere, and so the plasma is very strongly coupled, the above formulas must be modified. Very strongly coupled plasmas, however, are outside the scope of this chapter.

As an illustration, [Table 6.1](#) lists the key parameters for some typical plasmas, both terrestrial and celestial. The temperatures in the table, as customary in plasma physics, are expressed in electron volts using the correspondence $E = k_B T$.

In the rest of this section, some further elements of plasma physics are introduced, which are not directly necessary to follow the content of this chapter, but essential for the understanding of a later one ([Chap. 60 of Vol. 5](#)).

The *plasma frequency* is a figure of merit of plasmas worth mentioning:

$$\omega_p = \left(\sum_{\sigma} \omega_{p\sigma}^2 \right)^{1/2}. \quad (6.15)$$

As in the case of the Debye length, the plasma frequency ω_p is a function of plasma frequencies $\omega_{p\sigma}$ of individual particles of type σ .

$$\omega_{p\sigma} = \left(\frac{n_\sigma q_\sigma^2}{\epsilon_0 m_\sigma} \right)^{1/2}. \quad (6.16)$$

The plasma frequency arises from the fact that in plasmas, the densities of different charged particle fluids are coupled through emerging electrostatic forces. When charge neutrality is locally broken, a restoring force appears and an oscillation in particle densities arises with the plasma frequency. The electron plasma frequency ω_{pe} is the frequency of electron oscillations in a zero-temperature homogeneous plasma. In homogeneous nonmagnetized plasma, this oscillatory motion is capable of screening electric fields; therefore, electromagnetic waves (light) cannot propagate below the plasma frequency.

In controlled fusion experiments, as well as in astrophysics, magnetized plasmas play a very important role. Plasmas are said to be magnetized if the plasma is “immersed” into an equilibrium external magnetic field.

Charged particles move quite differently in a magnetized plasma than in a not magnetized medium. This is because they can only move freely along the field lines of the magnetic field. In the perpendicular direction, they gyrate around the field lines and no net perpendicular motion is present in zero order. Their motion can be described as follows.

The Lorentz equation for the movement of a particle of charge q and mass m in an electric field of strength \mathbf{E} and magnetic field of flux density \mathbf{B} is

$$m\dot{\mathbf{v}} = q(\mathbf{E} + \mathbf{v} \times \mathbf{B}). \quad (6.17)$$

If there is no electric field and the magnetic field is homogeneous, then the particle's gyration frequency around the magnetic field lines is $q|\mathbf{B}|/m$ along the perimeter of a circle with radius $m v_\perp / q|\mathbf{B}|$. Here, v_\perp is the component of the velocity perpendicular to the magnetic

■ Table 6.1

Some key plasma parameters for typical laboratory and celestial plasmas. Numbers are correct to only orders of magnitude

	Number density (m^{-3})	Temperature (eV)	λ_D (m)	Λ	Spatial size (m)
Solar corona	10^{15}	10^2	10^{-3}	10^7	10^8
Solar wind	10^7	10	10	10^9	10^8
Sun's core	10^{32}	10^3	10^{-11}	10	10^5
Earth's ionosphere	10^{11}	10^{-1}	10^{-2}	10^4	10^5
Magnetic fusion	10^{20}	10^4	10^{-4}	10^9	10
Inertial fusion	10^{31}	10^4	10^{-10}	10^2	10^{-5}
Dense laboratory plasma	10^{20}	1	10^{-6}	10^3	10^{-1}
Dilute laboratory plasma	10^{16}	1	10^{-4}	10^5	10^{-1}

field. The gyration frequency (gyrofrequency or *cyclotron frequency*) and the gyration radius (*Larmor radius*) are the two most important parameters that characterize magnetized plasmas.

If there is an electric field and/or the magnetic field is not quite homogeneous (however, the scale length of the inhomogeneity cannot be shorter than the Larmor radius), then there is a slow drift motion of the center of the Larmor circle in the direction perpendicular to both the direction of the inhomogeneity and the magnetic field. The value of this drift velocity is:

$$\mathbf{v}_{\text{drift}} = \frac{\mathbf{E} \times \mathbf{B}}{B^2} - \frac{mv_{\perp}^2}{2qB^3} \nabla |\mathbf{B}| \times \mathbf{B} + \frac{mv_{\parallel}^2}{qB^2} \boldsymbol{\kappa} \times \mathbf{B}, \quad (6.18)$$

where the first term is due to the electric field (**EcrosB drift**), the second term is due to the change in the magnitude of the magnetic field (**gradB drift**), and the third term is due to the curvature $\boldsymbol{\kappa}$ of the magnetic field (*curvature drift*).

To describe a plasma via the calculation of the paths of individual particles by solving the Lorentz equation would be not only computationally impossible, but also inadequate, as plasmas are *collective* ensembles of charged particles and one needs a set of equations that is capable of describing this collective character. One such set of equations is the equations of *magnetohydrodynamics (MHD)*. The three most important equations of MHD are the continuity equation, describing the advection of the mass density ρ with velocity \mathbf{U}

$$\frac{\partial}{\partial t} \rho + \nabla \cdot (\rho \mathbf{U}) = 0, \quad (6.19)$$

the equation of motion describing the advection of the momentum density $\rho \mathbf{U}$

$$\rho \left(\frac{\partial}{\partial t} \mathbf{U} + \mathbf{U} \cdot \nabla \mathbf{U} \right) = \mathbf{J} \times \mathbf{B} - \nabla P, \quad (6.20)$$

and the equation of state describing the advection of the pressure P

$$\frac{\partial}{\partial t} P + \mathbf{U} \cdot \nabla P = -\gamma P \nabla \cdot \mathbf{U}. \quad (6.21)$$

Here, γ is the adiabatic constant (the ratio of the specific heats) and \mathbf{J} is the electric current density flowing through the plasma.

After this small bypass into plasma physics, the journey can be continued toward the Sun.

6.5 Nuclear Reactions and Reaction Rates in the Sun

The conditions in the interior of the stars are quite different from those that scientists want to create inside a controlled fusion experiment on the Earth. In this section, only processes occurring in the core of lower branch main-sequence stars (like the Sun) will be dealt with. Stars of the upper branch of the main sequence are out of the scope of this article, not to mention Giants of different size and Dwarfs of different color.

When comparing a star with a terrestrial device of any kind, the most striking difference is in their size: stars are many million times more massive than anything humans can build. Consequently, gravity is the main force that confines the plasma inside a star.

The second very important difference is that stars must continuously produce energy for some billion years, whereas in a power plant steady state energy production is foreseen only for

days or maybe months. This comment is important because the cross sections of the reactions introduced in ▶ Sect. 6.2, although not as large as desired, are far too large to sustain the energy production in the stars. A star would simply burn out in some million years if it used a D–T mixture.

Stars of mass comparable to that of the Sun burn their fuel during most of their lives in two ways. One way involves the simplest hydrogen isotope, the proton, and the sequence of reactions is called the *proton–proton (p–p) chain* or *proton–proton cycle*. The other way uses ^{12}C isotopes as “catalysts” and is called the *carbon–nitrogen–oxygen (CNO) cycle*. Both reaction cycles are advantageous, because they involve a beta-decay event, and so the fusion rate is low enough for the fusion fuel to last for billions of years. The end product of both the proton–proton and the CNO cycle is ^4He because, compared to its neighbors in the chart of nuclides, ^4He is the most deeply bound.

In the case of the Sun, around 98% of the power comes from the p–p chain and only the remaining 2% from the CNO cycle.

▶ Figure 6.4 shows a block diagram of the complete p–p chain. As can be seen, there are several branches of the chain, with the most probable chain on the left-hand side.

▶ Table 6.2 shows the main reactions of the CNO cycle. Note the reactions that involve beta decay (those that involve an electron or a positron).

■ Fig. 6.4

The complete proton–proton chain with all its branches. This chain is the main source of energy in the stars of mass comparable to that of the Sun

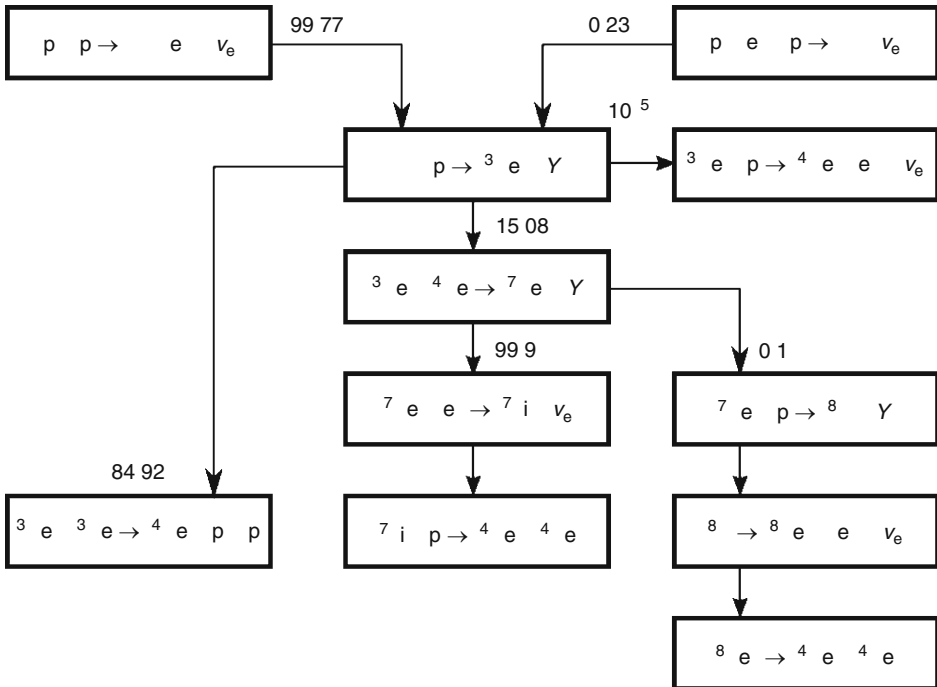

Table 6.2

Main reactions of the CNO cycle

^{12}C	+	p	\rightarrow	^{13}N	+	γ			+	1.95 MeV
^{13}N			\rightarrow	^{13}C	+	e^+	+	ν_{e}	+	2.22 MeV
^{13}C	+	p	\rightarrow	^{14}N	+	γ			+	7.54 MeV
^{14}N	+	p	\rightarrow	^{15}O	+	γ			+	7.35 MeV
^{15}O			\rightarrow	^{15}N	+	e^+	+	ν_{e}	+	2.75 MeV
^{15}N	+	p	\rightarrow	^{12}C	+	^4He			+	4.96 MeV

None of these reaction chains is suitable for terrestrial applications, because the reactions rates are so small that the maximum power that can be extracted from the plasma even in an optimum situation is only a few hundred milliwatts.

Abstract: At present there are over 3,000 known nuclides (see the [Appendix in Vol. 2](#) on the “Table of the Nuclides”), 265 of which are stable, while the rest, i.e., more than 90% of them, are radioactive. The chemical applications of the specific isotopes of chemical elements are mostly connected with the latter group, including quite a number of metastable nuclear isomers, making the kinetics of radioactive decay an important chapter of nuclear chemistry. After giving a phenomenological and then a statistical interpretation of the exponential law, the various combinations of individual decay processes as well as the cases of equilibrium and nonequilibrium will be discussed. Half-life systematics of the different decay modes detailed in [Chaps. 2](#) and [4](#) of this volume are also summarized.

7.1 The Exponential Law of Decay

7.1.1 Phenomenological Approach

The most fundamental quantity of radioactive decay is the activity A , meaning the number of atoms decaying in the specimen per time.

Historical units of activity. The formerly used unit of radioactivity – the curie (Ci) – was introduced in 1930. One curie was originally defined as the disintegration rate of 1 gram of pure ^{226}Ra . Radium was chosen as a reference because of its then importance among radioactive elements. However, it was rather disturbing that the value of the unit had to be changed from time to time as more accurate data were obtained for the decay of radium. Finally, the value of curie was fixed arbitrarily at 3.7×10^{10} disintegrations per second (1950). (During the 1930s, another unit: 10^6 disintegrations per second – called rutherford – was also suggested but it has never become widely known.)

SI unit of activity. Since 1975, the internationally recommended unit is the becquerel (Bq) defined as 1 disintegration per second (1 dps), but workers in nuclear and radiochemistry, especially those handling high activities, still stick to the old unit curie. Some authors prefer the notation “dps” to Bq and the acronym “dpm” (meaning decays per minute) also occurs as a unit of activity.

Intensive quantities related to the activity. In most samples, the radionuclides are not carrier free but inactive isotopes “carry” them and/or an inactive substance called matrix contains them. (The term no-carrier-added or n.c.a. only means that the production process of a radionuclide sample does not involve adding carrier to it. However, it may not be carrier free.) The specific activity of a radioactive sample is defined as the (absolute) activity of the radioactive sample divided by its mass (unit: Bq/kg). Similar quantities are the molar activity (unit: Bq/mol) and the activity concentration (unit: Bq/dm³), defined as the activity of the sample divided by its molar amount and volume, respectively.

Note that the term ‘specific activity’ is also used in the sense of the activity caused by a radioisotope of an element in a sample per the total mass of the element (or a compound of it) contained by the sample. Some authors use the term “specific radioactivity” in the sense of molar activity, although according to International Union of Pure and Applied Physics (IUPAP) and International Union of Pure and Applied Chemistry (IUPAC) recommendations the adjective “specific” should be reserved for naming quantities that are divided by mass. So the use of the term in the latter sense should be avoided.

Basic equations of activity. The activity A , being the measure of disintegration rate, is related to the number of radioactive atoms N through the following expression:

$$A = -\frac{\Delta N}{\Delta t} \approx -\frac{dN}{dt}, \quad (7.1)$$

where Δt is the observation period and $|\Delta N|$ is the number of atoms that have decayed during Δt .

It has been shown in the above equation that if Δt as well as $|\Delta N|/N$ are small enough – if a large number of atoms is observed in a short time interval – then $N(t)$ can be considered as a “smooth” enough function for which the ratio $\Delta N/\Delta t$ can be replaced by the derivative dN/dt .

Radioactive decay usually produces radiation particles (α , β) or photons (γ) that can be detected with some probability. Under favorable conditions, the observed activity A' thus determined will be proportional to the actual activity (also called absolute activity) A :

$$A' = \eta A, \quad (7.2)$$

where η (≤ 1) is the efficiency of detection.

It is also an empirical fact that if there are a larger number of atoms (e.g., if a large sample is prepared from the same homogeneous radioactive material), then the activity will be proportionally larger. Therefore, for a given type of radionuclide it can be written

$$A = \lambda N, \quad (7.3)$$

where the factor λ (dimension: 1/time; unit: s^{-1}) is called the decay constant.

Note that according to [Eq. \(7.3\)](#) the quantity of a radionuclide can be specified by its activity. (This is the “theoretical” background of the common practice that radioactive sources are sold/bought by the megabecquerel or millicurie.)

Determination of the decay constant. The above equation, combined with [Eq. \(7.2\)](#), also serves as a basis for the determination of the decay constant of long-lived radionuclides having very long half-lives (see [Eq. \(7.17\)](#)), which means that neither their activity nor their number is expected to change appreciably within a reasonable period of time that can be spent for their observation:

$$\lambda = \frac{A}{N} = \frac{A'}{\eta N}. \quad (7.4)$$

Comparing [Eqs. \(7.1\)](#) and [Eq. \(7.3\)](#) one gets

$$\frac{dN}{dt} = -\lambda N, \quad (7.5)$$

which is essentially the same differential equation that is characteristic of first-order reactions in chemistry with λ playing the role of the rate constant.

The solution of [Eq. \(7.5\)](#) yields the formula generally referred to as the exponential law of radioactive decay:

$$N = N(0)e^{-\lambda t}, \quad (7.6)$$

where $N(0)$ is the number of radioactive atoms present at $t = 0$.

Multiplying [Eq. \(7.6\)](#) by λ and then by η , and comparing the results with [Eqs. \(7.3\)](#) and [Eq. \(7.2\)](#) one finds that the same type of exponential law holds for the activities as well:

$$A = A(0)e^{-\lambda t}, \quad (7.7)$$

$$A' = A'(0)e^{-\lambda t}. \quad (7.8)$$

Note that [Eq. \(7.8\)](#) is especially useful for the determination of the decay constant of radionuclides with medium half-lives, i.e., whenever it is possible to “sit out” the change of activity, because observed activities are a lot easier to measure than either (absolute) activities or numbers of atoms (of specific nuclides). The latter is unavoidable, e.g., in the case of long-lived radionuclides when the determination of λ can only be done by using [Eq. \(7.4\)](#).

In the case of extremely short half-lives, the starting point of decay-constant determination is still something like [Eq. \(7.8\)](#), but special tricks/equipment (coincidence circuit, time-to-amplitude converter, multichannel analyzer) as well as special conditions (available start and stop signals informing of the “birth” and “death,” respectively, of individual nuclei/particles) are also needed. The waiting-time distribution shown in [Fig. 9.13 of Chap. 9 in Vol. 1](#) has also been obtained with such an apparatus, which is the standard equipment of Positron Annihilation Spectroscopy (PAS) measurements (see [Chap. 27 in Vol. 3](#)).

In olden times the lifetime distribution of short-lived nuclides was measured without a multichannel analyzer using the method of delayed coincidences. In this case, the start signals were delayed and the coincidence rate was plotted against the time of delay. The resulted graph showed the characteristic features of the exponential law, from which the decay constant could be determined by calculating the slope of the semilogarithmic (semilog) plot.

In the case of man-made chemical elements (e.g., transactinides) a different type of problem arises, namely, the number of decays that can be observed is just not enough to measure out the exponential law because only a couple of like atoms are produced at a time. The determination of the decay constant – or, more directly, that of the mean-life (see [Eq. \(7.18\)](#)) – in such a case can be performed by the method explained in [Sect. 19.3.4 of Chap. 19, Vol. 2](#). Some statistical background to this type of analysis is given in remark (#33), [Sect. 9.3.4, Chap. 9](#) in this volume.

There is another problem with man-made chemical elements, namely that their isotopes are short lived too. This, together with the need for their identification, calls for fast separation methods. The Automated Rapid Chemistry Apparatus (ARCA) II system and the Short-lived Isotopes Studied by the AKUFVE-technique (SISAK) equipment (both described in [Sect. 59.2.2 of Chap. 59, Vol. 6](#), on “Solvent Extraction and Ion Exchange in Radiochemistry”) are able to handle radionuclides with half-lives of ~ 10 s and ~ 1 s, respectively.

7.1.2 Stochastic Approach

The connection between the exponential law and some of the special distributions – binomial, Poisson, and exponential – will be detailed later in [Chap. 9](#), “Stochastics and Nuclear Measurements.” However, a simple illustration of the stochastic features will also be given here.¹

Consider a single radioactive atom of some kind. Let p denote the probability that it will disintegrate within a certain observation period Δt . Suppose that the atom is ageless in the sense that p is independent of how long it had existed before its observation was started. It stands to reason that the chance of decay increases with the length of the observation period. Moreover, it also seems reasonable to assume that for short enough Δt there is a proportionality

$$p = \lambda \Delta t, \quad (7.9)$$

where the proportionality constant λ only depends on the type of the atom (or, more specifically, on its readiness to decay).

The complementary event means that the atom is still intact after the period Δt . The probability of this is

$$P(\Delta t) = 1 - p = 1 - \lambda \Delta t. \quad (7.10)$$

Suppose that the atom has indeed survived the first Δt period of observation. Then the probability of its being “alive” even after the next Δt period is again $1 - p = 1 - \lambda \Delta t$.

According to probability theory, for the total observation time $2\Delta t$ one can write

$$P(2\Delta t) = (1 - \lambda \Delta t)^2. \quad (7.11)$$

Thus the probability that the atom will survive a period of $n\Delta t$ is

$$P(n\Delta t) = (1 - \lambda \Delta t)^n \quad (7.12)$$

which, with the notation $n\Delta t = t$, can be rewritten as

$$P(t) = \left(1 - \lambda \frac{t}{n}\right)^n. \quad (7.13)$$

For $n \rightarrow \infty$ (i.e., when the division of t to single periods of observation is infinitely fine) one can get the following expression for the probability that the atom does not decay in an arbitrarily long period t :

$$P(t) = e^{-\lambda t}. \quad (7.14)$$

For a large number of identical atoms, the exponential factor in [Eq. \(7.14\)](#) represents the fraction of survivors $N(t)/N(0)$ as a function of the time t . Thus the initial number of atoms $N(0)$ is expected to drop to $N(t)$ according to the following formula:

$$N(t) = N(0)e^{-\lambda t}. \quad (7.15)$$

Note that what has been just “derived” is the exponential law of decay (see [Eq. \(7.6\)](#)) justifying the notation λ (reserved for the decay constant throughout this chapter) for the proportionality constant in [Eq. \(7.9\)](#).

Using [Eq. \(7.15\)](#), one can introduce a more expressive quantity than the decay constant for the description of the “decayability” of radionuclides. The half-life $T_{1/2}$ is the time in which half of the atoms are expected to decay:

$$N(T_{1/2}) = N(0)e^{-\lambda T_{1/2}} = \frac{N(0)}{2}, \quad (7.16)$$

where

$$T_{1/2} = \frac{\ln 2}{\lambda} \approx \frac{0.693}{\lambda}. \quad (7.17)$$

Another characteristic time parameter of radioactive decay is the mean life τ , which is the expected value of the γ ($1, \lambda$) exponential distribution associated with radioactive decay (see [Chap. 9](#) in this Volume):

$$\tau = \int_0^{\infty} t f(t) dt = \lambda \int_0^{\infty} t e^{-\lambda t} dt = \frac{1}{\lambda}, \quad (7.18)$$

where $f(t) = \lambda e^{-\lambda t}$ is the density function of the lifetime distribution.

Comparing this result with [Eq. \(7.17\)](#), one can see that the mean life is proportional to the half-life:

$$\tau = \frac{T_{1/2}}{\ln 2} \approx 1.44 T_{1/2}. \quad (7.19)$$

It is common knowledge that τ is the time necessary for the atoms to be reduced to 1/e of their initial number

$$N(\tau) = N(0)e^{-\lambda\tau} = \frac{N(0)}{e} \approx 0.37N(0). \quad (7.20)$$

► Equation (7.20) shows that the drop in the number of survivors is larger than in the case of the half-life. The reason is obvious: according to ► Eq. (7.19), $\tau > T_{1/2}$.

Note that the “1/e rule” expressed by ► Eq. (7.20) is not a general criterion for mean times: it is a specific feature of the exponential distribution associated with the exponential law of simple decays. (See also the comment after ► Eq. (7.44).)

7.2 Independent Decays: Radionuclide Mixtures

If it turns out that the logarithmic plot of activity versus time is not a straight line, then this is an indication that the sample contains more than one radionuclide. The radionuclides thus detected may be genetically related to each other (i.e., one is produced by the other through radioactive transformation), or they can be independent of each other, forming a simple mixture (see ► Fig. 7.1). In this section the latter case will only be discussed.

In order to determine the individual decay constants of the mixture, count rates (i.e., observed activities) are to be measured as a function of time, provided that the half-lives are moderately long and comparable with each other. The number of measured points should be at least twice the number of radioactive components plus one (or, preferably, a lot more).

The analysis of the “nuclear spectrum” thus obtained (see ► Chap. 9 in this Volume) is based on the fact that the observed activities are additive and also that they are subject to the exponential law expressed by ► Eq. (7.8). Hence, for n radioactive components one can write

$$A'(t) = \sum_{i=1}^n A'_i(t) + b = \sum_{i=1}^n A'_i(0)e^{-\lambda_i t} + b \quad (7.21)$$

where $A'(t)$ is the observed activity of the mixture at time t , $A'_i(0)$ is the observed activity of the i th component at $t = 0$ and b is the background. The parameters ($2n + 1$ altogether), including the decay constants, can then be estimated by a least-square fit (see ► Chap. 9 in this Volume).

7.3 Branching Decays

Some radionuclides can disintegrate in two or more competing ways leading to different products. In the case of odd–odd nuclei, e.g., sitting nearest to the apex of one of the mass parabolas, negative β decay and electron capture (and in energetically favorable cases: positive β decay) are equally possible. For instance, the nucleus of ^{40}K , a nuclide used in radioactive dating (see ► Sects. 17.2, 17.15, and 17.16 in Chap. 17 of Vol. 2), can undergo both electron capture and β^- decay (see ► Fig. 7.2 and ref. Vértés et al. (1998) for more detail)

■ Fig. 7.1

Schematic representation of the logarithm of activity for a source containing the mixture of two radionuclides. Note that nuclide 1, due to its longer mean life, will survive nuclide 2, although its initial activity at $t = 0$ is much lower (10% of the total). This fact used to be the basis of the graphical decomposition of the decay curves of mixtures in the “pre-PC” age of nuclear science. The idea for obtaining the $A_2(t)$ values (red line) from the thick (black) curve of the experimental $A(t)$ values was to subtract the values of $A_1(t)$ extrapolated back along the blue line representing the asymptote of the thick line for $t \rightarrow \infty$

In the case of the decay series shown by ► Figs. 7.4–7.7, another type of branching decay occurs: α decay competes with β^- decay. For instance, ^{227}Ac , the eponymous member of the actinium ($4n + 3$) series (see ► Fig. 7.7), undergoes the following disintegration:

The additive property of the partial decay constants indicated above follows from the same property of the respective partial decay rates. In the case of ^{40}K , e.g., one can write

$$-\frac{dN_K}{dt} = \frac{dN_{\text{Ar}}}{dt} + \frac{dN_{\text{Ca}}}{dt} = \lambda_{\text{EC}}N_K + \lambda_\beta N_K = (\lambda_{\text{EC}} + \lambda_\beta)N_K = \lambda N_K. \quad (7.24)$$

Hence the half-life of ^{40}K according to ► Eq. (7.17) is

$$T_{1/2} = \frac{\ln 2}{\lambda} = \frac{\ln 2}{\lambda_{\text{EC}} + \lambda_\beta}. \quad (7.25)$$

According to ► Eqs. (7.24) and ► (7.6) the growth rates of ^{40}Ar and ^{40}Ca are

■ Fig. 7.2

Mass parabolas explaining the branching decay of ^{40}K . This type of branching is always associated with odd-odd nuclei. The parabolic dependence of the nuclear mass on the atomic number Z comes from a similar (but negative) dependence of the binding energy as expressed by the Weizsäcker formula (2.3) in Chap. 2. (The odd-odd parabola and the even-even one are shifted relative to each other by $2\delta/A^{3/4}$ according to the Weizsäcker formula. Note that in the case of odd- A isobars there is only one mass parabola (and therefore one minimum, see Fig. 14.5 in Chap. 14, Vol. 2) because the pairing energy term of the Weizsäcker formula is the same (zero) for even-odd and odd-even nuclei.) The mass access data used for the figure are taken from Sect. 11.6 of the Appendix of this Volume. Note that $^{40}_{20}\text{Ca}_{20}$ is a doubly magic nuclide, which explains why it has a lower mass (higher stability) than expected from the general trend expressed by the lower (blue) parabola

$$\frac{dN_{\text{Ar}}}{dt} = \lambda_{\text{EC}} N_{\text{K}} = \lambda_{\text{EC}} N_{\text{K}}(0) e^{-\lambda t}, \quad (7.26)$$

$$\frac{dN_{\text{Ca}}}{dt} = \lambda_{\beta} N_{\text{K}} = \lambda_{\beta} N_{\text{K}}(0) e^{-\lambda t}. \quad (7.27)$$

The numbers of the respective nuclides that are present at time t can be calculated by integration. Assuming that at $t = 0$ neither ^{40}Ar , nor ^{40}Ca was present, then

$$N_{\text{Ar}} = \lambda_{\text{EC}} \frac{N_{\text{K}}(0)(1 - e^{-\lambda t})}{\lambda}, \quad (7.28)$$

$$N_{\text{Ca}} = \lambda_{\beta} \frac{N_{\text{K}}(0)(1 - e^{-\lambda t})}{\lambda}. \quad (7.29)$$

Thus, it turns out that the atomic ratio of ^{40}Ar to ^{40}Ca is equal to the ratio of the partial decay constants called branching ratio at any moment:

$$\frac{N_{\text{Ar}}}{N_{\text{Ca}}} = \frac{\lambda_{\text{EC}}}{\lambda_{\beta}}. \quad (7.30)$$

(The schematic representation of such decay is shown by [Fig. 7.3](#).)

Therefore, the atomic fraction of either product is indicative of the contribution of the respective partial decay constant to the total λ . For instance, in the case of ^{40}Ar produced by electron capture (EC) one obtains

$$x_{\text{Ar}} = \frac{N_{\text{Ar}}}{N_{\text{Ar}} + N_{\text{Ca}}} = \frac{\lambda_{\text{EC}}}{\lambda_{\text{EC}} + \lambda_{\beta}} = \frac{\lambda_{\text{EC}}}{\lambda}. \quad (7.31)$$

Hence, for the products of several parallel decays the following equation holds:

$$\lambda_i = x_i \sum_{k=1}^n \lambda_k = x_i \lambda. \quad (7.32)$$

Fig. 7.3

Schematic representation of branching decay for $\lambda_1/\lambda_2 = 3$. The arrows shown between the curves of the daughters have the same length as the one displayed at the vertical axis between 1 and 3. The constant separation – considering that the vertical scale is logarithmic – means that the upper curve, representing daughter 1, is a scaled-up version of the lower curve. The value of the scaling factor (3) is determined by the ratio λ_1/λ_2 (See [Eq. \(7.30\)](#))

7.4 Successive Processes

7.4.1 General Kinetics of Decay Chains

It often happens that the decay product itself is also radioactive. Thus, a whole chain of radioactive transformations may evolve, forming a radioactive decay series (see ▶ Figs. 7.4–7.7).

Most of the naturally occurring radionuclides belong to one of three series shown in ▶ Figs. 7.4, ▶ 7.6, and ▶ 7.7 where the symbols of the elements that are represented in the given series are put in boxes. (See also ▶ Chap. 13 in Vol. 2 on “Natural Radioactive Decay

■ Fig. 7.4

The thorium ($4n + 0$) series is one of the four decay series, out of which three (including this one) are naturally occurring, while one (the $4n + 1$ series) is extinct on Earth. The numbering – $4n + 0$, $4n + 1$, $4n + 2$, and $4n + 3$ – refer to the residue class (modulo 4) of the possible mass numbers in each series. The explanation for the notation is that these series (see also ▶ Figs. 7.5–7.7 showing the same range of Z and A for better comparison) only include α decay (slanting arrows) and β decay (horizontal arrows), so the change of the mass number is either 4 or 0. Therefore, the members of the whole series belong to the same residue class (modulo 4) as their primary parent. (There are also some very weak branches of decay indicated in parentheses like spontaneous fission (SF) and different types of cluster decay when a C, O or even a Ne nucleus is emitted instead of an α particle.) Each of the four series represents an example for secular equilibrium due to the very long half-life of the primary parent of the series in comparison with any of the members. For instance, the half-life of ^{232}Th is $T_{1/2} = 1.405 \times 10^{10} \text{ a}$ – a value close to the estimated age of the Universe – while that of the longest-lived daughter, ^{228}Ra , is only $T_{1/2} = 5.75 \text{ a}$

■ Fig. 7.5

The neptunium ($4n + 1$) series is now extinct on Earth. This is due to the relatively short half-life of the primary parent ^{237}Np ($T_{1/2} = 2.14 \times 10^6$ a, which is less than the age of the human race). The nearly 2,136 half-lives, that have elapsed since the creation of our planet (about 4.57×10^9 years ago), have practically wiped out this process because only 1 out of 10^{643} neptunium-237 atoms is expected to survive. Now, the odds of survival are really bad, considering that 10^{643} Np atoms would “weigh” about 3×10^{618} kg, whereas the mass of the Sun is a mere 2×10^{30} kg, and even that of the Milky Way is only estimated to about 2×10^{41} kg

Chains.”) The primary parent and the final product of each series are indicated by shading the box of the respective elements.

It can be useful to determine the activity of a given member of a series at a given time t . The simplest case is when the first two members (the parent X_1 and its daughter X_2) are only considered:

where N_1 and N_2 are the numbers of atoms of X_1 and X_2 , respectively. (Some authors prefer to use the term mother rather than parent.)

The time dependence of the number of atoms and the activity (decay rate) of the parent X_1 follows directly from Eqs. (7.6) and (7.7):

$$N_1 = N_1(0)e^{-\lambda_1 t}, \quad (7.34)$$

$$A_1 = -\frac{dN_1}{dt} = \lambda_1 N_1 = \lambda_1 N_1(0)e^{-\lambda_1 t} = A_1(0)e^{-\lambda_1 t}. \quad (7.35)$$

■ Fig. 7.6

The uranium ($4n + 2$) series is the second of the three naturally occurring decay series on Earth. The half-life of the primary parent ^{238}U ($T_{1/2} = 4.5 \times 10^9$ a) nearly matches the estimated age of the Earth, so about half of the ^{238}U atoms that once existed are still around. In this series, Mg emission also occurs some of the ^{210}Tl nuclei undergo beta-delayed neutron emission. This establishes a vague interconnection with the ($4n + 1$) series

The daughter X_2 forms at a rate equal to the decay rate of the parent and simultaneously disintegrates at a rate determined by λ_2 :

$$\frac{dN_2}{dt} = \lambda_1 N_1 - \lambda_2 N_2. \quad (7.36)$$

Substituting \blacktriangleright Eq. (7.34) into \blacktriangleright Eq. (7.36) yields

$$\frac{dN_2}{dt} + \lambda_2 N_2 = \lambda_1 N_1(0) e^{-\lambda_1 t}. \quad (7.37)$$

The solution of ► Eq. (7.37) for the initial conditions $t = 0$: $N_1 = N_1(0)$, $N_2 = 0$ is

$$N_2 = N_1(0) \frac{\lambda_1}{\lambda_2 - \lambda_1} (e^{-\lambda_1 t} - e^{-\lambda_2 t}). \quad (7.38)$$

Thus the activity of the daughter is

$$A_2 = \lambda_2 N_2 = A_1(0) \frac{\lambda_2}{\lambda_2 - \lambda_1} (e^{-\lambda_1 t} - e^{-\lambda_2 t}). \quad (7.39)$$

■ Fig. 7.7

The actinium ($4n + 3$) series is the third one of the naturally occurring decay series on Earth. The half-life of the primary parent ^{235}U ($T_{1/2} = 7.04 \times 10^8$ a – note, for comparison, that the Cambrian Period started some 5.7×10^8 years ago) is approximately one sixth of the estimated age of the Earth. Thus, nearly 2^{-6} part (or, more exactly, just about 1%) of the ^{235}U atoms that once existed are still potentially available as nuclear fuel

More generally, the following system of differential equations is to be solved:

$$\begin{aligned}
 \frac{dN_1}{dt} &= -\lambda_1 N_1, \\
 \frac{dN_2}{dt} &= \lambda_1 N_1 - \lambda_2 N_2, \\
 \frac{dN_3}{dt} &= \lambda_2 N_2 - \lambda_3 N_3, \\
 &\vdots \\
 \frac{dN_n}{dt} &= \lambda_{n-1} N_{n-1} - \lambda_n N_n.
 \end{aligned} \tag{7.40}$$

The initial conditions considered are

$$\text{for } t = 0 : N_1 = N_1(0); \quad N_2 = N_3 = \dots N_n = 0. \tag{7.41}$$

The solution of the above system of equations can be found, e.g., in Vértés and Kiss (1987), Ehmann and Vance (1991) as well as several authors of this handbook refer to the result summarized by Eqs. (7.42)–(7.43) as the Bateman equation (Bateman 1910, see also in Choppin and Rydberg 1980). Other authors refer to the whole series of equations shown in Eq. (7.40) as Bateman equations.) For the n th member of the series ($n = 1, 2, 3, \dots$) one gets

$$N_n = N_1(0) \frac{f_n(t)}{\lambda_n} \equiv N_1(0) \sum_{k=1}^n a_{kn} e^{-\lambda_k t} \quad (7.42)$$

where $a_{11} = 1$, and the rest of the summation coefficients a_{kn} are given by the expression

$$a_{kn} = \frac{\prod_{i=1}^{n-1} \lambda_i}{\prod_{\substack{i>0 \\ i \neq k}} (\lambda_i - \lambda_k)}. \quad (7.43)$$

For more generalized forms of the above Bateman equations including activation by neutron capture see [Eqs. \(1.29\)–\(1.30\) in Chap. 38, Vol. 4](#), cited from Rubinson (1949).

For all the sophistication of the above result, some questions are easy to answer without using the explicit formulas. Such a question is, e.g., the mean time needed for the parent nucleus (X_1) to go through n steps of subsequent transformations. (For instance, one may be interested in the mean time needed for a ^{238}U atom to transform to ^{206}Pb through the series of decays shown in [Fig. 7.6](#).) Instead of integrating [Eq. \(7.42\)](#) (or, actually, $t f_n(t)$), one can translate the problem to a probability problem in the following way.

The subsequent periods of time T_i that are spent by a nucleus at the i th “stage” ($i = 1, 2, \dots, n$) are random variables with $\gamma(1, \lambda_i)$ exponential distributions (see [Chap. 9](#) for the notation). The total waiting time to get through n stages is $T = T_1 + \dots + T_n$. (Note that according to Rényi (1979) the function $f_n(t)$ in [Eq. \(7.42\)](#) plays the role of the density function of T .) What is actually needed is the expected value (τ) of T . According to [Eq. \(9.45\) in Chap. 9](#) one can directly write up the following result:

$$\tau = \sum_{i=1}^n \tau_i = \sum_{i=1}^n \frac{1}{\lambda_i}. \quad (7.44)$$

Note that the “1/e rule” (see [Eq. \(7.20\)](#)) does not apply to τ , because the distribution of T is only exponential in the trivial case of $n = 1$. To give a numerical example, suppose that the decay constants are nearly equal. If $\lambda_1 \approx \lambda_2 \approx \lambda$, then T has a $\gamma(n, \lambda)$ gamma distribution (see [Chap. 9](#) in this Volume) for which $\tau = n/\lambda$. One can easily verify, e.g., for $n = 2$, that the factor in question would then be $1 - F_2(2/\lambda) = 3e^{-2} \approx 0.41$ rather than $e^{-1} \approx 0.37$, where $F_2(t)$ is the distribution function of the $\gamma(2, \lambda)$ gamma distribution. In the given example, this would mean that about 59% ($= 100 - 41\%$) of the initial atoms rather than 63% ($= 100 - 37\%$) are expected to undergo both decays by the time $t = \tau \equiv 2/\lambda$. For large values of n , on the other hand, one gets 50%, because the gamma distribution can be approximated by normal distribution for which the expected value (τ) and the median ($T_{1/2}$) are equal (see [Chap. 9](#) in this Volume).

In one particular (however important) type of radioactive series, the “1/e rule” is still working. This happens when the half-life (and therefore the mean life) of one of the members is overwhelmingly large compared with all the others. This case, called secular equilibrium, is discussed separately due to its importance.

7.4.2 Radioactive Equilibrium and Nonequilibrium

It is often not necessary to bother with the general solution of the successive decay problem, because after some time the whole series can be analyzed stepwise, comparing the decay

constants of the individual decays. In order to introduce the concepts of equilibrium and nonequilibrium, it is worth starting with the analysis of the first two decays of the series shown by [Eq. \(7.33\)](#). Then, the decay of the second daughter will also be included, in order to be able to draw more general conclusions concerning the whole of the series. Under certain conditions some kind of equilibrium is established between the (primary) parent and its (first) daughter.

The condition for transient equilibrium – or *any* equilibrium for that matter – is $\lambda_1 < \lambda_2$ (or $\tau_1 > \tau_2$). In this case, after some time, the following relation holds:

$$e^{-\lambda_1 t} \gg e^{-\lambda_2 t}, \quad (7.45)$$

and therefore the second term becomes negligible in [Eqs. \(7.38\)](#) and [\(7.39\)](#).

Thus, the asymptotic behavior of the number of the daughter's atoms N_2 is described by the following formula:

$$N_2 \Rightarrow \frac{\lambda_1}{\lambda_2 - \lambda_1} N_1(0) e^{-\lambda_1 t} = \frac{\lambda_1}{\lambda_2 - \lambda_1} N_1. \quad (7.46)$$

From [Eq. \(7.46\)](#) one can easily get the asymptotic ratio of the numbers of atoms

$$\frac{N_2}{N_1} \Rightarrow \frac{\lambda_1}{\lambda_2 - \lambda_1}, \quad (7.47)$$

which shows that, for large enough t , the ratio of the number of daughter atoms to that of the parent atoms (N_2/N_1) becomes approximately constant.

The asymptotic behavior of the daughter's activity A_2 is obtained from [Eq. \(7.39\)](#) using [Eq. \(7.45\)](#):

$$A_2 \Rightarrow \frac{\lambda_2}{\lambda_2 - \lambda_1} A_1(0) e^{-\lambda_1 t} = \frac{\lambda_2}{\lambda_2 - \lambda_1} A_1. \quad (7.48)$$

Thus the asymptotic ratio of the activities is

$$\frac{A_2}{A_1} \Rightarrow \frac{\lambda_2}{\lambda_2 - \lambda_1}, \quad (7.49)$$

that is, the ratio of the activities becomes constant after some time. This can also be observed in [Fig. 7.8](#), where proportionality reveals itself as a constant separation between the logarithmic curves of A_1 and A_2 .

It can also be concluded from [Eq. \(7.49\)](#) that in transient equilibrium the daughter is more active than the parent. (This can also be seen in [Fig. 7.8](#).)

The following criterion can be set up for the minimum time required to approach the equilibrium condition defined by [Eq. \(7.49\)](#) to a given relative accuracy α :

$$\frac{\frac{\lambda_2}{\lambda_2 - \lambda_1} - \frac{A_2}{A_1}}{\frac{\lambda_2}{\lambda_2 - \lambda_1}} \leq \alpha, \quad (7.50)$$

where A_2/A_1 is the actual ratio of the activities as a function of time, i.e.,

$$\frac{A_2}{A_1} = \frac{\lambda_2}{\lambda_2 - \lambda_1} (1 - e^{-(\lambda_2 - \lambda_1)t}) \quad (7.51)$$

as follows from [Eqs. \(7.39\)](#) and [\(7.35\)](#).

■ Fig. 7.8

Schematic representation of (transient) equilibrium. The half-life of the parent nuclide considered is 10 units, while that of the daughter is 1 unit. Note that the maximum of the daughter's activity (see Eq. (7.58)) is reached somewhat later than that of the total activity. Note also that Eq. (7.53) works quite well, i.e., the logarithmic curves of A_1 and A_2 are already practically parallel at $t \approx 6.6$, which means that the ratio A_2/A_1 is nearly constant

Hence, criterion Eq. (7.50) can be rewritten in the following form:

$$e^{-(\lambda_2 - \lambda_1)t} \leq \alpha, \quad (7.52)$$

which eventually yields

$$t > \tau_2 \ln \frac{1}{\alpha}, \quad (7.53)$$

where τ_2 is the mean life of the (shorter-lived) daughter nuclide.

If, e.g., a criterion of 1% is set, then Eq. (7.53) yields $t > 4.6 \tau_2 \approx 6.6 T_{1/2}$. In other words, after about 6–7 half-lives (4–5 mean lives) of the daughter nuclide, the equilibrium condition is only about 1% away.

The condition for secular equilibrium is $\lambda_1 \ll \lambda_2$ (or $\tau_1 \gg \tau_2$). In this case, λ_1 can be neglected in comparison with λ_2 and Eq. (7.49) becomes even simpler:

$$\frac{A_2}{A_1} \Rightarrow 1, \quad (7.54)$$

that is, in secular equilibrium the activities are about equal

$$A_1 \approx A_2. \quad (7.55)$$

Secular equilibrium is illustrated by ► Fig. 7.9 in the special case of ^{226}Ra as the parent ($T_{1/2} = 1,600 \text{ a} = 584,000 \text{ d}$) and ^{222}Rn as its daughter ($T_{1/2} = 3.82 \text{ d}$).

If $\lambda_1 > \lambda_2$, then no equilibrium is reached at any time. Still, similarly to the case of equilibrium, the activity of the daughter passes through a maximum (see ► Fig. 7.10).

The asymptotic behavior of the daughter's activity A_2 is now different from that shown by ► Eq. (7.48), because it is the first term that becomes negligible in ► Eq. (7.39)

$$A_2 \Rightarrow \frac{\lambda_2}{\lambda_1 - \lambda_2} A_1(0) e^{-\lambda_2 t}. \quad (7.56)$$

Note that the above equation would describe the activity of a source prepared from the daughter's atoms, with the initial activity

$$A_2(0) = \frac{\lambda_2}{\lambda_1 - \lambda_2} A_1(0). \quad (7.57)$$

(See the intersection of the dotted line with the vertical axis in ► Fig. 7.10.)

It can be useful to know the time when the daughter reaches maximum activity, especially when the aim is to collect a radionuclide produced by radioactive decay.

■ Fig. 7.9

The change of activity in the case of secular equilibrium. The half-life of the parent nuclide ^{226}Ra is $T_{1/2} = 1,600 \text{ a}$, and that of the daughter ^{222}Rn is $T_{1/2} = 3.825 \text{ d}$. The time unit is the half-life of the daughter. Note that after the equilibrium has been reached, the activities of Ra and Rn become practically equal – the distinguishing feature of secular equilibrium. This means that the total activity doubles after 6–8 half-lives of the daughter

■ Fig. 7.10

Schematic representation of nonequilibrium. The half-life of the parent nuclide is taken as the time unit, and that of the daughter is 10 times longer. Note that the asymptote of the daughter's activity reflects the time characteristics of the daughter's own, whereas in the case of equilibrium it is determined by that of the parent (See the horizontal red line in Fig. 7.9, representing both the parent's activity and the asymptotic activity curve of the daughter)

The maximum of $A_2(t)$ (as well as of $N_2(t)$) is reached at the time

$$t_{\max} = \frac{1}{\lambda_2 - \lambda_1} \ln \frac{\lambda_2}{\lambda_1} \quad (7.58)$$

as one can easily verify by differentiating Eq. (7.39) (or Eq. (7.38)).

The analysis will now be extended to the three first decays of the series:

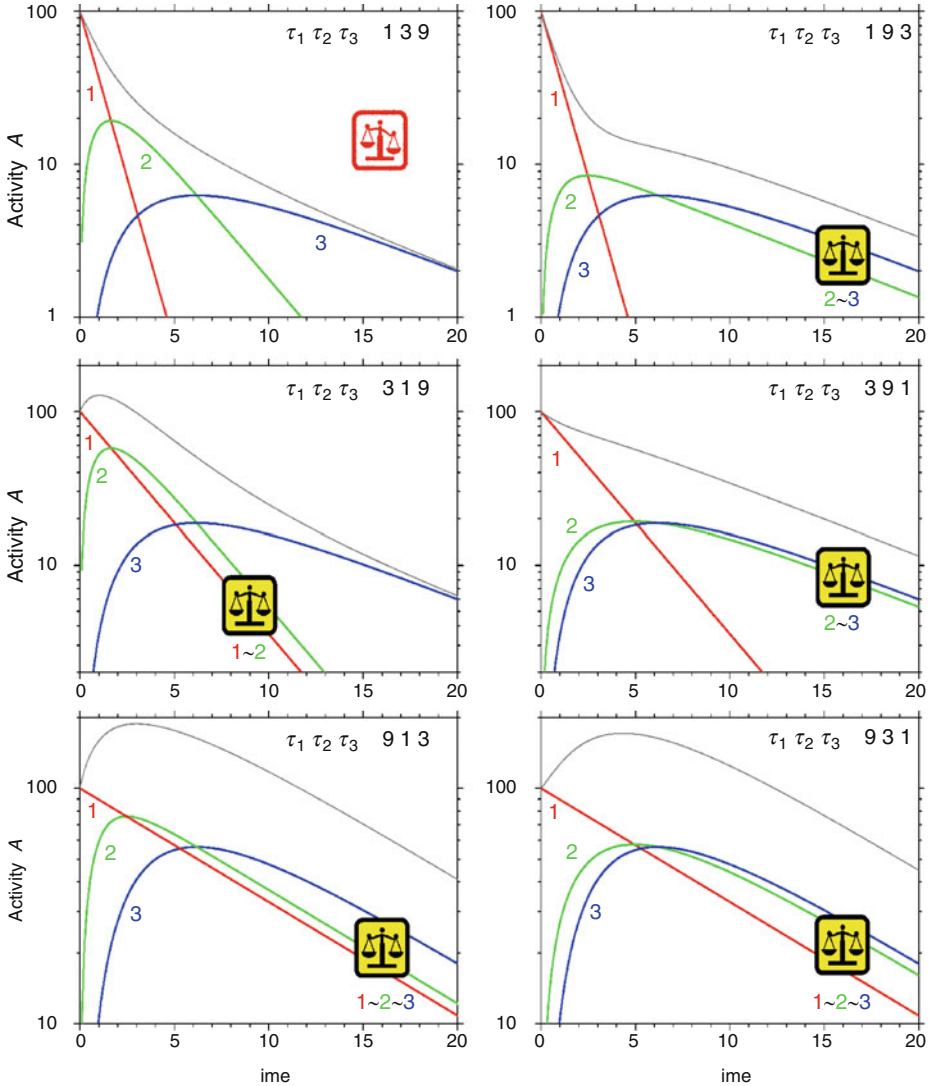

Using Eqs. (7.42) and (7.43), one can write for the activity of the second daughter

$$A_3 = \lambda_3 N_3 = A_1(0) \lambda_2 \lambda_3 \left(\frac{e^{-\lambda_1 t}}{(\lambda_2 - \lambda_1)(\lambda_3 - \lambda_1)} + \frac{e^{-\lambda_2 t}}{(\lambda_1 - \lambda_2)(\lambda_3 - \lambda_2)} + \frac{e^{-\lambda_3 t}}{(\lambda_1 - \lambda_3)(\lambda_2 - \lambda_3)} \right). \quad (7.60)$$

Figure 7.11 shows the activities versus time for the first three nuclides of a series as calculated from Eqs. (7.35), (7.39), and (7.60). The individual graphs represent the six possible permutations of a fast, a medium, and a slow decay characterized by mean lives 1, 3,

■ Fig. 7.11

Basic cases of decay series consisting of three steps. The balanced scales draw attention to the range where the logarithms of activities become parallel, an indication of equilibrium (\sim). The shortest mean life is selected as the time unit for each graph. The most interesting case is represented by the bottom left graph, showing that whenever the parent of the series is the longest-lived nuclide, sooner or later equilibrium will prevail along the whole series, no matter how the individual decay constants of the daughters are related to each other. According to the four upper graphs, the longest-lived member will eventually survive (all of) its predecessor(s)

and 9 time units, respectively. Careful analysis of the graphs makes possible to draw general conclusions about the asymptotic behavior of any series:

If X_k is the longest-lived member of the series, then – after a sufficiently long time – the members X_1, \dots, X_{k-1} will die out, and the series will be shortened to the subseries X_k, X_{k+1}, \dots with X_k as the primary parent.

No matter how the decay constants ($\lambda_{k+1}, \lambda_{k+2}, \dots$) of the daughters of X_k are related to each other, the fact that λ_k is smaller than the rest of the decay constants enforces an equilibrium between X_k and all of its daughters.

For instance, the first member of any of the naturally occurring radioactive series has a half-life of several orders of magnitude longer than any of its descendants (see [Figs. 7.4–7.7](#)). Therefore its decay constant (λ_1) is negligible in comparison with those of the decay products ($\lambda_1, \lambda_2, \dots, \lambda_n$). Similarly, the exponentials

$$e^{-\lambda_2 t}, e^{-\lambda_3 t}, \dots, e^{-\lambda_n t}, \dots \quad (7.61)$$

can also be neglected in comparison with $e^{-\lambda_1 t}$ after some time.

Everything considered, the first member of such a series is in secular equilibrium with all the others, i.e., [Eq. \(7.55\)](#) applies to any of the daughter nuclides:

$$A_1 \approx A_2 \approx \dots \approx A_n \approx \dots \quad (7.62)$$

If, therefore, all the decay products of uranium or thorium remain together in a rock or in an ancient compound, their activities become equal (after a period of time).

7.4.3 Decay After Activation

A special case of successive processes is that in which the parent (X_1) is stable, but it is induced to transformation by a nuclear reaction, the product of which (the “daughter” X_2) is radioactive. For instance, in the case of neutron activation instead of [Eq. \(7.33\)](#) one can write

where ϕ is the neutron flux density (neutrons $\text{cm}^{-2} \text{s}^{-1}$) and σ_1 is the cross section of the nuclear reaction induced by the neutrons (e.g., neutron capture):

Similar processes have an important part in neutron activation analysis (NAA, see [Chap. 30 in Vol. 3](#)) as well as in natural processes such as the formation of radiocarbon (see [Sect. 17.17 in Chap. 17 of Vol. 2](#)) in the atmosphere via the reaction

The equivalent of [Eq. \(7.36\)](#) is now

$$\frac{dN_2}{dt} = \phi\sigma_1 N_1 - \lambda_2 N_2. \quad (7.66)$$

When solving the above equation, it is usually assumed that ϕ and N_1 are constant. (The latter assumption means that only a tiny fraction of X_1 will be activated.) Therefore, the integration between 0 and t is straightforward, resulting in

$$A_2 = \lambda_2 N_2 = \phi \sigma_1 N_1 (1 - e^{-\lambda_2 t}). \quad (7.67)$$

The above equation shows that for a constant time of activation, the activity of the product will be proportional to N_1 , offering a simple technique for the quantitative analysis of the nuclide X_1 by NAA. According to [Fig. 7.12](#), the asymptotic limit of the activity is also proportional to N_1 . This fact is used, e.g., in the case of radiocarbon dating, in which the date of the death of an organism is eventually determined from the following type of equation:

$$A_2(t) = A_2(0)e^{-\lambda_2 t} \propto \phi \sigma_1 N_1 e^{-\lambda_2 t}. \quad (7.68)$$

For a general and detailed discussion of activation kinetics see [Chap. 38, Vol. 4](#), on the “Reactor-Produced Medical Radionuclides.”

7.5 Decay Constant (Half-Life) Systematics

This section gives a short summary of some results discussed in more detail in various parts of [Chap. 2](#) (“Basic Properties of the Atomic Nucleus”) and [Chap. 4](#) (“Nuclear Fission”) concerning the dependence of the decay constant on various physical parameters for the most

Fig. 7.12

Schematic representation of the activity of the radioactive product X_2 as a function of the time of activation. The time unit is the half-life of the product. The arrows point to the time calculated from [Eq. \(7.53\)](#), which now provides the minimum activation time needed to get 100% close to the asymptotic (i.e., the highest possible) value of the activity $A_2 \Rightarrow \phi \sigma_1 N_1$. It is clear that the gain in product activity halves in each subsequent half-life period, which makes longer irradiation times increasingly uneconomical from the viewpoint of radionuclide production

important decay modes. Since the notation in [Chap. 2](#) follows the “jargon” of nuclear physics, a “translation” between this chapter and [Chap. 2](#) will also be given. For instance, the text “decay constant (\rightarrow transition rate)” is meant to indicate that the decay constant is called transition rate in that particular part of [Chap. 2](#), which is referred to. The reader can find a very good theoretical introduction to this field in Friedlander et al. (1981) or in Lefort (1968).

7.5.1 Alpha Decay

Alpha emitters are found among the large- Z nuclides (e.g., $^{144}_{60}\text{Nd}_{84}$ and above) for which, not too far from the bottom of the stability valley (see [Fig. 7.13](#)), the number of neutrons exceeds that of the protons, i.e., the ratio N/Z is greater than 1. Under such conditions, the alpha decay,

Fig. 7.13

The stability valley of nuclei. The vertical projection of the bottom of the valley on the $Z \times A$ plane follows the line of stable nuclei (cf. [Fig. 2.7 in Chap. 2](#)) at an “altitude” expressed by the ratio of the nuclidic mass (M) and the mass number (A). The horizontal projection of the bottom of the valley onto the $(M/A) \times A$ plane is essentially the same as the graph labeled “experimental” in [Fig. 2.3 in Chap. 2](#), except that it is upside down. The isobaric cross sections of the valley are parabolic as a consequence of the Weizsäcker formula [\(2.3\) in Chap. 2](#). (See also the legend of [Fig. 7.2](#) in this chapter, as well as [Fig. 14.5 in Chap. 14, Vol. 2.](#)) The local dips marked are related to magic numbers (Ca: $N = 20$; Fe–Ni: $N = 28$, $Z = 28$; Y: $N = 50$; Ba: $N = 82$). Beta decay occurs all along the valley. On the near side of the valley β^- decay is predominant, on the far side β^+ decay and electron capture (EC) compete with each other as indicated on the parabola. Alpha decay occurs for $A > 60$ mainly on the far side of the valley

will further increase this ratio

$$\frac{N-2}{Z-2} > \frac{N}{Z} > 1. \quad (7.70)$$

Therefore, if a nuclide is situated at the low- N side of the valley (i.e., its N/Z ratio is less than for its most stable neighbors), alpha decay can move it closer to the bottom of the valley and so the nuclide is apt to undergo alpha decay. (In certain cases, even neutron-rich nuclei, e.g., some Po isotopes, may undergo α decay because the Q -value of the process turns out to be positive.)

During the early decades of nuclear physics it had been thought that the alpha radiation of each alpha-emitting nuclide was monoenergetic. It was not till 1929 that Rosenblum (1930) discovered the alpha radiation of ${}^{212}_{83}\text{Bi}$ consisting of alpha particles of different energies. Further experiments have demonstrated that alpha energies are always discrete even in such cases, and the energy excess still possessed by the nucleus above its ground level is emitted in the form of a gamma photon.

It should be noted that a different value of λ belongs to each different value of E_α . Thus the effective λ (as well as the effective $T_{1/2}$) for an α -emitting nucleus is determined by the sum of partial decay constants: $\sum \lambda_i$. (Note that this is a special type of branching decay consisting of α branches only.)

Alpha energies are usually between 4–6 MeV and these limits are exceeded only in a few cases. The total variation is marked by ${}^{144}_{60}\text{Nd}$ (1.8 MeV) and ${}^{212\text{m}}_{84}\text{Po}$ (11.7 MeV). On the other hand, the half-lives cover about 30 decimal magnitudes from ${}^{213}_{85}\text{At}$ (10^{-7} s) to ${}^{148}_{62}\text{Sm}$ (10^{16} a $\approx 3 \times 10^{23}$ s). Note that the above figures do not include those of the process ${}^8_4\text{Be} \rightarrow 2\alpha$ that keeps the alpha burning in massive stars under control. The half-life of this cosmologically important decay is only about 10^{-16} s or so (see [Chapter 12 in Vol. 2](#), on “The Origin of the Chemical Elements”).

As shown in [Chapter 2](#), there is a negative correlation between half-life and alpha energy. The strong energy dependence of partial half-lives explains why the complexity of alpha spectra remained undetected for such a long time: the branch producing the most energetic alpha particles often dominates the whole decay process.

The first decay-constant systematics proposed is called the Geiger–Nuttall rule (see [Eq. \(2.60\) in Chap. 2](#)). This rule, set up originally as a decay-constant – alpha-range relationship, can be readily converted into the following half-life – alpha-energy relationship:

$$\log\{T_{1/2}\} = a \log\{E_\alpha\} + b, \quad (7.71)$$

where $a < 0$ is a constant and $\{x\}$ stands for the numerical value of the physical quantity x in some unit $[x]$. On the other hand, b has a different (but constant) value for each decay series. So the logarithmic plots of the individual series are represented by parallel straight lines shifted according to the difference in the parameter b .

Note that the Geiger–Nuttall plot of the $4n + 3$ series is way above the $4n + 0$ and $4n + 2$ series (see [Fig. 7.14](#)). This is so because odd- Z and odd- N nuclei decay more slowly than even–even ones owing to shell effects. This kind of hindrance has saved, e.g., the very important even–odd nuclide ${}^{235}_{92}\text{U}_{143}$ – the primary parent of the $4n + 3$ series – from extinction on Earth (Friedlander et al. 1981).

Chapter 2 contains further expressions describing such systematics.

■ Fig. 7.14

Modern Geiger–Nuttall plot for the α -decaying nuclides of the four major decay chains including the three naturally occurring ones (starting from ^{232}Th , ^{238}U , and ^{235}U) once studied by the eponyms of this type of log–log presentation. The label of the fourth series (starting from ^{237}Np) is in gray color to indicate that this series has been wiped out from Earth due to its relatively short half-life. Note that the α half-lives sweep the range from less than a microsecond (see the labels along the right vertical axis) to 15 billion years (the estimated age of our Universe), which means a scale of ~ 24 decimal or ~ 80 binary orders of magnitude. The Q -values ($\sim E_\alpha$), on the other hand, only drop from 9 MeV to about 4 MeV, a range just about a little wider than 1 binary order of magnitude (i.e., a range covered by a factor of 2).

The empirical Taagepera–Nurmia formula (► Eq. (2.61), Chap. 2) describes the alpha half-life as the function of alpha-energy and the atomic number of the daughter nucleus. ► Figure 2.34 in Chap. 2 illustrates the relationship.

The theoretical Gamow–Condon–Gurney formula (► Eq. (2.65), Chap. 2) describes the alpha decay constant as a function of the alpha-energy (or rather the Q -value of the alpha decay), as well as the nuclear radius and the atomic number of the daughter.

The Gamow–Condon–Gurney formula only applies when the alpha particle is emitted with zero angular momentum. The probability for alpha decay taking away angular momentum is considerably smaller (see ► Eq. (2.68) and ► Table 2.8 in Chap. 2).

7.5.2 Beta Decay

Beta emitters are found all along the stability valley (see ► Fig. 7.13) starting from ^3_1H up to $^{253}_{98}\text{Cf}$.

If, as a result of β decay, excited nuclei are formed, the ground state will be reached through the emission of monoenergetic gamma photons. One might expect, therefore, that β radiation, too, is “monochromatic,” consisting of electrons with energy $Q_\beta - E_\gamma$ each. In reality, however, β spectra are of continuous character with an energy distribution extending from zero to $E_\beta = Q_\beta - E_\gamma$. The energy distribution of the neutrinos is also continuous, being the mirror image of the bell-shaped electron-energy distribution.

This holds both for negative and positive beta decay:

but not for electron capture, the alternative to positive beta decay

in which monoenergetic neutrinos are emitted since there is no third particle in the final state.

Maximum beta energies (E_β) span even wider range than alpha energies from the extremely soft 17–18 keV negatron (i.e., β^-) radiation of ${}_1^3\text{H}$ and ${}_{82}^{210}\text{Pb}$, to the very hard 14 MeV positron (i.e., β^+) radiation of ${}_5^8\text{B}$. The typical E_β range – from a few hundred keV to a few MeV – is lower than the usual range of alpha energies (4–7 MeV). Beta half-lives range from fractions of a second for nuclides far from the bottom of the valley of beta stability to billions of years exemplified by ${}_{19}^{40}\text{K}$ (1.25×10^9 a) and ${}_{37}^{87}\text{Rb}$ (4.7×10^{10} a), both of them being important for radioactive dating.

Double beta (2β) decay should also be mentioned here in which two beta particles and two neutrinos are emitted simultaneously. The typical half-life is on the order of 10^{20} a, and therefore such primordial radionuclides can be considered stable for any practical purpose. (Note that the estimated age of our Universe is only about 1.4×10^{10} a according to some recent measurements mentioned in [▶ Chap. 12 of Vol. 2.](#))

The energy dependence of the decay constant for negative β decay can be very roughly described by the following empirical formula similar to the Geiger–Nuttall rule:

$$\log(\lambda) = \alpha \log(E_\beta) + \beta, \quad (7.75)$$

where $\alpha > 0$ and β are constant for separate groups of β -decaying nuclides (Sargent 1933). The Sargent rule, expressed by the above formula, predicts a very steep increase of the decay constant as a function of the beta energy.

The theory of beta decay developed by Fermi is summarized in [▶ Chap. 2](#). The theoretical relationship describing the dependence of the beta decay constant on beta energy E_β ($\rightarrow E_0$) and atomic number Z is given by [▶ Eqs. \(2.82\) and \(2.83\) in Chap. 2](#). For allowed transitions one can approximately write

$$\lambda = \frac{\ln 2}{T_{1/2}} \propto f(Z, E_\beta) \quad (7.76)$$

where $f(Z, E_\beta)$ is the Fermi integral function defined by [▶ Eq. \(2.83\) in Chap. 2](#).

The product

$$ft \equiv f(Z, E_\beta) T_{1/2} \quad (7.77)$$

is called comparative half-life. The function f contains the trivial dependence of $(T_{1/2})^{-1}$ on the nuclear charge and size, on the decay energy and multipolarity (change of angular

momentum). Thus ft should only depend on the nuclear matrix elements, i.e., on the nontrivial nuclear structure effects. The ft varies in a wide range as shown in [Table 2.10 of Chap. 2](#), depending on the structure of the nucleus and the type of transition.

Still, the Fermi integral function $f(Z, E_\beta)$ is very useful even in the general case, because it can help visualize the overall dependence of the decay constant λ on the beta energy E_β and the atomic number Z . For instance, [Figs. 42A and B in Chap. 2](#) (as well as [Fig. 7.15](#)) show that (1) the probability for beta decay steeply increases with beta energy (this is equally true for positive and negative beta decay), (2) negative beta decay becomes more probable as the atomic number increases, (3) positive beta decay becomes less probable as the atomic number increases.

Friedlander et al. (1981) cite empirical formulas for the energy- and atomic-number dependence of the Fermi integral function. The following formulas (see also [Fig. 7.15](#)) are valid in the intervals $0 < Z \leq 100$ and $0.1 < E_\beta < 10$ (where Z is the atomic number of the daughter and E_β is the maximum of the beta energy):

$$\log f_{\beta^-} = 4 \log (E_\beta/\text{MeV}) - 0.005(Z - 1) \log (E_\beta/\text{MeV}) + 0.02 Z + 0.78, \quad (7.78)$$

$$\log f_{\beta^+} = 4 \log (E_\beta/\text{MeV}) - 0.009(Z + 1) \left(\log \frac{E_\beta/\text{MeV}}{3} \right)^2 - 0.007 Z + 0.79. \quad (7.79)$$

The respective EC formula gives best approximation for $E_\beta > 0.5$ MeV and for low values of Z (see also [Fig. 7.16](#)):

$$\log f_{\text{EC}} = 2 \log (E_\beta/\text{MeV}) + 3.5 \log (Z + 1) - 5.6. \quad (7.80)$$

Fig. 7.15

The Fermi integral function for negative (to the left) and positive beta decay (to the right) calculated from [Eqs. \(7.78\) and \(7.79\)](#). Note that the directions of the Z axes are different in accordance with an opposite trend in the Z dependence of f

■ Fig. 7.16

The Fermi integral function for electron capture calculated from ▶ Eq. (7.80). The figure shows that EC is most likely for larger values of Z

As mentioned before, electron capture is the alternative process to positive beta decay. For lower decay energies, electron capture often comes out on top from the competition, due to its less demanding energetic condition (see ▶ Sect. 2.4.2 in Chap. 2).

▶ Figure 2.42C in Chap. 2 shows the branching ratio $\lambda_{EC}/\lambda_{\beta^+}$ ($\rightarrow K/\beta^+$) as a function of E_{β} for different values of the atomic number. The figure demonstrates that, for a constant value of Z (i.e., when comparing different isotopes of the same chemical element), larger beta energy favors β^+ decay. At any given energy, on the other hand, heavier nuclides prefer to undergo EC. (Note that the larger Z , the larger is the probability to find a shell electron in the nucleus – a necessary condition for electron capture.)

Friedlander et al. (1981) also cite an approximate formula for the branching ratio of L- and K-capture in allowed transitions:

$$\frac{\lambda_L}{\lambda_K} = (0.0011 Z + 0.06) \left[\frac{E_L(v)}{E_K(v)} \right]^2, \quad (7.81)$$

where $E_L(v)$ and $E_K(v)$ are the energy of the neutrino for L- and K-capture, respectively. (The neutrino energy equals E_{β} less the binding energy of the electron.)

7.5.3 Gamma Decay

If, for some reason (e.g., as a consequence of α or β decay), an excited nucleus is formed, the excited state will sooner or later de-excite via gamma decay or alternative processes like internal

conversion or the emission of an electron-positron pair. The latter (rather rare) process is called pair emission. (Internal conversion and pair emission are the analogues of photoelectric effect and pair production, both discussed in [Chap. 8](#) on the “Interaction of Radiation with Matter.”)

In the case of γ decay,

the excitation energy (or, in other words, the transition energy $E_T = E_e - E_g$) is carried away by a γ photon (γ emission) as well as by the recoil of the nucleus:

$$E_T = E_\gamma + E_R. \quad (7.83)$$

Long-lived excited nuclei ($T_{1/2} \geq 1 \mu\text{s}$) are sometimes referred to as excited nuclear isomers and are indicated by a left superscript “m” standing for “metastable”:

In such cases the transition is referred to as isomeric transition (IT).

Excitation may sometimes provide protection against other types of (actual nuclear) decay. The excited isomer ${}^{114\text{m}}\text{In}$ serves with a good example of this. In this case first de-excitation takes place through γ emission ($T_{1/2} = 50 \text{ d}$, a very long half-life indeed for an excited state), and then the ground-state isomer ${}^{114}\text{In}$ is transformed by β^- decay ($T_{1/2} = 72 \text{ s}$).

It may also occur that, instead of a gamma photon, a shell electron is emitted. This alternative process for nuclear de-excitation is called internal conversion. Electron emission is then followed by the rearrangement of the electronic shell structure, which, in turn, is accompanied by X-ray emission, characteristic of the element concerned, or by the emission of another electron via Auger process.

The kinetic energy of a conversion electron is given by

$$E_{\text{ce}} = E_T - E_b > 0, \quad (7.85)$$

where E_b is the binding energy of the emitted shell electron and E_T is the transition energy.

Since the binding energy is different for the K-, L-, and M-shells, the kinetic energy of a conversion electron depends on the shell it was emitted from.

The so-called internal conversion coefficient (α) is defined as the ratio of the probability of electron emission (p_e) to that of gamma emission (p_γ):

$$\alpha = \frac{p_e}{p_\gamma} \quad (7.86)$$

The value of α is usually between 10^{-4} and 10^2 . It is calculated as the sum of partial values characteristic of the individual electronic shells:

$$\alpha = \alpha_K + \alpha_L + \alpha_M + \dots \quad (7.87)$$

where

$$\alpha_K = \frac{p_e(n=1)}{p_\gamma}; \alpha_L = \frac{p_e(n=2)}{p_\gamma}; \alpha_M = \frac{p_e(n=3)}{p_\gamma}; \dots \quad (7.88)$$

and n is the principal quantum number.

It is an empirical fact that $\alpha_K > \alpha_L > \alpha_M \dots$ whenever it is energetically possible to emit K, L, M, ... electrons (see [Eq. \(7.85\)](#)).

The dependence of the decay constant (\rightarrow transition rate) of low-energy excited isomers ($E_\gamma < 10$ MeV) on the energy (E_γ), electric ($\rightarrow \sigma = E$) or magnetic ($\rightarrow \sigma = M$) character, and on the multipolarity ($\rightarrow 2^L$; with a common notation: EL or ML) of the radiation as well as on the initial and final value of the nuclear spin ($\rightarrow J_i, J_f$) (and other structural properties of the nucleus) is given by [Eq. \(2.32\) in Chap. 2](#).

[Equations \(2.37\) and \(2.38\) in Chap. 2](#) show the explicit dependence of the decay constant (\rightarrow transition rate) of electric (EL) and magnetic (ML) 2^L -pole transitions, respectively, on the energy and multipolarity of the radiation, as well as on the nuclear radius in the special case of nuclei containing one single nucleon outside the closed core. The different sub-cases representing $E1, E2, \dots$ as well as $M1, M2, \dots$ transitions are summarized in [Table 2.7 of Chap. 2](#), as algebraic expressions of the mass number and the gamma energy. The energy dependence of the half-life is shown by [Fig. 2.13 in Chap. 2](#) for different multipole radiations. The logarithmic plot reveals that (1) the larger the transition energy, the faster the transition, (2) the lower the multipolarity, the faster the transition (the rule holds for allowed transitions and separately for EL and ML radiations); if therefore $E1$ (or $M1$) is allowed, then $E2, E3, \dots$ ($M2, M3, \dots$) can be neglected, (3) for any given multipolarity the electric transition is faster than the magnetic transition, (4) for any given energy, the transition rate decreases in the following order: $E1 > M1 > E2 > M2 > E3 > M3 > E4 > M4$.

The half-life of excited states (isomers) depends on the change of nuclear spin (ΔI) and parity in the transition as well as on the transition energy (E_T). The greater is ΔI , the longer is $T_{1/2}$, but an increase in E_T causes a decrease in the half-life.

7.5.4 Spontaneous Fission

It is known that the fission of heavy nuclei to lighter ones is an energy-producing process above about $A = 100$, however actual fission is only observed for $A \geq 230$. The reason why the instability of heavy nuclides does not lead to prompt fission automatically lies in the existence of the so-called fission barrier analogous to the potential barrier of alpha decay. Nevertheless, spontaneous fission *does* exist, in spite of the fission barrier. This can be explained (similarly to α decay) by tunneling. Since the probability for heavier particles to get across the barrier is less than that for α particles, the half-life for spontaneous fission is usually much longer than for α decay. However, some of the heavy transuranium elements fission with relatively short half-lives. ^{235}U nuclei undergo α decay with $T_{1/2} = 7 \times 10^8$ a and spontaneous fission with $T_{1/2} = 2 \times 10^{17}$ a, i.e., only one out of 300 million atoms disintegrates by fission. ^{254}Cf , on the other hand, decays only by spontaneous fission with a half-life of just 55 d, which is too short a time to be explained by tunneling.

The partial half-lives for spontaneous fission of even–even nuclei are shown in [Fig. 4.4 in Chap. 4](#) as the function of the fissility parameter Z^2/A . Note that there is a general trend for the half-life to decrease as the fissility parameter increases. However, the lines connecting the points representing the same (even- Z) element go through a maximum owing to shell effects. One can also observe that heavier elements (larger Z) tend to undergo spontaneous fission more easily. (Note that as the atomic number increases from $Z = 90$ to $Z = 106$, the partial half-life decreases about 30 orders of magnitude.)

It is interesting to note that when either Z or N is odd, the half-life tends to be much longer (see [Fig. 4.5 in Chap. 4](#)). On the other hand, the half-lives of the fission isomers are many orders of magnitude below the general trend (see [Fig. 4.31 in Chap. 4](#)).²

7.6 Editors' Note

1. The statistical nature of radioactive decay is a quantum effect and, as such, emerges from an intrinsic indefiniteness in the quantum mechanical state of each nucleus of a sample. Decay can thus be described as a time-dependent evolution of a single nucleus. However, quantum mechanics does not allow the existence of purely exponential decay. One can convince oneself of this statement by recognizing that (1) a pure exponential decay must have been started an infinitely long time ago and must last up to infinity; (2) in such a state the probability of finding the emitted particle in the vicinity of any point of space must decrease exponentially in time at the same rate. From proposal (2) it follows that such a state cannot be normalized, thus it cannot be a genuine quantum mechanical state. Nevertheless, one can introduce the exponential time dependence as an approximation in the Schrödinger equation, and end up with a generalized eigenvalue problem for the spatial factor of the wave function of the decaying state. This eigenfunction is called the Gamow wave function, and it turns out to be a good approximation to the exact time-dependent decaying state. The exact state departs from the exponential law at the time of its birth in a way that is specific to each nucleus and, again, toward the end of its life, i.e., after a great many half-lives have passed since its birth. These deviations from the decay law are, however, too delicate to have any practical consequences (p. 336).
2. It may be mentioned that there exist decay modes in between α decay and fission, which are called (heavy-) cluster decay. The typical clusters emitted are ^{14}C , ^{18}O , etc. (see [Figs. 7.4–7.7](#)). These decay modes are regarded as types of radioactivity, like α decay, since, the cluster is emitted in its ground state and the residual nucleus is brought about either in its ground state or in some low-lying excited state. In fission, the products are usually highly excited and de-excite partly via neutron emission. However, recently cold fission was also discovered; in that process the nucleus disintegrates into two nearly equal fragments with low excitation energies and hardly any particle emission. Cold fission is half-way between fission and cluster decay. All these exotic processes are extremely rare (p. 361).

Abstract: The effects of interactions of the various kinds of nuclear radiation with matter are summarized with special emphasis on relations to nuclear chemistry and possible applications. The Bethe–Bloch theory describes the slowing down process of heavy charged particles via ionization, and it is modified for electrons and photons to include radiation effects like bremsstrahlung and pair production. Special emphasis is given to processes involved in particle detection, the Cherenkov effect and transition radiation. Useful formulae, numerical constants, and graphs are provided to help calculations of the stopping power of particles in simple and composite materials.

8.1 Introduction

The interaction of nuclear radiation with matter is one of the most important aspects in nuclear chemistry, since most phenomena and applications of the discipline are, in one way or another, related to it. As a result of the interactions, changes may occur in the physical parameters and in the state (energy, direction, absorption) of the radiation particles as well as in the atoms and molecules of the substance (via ionization, excitation, nuclear reaction and, as a secondary effect, chemical reaction). The possible changes are summarized in [▶ Table 8.1](#).

The notation and units of the present review are summarized in [▶ Table 8.2](#). Relativistic notation is used: the particle speed β is given in units of c (speed of light in vacuum) and the (total) energy of the incident particle is $E = \gamma Mc^2$ (where γ is the relativistic Lorentz factor) which formula is then equally applicable to electrons and heavy particles. Throughout this chapter, the symbol E stands for the total (relativistic) energy of a particle including its rest energy Mc^2 , where M (without the subscript 0 used, e.g., in [▶ Chap. 3](#)) is the rest mass. The only exception is E_β , the maximum β -particle energy, which is a kinetic type of energy denoted elsewhere in this chapter by T .

For heavy particles and at low energies $E = \gamma Mc^2$ reduces to the classical $E = Mc^2 + Mu^2/2$, that is, the sum of rest energy and kinetic energy.

The effects of the interaction are classified according to the acting particle and the reacting constituents of the substance (shell electrons or atomic nuclei). The probabilities of different reactions are characterized by individual cross sections.

Basically, there are four different types of incident radiation: heavy charged particles, electron, photon, and neutron. (For neutron interactions see [▶ Chaps. 3 and 4](#) in this Volume as well as [▶ Chap. 38](#) in Vol. 4.) In this review the logic of Bichsel et al. (2002) is followed; however, while discussing the low-energy phenomena extensively, high-energy aspects are enlarged upon rather sparingly since the latter are much less important in nuclear chemistry.

8.2 Heavy Charged Particles

8.2.1 The Bethe–Bloch Equation

At not too high energies, the charged particles other than electrons or positrons (i.e., muons, pions, protons, or atomic nuclei like the α particle) lose their kinetic energy primarily by ionization. The possible interactions are summarized in [▶ Table 8.3](#).

Table 8.1

Classification of radiation-matter interactions, phenomena involved, and examples of application in chemistry

Interacting partner		Radiation				Matter			
Phenomenon	Energy loss	Scattering		Absorption		Stopping in matter (decay, atomic or nuclear absorption)	Ionization, atomic excitation (chemical changes)	Nuclear excitation	Nuclear reaction
		Elastic	Inelastic	Transformation (pair production, annihilation)

■ **Table 8.2**

Summary of the physical quantities used in this chapter. The notation of Bichsel et al. (2002) is followed

Symbol	Definition	Value and/or unit
$\alpha = e^2/(4\pi\epsilon_0\hbar c)$	Fine structure constant	1/137.036
c	Speed of light in vacuum	299 792 458 m/s
$\beta = u/c$	Relative speed of the incident particle	
$\gamma = \sqrt{1/(1 - \beta^2)}$	Relativistic factor	
M	Rest mass of incident particle	MeV/ c^2 , GeV/ c^2
$E = \gamma Mc^2$	Particle energy	MeV, GeV
$T = Mu^2/2$	Non-relativistic kinetic energy	
ze	Particle charge	
$m_e c^2$	Electron rest mass $\times c^2$	0.511 MeV
$r_e = e^2/(4\pi\epsilon_0 m_e c^2)$	Classical electron radius	2.817940×10^{-15} m
Z	Atomic number of absorber	
A	Molar mass of absorber atoms	g/mol
N_A	Avogadro's constant	6.022142×10^{23} mol $^{-1}$
$K = 4\pi N_A r_e^2 m_e c^2$	Constant in stopping power	0.307075 MeV cm 2
ρ	Density of medium	g/cm 3
I	Mean (electronic) excitation energy of an element	eV
δ	Density effect correction	
N_e	Electron (number) density	Units of r_e^{-3}
$\hbar\omega_p = \sqrt{4\pi N_e r_e^2 m_e c^2}/\alpha$	Plasma energy	$28.816 \sqrt{\rho (Z/A)}$ eV
ω_j	Mass fraction of j th element in a compound or mixture	
n_j	Number of j th kind of atom in a compound or mixture	
X_0	Radiation length (in surface density)	g/cm 2
E_c	Critical energy for electrons	MeV
$E_{\mu c}$	Critical energy for muons	GeV
$E_s = \sqrt{4\pi/\alpha} m_e c^2$	Scale energy	21.2052 MeV

The mean rate of energy loss, i.e., the **stopping power** is given by the Bethe–Bloch equation (Bethe and Ashkin 1953; Leo 1987; Bichsel et al. 2002):

$$-\frac{dE}{dx} = K Z^2 \frac{Z}{A} \frac{1}{\beta^2} \left[\frac{1}{2} \ln \frac{2m_e c^2 \beta^2 \gamma^2 T_{\max}}{I^2} - \beta^2 - \frac{\delta}{2} - \frac{C}{Z} \right] \quad (8.1)$$

where T_{\max} is the maximum kinetic energy which the incident particle can impart to a free electron in a collision, C/Z is the shell correction, C and δ are adjustable constants, characteristic of the medium, and the other quantities are defined in ► Table 8.2.

■ **Table 8.3**

Classification of the interactions of heavy charged particles in matter

Reacting constituent	Changes in	
	Radiation	Substance
Crystal lattice	Channeling	None
Shell electrons	Slowing down	Excitation, ionization, transition radiation Cherenkov radiation
	Atomic capture	Chemical changes
Atomic nuclei	Nuclear absorption particle decay	Nuclear reaction, chemical changes
Coulomb field of the nucleus	Scattering Slowing down	Recoil of atoms

In order to make the stopping power formulation applicable to both gases and condensed media, surface density is used instead of thickness, or in other words, the thickness x of the medium is measured in units of g/cm^2 .

The Bethe–Bloch equation reproduces the experimental data in the energy region from a few MeV to a few GeV with the precision of about 1%. At lower energies atomic shell effects, at higher energies radiation losses come into play.

At low and intermediate energies (i.e., practically for all purposes of the present book) for a particle with rest mass M and momentum $M\beta\gamma c$ the maximum imparted energy can be approximated as i

$$T_{\max} = \frac{2m_e c^2 \beta^2 \gamma^2}{1 + 2\gamma \frac{m_e}{M} + \left(\frac{m_e}{M}\right)^2} \approx 2m_e c^2 \beta^2 \gamma^2 \left(\frac{2m_e \gamma}{M} \ll 1 \right). \quad (8.2)$$

This approximation introduces, e.g., a ~6% error for the stopping power of muons in copper at 100 GeV.

Using ► Eq. (8.2) in ► Eq. (8.1) one gets the simplified form of the Bethe–Bloch equation

$$-\frac{dE}{dx} = K z^2 \frac{Z}{A} \frac{1}{\beta^2} \left[\ln \frac{2m_e c^2 \beta^2}{I(1 - \beta^2)} - \beta^2 \right] \quad (8.3)$$

where the density effect correction and the shell correction have been also neglected.

The effective ionization energy (or excitation energy) can roughly be approximated as $I = 10 Z \text{ eV}$. A better approximation is given by Leo (1987):

$$\frac{1}{z} = \begin{cases} 12 + 7/Z & Z < 13 \\ 9.76 + 58.5 Z^{-1.19} & Z \geq 13 \end{cases} \quad (8.4)$$

and experimentally adjusted values are tabulated by Groom et al. (2001).

Thus the stopping power depends on the charge and velocity of the incident particle as well as on the effective ionization potential and the atomic and mass numbers of the atoms of the medium.

The stopping power as computed for muons in copper (Bichsel et al. 2002; Groom et al. 2001) is shown in ► Fig. 8.1. Nuclear losses are significant at the lowest energies only, where the

■ Fig. 8.1

Stopping power vs. relative momentum, $\beta\gamma = p/Mc$, for muons in copper. The solid curve indicates the total stopping power, the dash-dotted and dashed lines the Bethe–Bloch equation with and without density effect correction. The vertical bands separate the validity regions of various approximations indicated in the figure. The dotted line denoted with μ^- indicates the Barkas effect. In the Bethe–Bloch region the stopping power scales with the particle mass and Z/A of the medium

difference between positive and negative particles is also noticeable due to the polarization of the medium (**Barkas effect**, Barkas et al. 1956). The Bethe–Bloch curve (dashed and dash-dotted lines) goes through a flat minimum (minimum ionizing region) and then slowly increases again due to radiation losses. The density effect correction δ is important at very high energies only. Most relativistic particles of laboratory energies have energy loss rates close to the minimum; those are called **minimum ionizing particles** or MIPs.

One can get an estimate (Bichsel et al. 2002) of the stopping power of various particles in various substances using ▶ Fig. 8.2. In ▶ Fig. 8.3 the ionization stopping power is plotted for various charged particles as measured in copper as a function of kinetic energy: one can see the scaling with particle mass.

Note, however, the substantial difference at high energies due to the strong interaction: pions are only slightly heavier than muons, and high-energy muons are almost impossible to contain in matter (all high-energy calorimeters are encircled by detectors to detect the escaping muons), whereas even the highest-energy pions produced in particle collisions are contained in materials of moderate thickness (e.g., the so-called hadron calorimeters of high-energy detectors).

One can deduce via integration of the Bethe–Bloch equation the R range of particles losing energy in matter via ionization only. As the stopping power scales with momentum, R/M will

■ Fig. 8.2

Stopping power due to ionization according to the Bethe–Bloch equation vs. relative momentum $\beta\gamma = p/Mc$ of heavy charged particles in liquid hydrogen, gaseous helium, carbon, aluminum, iron, tin and lead. Momentum scales are shown below the plot for muons, pions and protons and an energy scale for protons above

scale with $\beta\gamma$. Ranges in surface density units are presented in ▶ Fig. 8.4 for various particles and elements.

8.2.2 Stopping Power at Low Energies

At low energies electron shell effects should also be taken into account by using the C/Z shell correction, see (Groom et al. 2001) for details. The Bethe–Bloch equation (▶ Eq. (8.1)) is based on first-order Born approximation. Higher order effects, important at low energies only, can be included by adding a term $z^2 L_2(\beta)$ in the square brackets of ▶ Eq. (8.1) where $L_2(\beta)$ is an empirical function of particle speed.

■ Fig. 8.3

Stopping power due to ionization, according to the Bethe–Bloch equation, vs. kinetic energy of heavy charged particles in copper

The Barkas effect, which makes the stopping power for negative and positive particles different in matter, can also be included there as a term $zL_1(\beta)$; it makes the energy loss for a slow negative particle lower than for a positive one under identical conditions due to polarization of the medium. This effect is studied in detail at the Antiproton Decelerator at CERN (Moeller et al. 2002).

For low particle speeds ($0.01 < \beta < 0.05$) there is no satisfactory theory and so semi-empirical formulae are used. The most popular ones are those proposed by Groom et al. (2001), Andersen and Ziegler (1977) and Lindhard (1954). At the lowest energies, for example, for protons below a few hundred eV, non-ionizing nuclear energy loss dominates the stopping power (Groom et al. 2001; Ziegler et al. 1985).

Thus, for instance, for protons in copper, the nuclear plus electronic stopping power is $113 \text{ MeV}/(\text{g cm}^{-2})$ at $T = 10 \text{ keV}$ kinetic energy ($4.3 \text{ MeV}/c$ momentum), then it rises to a maximum of $210 \text{ MeV}/(\text{g cm}^{-2})$ at $100\text{--}150 \text{ keV}$ ($15 \text{ MeV}/c$), and then it falls to $120 \text{ MeV}/(\text{g cm}^{-2})$ at 1 MeV ($44 \text{ MeV}/c$); see the lower momentum part in ▶ Fig. 8.1. Above $0.5\text{--}1 \text{ MeV}$ the Bethe–Bloch equation is adequate (Groom et al. 2001).

As the energy decreases, the stopping power increases according to the Bethe–Bloch formula. The plot of energy loss (which can be related to specific ionization) along the path of a charged particle penetrating a medium is called the **Bragg curve**. A typical Bragg curve is depicted in ▶ Fig. 8.5 for a proton of $\sim 26 \text{ MeV}$ initial energy (Besserer et al. 1997).

The sharp peak at the end of the penetration track of the charged particles is very important in nuclear medicine (e.g., when irradiating living tissue) as it ensures that most of the energy is deposited where the particle is stopped. This is especially promising for pions and antiprotons as they form **exotic atoms** (i.e., an atom where a pion or an antiproton is bound in an atomic orbit) and get absorbed by the nucleus, causing its fragmentation or fission (see ▶ Chap. 28 in Vol. 3). After nuclear capture in an exotic atom, the energy deposited by the nuclear fission fragments (created when the particle is absorbed by the nucleus) significantly increases the

■ Fig. 8.4

Penetration range (R) per particle mass vs. $\beta\gamma = p/Mc$ for heavy charged particles in liquid hydrogen, gaseous helium, carbon, aluminum, iron and lead. Momentum scales are shown for muons, pions and protons

local damage of the tissue. The energy of the particle should be chosen so that the region of stopping be concentrated on the malignant tissue (Lea 1962).

8.2.3 Energy Loss in Mixtures and Compounds

A mixture or compound can be treated as consisting of thin layers of pure elements in the correct proportion according to their mass fractions w_j (Bragg additivity):

$$\left\langle \frac{dE}{dx} \right\rangle = \sum_j w_j \left. \frac{dE}{dx} \right|_j \quad (8.5)$$

where $dE/dx|_j$ is the mean rate of energy loss in the j th element.

■ Fig. 8.5

Typical Bragg curve: deposited energy per distance (dE/dx) vs. penetration depth for protons of ~26 MeV initial energy. The experimental data are reasonably well described by theory and simulation

In principle, similar expressions can be used to estimate average $\langle Z/A \rangle$, $\langle I \rangle$ and $\langle \delta \rangle$ values; for instance,

$$\left\langle \frac{Z}{A} \right\rangle = \sum_j w_j \frac{Z_j}{A_j} = \frac{\sum_j n_j Z_j}{\sum_j n_j A_j}. \quad (8.6)$$

Note that this type of approximation underestimates $\langle I \rangle$ as in a compound the electrons are more tightly bound than in the elements, and $\langle \delta \rangle$ has no relevance as it is the effective electron density that matters. Those quantities have been tabulated for many compounds and nearly 200 mixtures by Sternheimer et al. (1984) and Seltzer and Berger (1984).

8.2.4 Fluctuations in the energy loss

In practice one uses the quantity $(-dE/dx)\Delta x$, the mean energy loss in a layer of Δx thickness. For finite Δx there will be fluctuations in the actual values, the distribution will be skewed toward higher values (**Landau tail**, Landau 1944) and only for thick layers ($T_{\max} \ll (-dE/dx)\Delta x$) will the distribution be Gaussian (see ▶ Sect. 9.3.6 in Chap. 9 on the “Stochastics and Nuclear Measurements”).

The fluctuations in energy loss are due to high-energy knock-on electrons and to the small number of collisions involving large energy transfers. In practice, one measures the *deposited* rather than the *lost* energy. When large amounts of energy are carried away by knock-on

electrons one may prefer to consider a mean energy loss by excluding single energy transfers greater than a given cutoff T_{cut} . This restricted loss rate (Bichsel et al. 2002) with a modified Bethe–Bloch equation is

$$-\frac{dE}{dx}\bigg|_{T < T_{\text{cut}}} = K_Z^2 \frac{Z}{A} \frac{1}{\beta^2} \left[\frac{1}{2} \ln \frac{2 m_e c^2 \beta^2 \gamma^2 T_{\text{upper}}}{I^2} - \frac{\beta^2}{2} \left(1 + \frac{T_{\text{upper}}}{T_{\text{max}}} \right) - \frac{\delta}{2} - \frac{C}{Z} \right] \quad (8.7)$$

where T_{upper} is the smaller of T_{cut} and T_{max} .

8.2.5 Secondary Electrons, Ionization Yields

The distribution of energetic knock-on electrons (δ rays) with kinetic energies $T \gg I$ is given by Rossi (1952) as

$$-\frac{d^2N}{dTdx} = \frac{1}{2} K_Z^2 \frac{Z}{A} \frac{1}{\beta^2} \frac{F(T)}{T^2} \quad (I \ll T \leq T_{\text{max}}), \quad (8.8)$$

where N is the number of electrons and the value of the $F(T)$ function is about unity for $T \ll T_{\text{max}}$; explicit formulae are given by Rossi (1952).

The total energy loss can be related to the number of ion pairs produced near the particle track. This relation becomes complicated for relativistic (β approaches to 1) particles due to the escape of energetic knock-on electrons whose range may exceed the dimensions of the sample. The mean local energy dissipation per ion pair produced, W , is essentially constant for relativistic particles and slowly increases at lower energies (Bichsel et al. 2002). It can be sensitive to the presence of contaminants in gases and may be influenced by subsequent recombination. The ionization yields are very important for a number of applications, especially for radiation detectors.

8.2.6 Single Scattering

A charged particle moving in a medium is deflected many times at small angles. This is mostly due to Coulomb scattering on nuclei, but for hadronic particles at low energies, the strong interaction also contributes. For really heavy projectiles (like the α particle) in very thin targets multiple scattering has a low probability and the angular dependence of the cross section can be described in the following way (Vértes and Kiss 1987).

Due to the Coulomb interaction a nucleus at rest forces an approaching α particle to follow a hyperbolic orbital. For this orbital one can write:

$$\cot \frac{\theta}{2} = l \frac{Mu_{\alpha}^2}{2Ze^2}, \quad (8.9)$$

where $l = \overline{OA}$ as shown in  Fig. 8.6, and M and u_{α} are the mass and speed of the α particle, respectively.

If a flux of Φ_0 of α particles per unit area per unit time is being used, the number of particles per unit time crossing the ring-shaped cross section marked off by radii l and $(l + dl)$ around the nucleus is:

$$dN_{\theta} = \Phi_0 2\pi l dl. \quad (8.10)$$

■ Fig. 8.6

The trajectory of an alpha particle in the vicinity of an atomic nucleus with charge Ze

By substituting the expression of l from ► Eq. (8.9) into ► Eq. (8.10) one can write:

$$dN_\theta = \Phi_0 2\pi \left(\cot \frac{\theta}{2} \right) \left(\frac{2Ze^2}{Mu_\alpha^2} \right)^2 \frac{1}{\sin^2 \frac{\theta}{2}} d\left(\frac{\theta}{2} \right). \quad (8.11)$$

The quantity dN_θ can also be expressed as

$$dN_\theta = n_\theta d\omega \quad (8.12)$$

where n_θ is – apart from a constant factor – a probability density function (see ► Chap. 7 in this Volume) characterizing the “frequency” of scattering events per unit time in the solid angle $d\omega$ defined by θ and $\theta + d\theta$. Therefore:

$$d\omega = 2\pi \sin \theta d\theta. \quad (8.13)$$

Using ► Eqs. (8.11–8.13), one obtains:

$$\frac{n_\theta}{\Phi_0} = \left(\frac{Ze^2}{Mu_\alpha^2} \right)^2 \frac{1}{\sin^4(\theta/2)}. \quad (8.14)$$

The inverse proportionality to $\sin^4(\theta/2)$ ensures that single scattering leads to very small angles.

The fraction of energy retained by the scattered particle is (Turkevich et al. 1967)

$$\frac{E_\theta}{E_0} = \left[\frac{(4/A) \cos \theta + \sqrt{1 - (4/A)^2 \sin^2 \theta}}{1 + 4/A} \right]^2. \quad (8.15)$$

In thick samples the multiple Coulomb scattering distribution is well described by the **Molière distribution** (Molière 1947, 1948, 1955; Bichsel et al. 2002), which can be approximated for many applications by a Gaussian angular distribution of a width (i.e., standard deviation)

$$\theta_0 = \frac{13.6 \text{ MeV}}{\beta c p} z \sqrt{\frac{x}{X_0}} \left[1 + 0.038 \ln \frac{x}{X_0} \right], \quad (8.16)$$

where p , β , c and z are the momentum, velocity and charge number of the incident particle, and x/X_0 is the thickness in units of radiation length (defined as follows, in ► Sect. 8.3.2.4).

► Eq. (8.16) is accurate to 11% for thicknesses $10^{-3} < x/X_0 < 100$ (Bichsel et al. 2002).

8.3 Interaction of Electrons with Matter

The interaction of electrons with matter is different from that of heavier charged particles for two reasons. One of them is the electron mass which is more than two orders of magnitude lower than that of the second lightest charged particle, the muon; this makes photon radiation very important in the stopping power of electrons even at lower energies. The other reason is that at low energies, the interaction with shell electrons dominates and that is collision between identical particles, which has to be taken into account in the calculations.

Electrons (β radiation) excite and ionize the atoms and molecules of the substance, they are scattered by the electric field of the atomic nuclei and undergo inelastic collisions with shell electrons. They give kinetic energy to shell electrons or emit energy in the form of bremsstrahlung (an expression taken from German meaning *brake radiation*) while slowing down in the Coulomb field of nuclei. Thus part of the initial electron energy gets absorbed in the substance while another part can get out. These interactions are summarized in [Table 8.4](#).

At low energies electrons and positrons lose their energy predominantly via ionization although other processes can also contribute. Among the latter are Møller (electron-electron) scattering, $e^-e^- \rightarrow e^-e^-$, Bhabha (electron-positron) scattering, $e^+e^- \rightarrow e^+e^-$, and positron annihilation, $e^+e^- \rightarrow \gamma\gamma$ on the electrons of the substance. The total stopping power of the substance for electrons is the sum of the fractional energy losses by collisional and radiation processes (ionization and bremsstrahlung):

$$\frac{dE}{dx} = \left(\frac{dE}{dx} \right)_{\text{ion}} + \left(\frac{dE}{dx} \right)_{\text{brems}}. \quad (8.17)$$

8.3.1 Energy Loss of Electrons by Ionization

The Bethe–Bloch equation has to be modified for this case, and it will be valid both for electrons and positrons. The maximal energy transfer will become $T_{\text{max}} = T_e/2$ and the Bethe–Bloch formula becomes (Leo 1987)

$$-\left(\frac{dE}{dx} \right)_{\text{ion}} = \frac{K Z}{2 A \beta^2} \left[\ln \frac{\tau^2(\tau + 2)}{2(I/m_e c^2)^2} + F(\tau) - \delta - 2 \frac{C}{Z} \right] \quad (8.18)$$

where $\tau = T_e/(m_e c^2)$, T_e is the kinetic energy of the electron and

Table 8.4

Classification of the interactions of electrons (β radiation) in matter

Reacting constituent	Changes in	
	Radiation	Medium
Shell electrons	Slowing-down, absorption	Excitation, ionization, transition radiation, Cherenkov radiation, chemical changes
Coulomb field of the nucleus	Scattering, slowing-down, absorption	Nuclear reaction, chemical changes

$$F(\tau) = \begin{cases} 1 - \beta^2 + \frac{\tau^2/8 - (2\tau+1)\ln 2}{(\tau+1)^2} & \text{for } e^- \\ 2 \ln 2 - \frac{\beta^2}{12} \left(23 + \frac{14}{\tau+2} + \frac{10}{(\tau+2)^2} + \frac{4}{(\tau+2)^3} \right) & \text{for } e^+. \end{cases} \quad (8.19)$$

Note that Cherenkov radiation is very important for fast electrons, but its contribution to the energy loss is small and it is included in [Eq. \(8.18\)](#) (Leo 1987).

The ionization energy loss of non-relativistic electrons can be approximated (Vértes and Kiss 1987) as

$$-\left(\frac{dE}{dx}\right)_{\text{ion}} = \frac{2\pi e^4}{T_e} \frac{N_A Z}{A} \ln \frac{1.66 T_e}{I}. \quad (8.20)$$

For relativistic electrons or positrons the following equation can be used (Vértes and Kiss 1987)

$$-\left(\frac{dE}{dx}\right)_{\text{ion}} = \frac{2\pi e^4}{m_e c^2} \frac{N_A Z}{A} \left(\ln \frac{E^3}{2m_e c^2 I^2} + \frac{1}{8} \right). \quad (8.21)$$

[Figure 8.7](#) presents ionization energy loss curves for electrons in some common materials.

Fig. 8.7

Energy loss of electrons owing to ionization in different absorbers (Vértes and Kiss 1987)

8.3.2 Energy Loss of Electrons by Radiation

8.3.2.1 Nuclear Bremsstrahlung

Bremsstrahlung accompanies the slowing down of charged particles in the Coulomb field of nuclei and atomic electrons. For a detailed treatment of bremsstrahlung the reader is referred to (Leo 1987); here some practical approximations are only given.

Since bremsstrahlung is a result of the interaction of the fast electron with the Coulomb field of the nucleus, the screening of the latter by atomic electrons plays an important role. This screening is characterized by the parameter (Leo 1987)

$$\xi = \frac{m_e c^2 E_f}{E_i E_f \alpha Z^{1/3}} \quad (8.22)$$

where E_i and E_f are the initial and final energy of the scattered electron ($E_f = E_i - E_\gamma$). Parameter ξ is related to the Thomas-Fermi radius of the atom ($\propto Z^{1/3}$); for no screening $\xi \gg 1$, and for complete screening $\xi = 0$.

At moderate energies ($m_e c^2 \ll E \ll m_e c^2 / Z^{1/3} \alpha$) the incident electron will feel no screening of the nucleus by the atomic electrons ($\xi \gg 1$), and the stopping power due to bremsstrahlung will be

$$-\left(\frac{dE}{dx}\right)_{\text{brems}} = 4r_e^2 \alpha \frac{N_A Z^2}{A} E \left[\ln \frac{2E}{m_e c^2} - \frac{1}{3} - f(\alpha Z) \right] \quad (8.23)$$

where (with the notation $a = \alpha Z$)

$$f(\alpha Z) = f(a) = a^2 \left[\frac{1}{1+a^2} + 0.20206 - 0.0369 a^2 + 0.0083 a^4 - 0.002 a^6 \right] \quad (8.24)$$

is the Coulomb correction which takes into account the interaction of the outgoing electron with the Coulomb field of the nucleus (Davies et al. 1954). High-energy electrons ($\xi \approx 0$; $E \gg m_e c^2 / Z^{1/3} \alpha$) will sense complete screening and their bremsstrahlung stopping power will become (Leo 1987)

$$-\left(\frac{dE}{dx}\right)_{\text{brems}} = 4r_e^2 \alpha \frac{N_A Z^2}{A} E \left[\ln(183 Z^{1/3}) + \frac{1}{18} - f(\alpha Z) \right]. \quad (8.25)$$

8.3.2.2 Electron-Electron Bremsstrahlung

Fast electrons also radiate in the field of the atomic electrons. This electron-electron bremsstrahlung has cross section very similar to that of the nuclear one except that it is proportional to Z instead of Z^2 . Thus, for the total energy loss, one approximately includes electron-electron bremsstrahlung as well if in the aforementioned equations Z^2 is replaced by $Z(Z+1)$ (Leo 1987).

8.3.2.3 Critical Energy

Critical energy, in general, is defined as the particle energy at which the ionization energy loss equals the radiation one. As the radiation losses depend very sensitively on the absorber

■ **Table 8.5**

Critical electron energies of selected absorbers (Leo 1987) including some detector materials

Material	Critical energy (MeV)
Air (STP)	102
H ₂ O	92
Al	51
Fe	27.4
Cu	24.8
Pb	9.51
Anthracene	105
Lucite	100
Nal	17.4
Polystyrene	109

material, the critical energy for electrons, E_c , is considered to be an important material constant. It can be roughly estimated by (Bethe and Ashkin 1953)

$$E_c = \frac{1600 m_e c^2}{Z}. \quad (8.26)$$

Critical electron energies of some commonly used materials are listed in ► [Table 8.5](#).

8.3.2.4 Radiation Length

Radiation length is a material constant similar to the critical energy and it is more widely used: it is the thickness over which the energy of an electron is reduced to a fraction $1/e$ of its original value due to radiation only. As in first order ► [Eqs. \(8.23\)](#) and ► [\(8.25\)](#) linearly depend on energy, the energy of a high-energy electron having passed through an absorber will depend on the absorber's surface density x as

$$E(x) = E_0 \exp(-x/X_0) \quad (8.27)$$

where X_0 is the radiation length of the absorber. Thus the fractional energy loss is roughly independent of the type of material when the absorber thickness is expressed in radiation lengths. ► [Table 8.6](#) quotes radiation lengths for some materials.

There is a simple formula to estimate the radiation lengths of elements (Bichsel et al. 2002):

$$X_0 = \frac{716.4 A}{Z(Z+1) \ln(287/\sqrt{Z})} \quad (8.28)$$

(in units of g/cm^2) and for mixtures and compounds one can use the Bragg additivity rule:

$$\frac{1}{X_0} = \sum_i w_i \frac{1}{X_0^i} \quad (8.29)$$

where w_i is the mass fraction of element i with radiation length X_0^i .

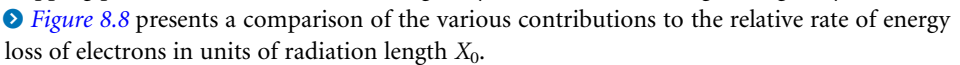

Note that the radiation length cannot be defined for low-energy electrons as their rest mass $m_e c^2$ cannot “disappear” and the kinetic energy may not be large enough to cover the energy loss required.

■ **Table 8.6**

Radiation lengths of selected absorbers (Leo 1987) including some detector materials

Material	Radiation length	
	X_0	
	(g/cm ²)	(cm)
Air (STP)	36.20	30,050
H ₂ O	36.08	36.1

Polystyrene	43.80	42.9
BaF ₂	9.91	2.05
Bismuth germanate (BGO)	7.98	1.12

8.3.3 Electron Stopping Power

The ionization loss varies logarithmically with energy and linearly with Z , whereas the radiation loss increases almost linearly with energy and quadratically with Z . Thus the electron stopping power is dominated at low energies by ionization, and at high energies by radiation.  [Figure 8.8](#) presents a comparison of the various contributions to the relative rate of energy loss of electrons in units of radiation length X_0 .

Bremsstrahlung is very important for electrons and positrons: as its emission probability is inversely proportional to the particle mass, its contribution to the energy loss is four orders of magnitude less for the second lightest particle, muon ($M_\mu = 106 \text{ MeV}/c^2$), than for electron.

With scattering effects neglected, the total stopping power of low to intermediate energy electrons (β radiation) is approximately

$$-\left(\frac{dE}{dx}\right)_{\text{electron}} = -\left(\frac{dE}{dx}\right)_{\text{ion}} - \left(\frac{dE}{dx}\right)_{\text{brems}}, \quad (8.30)$$

and the ratio of ionization to bremsstrahlung energy loss rates is (Vértés and Kiss 1987)

$$\left(\frac{dE}{dx}\right)_{\text{brems}} / \left(\frac{dE}{dx}\right)_{\text{ion}} \approx \frac{Z T_e}{800 \text{ MeV}}. \quad (8.31)$$

8.3.4 Electron Scattering

Electrons and positrons can scatter on the nuclei and on the electrons of the medium. The role of these processes in the energy loss of electrons in matter is small at low energies and negligible above the critical energy (Bichsel et al. 2002) as shown in  [Fig. 8.8](#).

■ Fig. 8.8

Contributions of various processes to the relative rate of energy loss for electrons and positrons in lead. On the left scale x is given in units of radiation length ($X_0(\text{Pb}) = 6.37 \text{ g/cm}^2$), whereas on the right one it is in g/cm^2

8.3.5 Absorption of β Radiation

For the description of β absorption at low energies empirical relations can be used (see, e.g., Vértés and Kiss 1987). The absorption equation is

$$I(x) = I_0 e^{-\mu_m x} \quad (8.32)$$

where I_0 and $I(x)$ are the numbers of electrons entering and leaving the sample of thickness x (measured in g/cm^2) and μ_m is the mass attenuation coefficient depending on E_β , the maximum (kinetic) energy of the electrons produced by the given β decay, and the properties of the absorber. Vértés and Kiss (1987) quote the following empirical formulae:

$$\{\mu_m\} = \begin{cases} \frac{35Z}{\{A\} \{E_\beta\}^{1.14}} & (Z < 13) \\ \frac{7.7 Z^{0.31}}{\{E_\beta\}^{1.14}} & (Z \geq 13), \end{cases} \quad (8.33)$$

where the braces indicate numerical values of the respective quantities measured in the following units: $[A] = \text{g/mol}$, $[E_\beta] = \text{MeV}$ and $[\mu_m] = \text{g}^{-1}\text{cm}^2$. For mixtures and compounds, the attenuation coefficient can be averaged in the usual way:

$$\mu_m = \sum_i w_i \mu_m^i \quad (8.34)$$

where w_i is the mass fraction of component i in the compound and μ_m^i is its mass attenuation coefficient. See ▶ Fig. 2.39 in Chap. 2 of this Volume for a typical β spectrum as well as ▶ Fig. 48.23 in Chap. 48, Vol. 5, for the energy spectra of various β decays.

8.3.6 Cherenkov Radiation and Transition Radiation

There are two kinds of radiation which are characteristic of all fast charged particles, heavy or light, in all kinds of matter: Cherenkov radiation and transition radiation. Although these processes are not that important when estimating energy losses, both are widely used in detecting and identifying charged particles, especially in nuclear and particle physics experiments (Cherenkov and transition radiation detectors, see [Chap. 48](#) in Vol. 5). Here they are treated as radiation induced by electrons as both are characteristic of very fast (more or less relativistic) particles and so play a most important role for the lightest charged particles, electrons and positrons.

8.3.6.1 Cherenkov Radiation

In a medium with refraction index $n > 1$ the speed of light is $u_{\text{rad}} = c/n$. Relativistic particles can propagate there faster than the light and they lose energy via Cherenkov radiation, visible light along a cone under the angle (see [Fig. 8.9](#))

$$\cos \theta = \frac{1}{n\beta} \quad (8.35)$$

or, equivalently,

$$\theta = \arccos \frac{1}{n\beta} \approx \sqrt{1 - 1/(n\beta)^2} \quad (8.36)$$

for small θ (Bichsel et al. 2002), as the interference of waves will prevent radiation in any other direction.

According to Frank and Tamm (1937) in this case the medium becomes polarized and the polarization ceases via the emission of electromagnetic waves. The energy loss via Cherenkov radiation is

$$-\left(\frac{dE}{dx}\right)_C = \frac{4\pi e^2}{\rho c^2} \int_{\beta n(\omega) > 1} \left(1 - \frac{1}{n^2 \beta^2}\right) \omega d\omega, \quad (8.37)$$

where $n(\omega)$ is the refraction index as a function of the photon angular frequency ω . This energy loss is included in the Bethe–Bloch equation, and it is small as compared to the collisional loss (Leo 1987): for condensed substances it is about $10^{-3} \text{ MeV cm}^2 \text{ g}^{-1}$, for hydrogen gas it is $0.1 \text{ MeV cm}^2 \text{ g}^{-1}$ and for heavier gases $0.01 \text{ MeV cm}^2 \text{ g}^{-1}$.

The number of Cherenkov photons produced in a unit path length x and unit photon energy $E_{\text{rad}} = \hbar\omega$ interval by a particle of charge ze is (Bichsel et al. 2002)

$$\frac{d^2 N}{dE_{\text{rad}} dx} = \frac{\alpha z^2}{\rho \hbar c} \sin^2[\theta(E_{\text{rad}})] \approx (370 \text{ eV}^{-1} \text{ cm}^{-1}) \sin^2[\theta(E_{\text{rad}})] \quad (8.38)$$

where $\theta(E_{\text{rad}})$ is the energy dependent angle shown in [Fig. 8.9](#). The approximation expressed by the second half of the formula is valid only for $z = 1$.

In order to get the total number of observed photons, the aforementioned formula has to be multiplied by the response function of the optical transducer (i.e., the absorption characteristics of the light guide) and integrated over all E_{rad} .

■ Fig. 8.9

Propagation cone of the Cherenkov radiation of a certain frequency in a medium of refraction index n . Note that because the refraction index n depends on the radiation frequency and thus on the radiation energy $E_\gamma = \hbar\omega$, the angle θ is also energy dependent as expressed by ► Eq. (8.35)

8.3.6.2 Transition Radiation

In a medium containing N_e quasi-free electrons in unit volume, an electromagnetic radiation with ω frequency will have a phase velocity (i.e., velocity at which the phase of the wave of a given frequency propagates)

$$u_{\text{rad}} = \frac{c}{n} = \frac{c}{\sqrt{1 - \frac{N_e e^2}{\epsilon_0 m_e \omega^2}}} \quad (8.39)$$

where n is the refraction index.

The radiation can propagate if the refraction index is real, i.e.

$$\omega > \omega_p = \sqrt{\frac{N_e e^2}{\epsilon_0 m_e}} \quad (8.40)$$

where ω_p is the **plasma frequency** of the medium (see, e.g., Bichsel et al. 2002). As in real media the electrons cannot always be considered quasi-free, the plasma frequency is an empirical constant characterizing the substance.

Transition radiation is emitted when a fast charged particle passes the boundary of two media with different relative permittivity. It is caused by the fact that the electric displacement, $\mathbf{D} = \epsilon\epsilon_0\mathbf{E}$ changes continuously through a boundary, but the electric field strength \mathbf{E} jumps (however, if there is a surface charge, then \mathbf{D} jumps). When a charged particle approaches a boundary, with its mirror charge on the boundary they make a dipole which changes in time; that is why the radiation is emitted. This is significant for extreme relativistic particles only with $\gamma = 1/\sqrt{1 - \beta^2} \gg 1$.

When such a particle passes through a thin absorber (foil) with plasma frequency ω_{p1} and enters a medium with ω_{p2} it radiates photons of frequency $\omega \gg \omega_{p1}$ with a double differential energy distribution

$$\frac{dE_{\text{tr}}}{d\omega d\Omega} = \frac{\hbar d_1 \omega}{2c} \left[\gamma^{-1} + \theta^2 + \frac{\omega_{p1}^2}{\omega^2} \right]^{-1} \quad (8.41)$$

where d_1 is the thickness of the foil. This is a radiation in the X-ray region, which is strongly forward peaked with a cone angle of $\theta \approx 1/\gamma$. The total energy radiated for $\omega_{p1} \gg \omega_{p2}$ is $E_{\text{tr}} = \alpha z^2 \gamma \hbar \omega_{p1}/3$.

■ **Table 8.7**

Classification of the interactions of photons (X-ray and γ radiation) in matter. The Z -dependence of the σ cross section of the interaction is also shown

Reacting constituent	Absorption	Scattering	
		Elastic	Inelastic
Shell electrons	Photoelectric effect: $\sigma \propto Z^4$	Rayleigh scattering: $\sigma \propto Z^2$	Compton effect: $\sigma \propto Z$
		Thomson scattering: $\sigma \propto Z$	
Atomic nuclei	Photonuclear reaction (γ, n), (γ, p), etc.: $\sigma \propto Z$	(γ, γ) scattering: $\sigma \propto Z^2$	(γ, γ') scattering
	resonance absorption		
Coulomb field of nuclei	Pair production: $\sigma \propto Z^2$		

8.4 Interaction of Photons with Matter

When photons penetrate a substance, they can interact with the nuclei or with the shell electrons. ▶ [Table 8.7](#) shows a classification of the interactions of photons (X-ray and γ radiation) in matter. The dependence of the cross section σ of the interaction on the atomic number Z of the medium is also shown. Note that the Compton effect is inelastic for the atom but it is treated theoretically as elastic scattering on *free* electrons as the binding energy of the atomic electron is much smaller than that of the scattered electron.

The cross sections (Bichsel et al. 2002) of various kinds of photon interactions with matter are compared in ▶ [Figs. 8.10](#) and ▶ [8.11](#). ▶ [Figure 8.10](#) is restricted to the MeV energy region of nuclear γ rays, whereas ▶ [Fig. 8.11](#) encompasses the widest possible range.

8.4.1 Compton Effect

In the Compton effect, part of the energy and the momentum of the photon is transferred to a shell electron. As a consequence, the energy and the direction of propagation of the photon will change (see ▶ [Fig. 8.12](#)).

Since the binding energy of the electron is negligible as compared to E_γ , the electron is assumed to have been free before the collision. Using energy and momentum conservation, one obtains that the photon energy changes as

$$E_\gamma - E'_\gamma = \frac{E_\gamma E'_\gamma}{m_e c^2} (1 - \cos \theta), \quad (8.42)$$

and the wavelength changes as

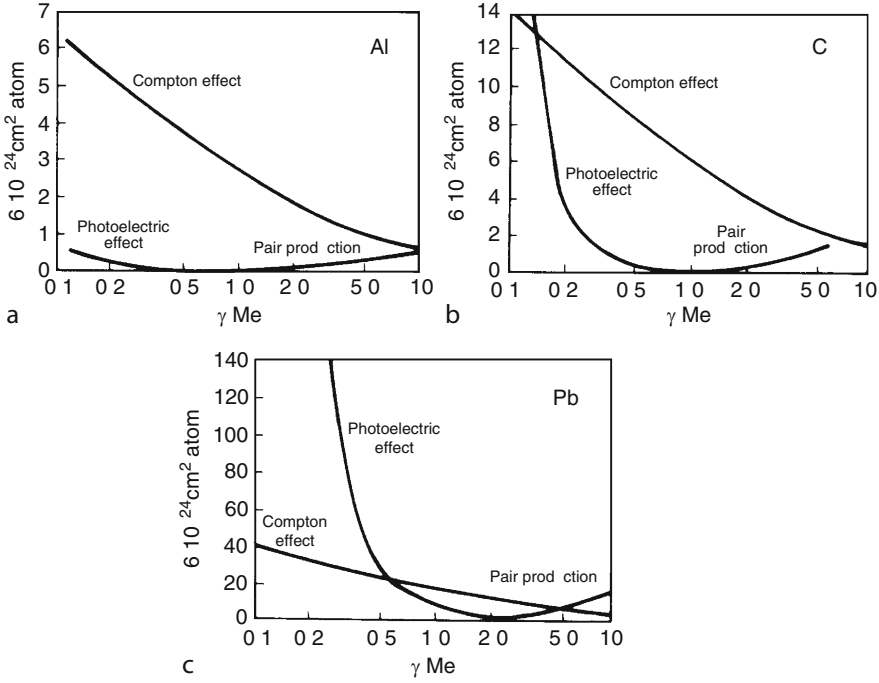

$$\lambda' - \lambda = \frac{h}{m_e c} (1 - \cos \theta). \quad (8.43)$$

Klein and Nishina (1929) performed a full quantum mechanical calculation using Dirac's equation for the electron. For unpolarized incident photons they obtained for the differential cross section

$$\frac{d\sigma_C}{d\Omega} = \frac{1}{2} \left[\frac{r_e}{1 + a(1 - \cos \theta)} \right]^2 \left[1 + \cos^2 \theta + \frac{a(1 - \cos \theta)^2}{1 + a(1 - \cos \theta)} \right] \quad (8.44)$$

■ Fig. 8.10

Energy dependence of the cross sections of Compton effect, photoelectric effect and pair production in various materials: (a) aluminum, (b) copper, and (c) lead

and for the total cross section

$$\sigma_C = \frac{2\pi e^4}{(m_e c^2)^2} \times \left\{ \frac{1+a}{a^2} \left[\frac{2(1+a)}{1+2a} - \frac{1}{a} \ln(1+2a) \right] + \frac{1}{2a} \ln(1+2a) - \frac{1+3a}{(1+2a)^2} \right\} \quad (8.45)$$

where $a = E_\gamma/(m_e c^2)$ and $d\Omega$ is the solid angle between the cones of angles θ and $\theta + d\theta$. The maximum kinetic energy of the scattered electron is

$$T_e^{(\max)} = E_\gamma \frac{2a}{1+2a} < E_\gamma. \quad (8.46)$$

There is a sharp drop at the end of the continuous energy spectrum of the Compton electrons, the **Compton edge**, distinctly below the full energy of the original photon. The electron energy reaches its maximum when the photon is totally back scattered ($\theta = 180^\circ$). The energy of such backscattered photons $E_\gamma' = E_\gamma - T_e^{(\max)}$ is therefore at minimum, but for this minimum one has $E_\gamma' > 0$ owing to [Eq. \(8.46\)](#).

The Compton scattering was the first observation of the dual – wave and particle – nature of electromagnetic radiation.

■ Fig. 8.11

Total cross section (in units of 1 barn = 10^{-28} m²) of photon interaction in carbon and lead as a function of photon energy and the contributions of the following processes: photoelectric effect, Rayleigh and Compton scattering, pair production in the field of the nucleus (nuclear p.p.) and of the shell electrons (electron p.p.). Note the resonances ("edges" as they are called) in photoelectric effect. The total cross section curve is flat for another two orders of magnitude in energy beyond the plot

■ Fig. 8.12

Geometrical scheme of the Compton effect. An incoming photon of energy $E_\gamma = h\nu$ kicks out a shell electron which acquires energy E_e ; the scattered photon proceeds at angle θ with energy $E'_\gamma = h\nu'$

8.4.2 Thomson and Rayleigh Scattering

Thomson and Rayleigh scattering are the classical equivalents of the Compton effect with the exception that no (internal) energy is transferred to the atoms, they are neither ionized nor excited, just the direction of the photon is changed.

The electromagnetic field of the propagating photon polarizes the atoms and molecules of the medium and induces electric dipoles which then create secondary electromagnetic radiation in all directions. For moderately low energy ($E \approx 100$ keV) photons, the medium can be considered to be practically homogeneous, the photon is scattered by an atom as a whole, and one speaks of **Rayleigh or coherent scattering**.

If the photon energy is so low that it cannot cause Compton effect, one has elastic scattering on free electrons (**Thomson scattering**). In the classical limit, the Klein-Nishina formula reduces to the Thomson cross section:

$$\sigma = \frac{8\pi}{3} r_e^2. \quad (8.47)$$

8.4.3 Photoelectric Effect

As a result of the photoelectric effect, the total energy of the photon is transferred to a shell electron. If the binding energy of the shell electron is E_b , the emitted electron will have the kinetic energy

$$T_e = E_\gamma - E_b. \quad (8.48)$$

Momentum conservation prohibits photoelectric effect on free electrons; the atom has to absorb the recoil momentum. Electrons with the largest binding energy still accessible for the photon are preferred in the cross section; as the photon energy approaches from above the binding energy of the K-electrons, the cross section increases, followed by a sharp drop

(K absorption edge) when it becomes lower, and this is repeated at the L- and M-energies. As shown by [Fig. 8.11](#), photon absorption at low energies is dominated by the photoelectric effect. In carbon there is a very prominent K absorption edge whereas the spectrum of lead shows several absorption edges.

The partial mass attenuation coefficient (in units of $\text{g}^{-1} \text{cm}^2$) of the photoelectric effect is determined by the empirical formula

$$\{\mu_{\gamma, \text{ph}}\} = 8.9 \times 10^{-6} \frac{Z^{4.1}}{\{A\}} \{\lambda\}^n, \quad (8.49)$$

where $n \approx 3$ and the numerical values are understood in the following units: $[\mu_{\gamma, \text{ph}}] = \text{g}^{-1} \text{cm}^2$, $[A] = \text{g}^{-1} \text{mol}$, and for the photon wavelength $[\lambda] = \text{nm}$.

The photoelectric effect is followed by the deexcitation of the atom via X-ray transitions or by the emission of a secondary electron (**Auger effect**, see later in [Sect. 8.5.2](#)). As above the K edge absorption dominates, one can collect a complete X-ray spectrum from the subsequent electron transitions. The energy and intensity of the X-rays are characteristic of the composition of the emitter. Thus, γ sources can be used to induce photoelectric effect and subsequent X-ray transitions in order to make qualitative and quantitative analyses of samples, which is called the **X-ray fluorescence** method.

Internal conversion can be considered as a special case of the photoelectric effect, occurring when the γ -photon emitted after nuclear decay does not leave the atom but transfers its whole energy to a shell electron.

8.4.4 Pair Production

If the photon energy is greater than the total rest energy of an electron-positron pair, 1.022 MeV, it can create one. For energy-momentum conservation pair production requires a third body, so pairs are usually created in the Coulomb field of an atomic nucleus. Theoretically, it is related to bremsstrahlung, and the cross section (Leo 1987) depends on the energy of the photon and the atomic number of the element. At “moderate” energies ($m_e c^2 \ll E_\gamma \ll m_e c^2 Z^{1/3}/\alpha$) the pair production cross section is

$$\sigma_{\text{pair}} = 4Z^2 \alpha r_e^2 \left[\frac{7}{9} \left(\ln \frac{2E_\gamma}{m_e c^2} - f(\alpha Z) \right) - \frac{109}{54} \right], \quad (8.50)$$

and at high energies (complete screening, $E_\gamma \gg m_e c^2 Z^{1/3}/\alpha$),

$$\sigma_{\text{pair}} = 4Z^2 \alpha r_e^2 \left\{ \frac{7}{9} [\ln(183 Z^{1/3}) - f(\alpha Z)] - \frac{1}{54} \right\}, \quad (8.51)$$

where the Coulomb correction factor $f(\alpha Z)$ is defined in [Eq. \(8.24\)](#).

Similarly to bremsstrahlung, pair production can occur in the field of the atomic electrons as well, and, to include this mechanism in the cross section approximately, Z^2 should be replaced by $Z(Z+1)$ (Leo 1987).

8.4.5 Photon-Photon Interaction

At “moderate” energies photons do not interact with each other. A propagating photon can, however, convert into a (virtual) particle-antiparticle pair for very short times and distances as

allowed by Heisenberg's uncertainty principle. Thus a high-energy photon ($E_\gamma > 1$ GeV) can interact with the virtual constituents of another photon as well. For instance, in high-energy electron-positron scattering emission of quark pairs can be observed. This is explained to be the result of an interaction between two photons emitted by the colliding particles (Nisius 2000).

8.4.6 Photon Attenuation

The energy loss of photons in matter can be characterized by the cross section of the process and also by the **mean free path** of photons between interactions. The latter can be expressed in units of surface density, and then it is called **mass attenuation length**. Photon attenuation lengths for various elements are shown in Fig. 8.13 as taken from Bichsel et al. (2002).

With increasing photon energy pair production dominates and at high energies (complete screening) the differential cross section becomes

$$\frac{d\sigma}{dE_\pm} = \frac{A}{X_0 N_A} \left[\frac{4}{3} a(1-a) \right], \quad (8.52)$$

where $a = E_\pm/E_\gamma$ is the fraction of photon energy transferred to the electron or positron. Note that the cross section is symmetric for a and $1-a$. In the high-energy limit the total cross section is

$$\sigma = \frac{7}{9} \frac{A}{X_0 N_A}. \quad (8.53)$$

According to Bichsel et al. (2002), the aforementioned equation is valid within a few percent down to 1 GeV, especially for high- Z materials.

Fig. 8.13

The photon mean free path (mass attenuation length) as a function of photon energy for various absorbers (Bichsel et al. 2002). The photon intensity after traversing the absorber of thickness x is $I = I_0 \exp(-x/\lambda)$

8.5 Complex Interactions

The interaction of nuclear radiation with matter is usually a multi-step process. If the primary particle does not lose all of its energy in a single step, it will enter other interactions. Moreover, secondary particles (emitted electrons or photons) can emerge and take part in secondary interactions. The chain of subsequent effects stops only when the whole energy of the primary particle has been dispersed in such small quantities that they cannot cause changes in the substance any more.

8.5.1 Electron-Photon Showers

As fast electrons create photons and photons create electron-positron pairs and kick out atomic electrons while slowing down, one always detects cascades (showers) of fast electrons and high-energy photons together. Moreover, as mentioned earlier, the phenomenological quantum-mechanical treatments of, e.g., bremsstrahlung and pair production are the same. Experimentally, these cascades are well described by electron-gamma-shower (EGS) simulations using the Monte Carlo method. The substances can be characterized by radiation lengths X_0 for electron and photon attenuation: comparing the pair production and bremsstrahlung cross sections, the **pair production length** of a high-energy photon will be approximately $(9/7) X_0$.

8.5.2 Auger Effect

As a common consequence of any interaction of nuclear radiation with matter, electron vacancies are created in the K, L, M shells of the atoms. Radioactive decay can also create vacancies in the daughter atoms (electron capture, internal conversion). Electron vacancies can cause X-ray transitions or – as shown by Auger (1925) – the vacancy is filled at the expense of a shell electron emission with the energy

$$E_A = \Delta E_b - E_b, \quad (8.54)$$

where E_b is the binding energy of the emitted electron and ΔE_b is the energy released by the shell rearrangement process (Nix 2002).

Formally, the Auger effect can be interpreted as a two-step process: first an X-ray photon is emitted, which is then absorbed via photoelectric effect in the same atom. The Auger effect may cause further ionization of a given atom and so multiply ionized atoms can be formed in Auger cascades, especially in high- Z atoms. This, in turn, can cause chemical changes, so the Auger effect has an important role in the mechanism of radiochemical reactions.

A special symbolism has been developed for the Auger effect for indicating the kind of internal rearrangement as well as the origin of the emitted electron. For example, the meaning of KLL is that a primary vacancy in the K shell was filled by an L electron and another L electron was released. Subshells can also be distinguished by precise measurements. For instance, the L shell has three subshells and so six kinds of KLL Auger electrons exist: KL_1L_1 , KL_1L_2 , KL_1L_3 , KL_2L_2 , KL_2L_3 and KL_3L_3 .

➤ *Figure 8.14* shows the measured energy spectrum of KLL Auger electrons of zirconium (Hörnfeldt et al. 1962).

■ Fig. 8.14

The energy spectrum of KLL Auger electrons in Zr. The full lines indicate the resolved components

■ Fig. 8.15

Typical energy spectra of Auger electrons measured in palladium (Nix 2002). The differential spectrum on the right is obtained by differentiating the integral one on the left. Most of recent works present differential spectra

In practice one measures the kinetic energy of the emitted electrons. Figure 8.15 presents (Nix 2002) the energy spectrum of Auger electrons emerging from palladium when bombarded by a 2.5 keV electron beam. The differential spectrum on the right is obtained by differentiating the energy spectrum on the left. Most of the contemporary works present differential Auger spectra (see, e.g., Figure 8.16 and Handbook of Analytical Methods 2002) for several reasons: the peaks are easier to locate and there are ways to measure differential Auger spectra directly.

The binding energy of shell electrons, and, consequently, the kinetic energies of the released Auger electrons are influenced by chemical bonds, and that enables Auger spectroscopy to provide important information on the chemical structure via the energy distribution of Auger electrons. However, Auger electrons formed well within the bulk of a sample cannot get out due

■ Fig. 8.16

The differential energy spectrum of Auger electrons in stainless steel

to their short range; Auger spectra like that in Fig. 8.16 can be measured for electrons originating from a thin ($<10^{-6}$ m) surface layer. This makes Auger spectroscopy a surface-testing method.

9.7 Summarizing Tables 453

Abstract: The term “stochastics” in the title roughly translates into “random features.” So it refers to anything related to probability theory, statistics, and, of course, stochastic processes. Some of the facts of probability and statistics, including special distributions relevant to nuclear measurements, have been summarized. Examples of the nuclear applications of stochastic processes have also been given. A separate section has been devoted to the analysis of nuclear spectra.

9.1 Introduction

Louis Lyons writes in the preface of his book *Statistics for Nuclear and Particle Physicists* (Lyons 1986) that “one cannot learn statistics simply by reading a book on the subject.” This also applies to “stochastics”, defined by Hans-Otto Georgii as “a term comprising both probability theory and statistics” in Footnote 1 of his book titled *Stochastics: Introduction to Probability and Statistics* (Georgii 2008). Therefore, the author of this chapter must be content with summarizing the relevant facts of probability and statistics and pointing out possible connections with nuclear measurements. As regards sampling distributions, parameter estimation, etc., the reader is referred to Lyons (1986) as well as to Press et al. (1999). The only exception will be the χ^2 distribution, which is a valuable goodness-of-fit tool in nuclear spectroscopy. A few examples of the nuclear applications of stochastic processes, a field usually excluded from short studies of this type, will also be cited.

Nuclear aspects (as well as some other important points of reference) will be phrased in the form of remarks numbered thus: (#1), (#2), etc. Such remarks also serve occasionally as an interface between the (mathematical) terminology used in this chapter and the terminologies used by other authors from different fields of nuclear science. The numbering of the remarks may also help to follow a train of thought that is unfolded over several sections or subsections.

9.2 Distributions of Random Variables

To establish uniform notation and to provide the reader with a convenient reference/vocabulary, some of the concepts and formulas of probability theory and statistics are summarized here because they will be referred to later in this chapter.

9.2.1 Measures of the “Location” of a Distribution

Expected value. Among the location parameters, designed to show where the “bulk” of a distribution is concentrated, the expected value (denoted by μ , also called mean) is considered as standard (provided that it exists). If it is necessary to emphasize that the expected value belongs to the random variable X , then the notation $E(X)$ is used. Alternative notations are $\langle X \rangle$ and μ_X .

(#1) Frequently used synonyms for the expected value/mean are *expectation value*, *mathematical expectation* or just *expectation*. In physics and other fields of science (except mathematics), the expected value is often referred to, in a rather careless way, as “average,” but this

term will be reserved here for the estimate of the mean as defined by [Eq. \(9.29\)](#). In physics, it is also customary to use the symbol \bar{X} for the mean, but – in this chapter at least – the horizontal overbar will denote the sample mean, in other words, the “real” average.

The expected value of a discrete distribution is calculated from its mass function $p(x) \equiv P(X = x)$, where P means probability. The formula is

$$E(X) \equiv \sum_{\forall i} x_i p_i \quad (9.1)$$

where p_i is the weight of the i th spectrum point x_i . (The expression “spectrum point” refers to any of the “allowed” values of a discrete random variable in this context, and therefore it has nothing to do with the nuclear spectra discussed in [Sect. 9.6](#).) For spectrum points $P(X = x_i) \equiv p_i$. If x is not a spectrum point, then $P(X = x) = 0$.

The distribution function of discrete distributions is calculated from the following sum:

$$F(x) \equiv \sum_{\forall i: x_i < x} p_i \quad (9.2)$$

For normalized distributions, $F(\infty) = 1$.

Integral valued random variables are an important class of discrete distributions. Their spectra consist of the integers: 0, 1, 2, ... The expected value is

$$E(X) \equiv \sum_{i=0}^{\infty} i p_i. \quad (9.3)$$

For continuous distributions, the expected value of X is calculated from the density function f as follows:

$$E(X) \equiv \int_{-\infty}^{+\infty} x f(x) dx. \quad (9.4)$$

The distribution function of continuous distributions is calculated from the following integral:

$$F(x) \equiv \int_{-\infty}^x f(u) du. \quad (9.5)$$

For normalized distributions, $F(\infty) = 1$.

It follows from [Eq. \(9.5\)](#) that the density function is the derivative of the distribution function:

$$f(x) = \frac{dF(x)}{dx}. \quad (9.6)$$

(#2) Note that in various fields of science, when people talk about averaging a physical quantity, they usually mean calculating the expected value of that quantity (considered but not necessarily declared as a random variable). The truth is revealed by the fact that they use formulas like [Eqs. \(9.1\)](#) and [Eq. \(9.4\)](#) for those calculations. Also, the mass function and the density function are often not distinguished, but they are referred to by the same expressions: *probability density* or *differential distribution function* and sometimes, rather loosely, as “distribution function” or just “distribution.”

The explanation of the adjective “differential” is made clear by [Eq. \(9.6\)](#).

If the density function or the mass function is referred to as “distribution function,” then the “real” distribution function is normally called *integral distribution function*. The reason for the name is clear from [Eq. \(9.5\)](#).

As a matter of fact, very often no reference is made to any distribution at all, although a careful analysis of the problem reveals that some of the quantities are *un-normalized density functions*. The various quantities referred to as *neutron flux* – actually different types of joint density functions of multivariate distributions – are good examples of this. These are usually denoted by the same symbol (either φ , ϕ , or Φ) no matter how many and which of the possible variables (space coordinates, solid angle, speed or energy or, alternatively, lethargy) are considered or made to disappear by integration. (See, for instance, [Chap. 38 in Vol. 4](#) and [Chap. 57 in Vol. 6](#).) To make things even more confusing, the only related quantity “defined” by Union of Pure and Applied Physics (IUPAP) bears the name *neutron flux density*, (unit: number of neutrons per square centimeter per second), although this is the least “density-function-like” of the whole family of related quantities. When in doubt as regards the type of neutron flux that is encountered, *dimensional analysis* can be suggested as a guide.

The “distributions” scientists do their “averaging” with are in fact un-normalized density functions most of the time. That is, in the continuous case, e.g., the “averaging” in physics typically goes like this:

$$\langle x \rangle = \frac{\int_{-\infty}^{+\infty} x g(x) dx}{\int_{-\infty}^{+\infty} g(x) dx} = \frac{1}{A} \int_{-\infty}^{+\infty} x g(x) dx. \quad (9.7)$$

where A^{-1} is called the normalizing factor converting the un-normalized density function $g(x)$ to the normalized one, $f(x) = A^{-1} g(x)$, for which

$$\int_{-\infty}^{+\infty} f(x) dx = \frac{1}{A} \int_{-\infty}^{+\infty} g(x) dx = \frac{A}{A} = 1. \quad (9.8)$$

as it should be. (Needless to say, the integration limits can be different from those indicated.)

(#3) Note also that [Eq. \(9.7\)](#) is written in the way as usually done outside mathematics, i.e., the symbol x is used both for denoting the random variable (*on the left*) and for indicating the assumed values of that same variable (*on the right*). (According to the convention followed in this chapter, the notation should be X on the left.) However, this does not affect the results of such calculations at all; only the notation is somewhat confusing (to a mathematician anyway), but that is how most people do it in practice. (As a matter of fact, the author himself has to concentrate very hard to keep to his chosen role as a “mathematician,” but he probably fails occasionally, anyway.)

(#4) Another type of “averaging” mentioned here is actually beyond the scope of this chapter. In *quantum physics*, the most common symbolism for the calculation of the expected value of a physical quantity q (characterized by the operator \hat{q}) in the quantum state described by the (complex) wave function $\Psi(\mathbf{r})$ is

$$\langle q \rangle = \langle \Psi | \hat{q} | \Psi \rangle \equiv \int \Psi^* \hat{q} \Psi dV. \quad (9.9)$$

where the integration goes by the volume element dV (over the whole space) and Ψ^* is the complex conjugate of Ψ . Here the product $\Psi^* \Psi$ is referred to as probability density too. It is indeed normalized to 1 as one would rightly expect from a density function:

$$\int \Psi^* \Psi dV = 1. \quad (9.10)$$

Median. The median $X_{1/2}$ is the point along the x -axis that represents the middle of the distribution, in the sense that X values smaller and greater than $X_{1/2}$ are equally probable. For a continuous distribution, this is the point where the distribution function $F(x)$ reaches half of the maximum:

$$F(X_{1/2}) = \frac{1}{2}. \quad (9.11)$$

For statistical samples the median is either the middle element (for an odd sample size) or the average of the two middle elements (for an even sample size) when the elements are arranged in increasing order (ordered sample).

(#5) As a familiar example of the median in nuclear science, the half-life $T_{1/2}$ of a radio-nuclide should be mentioned. (See ▶ Sect. 9.4.4 as well as the right-hand panels in ▶ Fig. 9.1.)

Mode. The mode m represents the local maximum (or one of the local maxima) of the density/mass function. It is usually referred to as the most probable value in physics and chemistry. (In the case of discrete distributions, only the spectrum points are considered when looking for maxima.) If there is only one maximum, the distribution is called *unimodal*; if there are two maxima, the distribution is called *bimodal* and so on.

Connection between location parameters. The existence of expected value depends on the convergence of the sum/integral from which it is calculated. If the expected value does not exist, the rest of the location parameters can still be used as substitutes. (For multimodal distributions, the modes can be actually more useful than the single expected value because they also convey information about the shape of the distribution.)

For symmetrical unimodal distributions the location parameters coincide with the center of symmetry c of the mass/density function (like the normal or Gaussian distribution whose density function is shown on the upper left graph in ▶ Fig. 9.1 as well as in ▶ Fig. 9.2):

$$\mu = X_{1/2} = m = c. \quad (9.12)$$

For asymmetrical unimodal distributions (see the upper right graph in ▶ Fig. 9.1) the following “rule of thumb” is often cited: The median divides the distance between the mode and the mean in the approximate ratio 2:1, i.e.,

$$(X_{1/2} - m) : (\mu - X_{1/2}) \approx 2 : 1. \quad (9.13)$$

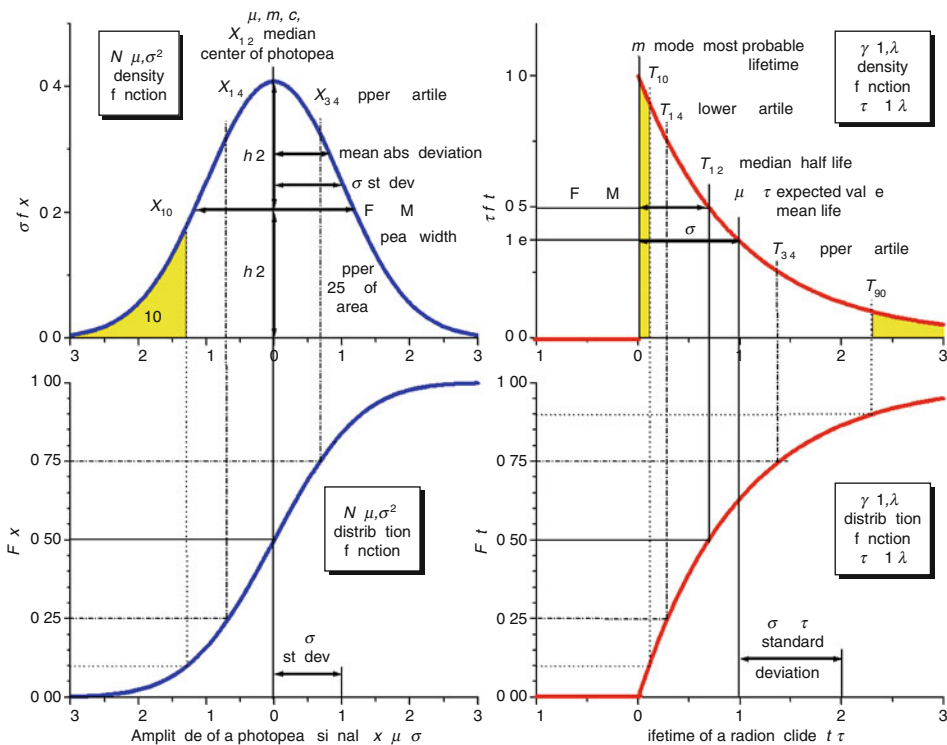

9.2.2 Useful Tools: Generating Function and Characteristic Function

Law of the Unconscious Statistician (Goodman 1988). The expected value of the random variable Y obtained by the function/transformation $Y = g(X)$ is calculated analogously to ▶ Eqs. (9.1) and ▶ (9.4) using the mass/density function of X :

$$E(g(X)) = \sum_{\forall i} g(x_i) p_i; \quad E(g(X)) = \int_{-\infty}^{+\infty} g(x) f(x) dx. \quad (9.14)$$

Fig. 9.1

Presentation of the location and dispersion parameters of a symmetric (normal) and an asymmetric (exponential) distribution by the help of the density function (*upper panels*) and the distribution function (*lower panels*). The shaded areas under the density curves represent 10% of the total area under them in accordance with the meaning of the 10 percentile ($X_{10\%}$) and with the meaning of the percentile and with the relationship between the density function and the distribution function shown by Eq. (9.5). Note that for an asymmetric distribution the “+” and “−” error intervals measured from the mean to complementary values of quantiles/percentiles are different, whereas for a symmetric distribution the estimate of the mean obtained from a single observation of X can always be given as $x \pm \Delta x$ no matter how the error Δx is calculated (e.g., it can be given in terms of the 95% (+) and 5% (−) percentiles, or it can be set equal to 2σ as usual). In practice, most people give their measured or calculated “results” with the “ \pm ” convention without paying any attention to the actual shape of the “error distribution”

Special applications of the above formula are the moments of a distribution. The n th moment is defined as follows:

$$M_n \equiv E(X^n). \quad (9.15)$$

In particular, the first moment is equal to the expected value

$$M_1 \equiv E(X) = \mu. \quad (9.16)$$

■ Fig. 9.2

Normal distribution is a well-studied distribution. If one has a good reason to believe (e.g., if this belief is based on the central limit theorem) that a distribution is normal (or Gaussian as often called) one can foretell that ~68% of the data will be within $\mu \pm \sigma$, where the mean μ is estimated by ▶ Eq. (9.29) and the standard deviation σ by ▶ Eq. (9.32), for instance. It is also clear that ~95.5% of the data should be within $\mu \pm 2\sigma$, and less than 0.3% is expected to be outside the $\mu \pm 3\sigma$ interval

The square root of the second moment (also called mean-square) – one of the “effective means” used – is usually referred to as the root mean square or rms:

$$\text{rms} \equiv \sqrt{M_2} = \sqrt{E(X^2)}. \quad (9.17)$$

Beside the rms, other types of effective means can be defined by the formula

$$\text{effective mean} \equiv g^{-1}\{E[g(X)]\} \quad (9.18)$$

where g^{-1} is the inverse of the function g . A further example of the effective means is the harmonic mean, i.e., the reciprocal of the mean-reciprocal:

$$\text{harmonic mean} \equiv [E(X^{-1})]^{-1}. \quad (9.19)$$

(#6) Note that the reduced mass $m_r = m_1 m_2 / (m_1 + m_2)$ of two masses m_1 and m_2 often cited in this book is exactly one half of their harmonic mean as the reader can easily check by assigning the same weight $p_i = 1/2$ when applying ▶ Eq. (9.1) to the simple calculation. Division by two causes the reduced mass to deserve its name inasmuch as it is always less than either of the masses. On the other hand, the harmonic mean itself always lies between m_1 and m_2 as one can rightly expect from a mean of any type. (See also ▶ Sect. 9.6.4.)

Generating function. The generating function is defined for integral valued random variables, the spectra of which consist of $0, 1, 2, \dots$ with weights p_0, p_1, p_2, \dots . The generating function of X is defined as the expected value of the exponential function s^X :

$$G(s) \equiv E(s^X) = \sum_{k=0}^{\infty} p_k s^k. \quad (9.20)$$

Since the distribution is normalized, $G(1) = 1$. The generating function (just like the mass function) contains all the information about the distribution. For instance, the expected value and the variance of X (see later on) can be calculated from its derivatives as follows:

$$E(X) = \mu = G'(1); \quad D^2(X) = G''(1) + \mu(1 - \mu). \quad (9.21)$$

Characteristic function. The characteristic function of continuous distributions is the expected value of the complex exponential function e^{iuX} (where $i^2 = -1$). In other words, it is the Fourier transform of the density function f :

$$\varphi(u) \equiv E(e^{iuX}) = \int_{-\infty}^{+\infty} e^{iuX} f(x) dx. \quad (9.22)$$

Since the distribution is normalized, $\phi(0) = 1$. The characteristic function (just like the density function) contains all the information about the distribution. For instance, the expected value and the variance of X can be calculated from its derivatives as follows:

$$E(X) = \mu = \frac{1}{i} \varphi'(0); \quad D^2(X) = -\varphi''(0) - \mu^2. \quad (9.23)$$

Both the characteristic function and the generating function represent a transformation T for which the following theorem holds (Korn and Korn 1968). Let X and Y denote independent random variables with density/mass functions f_X and f_Y . Let f_{X+Y} denote the density/mass function of the sum $X + Y$. Then one can write

$$T(f_{X+Y}) = T(f_X)T(f_Y). \quad (9.24)$$

The above formula serves as a basis for the deconvolution as well as for the addition theorems that will be cited later on in connection with different distributions.

9.2.3 Measures of the “Dispersion” of a Distribution

Variance. Among the dispersion parameters characterizing the “spread” of a distribution, the variance is considered as standard (provided that it exists). The variance is denoted by σ^2 or, if it has to be emphasized that it is the variance of the random variable X , the notation is $D^2(X)$, $\text{Var}(X)$, or σ_X^2 . The variance of X is calculated as follows:

$$D^2(X) \equiv E[(X - \mu)^2] = M_2 - \mu^2. \quad (9.25)$$

where $M_2 \equiv E(X^2)$ is the second moment of X . (The first moment is $M_1 \equiv \mu$.)

Standard deviation. The standard deviation of X is calculated from the variance

$$D(X) \equiv \sqrt{D^2(X)}. \quad (9.26)$$

Further notations: σ or σ_X . The relative deviation is the ratio of the standard deviation to the expected value

$$\sigma_{\text{rel}} \equiv \frac{\sigma}{\mu}. \quad (9.27)$$

Mean absolute deviation. The (mean) absolute deviation of X is

$$\text{AbsD}(X) \equiv E(|X - \mu|). \quad (9.28)$$

Whenever the expected value exists, so does the absolute deviation. (The standard deviation may not exist, even if the expected value exists.)

Interquantile range. This type of “measure” works even if the expected value does not exist.

The p quantile/fractile is a (not necessarily unique) point X_p along the x -axis, where the distribution function reaches a given p fraction of the maximum, i.e., where $F(X_p) = p$. Special types of quantiles are the quartiles ($p = 1/4, 1/2, 3/4$), the deciles ($p = 0.1, 0.2, \dots, 0.9$), and the percentiles ($p = 0.01, 0.02, \dots, 0.99$).

Quantiles can be used for the characterization of the spread of the distribution by giving the distance between the points X_p and X_{1-p} . For instance, the 10–90-percentile range means the difference $X_{0.9} - X_{0.1}$, where $X_{0.1}$ and $X_{0.9}$ are the 10 and the 90 percentile, respectively. It follows from the definition that about 80% of the observed values of X are supposed to lie in this range and about 20% outside.

The interquartile range characterizes the spread of the distribution with the distance between the lower and the upper quartiles: $X_{3/4} - X_{1/4}$. (The lower, middle, and the upper quartiles mean the 25, 50, and 75 percentiles, respectively.)

According to the above terminology, the median can be either considered as the middle quartile ($X_{2/4}$), or as the 50 percentile ($X_{0.5}$) of the distribution.

Halfwidth. The spread of a unimodal (continuous) distribution is sometimes characterized by its halfwidth meaning its full width at half maximum abbreviated as FWHM. The term refers to the total width of the density function (peak) between the points, where its height is half of the maximum.

The relative width is the ratio of the FWHM to the expected value: $\text{FWHM}_{\text{rel}} = \text{FWHM}/\mu$.

9.2.4 Estimation of Expected Value and Variance

Estimation of the expected value. The expected value is estimated by the average (also called the sample mean or arithmetic mean):

$$\hat{\mu} = \bar{X} \equiv \frac{1}{n} \sum_{k=1}^n X_k \quad (9.29)$$

where “ $\hat{\mu}$ ” reads “the estimate of μ .” According to [Eq. \(9.45\)](#), this estimate is unbiased, that is,

$$E(\bar{X}) = \mu. \quad (9.30)$$

(#7) As mentioned before, in physics, the horizontal overbar above a variable is often used to indicate its expected value, but this notation will be reserved here for the average.

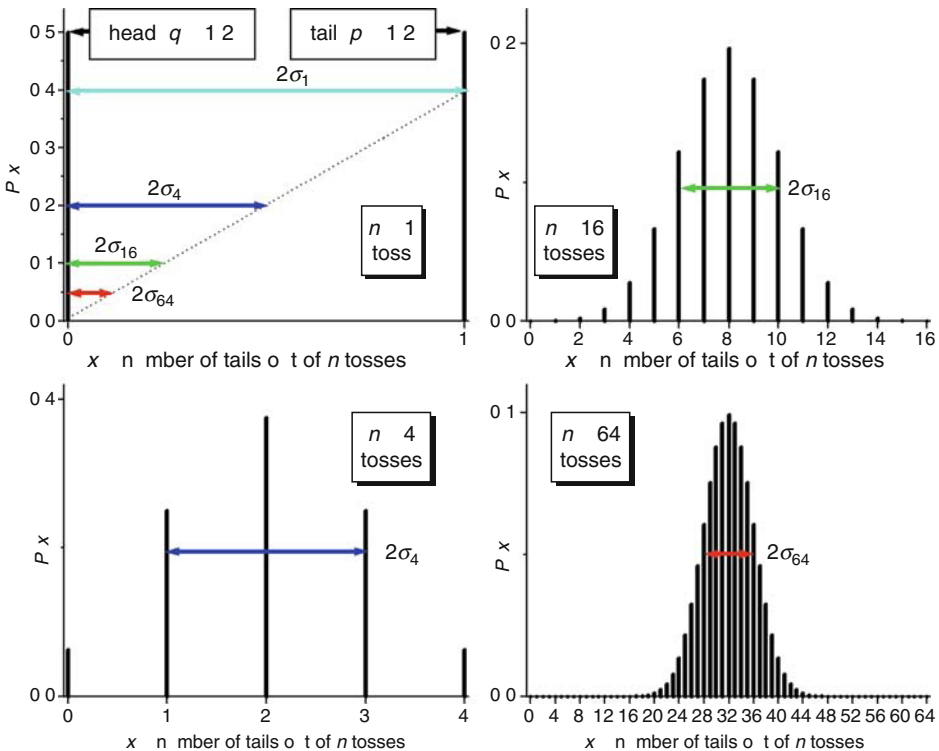

According to [Eq. \(9.47\)](#), the uncertainty of expected-value estimation is determined by the variance of the average

$$D^2(\bar{X}) = \frac{1}{n} D^2(X) \equiv \frac{1}{n} \sigma^2; \quad D(\bar{X}) = \frac{1}{\sqrt{n}} D(X) = \frac{1}{\sqrt{n}} \sigma \quad (9.31)$$

i.e., if the accuracy of expected-value estimation is to be increased by a factor of 2, 3, or N , then 4, 9, N^2 times as many data need to be averaged (see [Fig. 9.3](#)).

■ Fig. 9.3

The above sequence of graphs shows the distributions of the possible outcomes of four series of coin tossing – four series of Bernoulli trials – each representing one particular $B(n, p)$ binomial distribution (see later on). The probability of heads/tails has been fixed to $q = p = 0.5$, and the number of tosses ($n = 1, 4, 16, 64$) has been increased by a factor of 4 in the subsequent Bernoulli series. The graphs demonstrate several things at the same time. (1) Central limit theorem: The sum of a large enough number of independent random variables having a common distribution (such as the total number of tails obtained in a long series of single tosses) is normally distributed. (2) The binomial distribution can be approximated by normal distribution if n is large enough. (3) According to the upper left graph, if the number of data is quadrupled, then the accuracy of the average will double. (Note that the lengths of the $2\sigma_n$ double arrows copied from the rest of the graphs halve as n gets four times larger.) The average comes into the picture because the ratio x/n (lying between 0 and 1) can also be interpreted as the average of n Bernoulli random variables that can only assume the values 0 and 1 (see later on). (4) Law of large numbers: As n increases, the relative width of the binomial distribution gradually diminishes, which guarantees that the relative frequency x/n observed will eventually match the probability $p = 0.5$ as $n \rightarrow \infty$ (Note that the ratio x/n represents not only the average value of the Bernoulli variable, but also the relative frequency of tails in a concrete Bernoulli series)

Estimation of variance. The variance is normally estimated by the following formula of the empirical variance/sample variance (note that the sample mean \bar{X} is determined from the same set of data as the sample variance itself):

$$\hat{\sigma}^2 = s^{*2} \equiv \frac{1}{n-1} \sum_{k=1}^n (X_k - \bar{X})^2. \quad (9.32)$$

The above formula looks rather surprising having the form of a “spoiled” average. Its use, however, is justified since the variance estimate thus obtained is unbiased, i.e.,

$$E(s^{*2}) = \sigma^2. \quad (9.33)$$

If the expected value μ is exactly known, then the “unspoiled” averaging

$$\hat{\sigma}^2 = s^2 \equiv \frac{1}{n} \sum_{k=1}^n (X_k - \mu)^2 \quad (9.34)$$

delivers the unbiased estimate for the variance. Note that the estimate calculated from [Eq. \(9.32\)](#) tends to be greater than that obtained from [Eq. \(9.34\)](#) by a factor of $n/(n-1)$. Thus, the difference is only significant when the sample size n is small. However, for small samples variance estimation is rather meaningless anyway. Therefore in most practical cases the choice between the two formulas is only a matter of taste/convenience (i.e., whichever formula is available it will do). The estimate of standard deviation in either case is

$$\hat{\sigma} = \sqrt{\hat{\sigma}^2}. \quad (9.35)$$

Weighted average. It is a common situation that the value of a physical quantity is determined from different types of experiments, and the experimental values (X_k) obtained for those quantities have their own (different) accuracies characterized by the standard deviation (σ_k). When the error distribution of each experimental value can be considered normal, then the maximum likelihood estimate of the expected value of the physical quantity is given by the following weighted average (Orear 1987):

$$\hat{\mu} = \frac{\sum_{k=1}^n \frac{1}{\sigma_k^2} X_k}{\sum_{k=1}^n \frac{1}{\sigma_k^2}}. \quad (9.36)$$

The variance of the expected-value estimate is now (Leo 1987)

$$D^2(\hat{\mu}) = \frac{1}{\sum_{k=1}^n \frac{1}{\sigma_k^2}}. \quad (9.37)$$

It is easy to verify that if the errors of the X_k variables are equal (i.e., when the experimental values have been determined from the same experiment with the same experimental error $\sigma_k \equiv \sigma$), then [Eq. \(9.36\)](#) changes over to the usual formula of simple arithmetic average as shown by [Eq. \(9.29\)](#) whose uncertainty is given by [Eq. \(9.31\)](#).

9.2.5 Measures of the “Association” of Two Distributions

In the following formulas, the subscripts 1 and 2 refer to the random variables X and Y respectively. The independence of the random variables X and Y means that their joint

distribution function is equal to the product of their respective (one-dimensional) distribution functions:

$$F(x, y) = F_1(x)F_2(y). \quad (9.38)$$

In the case of continuous distributions, independence also means that the joint density function is equal to the product of the individual density functions:

$$f(x, y) = f_1(x)f_2(y). \quad (9.39)$$

The covariance of X and Y is defined as

$$\sigma_{12} \equiv \text{Cov}(X, Y) \equiv E((X - \mu_1)(Y - \mu_2)) = E(XY) - \mu_1\mu_2. \quad (9.40)$$

The correlation coefficient of X and Y is given by

$$\rho_{12} \equiv R(X, Y) \equiv \frac{\text{Cov}(X, Y)}{D(X)D(Y)} \equiv \frac{\sigma_{12}}{\sigma_1\sigma_2}. \quad (9.41)$$

The correlation coefficient is a number lying in the interval $[-1, +1]$.

If X and Y are independent, then they are also uncorrelated, i.e.,

$$\rho_{12} = 0. \quad (9.42)$$

If there is a linear relationship between X and Y , then

$$|\rho_{12}| = 1 \quad (9.43)$$

i.e., the correlation reaches its maximum. More exactly, if $Y = aX + b$, then

$$\rho_{12} = \begin{cases} +1 & \text{if } a > 0 \\ -1 & \text{if } a < 0 \end{cases}. \quad (9.44)$$

Owing to this result, one might conclude (erroneously) that whenever there is a strong relationship between X and Y (e.g., when Y is the function of X), then the variables must be correlated. However the truth is that one can find such distributions and such a strong (however nonlinear) relationship between X and Y , which makes them uncorrelated.

All things considered, one can only state with certainty that if X and Y are correlated, they cannot be independent.

9.3 Sums and Products, Error Propagation

In this section, the “algebra” of random variables will be rehearsed from the viewpoint of error propagation. Convolution, central limit theorem, as well as random sums (i.e., sums of a random number of random variables) are also included here because of their importance in nuclear applications.

9.3.1 Expected Value and Variance of Linear Expressions

Expected value of linear combinations. For any sequence of random variables as well as constants a and b_k one can write

$$E\left(a + \sum_{k=1}^n b_k X_k\right) = a + \sum_{k=1}^n b_k \mu_k. \quad (9.45)$$

Corollaries	
Expected value of a constant	$E(a) = a$
Shift in general	$E(a + X) = a + E(X)$
Change of scale in general	$E(bX) = bE(X)$
Addition/subtraction in general	$E(X \pm Y) = E(X) \pm E(Y)$

Variance of the sum of random variables. One can write for any choice of two random variables that

$$D^2(X \pm Y) = D^2(X) + D^2(Y) \pm 2\text{Cov}(X, Y). \quad (9.46)$$

For independent random variables, the covariances are zero, thus the following formula holds for the variance of the linear combination of several variables:

$$D^2\left(a + \sum_{k=1}^n b_k X_k\right) = \sum_{k=1}^n b_k^2 D^2(X_k). \quad (9.47)$$

Corollaries	
Standard deviation of a constant	$D(a) = 0$
Shift in general	$D(a + X) = D(X)$
Change of scale in general	$D(bX) = b D(X)$
Addition/subtraction for independence	$D^2(X \pm Y) = D^2(X) + D^2(Y)$

Note that the variances add up even if the variables are subtracted, i.e., the errors do not cancel each other out. (Actually, the standard deviations of independent random variables are related to each other like the lengths of orthogonal vectors from which the length of the resultant vector is calculated according to the multidimensional version of the Pythagorean theorem.)

Standardization. Standardization is a special application of the shifting and scale-changing transformations:

$$Y = \frac{X - E(X)}{D(X)} = \frac{X - \mu}{\sigma}. \quad (9.48)$$

The standardized random variable Y obtained this way has 0 for its expected value and 1 for its standard deviation as well as for its variance.

Standardization usually leads out from the distribution family of X . For instance, if X is distributed as Poisson, then Y is certainly not. However, if X happens to be $N(\mu, \sigma^2)$ normal, then Y is an $N(0, 1)$ standard normal random variable. For instance, the left panel in [Fig. 9.1](#) makes use of standardization to show the properties of one-dimensional normal distributions. As standardization shifts the distribution such that the mean becomes 0, this transformation applied to the exponential distribution on the right panel in the same figure would result in a shifted exponential, which however is not considered an exponential distribution. (The exponential distribution is kind of “attached to the soil” as its mode is at $t = 0$ by definition.)

9.3.2 The Central Limit Theorem

Let X be a random variable with any distribution, having expected value μ and standard deviation σ . Let X_i denote the random variable representing the i th result of n independent trials to observe X . (The random variables X_i are obviously independent of each other and they have the same distribution as X .) Then the sample mean $\bar{X} \equiv (X_1 + X_2 + \cdots + X_n)/n$ is asymptotically $N(\mu, \sigma^2/n)$ normal (as a random variable).

The practical content of the central limit theorem is as follows. If one wants to figure out the “exact” value of a physical quantity by calculating the average of measured data, then (1) the estimate thus obtained is still not completely accurate. However, (2) the accuracy is better than that of the original data (it is clear: otherwise the averaging would not make any sense at all). Moreover it is also reasonable to assume that (3) the somewhat erroneous estimates that can be obtained for the “exact” value in this way are normally distributed about the said “exact” value, no matter what the original data distribution was like (e.g., it could be uniform or exponential or anything provided that the expected value and the variance exist).

The central limit theorem makes normal distribution one of the most important continuous distributions. Also, the fact that a lot is known about normal distribution makes the central limit theorem a very practical thing, namely, whenever it is in action, it is easy to judge how large deviations are to be expected from a given mean and how often a given deviation is likely to occur (see [Fig. 9.2](#)).

Note that the theorem can be phrased not only for averages but also for sums (see [Fig. 9.3](#)) and, moreover, with much weaker conditions than specified above. For n -sums, e.g., the central limit theorem can be phrased like this: Under the conditions specified above, the sum $\Sigma_n \equiv (X_1 + X_2 + \cdots + X_n)$ is asymptotically $N(n\mu, n\sigma^2)$ normal.

9.3.3 Convolution and Deconvolution

The convolution and the sum of independent random variables. If X and Y are independent (continuous) random variables with density functions f_X and f_Y , as well as distribution functions F_X and F_Y , respectively, then the density function f_{X+Y} and the distribution function F_{X+Y} of the random variable $Z = X + Y$ are given by the following convolutions:

$$f_{X+Y}(z) = f_X * f_Y(z) \equiv \int_{-\infty}^{+\infty} f_X(z-u)f_Y(u) du, \quad (9.49)$$

$$F_{X+Y}(z) = F_X * F_Y(z) \equiv \int_{-\infty}^{+\infty} F_X(z-u) dF_Y(u) = \int_{-\infty}^{+\infty} F_X(z-u)f_Y(u) du. \quad (9.50)$$

The integral determining f_{X+Y} is called the convolution of density functions, that determining F_{X+Y} is referred to shortly as the convolution of the distributions. (The latter can also be calculated when X is discrete with a finite number of spectrum points. Then, in the case of continuous distributions, the density function f_{X+Y} can be obtained by differentiation if necessary.) The convolution as an operation is commutative, just like the addition. If the distributions are such that $f_i(u) = 0$, for $u \leq a_i$, then

$$f_1 * f_2(z) = \int_{a_2}^{z-a_1} f_1(z-u)f_2(u) du. \quad (9.51)$$

If therefore $a_1 = a_2 = 0$, then the integration proceeds between 0 and z .

(#8) Uniform distribution: $U(a, b)$. Later on it will be convenient sometimes to refer to the (continuous version of the) uniform distribution that is characterized by a rectangular density function between the limits a and b . More precisely, the density function of the $U(a, b)$ uniform distribution is $f(x) = 1/(b-a)$ in the interval (a, b) and $f(x) = 0$ elsewhere. Its expected value is $\mu = (a+b)/2$ and its variance is $\sigma^2 = (b-a)^2/12$. The density function of the uniform distribution $U(0, 1)$ is shown in [Fig. 9.4](#).

Deconvolution. Making use of the property of the characteristic function (Fourier transform) expressed by [Eq. \(9.24\)](#), a simple solution exists for expressing one of the components from a (density) function having the form of a convolution

$$\varphi(f_{X+Y}) = \varphi(f_X * f_Y) = \varphi(f_X)\varphi(f_Y). \quad (9.52)$$

Fig. 9.4

This figure shows the rectangular density function of the uniform distribution $U(0, 1)$ together with its convolutions. Generating $U(0, 1)$ (pseudo) random numbers is a standard feature of many “scientific” calculators. The convolution power $U*U$ represents the distribution of the sum of two such numbers. Similarly, if three such numbers are added, the distribution of the sum will be $U*U*U$. The example demonstrates how soon central limit theorem can be caught in the act even in the case of a distribution far from being bell shaped. Note that the density function of $U*U*U$ is composed of parabolic fragments but still it is rather close in shape to that of a normal distribution of the same mean and variance

■ Fig. 9.5

Three basic types of Bernoulli distribution classified according to the ratio of p ("success" $\Leftrightarrow 1$) to q ("failure" $\Leftrightarrow 0$). Any series of Bernoulli trials results in binomial distribution (see ► Fig. 9.3), however only the third type, characterized by a low probability of success, leads to Poisson distribution. Radioactive decay usually belongs to the latter category

In this case, namely, the density function of X , e.g., can be expressed by the inverse Fourier transform

$$f_X = \varphi^{-1} \left(\frac{\varphi(f_X * f_Y)}{\varphi(f_Y)} \right). \quad (9.53)$$

(#9) The significance of convolution/deconvolution exceeds the boundaries of probability theory. Some nuclear spectra can also be described by a convolution-type integral. For instance, a transmission *Mössbauer spectrum* (see ► Chap. 25 in Vol. 3) is the convolution of two functions one of which is characteristic of the source of radiation while the other of the absorber (sample). The latter function contains all the parameters that the spectroscopist can be interested in, which explains why some methods of spectrum evaluation include the calculation of deconvolution as well.

9.3.4 Random Sums

Sums of a random number of random variables – in short: random sums – are often encountered at several stages of radiation detection. The problem usually presents itself disguised as a product.

Consider about μ_N items, each consisting of about μ_X parts (or, alternatively, each weighing/measuring/worth about μ_X kg/m/dollars). Obviously the whole lot of parts (mass/length/value) adds up to about $\mu_N\mu_X$ (kg/m/dollars). The question to be answered is the following. What is the error of this “product”?

The answer is given by the following theorem (Feller 1968; Korn and Korn 1968). This theorem gives the solution for the recurring problem of Bernoulli sampling that will be discussed later on.

Let X_1, X_2, \dots, X_N be a sequence of mutually independent (integral valued) random variables with a common distribution. Let N be itself an integral valued variable, being independent of the others. Let $\Sigma_N = X_1 + X_2 + \dots + X_N$. Let $G_X(s)$ denote the (common) generating function of the variables X_1, X_2, \dots, X_N . Let $G_N(s)$ be the generating function of N , and $G_\Sigma(s)$ that of the random sum Σ_N . One can write

$$G_\Sigma(s) = G_N(G_X(s)). \quad (9.54)$$

Applying the chain rule of differentiation to [Eq. \(9.54\)](#), the expected value and the variance of the random sum can be easily calculated using [Eq. \(9.21\)](#):

$$\mu_\Sigma = \mu_N\mu_X; \quad \sigma_\Sigma^2 = \mu_X^2\sigma_N^2 + \mu_N\sigma_X^2 \quad (9.55)$$

Thus the square of the relative deviation of the random sum is

$$\left(\frac{\sigma_\Sigma}{\mu_\Sigma}\right)^2 = \left(\frac{\sigma_N}{\mu_N}\right)^2 + \frac{1}{\mu_N} \left(\frac{\sigma_X}{\mu_X}\right)^2. \quad (9.56)$$

This asymmetrical result implies that if the (expected) number of terms is large enough, then the variance of the random sum is principally determined by the variance of the number of these terms (i.e., the variance of the individual terms is of relatively less importance). It is worthwhile to compare this result with [Eq. \(9.61\)](#), showing the formula of error propagation for “real” products.

9.3.5 General Approximation of Error Propagation

For any sequence of random variables, the following approximation holds for the error of the formula $f(X_1, X_2, \dots, X_n)$ calculated from these variables:

$$D^2(f) \approx \sum_{i=1}^n \left[\left(\frac{\partial f}{\partial x_i} \right)_{x=\mu}^2 D^2(x_i) \right] + 2 \sum_{i < j} \left[\left(\frac{\partial f}{\partial x_i} \right)_{x=\mu} \left(\frac{\partial f}{\partial x_j} \right)_{x=\mu} \text{Cov}(x_i, x_j) \right]. \quad (9.57)$$

If the variables are mutually independent, then the second sum containing the covariances becomes zero and therefore

$$D^2(f) \approx \sum_{i=1}^n \left[\left(\frac{\partial f}{\partial x_i} \right)_{x=\mu}^2 D^2(x_i) \right]. \quad (9.58)$$

The subscript $x = \mu$ is to indicate that the derivatives must be calculated at the expected values of the variables. (In practical terms, the expected value is the “exact” value around which the “measured” value of the variable fluctuates.)

[Equations \(9.57\)–\(9.58\)](#) have been obtained from the (first-order) differential – from a linear approximation – of the function $f(X_1, X_2, \dots, X_n)$. Therefore, the related formulas are

quite general in the sense that f can be any type of differentiable function; however, the approximation can only be used for continuous variables and for relatively small errors. On the other hand, \blacktriangleright Eqs. (9.46)–(9.47) obtained for linear expressions – actually the special cases of \blacktriangleright Eqs. (9.57)–(9.58) – are exact.

9.3.6 Formulas for Products/Ratios of Independent Random Variables

For the expected value of products/ratios, the following exact formula holds:

$$E\left(\frac{XY}{Z}\right) = E(X)E(Y)E\left(\frac{1}{Z}\right). \quad (9.59)$$

If $D^2(Z)/E^3(Z)$ is small enough, then the following approximation can be derived by expanding the expression $1/Z$ into Taylor series about $E(Z)$:

$$E\left(\frac{XY}{Z}\right) \approx \frac{E(X)E(Y)}{E(Z)}. \quad (9.60)$$

The approximation of standard deviation of products/ratios can be obtained from the appropriate form of \blacktriangleright Eq. (9.58):

$$\left[\frac{D\left(\frac{XY}{Z}\right)}{E\left(\frac{XY}{Z}\right)}\right]^2 \approx \left[\frac{D(X)}{E(X)}\right]^2 + \left[\frac{D(Y)}{E(Y)}\right]^2 + \left[\frac{D(Z)}{E(Z)}\right]^2. \quad (9.61)$$

One can see that, in the case of multiplication and division, it is the squares of the relative deviations that add up, rather than the variances. Note that the last term representing division is also added rather than subtracted in the above formula.

As shown earlier, \blacktriangleright Eq. (9.56) gives a different error formula for a different type of “product.” In the case of products therefore it is worthwhile to think it over whether or not a random sum is hiding behind the problem. This can only happen, of course, when one of the variables is an integer having no dimension.

9.4 Special Distributions

The distributions summarized on the next few pages play important role in nuclear measurements as well as in the evaluation of nuclear spectra.

9.4.1 Bernoulli Distribution: $B(1, p)$

Mass function: $P(X = x; p) = \begin{cases} p & \text{if } x = 1 \\ q & \text{if } x = 0 \end{cases}$ where $q = 1 - p$	
Generating function: $G(s) = q + ps$	
Expected value: p	Mode: $\begin{cases} 1 & \text{if } p \geq q \\ 0 & \text{if } p \leq q \end{cases}$
Variance: pq	Relative deviation: $\sqrt{\frac{q}{p}}$

Some authors consider the terms Bernoulli distribution and binomial distribution synonyms. As it will turn out later, it has some advantages to handle this simplest variant of binomial distributions separately.

Interpretation. Consider a dichotomous experiment that has only two possible outcomes (alternative events) like a “coin toss.” One of the alternative outcomes (e.g., “heads”) is generally called “success” while the other (e.g., “tails”) “failure.” The probability of “success” is denoted by p , that of “failure” by $q = 1 - p$. Now, the Bernoulli variable X is defined as follows:

$$X(\text{“success”}) \equiv 1; \quad X(\text{“failure”}) \equiv 0. \quad (9.62)$$

(#10) The repeated independent trials associated with such a dichotomous “game” are called Bernoulli trials.

(#11) As regards nuclear methods, another dichotomous game comes to mind: the fate of a radioactive nucleus in a period of time. The alternative outcomes are “decay” (characterized by probability p) and “survival” (characterized by probability q).

(#12) $B(1, p)$ Bernoulli random numbers can be easily obtained from $U(0, 1)$ random numbers uniformly distributed in the interval $(0, 1)$. (As mentioned before, such random numbers are readily available using “scientific” calculators.) The algorithm is straightforward: one chooses $X = 1$, whenever the $U(0, 1)$ uniform random number happens to be less than p , and chooses $X = 0$ otherwise.

9.4.2 Binomial Distribution: $B(n, p)$

Mass function: $P(X = x; n, p) = \binom{n}{x} p^x q^{n-x} \quad (x = 0, 1, \dots, n) \quad q = 1 - p$	
Generating function: $G(s) = (q + ps)^n$	
Expected value: $\mu \equiv np$	Mode: $\begin{cases} \mu - q & \text{and} \\ \mu + p \\ \lfloor \mu + p \rfloor \end{cases} \quad \begin{cases} \text{if } \mu + p \text{ is integer} \\ \\ \text{if } \mu + p \text{ is not integer} \end{cases}$
Variance: $npq = \mu q$	Relative deviation: $\sqrt{\frac{q}{\mu}} = \sqrt{\frac{q}{pn}}$

Interpretation. Consider a dichotomous “game.” Let p denote the probability of “success” in a single trial. Suppose that a series of n Bernoulli trials have been performed. Let X_1, X_2, \dots, X_n denote the independent Bernoulli variables belonging to the respective trials. Then the random variable $X \equiv X_1 + \dots + X_n$ has a $B(n, p)$ binomial distribution.

(#13) Note that X means the number of successful outcomes in the series of n Bernoulli trials. Note also that the above interpretation justifies the use of the symbol $B(1, p)$ for the Bernoulli distribution.

(#14) The above remark provides a straightforward recipe for the simulation of $B(N, p)$ random numbers if a $U(0, 1)$ random number generator is available. One only has to generate N random numbers of $B(1, p)$ Bernoulli distribution according to remark (#12). The sum of the N Bernoulli numbers will then result in a $B(N, p)$ random number.

(#15) The coin-toss game can be performed either by tossing one single coin n times, or by tossing n coins simultaneously. If the only question is the probability of tossing exactly x “heads” out of n tosses, then the two games are essentially identical, and the answer is provided by the mass function of the $B(n, p)$ binomial distribution. (It follows from symmetry that by swapping the roles one gets a similar formula for the number of “tails,” too.)

(#16) Referring to remark (#11), the simultaneous “coin-toss game” can be paraphrased thus: Consider n identical radioactive nuclei, any of which decays with the same probability p during a certain period of observation. What is the probability that exactly x nuclei will decay? The answer is given by the mass function of the $B(n, p)$ distribution. In other words, the fluctuation of the number of nuclei that actually decay over a given period of time can be described by the binomial distribution. (It follows from symmetry that by swapping roles – let p denote the probability of “survival,” and x the number of nuclei escaping decay over the same period – the same distribution will be obtained for the number of “survivors.”)

(#17) Let n denote the number of radionuclei like before. Let p represent the probability that a selected nucleus will decay within a given period of time, and η the probability that the decay of a nucleus will be actually observed with the given detector system. Then $p\eta$ obviously measures the probability that a given nucleus decays over the period of time *and* this decay will be actually observed. What is the probability that exactly x nuclei will be observed to decay? The answer is given by the mass function of the $B(n, p\eta)$ distribution. In other words, the fluctuation of the number of counts measured (without background) over a given period of time can be described by the binomial distribution.

This result will be referred to as the Bernoulli sampling of binomial distribution, because the problem can also be presented in the following way: The number of decayed nuclei has a $B(n, p)$ distribution. Let X denote the actual number of nuclei that have decayed over the given period of time. Now a $B(1, \eta)$ Bernoulli sampling is performed on the decayed nuclei, i.e., the individual decays are considered one after the other and either accepted with probability η (meaning that the decay of the nucleus has been detected) or discarded with probability $1 - \eta$ (the decay of the nucleus has escaped detection). The question is how many decay events have been detected altogether and how these detected numbers are distributed in a whole series of like experiments. Thinking it over, one has a series of Bernoulli trials here, the length of which (X) itself is a random variable with a $B(n, p)$ distribution. Therefore the task is to add up X random variables having $B(1, \eta)$ Bernoulli distribution each. Using [Eq. \(9.54\)](#) obtained for random sums, one finds that this sum – the number of decay events actually observed or, which is the same, the number of counts has $B(n, p\eta)$ distribution, where p is the probability of decay and $\eta < 1$ is the probability/efficiency of detection.

(#18) It is easy to verify that for large values of n , i.e., for large μ , the mode(s) of binomial distribution is (are) practically equal to the expected value, which means that the expected value doubles as the most probable value. On the other hand, the relative deviation rapidly decreases with increasing n or μ . This means that the distribution – obeying the law of large numbers – is gradually “shrinking” on the expected value (see [Fig. 9.3](#)).

Owing to this, if a large enough number of counts have been measured, that single number can be considered as a fairly good estimate of the expected value. (This statement is not at all true for any distribution.) Of course, in the case of such a one-point estimate it is impossible to find out whether or not the measured data point squares with the assumption that the equipment has been faultless.

9.4.2.1 Properties

Addition theorem. If X_1 and X_2 are independent random variables with $B(n_1, p)$ and $B(n_2, p)$ distribution, respectively, then the random variable $X = X_1 + X_2$ has $B(n_1 + n_2, p)$ distribution.

(#19) As regards the example mentioned in remark (#16), the above property means that if there are two “heaps” of identical radionuclei, then not only the separate counts have binomial distribution (with expected values n_1p and n_2p as well as variances n_1pq and n_2pq , respectively), but the total number of counts as well (with expected value $(n_1 + n_2)p$ and variance $(n_1 + n_2)pq$). Choosing 1 s as the time of observation, the addition theorem expresses the additive property of activity.

Normal approximation (De Moivre–Laplace limit theorem). It follows from the interpretation as well as from the central limit theorem that for large enough values of npq ($npq \geq 6$ suffices already) the binomial distribution can be approximated by a normal distribution with expected value $\mu = np$ and variance $\sigma^2 = npq$ (see [Figs. 9.3](#) and [9.6](#)):

$$B(n, p) \approx N(np, npq). \quad (9.63)$$

Poisson approximation. For small enough values of p and large enough values of n ($p \leq 0.1$ and $n \geq 20$ will do) the binomial distribution can be approximated by a Poisson distribution with parameter (expected value) $\mu = np$ (see [Figs. 9.5](#) and [9.7](#)):

$$B(n, p) \approx \Pi(np). \quad (9.64)$$

(#20) Consider again the example in remarks (#16)–(#17). If the observation period is very short compared to the half-life of the radionuclide in question (i.e., $p \ll 1$) and if the total number of nuclei observed is large enough, then the number of decay events/counts has a

■ Fig. 9.6

The $N(np, npq)$ normal distribution provides a rather good approximation for the $B(n, p)$ binomial distribution irrespective of the value of p provided that $npq \geq 6$. In the example shown n is merely 59, and npq is only 10, however the “fit” is quite good already

■ Fig. 9.7

The $B(n, p)$ binomial distribution can be approximated with the $\Pi(np)$ Poisson distribution even for small values of $\mu = np$ provided that the probability of success in a single trial is small ($p \leq 0.1$). Note that the “fit” is reasonably good at $p = 0.1$, although the value of μ is only $np = 10$. For $p = 0.01$, on the other hand, the “fit” looks almost perfect (see ► Fig. 9.5)

Poisson distribution. This serves with a simple “recipe” for the estimation of the standard deviation:

$$s \approx \sigma = \sqrt{\mu} \approx \sqrt{\bar{X}}. \quad (9.65)$$

(#21) Continuing from the previous remark the following conclusion can be drawn: If the number n of the radionuclides is large enough, which is usually the case, then the number of decay events/counts is normally distributed. Therefore, the expected fluctuation of counts, e.g., can be judged by the “rules” of normal distribution (see ► Table 9.3). For instance, the counts X_i collected over the same length of time are supposed to lie in the error intervals “ $\mu \pm 1\sigma$,” “ $\mu \pm 2\sigma$,” and “ $\mu \pm 3\sigma$ ” with the following frequencies (provided that the total time needed for the series of measurements is short enough compared to the half-life of the radionuclide):

$$\bar{X} \pm \sqrt{\bar{X}} : 68\%; \quad \bar{X} \pm 2\sqrt{\bar{X}} : 95.4\%; \quad \bar{X} \pm 3\sqrt{\bar{X}} : 99.7\%. \quad (9.66)$$

9.4.3 Poisson Distribution: $\Pi(\mu)$

Mass function: $P(X = x; \mu) = \frac{\mu^x}{x!} e^{-\mu} \quad (x = 0, 1, 2, \dots)$	
Generating function: $G(s) = e^{\mu(s-1)}$	
Expected value: μ	Mode: $\begin{cases} \mu - 1 & \text{and} \\ \mu \\ \lfloor \mu \rfloor \end{cases} \quad \begin{cases} \text{if } \mu \text{ is integer} \\ \text{if } \mu \text{ is not integer} \end{cases}$
Variance: μ	Relative deviation: $\frac{1}{\sqrt{\mu}}$

Interpretation. Consider a recurring instantaneous rare event (like the arrival of a background pulse), which repeats itself at random over time. The task of the experimenter is to count such events over a certain observation period ΔT . Suppose that the following general conditions are satisfied:

1. The outcome of the observation does not depend on the location of ΔT along the time axis.
2. The occurrences of the event in separated time intervals are stochastically independent. Suppose that the following “rarity” and “time-proportionality” conditions are also fulfilled in the case of very short periods of time $\Delta t \ll \Delta T$:
3. If the observation period ΔT is divided to n equal intervals – “time cells” – of length $\Delta t = \Delta T/n$, then the majority of such intervals would not contain any event at all, while the rest contain exactly one event each, provided that n is large enough ($n \rightarrow \infty$). That is, the possibility of events appearing in doublets is excluded if the “time cells” considered are small enough.
4. At the above fine time-scale the (single) occurrence of the event within a “time cell” is proportional to the length Δt of the interval:

$$p = P(1) = \frac{\mu}{\Delta T} \Delta t = \frac{\mu}{n}. \quad (9.67)$$

If the above assumptions are satisfied, then the total number of events observed (i.e., the number of counts X) has a $\Pi(\mu)$ Poisson distribution.

(#22) Condition 4 can be better understood, if μ is regarded as the expected number of events occurring over the observation period ΔT . (According to the data in the box of characteristic parameters, this interpretation is justified, because $E(X) = \mu$ for the Poisson distribution.) Thus the ratio μ/n equals the average number of events occurring in a single “time cell.” Note that as n approaches infinity, this average sooner or later drops below 1, however large the value of μ is (e.g., $\mu/n \approx k/m$, where $k < m$). Owing to condition 3, this means that – asymptotically – on an average k cells out of m contain exactly one event each, while the rest are empty. In other words, the probability that a cell is “filled” with an event is $k/m (\approx \mu/n)$, i.e., condition 4 is satisfied.

(#23) The above conditions are fulfilled, e.g., in the case of the background caused by cosmic radiation and the like. Therefore, background counts observed over a given period of time have Poisson distribution.

(#24) It is clear that, for large values of μ , the mode(s) is(are) practically equal to the expected value, i.e., the expected value doubles as the most probable value in the case of the Poisson distribution. On the other hand, the relative deviation rapidly decreases as μ increases. Thus, the distribution is gradually “shrinking” on the expected value.

Consequently, if a large enough background is measured, then this single measurement can provide a fair estimate for the expected value, the square root of which can be used for the estimation of the standard deviation. (See also remark (#18) on the unreliability of such one-point estimates.)

9.4.3.1 Properties

Bernoulli sampling. Consider a random variable with a $\Pi(\mu)$ Poisson distribution, which counts the occurrences of certain types of events (e.g., events of radioactive decay). Now a

$B(1, \eta)$ Bernoulli sampling is performed on the counted events, meaning that the events are either accepted with probability η , or discarded with probability $(1 - \eta)$. For instance, η can indicate the efficiency of detection, in which case “acceptance” means that the decay event in question has been actually detected. It follows from [Eq. \(9.54\)](#) that the number of events passing such a sampling (e.g., the number of detector pulses caused by the radiation of decaying nuclei) has a $\Pi(\mu\eta)$ Poisson distribution. (See also remark (#17).)

Addition theorem. If X_1 and X_2 are independent random variables with Poisson distributions $\Pi(\mu_1)$ and $\Pi(\mu_2)$, respectively, then the random variable $X = X_1 + X_2$ has a $\Pi(\mu_1 + \mu_2)$ Poisson distribution.

(#25) As a consequence of remark (#20) as well as due to the addition theorem, the following conclusion can be drawn: Suppose that decay events are observed in a specimen that contains a mixture of two (or more) radionuclides. If the observation period is short enough in comparison with any of the half-lives (i.e., any single nucleus will survive the period with a high probability), then the total number of decay events has a Poisson distribution. It follows from the property of Bernoulli sampling that the same applies to the total number of counts.

(#26) Continuing from the previous remark as well as remark (#23), the following conclusion can be drawn: The number of counts measured with background also has a Poisson distribution.

Normal approximation. It follows from the addition theorem and from the central limit theorem that for large enough μ the Poisson distribution can be approximated by a normal distribution (see [Fig. 9.8](#))

$$\Pi(\mu) \approx N(\mu, \mu). \quad (9.68)$$

■ Fig. 9.8

The $N(\mu, \mu)$ normal distribution provides an almost perfect fit for the $\Pi(\mu)$ Poisson distribution at as low a parameter value as $\mu = 100$

(#27) Continuing from the previous remarks, the following conclusion can be drawn: If the counts measured together with background are large enough, then their fluctuation can be judged by the “rules” of the normal distribution in the same way as suggested in remark (#21). See [Eq. \(9.66\)](#) and [Table 9.3](#).

9.4.4 Exponential Distribution: $\gamma(1, \lambda)$

Density function: $f(t) = \begin{cases} \lambda e^{-\lambda t} & \text{if } t > 0 \\ 0 & \text{if } t \leq 0 \end{cases}$	
Distribution function: $F(t) = 1 - e^{-\lambda t}$	
Characteristic function: $\varphi(u) = (1 - iu/\lambda)^{-1}$	
Expected value: $\tau \equiv \frac{1}{\lambda}$	Median: $T_{1/2} \equiv \frac{\ln 2}{\lambda} \approx \frac{0.7}{\lambda}$
Variance: $\frac{1}{\lambda^2}$	Relative deviation: 1

Interpretation. Consider an “ageless” but “mortal” entity the lifetime of which is characterized by the random variable $T \in (0, \infty)$. Agelessness means that – at any moment of its life – the life expectancy of such an entity is independent of its age, i.e., of the time it has already lived up to that point. Therefore if it is still alive at the moment $t > 0$ (i.e., if $T > t$), then the (conditional) probability of still finding it alive at a later moment $t + s$ only depends on the time elapsed since the moment t (i.e., it only depends on s):

$$P(T > t + s | T > t) = P(T > s). \quad (9.69)$$

Suppose that the probability that the entity’s “death” (or “decay” as is usually called) occurs within a given time interval is proportional to the length Δt of that interval, provided that Δt is small enough. In other words, $P_{\text{decay}} = 1 - P(T > \Delta t) = \lambda \Delta t$, where λ is the decay constant.

If the above conditions are satisfied, then the lifetime T is a random variable with $\gamma(1, \lambda)$ exponential distribution.

(#28) It is obvious that the above conditions have been “tailored” to fit the disintegration of radioactive nuclei. Consequently, the lifetime distribution of radionuclei is exponential. The same is true for the excited states of nuclei as well as atoms.

There are cases when the exponential distribution is related to waiting times between random events rather than to lifetimes. In such cases the adjective “ageless” is swapped for “memoryless” (Goodman 1988). Anyway, both metaphors are verbal expressions for the same mathematical condition and as such they determine the same (exponential) distribution.

Another phenomenon related to exponential distribution is the absorption (attenuation) of gamma photons in a homogeneous absorber. The correspondence between the roles is as follows: $t \Leftrightarrow d$ (depth of penetration), $\lambda \Leftrightarrow \mu_1$ (linear attenuation coefficient), $T_{1/2} \Leftrightarrow D_{1/2}$ (halving thickness), $\tau \Leftrightarrow \delta$ (mean free path). Agelessness is translated now to indefatigability meaning that the photons – in contrast to ionizing particles – are not losing energy in a continuous way as they proceed in the absorber. However, being mortal, they may “drop dead” suddenly via photoelectric effect, for instance.

(#29) The distribution function (see the red curve in [Fig. 9.9](#)) expresses the monotonically increasing probability that the nucleus will decay sometime over the period $(0, t)$. The “mortality” of the atom is expressed by the normalization condition $F(\infty) = 1$ (which is fulfilled). The fact, on the other hand, that the atom was actually found “living” at the moment

0 corresponds to the condition $F(0) = 0$ (also fulfilled). Thus the probability that the atom will survive t is

$$1 - F(t) = e^{-\lambda t}. \quad (9.70)$$

(#30) Using the above equation, one can get exponentially distributed random numbers from uniformly distributed ones having $U(0, 1)$ distribution. If, namely, the random number/variable X is uniformly distributed in the interval $(0, 1)$, then the random number/variable T calculated from the formula

$$T = -\frac{\ln X}{\lambda} \quad (9.71)$$

will have a $\gamma(1, \lambda)$ exponential distribution (Goodman 1988; Lux and Koblinger 1991).

(#31) In the case of the lifetime distribution of radionuclides, excited states, etc., the expected value τ is called the mean life, while the median $T_{1/2}$ is referred to as the half-life. The explanation for the name “half-life” is given in the next subsection on the exponential law of radioactive decay. It will be shown that the half-life is independent of the time elapsed, which is an obvious proof of the agelessness of radionuclides. Note that physicists often use the term lifetime not only in the sense it is used in this chapter, but also in the sense mean life. Fortunately, in the really important cases, i.e., when quantitative statements are made (e.g., “the lifetime of the radionuclide is 10 s”), the ambiguity is removed and the reader can be sure that such a statement actually refers to the mean life.

■ Fig. 9.9

The exponential distribution function $F(t)$ (red curve) expresses the probability that the “entity” – looking at it from the present moment 0 – will be “dead” by the moment t (i.e., that it will decay somewhere between 0 and t). The blue curve, on the other hand, shows the probability of the complementary event, i.e., that the same “entity” will survive the period $(0, t)$. For $t > 0$ the curve of the exponential density function is obtained from the blue curve by multiplying the latter with λ (However, for $t \leq 0$, the density function is zero, not 1, as shown in ► Fig. 9.1)

(#32) Looking at the location parameters of exponential distribution, it must be clear that the rule of thumb expressed by [Eq. \(9.13\)](#) works fairly well for the mode (0), median ($T_{1/2}$), and mean (τ), the ratio of their respective distances being 0.7:0.3 (= 2.1:0.9). This ratio is almost equal to the predicted ratio 2:1 (see also the upper right diagram in [Fig. 9.1](#)).

(#33) The relative-deviation formula ($\sigma_{\text{rel}} = 1$) explains why it is practically hopeless to give a usable mean-life estimate from the observation of the decay of a single atom. (Remember, however, that in the case of the Poisson distribution a large enough observed value could be considered as a fairly good estimate of the expected value.) On the other hand, if the time-scale is changed to logarithmic, e.g., by one of the following transformations:

$$w = \ln t \quad \text{or} \quad u = \ln \frac{t}{\tau} \quad (9.72)$$

(but decimal logarithm will also do), then the density function of the new variable (readily obtained from the exponential distribution function by differentiation using the chain rule):

$$f(w) = \frac{1}{\tau} \exp\left(w - \frac{e^w}{\tau}\right) \quad \text{or} \quad f(u) = \exp(u - e^u) \quad (9.73)$$

reaches its maximum at the value corresponding to the condition $t = \tau$ (Schmidt et al. 1984).

The halfwidth of the asymmetric bell-shaped curve in [Fig. 9.10](#) is rather large (FWHM ≈ 2.5 representing about a decimal order of magnitude in uncertainty); however, it can serve as a basis for estimating the mean life τ from the mode of a histogram that has been drawn using the logarithm of a few dozens of lifetime data. For an interesting application of this method used

Fig. 9.10

The density function of the logarithm of exponentially distributed lifetimes. Using this trick, the estimation of the mean life can be reduced to the determination of the mode (i.e., the most frequent value) of a logarithmized lifetime histogram related to the above distribution. This method can be used whenever the number of lifetimes that can be measured is so small that the standard method of mean life determination ($\tau = 1/\lambda$) based on the exponential fit of lifetime data fails. See also remark (#35)

for identifying a couple of man-produced transactinide atoms, see [Sect. 19.3.5, Chap. 19, Vol. 2](#).

9.4.4.1 Connection with the Exponential Law of Radioactive Decay

Suppose that at moment zero there are N_0 atoms “alive.” The question is how many atoms will live at moment t . Let $N(t)$ denote this number. Now if the experiment is repeated several times starting with the same number of atoms (N_0), then the number of the survivors would vary showing that $N(t)$ is a random variable. In other words, the $N(t)$ values would fluctuate about their time-dependent mean $\langle N \rangle(t)$. For any fixed value of t , $N(t)$ has a $B[N_0, p(t)]$ binomial distribution for which the value of $p(t)$ – the probability that a given atom is still intact at moment t – is calculated from [Eq. \(9.70\)](#) as explained in remark (#29) and [Fig. 9.9](#):

$$P(N(t) = k) = \binom{N_0}{k} (e^{-\lambda t})^k (1 - e^{-\lambda t})^{N_0 - k} \quad (k = 0, 1, \dots, N_0). \quad (9.74)$$

Now if the question is put this way: How many atoms *are expected* to live at moment t ?, then the answer is provided by the expected value of the binomial distribution is

$$\langle N \rangle(t) \equiv E_B(N(t)) = N_0 e^{-\lambda t}. \quad (9.75)$$

One can easily recognize the exponential law of radioactive decay in the above formula. The correspondence $\langle N \rangle(t) \Leftrightarrow N$ means that the exponential law applies to the expected number of atoms rather than to the concrete numbers that are measured. The latter show a fluctuation about those expectations according to the standard deviation of the binomial distribution

$$\sigma_N(t) = D_B(N)(t) = \sqrt{N_0 e^{-\lambda t} (1 - e^{-\lambda t})} = \sqrt{\langle N \rangle(t) (1 - e^{-\lambda t})}. \quad (9.76)$$

Note that the above formula gives $\sigma = 0$ both for $t = 0$ and for $t = \infty$. This is due to the following certainties: (1) all of the N_0 atoms were intact at time 0; (2) all of them will decay sooner or later.

As for medium lengths of time (i.e., for periods that are commensurable with the mean life of the atoms), the acceptability of the approximation $\langle N \rangle(t) \approx N$ can be judged by the relative deviation formula

$$\sigma_{\text{rel}}(t) = \frac{\sigma_N(t)}{\langle N \rangle(t)} = \sqrt{\frac{1 - e^{-\lambda t}}{\langle N \rangle(t)}} < \frac{1}{\sqrt{\langle N \rangle(t)}}. \quad (9.77)$$

The above result conveys a reassuring message, namely, if the number of intact atoms is still large enough, then the uncertainty of their number (as expressed by the relative deviation) is negligible. That means that the deterministic expression

$$N = N_0 e^{-\lambda t} = N_0 e^{-t/\tau} = N_0 2^{-t/T_{1/2}} \quad (9.78)$$

usually referred to as the exponential law of radioactive decay stands the test of statistics as well.

(#34) The reason for calling the median “half-life” can be best understood from that variant of the exponential law in which the usual base e is changed to 2. The last expression in [Eq. \(9.78\)](#) shows that N_0 – representing the number of atoms present at time $t = 0$ – will drop to $N_0/2$ by the time $t = T_{1/2}$. Then, after another half-life, the number of survivors will be halved again, and so on. Experience shows that the half-life of radionuclei is independent of both the choice of the origin and the number of halving cycles that have already elapsed. This

can be regarded as a proof for the agelessness of radionuclei. (If they were subject to aging, then the half-life should gradually decrease – an indication that the rest of the population is getting closer to the end of their lives.)

(#35) The exponential law can be written formally as

$$\mu(t) = \mu(t; b) = \mu(t; b_1, b_2) = b_1 e^{-b_2 t}. \quad (9.79)$$

The above expression is an example of a model function, which fits the nuclear spectrum consisting of the spectrum points

$$(t_i, N(t_i)) \quad i = 1, 2, \dots, k \quad (9.80)$$

at an appropriately chosen value (\mathbf{a}) of the parameter vector \mathbf{b} :

$$\mathbf{b} = (b_1, b_2) = (N_0, \lambda) \equiv \mathbf{a} \quad (9.81)$$

The term fitting ideally means that [Eq. \(9.79\)](#) will produce the expected value of $N(t_i)$ for any value of the independent variable t_i . (See [Sect. 9.6](#) on fitting nuclear spectra.) Note that the expression “spectrum point” is used here in the same sense as in [Sect. 9.6](#). See in contrast one of the comments after [Eq. \(9.1\)](#).

9.4.4.2 Exponential Law in a Binomial Way

[Figures 9.11](#) and [9.12](#) help to understand the connection between exponential law on the one part as well as binomial distribution and exponential distribution on the other.

[Figure 9.11](#) shows the possible “fate” of 1,000 atoms through 28 subsequent periods of time – time units – by taking a census of the population at the end of each period. The population numbers $N(t)$ have been simulated by a sequence of random numbers with $B(N, p)$ distributions. (See remark (#14) for the recipe.) The value of the parameter p – representing the probability that a single atom will survive the next period – has been fixed to $p = 0.9$. Thus the starting value of $N(t) \equiv N_t$ has been $N_0 = 1,000$, then the number of survivors has been decreased stepwise by using the recursion algorithm $B(N_{t-1}, p) \Rightarrow N_t$.

The time-dependence of the expected number of survivors is expressed by the monotonically decreasing sequence of the binomial expected values $N_0 p, (N_0 p)p, [(N_0 p)p]p, \dots, N_0 p^{[t]}$. Note that this sequence consists of the substitution values of a decreasing exponential function taken at the end of each period. The explanation for this is as follows. Since no atoms are born in any of the periods, each “census” simplifies to a survival test. The mathematical equivalent of this is the $B(1, p)$ Bernoulli sampling of the $B(N_{t-1}, p)$ distribution of the previous population. Note that the exponential character of the expected value as a function of time is explained by the fact that the Bernoulli sampling has been performed with the assumption that the probability of survival is the same for each period ($p \equiv 0.9$). This assumption, on the other hand, is equivalent to the assumption of agelessness, which, in turn, implies the exponential character of the lifetime distribution.

The exponential function obtained for the expected value can be rewritten in e-based form as well with the notation $\{\lambda\} = \ln(1/p)$, and if the unit $[\lambda] = [t]^{-1}$ is attributed to the “new” physical quantity λ (which may be called the “decay constant”) one can write

$$\langle N \rangle(t) = N_0 p^{[t]} = N_0 e^{-\ln(1/p)\{t\}} = N_0 e^{-\{\lambda\}\{t\}} = N_0 e^{-\lambda t}, \quad (9.82)$$

which can be considered as the stochastic reinterpretation of the decay law.

■ Fig. 9.11

The possible fate of 1,000 atoms followed by simulation. The probability that a given atom will survive a single time unit has been fixed at $p = 0.9$. The number of survivors decreases monotonically according to a step function that follows the curve of an exponential function. On the abscissa, the standard notation is used as recommended by IUPAP to express the physical quantity t as a product of a numerical value $\{t\}$ and a unit $[t]$ (See the text for more detail)

If the probability of decay ($q = 1 - p$) is small (e.g., in the given case it is only 0.1), then the factor $\ln(1/p)$ can be expanded into a Taylor series, yielding a probabilistic interpretation for the decay constant λ :

$$\lambda[t] = \frac{\lambda}{[\lambda]} = \{\lambda\} = \ln \frac{1}{p} = -\ln(1 - q) \approx q. \quad (9.83)$$

Thus λ measures the probability that a selected atom will decay during the time unit, provided that this probability (and, consequently, λ) is small enough ($q \ll 1$), which, in turn, depends on how long a time unit has been selected. In other words, the numerical value of the decay constant must be sufficiently small ($\ll 1$) at the given choice of time unit, in order that the probabilistic interpretation can work. (Note that this interpretation corresponds to the second condition fixed at the interpretation of the exponential distribution.)

► Figure 9.12 shows the change of the simulated $N(t)$ values, i.e., the simulated numbers of decay events occurring in the time unit. The corresponding expected value is

$$\langle n \rangle(t) = -\Delta \langle N \rangle(t) = -N_0(p^{\{t\}} - p^{\{t\}-1}) = -N_0(p - 1)p^{\{t\}-1} = N_0 \frac{q}{p} p^{\{t\}} = N_0 \frac{q}{p} e^{-\lambda t}. \quad (9.84)$$

Comparing ► Eqs. (9.82) and ► (9.84) as well as ► Figs. 9.11 and ► 9.12 one can see that the time dependence of the number of decay events follows the same exponential rule as that of the number of intact atoms themselves.

■ Fig. 9.12

The numbers of decay events pictured have been obtained by forming the difference of the subsequent step-heights of the simulated step function in ► Fig. 9.11. Note that the “observed” numbers of decay events are not at all monotonically decreasing in time. However, fluctuating up and down, they follow the same exponential curve as the numbers of atoms themselves

9.4.4.3 The Poisson Connection

If the parameter μ of the Poisson distribution means the expected number of pulses arriving over a certain time interval t , then the equation

$$\nu \equiv \mu/t \quad (9.85)$$

will define the mean frequency of such pulses.

The probability that in the period t exactly x pulses arrive at a given mean frequency ν can be calculated from the mass function of the $\Pi(\nu t)$ Poisson distribution

$$P(X = x; \nu, t) = \frac{(\nu t)^x}{x!} e^{-\nu t} \quad (x = 0, 1, 2, \dots). \quad (9.86)$$

Hence the probability that no pulse is counted in the observation period t is

$$P(X = 0; \nu, t) = e^{-\nu t}. \quad (9.87)$$

Note that ► Eq. (9.87) also expresses the probability that the waiting time T (i.e., the time elapsed between subsequent pulses) – a continuous random variable – will be greater than t :

$$P(T > t) = e^{-\nu t}. \quad (9.88)$$

Thus the distribution function of the waiting time T is identical with that of the $\gamma(1, \nu)$ exponential distribution

$$F(t) = P(T \leq t) = 1 - P(T > t) = 1 - e^{-\nu t}. \quad (9.89)$$

(#36) This statement can be reversed, i.e., if the waiting time between pulses has a $\gamma(1, \nu)$ distribution, then the number $X(t)$ of the pulses counted over the period t is a random variable with a $\Pi(\nu t)$ Poisson distribution. Since the time is an explicit parameter here, the word “process” appears to be an appropriate expression. As a matter of fact, the “function” $X(t)$ is referred to as Poisson process in the theory of stochastic processes.

(#37) Continuing from remark (#26), the following conclusion can be drawn: Consider a radioactive specimen. If the detector pulses (including the background) arrive at a mean frequency ν , then the counts registered over the counting period t have a $\Pi(\nu t)$ Poisson distribution, and the waiting times between pulses have a $\gamma(1, \nu)$ exponential distribution.

(#38) Continuing from the previous remark, the following conclusion can be drawn: If the background can be neglected, then the mean frequency ν equals the source strength or observed activity. Thus it is the observed activity rather than the decay constant, which directly appears in the exponential density function of the waiting times (see [Fig. 9.13](#)). The value of the decay constant comes into the picture only indirectly through the expression

$$\nu = \eta \lambda N \quad (9.90)$$

where η is the efficiency of the detecting system for the radiation produced by the decay and N is the number of radionuclei that are still intact.

(#39) The Poisson process can be used for the estimation of the count rate of chance coincidences. Let ν_1 and ν_2 denote the mean frequencies of pulses/signals coming from two independent detectors (signal channels). The resolving time of the coincidence circuit is θ , and the counting time is t . (A coincidence circuit only sends out an output signal, if – within the resolving time θ – an input signal coming from channel 1 is followed by an input signal from channel 2 or vice versa. Since the two types of successful events exclude each other, the coincidences estimated separately are to be added up in order to get the total number of coincidences over the counting time t .)

Suppose that an input signal is received from channel 1. The probability that no signal will arrive from channel 2 within the resolving time θ is $\exp(-\nu_2\theta)$, because the waiting times have exponential distribution. (It follows from the memorylessness of the exponential distribution that no matter when one starts measuring the subsequent waiting times, the same time distribution evolves. In other words – see [Fig. 9.13](#) – it does not matter whether one uses the previous pulse of the very same sequence as a starting signal, or one just starts measuring the time at a random moment by leaving the business of starting to the pulses of another sequence.) The probability of the complementary event (i.e., that a signal will arrive from channel 2 within the resolving time θ) is $1 - \exp(-\nu_2\theta)$. Since the coincidence circuit is used for sorting out chance coincidences, one can assume that the exponent is so small that Taylor expansion is allowed. Hence the probability in question is $\nu_2\theta$. This probability can be considered as a type of “efficiency of detection” by which the coincidence circuit “filters” (i.e., performs Bernoulli sampling on) the signals coming from channel 1. Since the latter have a $\Pi(\nu_1 t)$ Poisson distribution, the Bernoulli sampling will result in a number of chance coincidences with a $\Pi(\nu_1 \nu_2 \theta)$ distribution. Due to symmetry, the same result is obtained when channel 2 provides the start signal and channel 1 the stop signal. All in all, the total number of chance coincidences have a $\Pi(2\nu_1 \nu_2 \theta)$ distribution owing to the addition theorem of the Poisson distribution. Thus the expected number of chance coincidences is about $2\theta\nu_1\nu_2 t$, from which the mean frequency of chance coincidences is as follows:

$$\nu_{12} = 2\theta\nu_1\nu_2. \quad (9.91)$$

■ Fig. 9.13

Experimental distribution of the waiting times between the pulses coming from two independent radioactive sources containing ^{22}Na . The labels (e.g., strong–strong) refer to the strengths (i.e., the observed activities) of the sources, which produced the start signal and the stop signal, respectively, for the time measurement. One can see that the slope of each curve is determined by the mean frequency (strength) of the source producing the stop signals. Note also that the start signals are released at random moments and their sequence is completely independent of the sequence of the stop signals. This result well demonstrates the memorylessness of exponential distribution. The same experiment is usually suggested to produce “white” noise (i.e., random signals that are uniformly distributed in time) for the Positron Annihilation Spectroscopy (PAS) measurements (see ● Chap. 27 in Vol. 3). Our results clearly indicate, however, that the noise obtained this way can only be considered “white” in the same way as a finite section of the exponential curve can be regarded horizontal

(#40) It is a common mistake with “beginners” that they directly apply the Poisson-type error estimation to the count rate $v = n/t$ calculated from the count n registered over a period of t in the belief that the “error” of the count rate is $\pm \sqrt{v}$. Dimensional analysis, however, reveals that this cannot be the case, because if one chooses to “measure” v in s^{-1} , then the unit of its “error” calculated this way will be $\text{s}^{-1/2}$, which does not make any sense. Actually, the “square-root” rule applies to “unprocessed” counts only, i.e., to n in the given case.

Now, the correct error calculation of the count rate v goes like this. For clarity’s sake, the notation recommended by IUPAP for scalar-type physical quantities will be used, i.e., $a = \{a\}[a]$, where a is a physical quantity, $\{a\}$ is its numerical value, and $[a]$ is the unit in which a is given (Cohen and Giacomo 1987). Thus the error of the counts is $\sqrt{n} = \sqrt{vt} = \sqrt{\{v\}[v]\{t\}[t]} = \sqrt{\{v\}\{t\}}$, because $[v] = [t]^{-1}$. Since v is obtained from n by dividing it by t , the “change-of-scale” rule of standard deviation yields for the error of v $\sqrt{n}/t = \sqrt{\{v\}\{t\}}/(\{t\}[t]) = \sqrt{\{v\}/\{t\}}/[t]$. Note that the error calculation is performed on dimensionless numbers with the time unit fixed for all the quantities involved. So the correct data presentation of count rates can be either $(\{v\} \pm \sqrt{\{v\}/\{t\}})[t]^{-1}$ or simply $n/t \pm \sqrt{n}/t$.

Note also that, owing to the erroneous practice mentioned above (which, dimension aside, can be rewritten in the form $\{v\} \pm \sqrt{\{v\}}$ for better comparison), the standard deviation will be either over- or underestimated depending on whether the counting time t is shorter or, respectively, longer than the time unit used for the count-rate calculation. In the case of a 1-min measurement, e.g., if the time unit is the second, then the error is overestimated; if the unit is the hour, then it is underestimated. The (numerically) correct result is only obtained if the time unit happens to be the minute.

(#41) It is a fairly common task in nuclear science to tell whether a hypothetical decay would occur. The problematic part is represented by measurements, which have a negative outcome, when none of the atoms subjected to surveillance are found to decay during the observation period. Then the original question always remains open and new questions arise. (1) What would have happened, if the observation period had been longer (in which case [Eq. \(9.87\)](#) would have given more chance for a positive result)? (2) What would have happened, if more “suspicious” atoms had been subjected to the surveillance (in which case [Eq. \(9.90\)](#) would have provided larger v value, and therefore [Eq. \(9.87\)](#), again, would have increased the chances of a positive outcome)?

It is clear that the possibility of decay can never be excluded in cases like that. However, one can still specify a finite upper boundary v_0 , so that the “real” frequency v of the decay is lower than this limit with certain probability. Therefore, this upper boundary depends on the confidence level α set in advance (Leo 1987):

$$v_0 = \eta \lambda_0 N = -\frac{\ln(1 - \alpha)}{t}. \quad (9.92)$$

For instance, 90% certainty means a confidence level $\alpha = 0.9$.

[Equation \(9.92\)](#) can be “deduced” from [Eq. \(9.87\)](#) using common-sense considerations. Suppose that an experimenter decides to make a guess at the value of v . There is only one piece of information available for him or her, namely, that no signal could be detected over a certain observation period t . Then, the best thing he or she can do is form the weighted “average” of all the possible ($0 \leq v < \infty$) values of v , using the weights provided by [Eq. \(9.87\)](#):

$$\bar{v} = \frac{\int_0^{\infty} v e^{-vt} dv}{\int_0^{\infty} e^{-vt} dv} = \int_0^{\infty} v t e^{-vt} dv$$

The advantage of this type of weighting is that it tends to suppress large values of v , for which negative outcome is not likely to occur. On the other hand, it accentuates small values of v , which are more compatible with the negative result.

Note that, according to [Eq. \(9.4\)](#), the integral on the right-hand side of the above equation has the shape of an expected-value formula with the (exponential) density function

$$f(v) = t e^{-vt}$$

in which the variable and the parameter have swapped roles with each other. Hence the “probability” of $v \leq v_0$ is

$$\alpha \equiv P(v \leq v_0) = \int_0^{v_0} f(v) dv = 1 - e^{-v_0 t}$$

which yields [Eq. \(9.92\)](#).

9.4.5 Gamma Distribution: $\gamma(r, \nu)$

The relation of gamma distribution to exponential distribution is similar to that of binomial distribution to Bernoulli distribution in so far as the former (i.e., gamma and binomial) is the convolution power of the latter (i.e., exponential and Bernoulli, respectively), while the latter is a special case of the former. Gamma distribution is also related to the Poisson process (see the interpretation given below). However, in the case of the Poisson process one is looking for the distribution of $X(t)$, the number of signals that arrive over a fixed period of time t . In the case of the gamma distribution, on the other hand, one is interested in the distribution of the time T that is needed for a given number of random signals to arrive.

Density function: $f_r(t) = \begin{cases} \frac{(vt)^{r-1}}{\Gamma(r)} v e^{-vt} & \text{if } t > 0 \\ 0 & \text{if } t \leq 0 \end{cases}$	
Characteristic function: $\varphi(u) = (1 - iu/\nu)^{-r}$	
Mean frequency: $\tau_r^{-1} = \frac{\nu}{r}$	
Expected value: $\tau_r \equiv \frac{r}{\nu}$	Mode: $\frac{r-1}{\nu}$
Variance: $\frac{r}{\nu^2}$	Relative deviation: $\frac{1}{\sqrt{r}}$

In the above expressions the order r and the parameter ν are positive real numbers, and $\Gamma(r)$ is the complete gamma function.

Interpretation. Let T_1, T_2, \dots, T_n be a sequence of independent random variables with $\gamma(1, \nu)$ exponential distribution. Then the random variable defined by the sum $T = T_1 + \dots + T_n$ has a gamma distribution of the n th order with parameter ν . In other words, T has a $\gamma(n, \nu)$ gamma distribution (See Rényi 1970, 1979).

(#42) Note that, according to this interpretation, the exponential distribution of parameter ν can be rightly considered as a $\gamma(1, \nu)$ distribution, i.e., it belongs to the family of the gamma distributions (see [Fig. 9.14](#)). Later on it will be pointed out that the sum of squares of independent random variables with $N(0, 1)$ standard normal distribution also has a special type of gamma distribution called χ^2 distribution.

(#43) For the complete gamma function

$$\Gamma(r) \equiv \int_0^{\infty} e^{-x} x^{r-1} dx \quad (9.93)$$

the following recursion formula holds: $\Gamma(r+1) = r \Gamma(r)$.

In particular, $\Gamma(1/2) = \sqrt{\pi}$, $\Gamma(1) = 1$, and $\Gamma(n) = (n-1)!(n=1, 2, \dots)$.

(#44) Note that the relative deviation rapidly decreases with the increasing number of waiting periods ($n = r$). This property of the gamma distribution is utilized by the scalers, which only produce an output signal on the arrival of the n th input signal. (In this context n is called the scaling factor.) The actual signal frequencies of scalers are, therefore, much more uniform (i.e., the signals follow the “rhythm” of the mean frequency much more “smoothly”), than the original signals themselves (see [Fig. 9.14](#)).

(#45) The decimal display of regular counters is in fact a realization of a series of scalers with scaling factors $n = 10^0, 10^1, 10^2$, etc. (see [Fig. 9.15](#)). Consequently, while the “switching times” of the lowest digit ($n = 10^0 = 1$) have exponential distribution in accordance with the

■ Fig. 9.14

Density functions of gamma distributions of integral order with the parameter value fixed at $\nu = 1$. The order $r = 1$ is characterized by the well-known asymmetric density function of the exponential distribution. However, as the order increases, the asymmetry decreases, and for as low an order as $r = 16$, an appropriately chosen normal distribution gives an acceptable fit. The gamma distribution is characteristic of the waiting times between scaled events (scalar signals). In that context the order r is called the scaling factor, and ν is the mean frequency of the original (i.e., unscaled) signals

Poisson process, those of the rest are characterized by the density functions of the gamma distributions of the order $n = 10^1, 10^2$, etc.:

$$f_n(t) = \frac{(vt)^{n-1}}{(n-1)!} v e^{-vt}. \quad (9.94)$$

Thus the relative deviation of the “switching time” of the third (10^2) digit is about 10%, and that of the fifth (10^4) digit is only about 1%, which means that the figures at the fifth decimal place seem to “rotate” almost steadily (See Knoll 1979).

9.4.5.1 Properties

Addition theorem. If X_1 and X_2 are independent random variables with $\gamma(r_1, \nu)$, and $\gamma(r_2, \nu)$ gamma distribution, respectively, then the random variable $X = X_1 + X_2$ has a $\gamma(r_1 + r_2, \nu)$ gamma distribution.

Normal approximation. For large enough values of r , the $\gamma(r, \nu)$ gamma distribution can be approximated by an $N(r/\nu, r/\nu^2)$ normal distribution (see the graph in ► Fig. 9.14 to the right). (If the order $r = n$ is an integer, then this follows directly from the interpretation and from the

Fig. 9.15

When counting the particles/photons emitted by a radioactive specimen, each decimal digit of the counter switches to the next figure after a waiting time determined by a gamma distribution the order of which (n), in turn, is determined by the decimal place of the digit. Note that a narrower distribution means a steadier rhythm of switching. For better comparison, the density functions have been renormalized so that the geometric area under each curve is the same

central limit theorem.) The normal probabilities for deviations from the mean ($\mu \pm d\sigma$) can be found in [Table 9.3](#).

9.4.6 Normal Distribution: $N(\mu, \sigma^2)$

Density function: $f(x) = \frac{1}{\sigma} f_{01}\left(\frac{x-\mu}{\sigma}\right) = \frac{1}{\sqrt{2\pi}\sigma} \exp\left[-\frac{1}{2}\left(\frac{x-\mu}{\sigma}\right)^2\right]$	
Distribution function: $F(x) = F_{01}\left(\frac{x-\mu}{\sigma}\right) = \frac{1}{2}\left[1 + \operatorname{erf}\left(\frac{1}{\sqrt{2}}\frac{x-\mu}{\sigma}\right)\right]$	
Error function: $\operatorname{erf} x = -\operatorname{erf}(-x) = \frac{2}{\sqrt{\pi}} \int_0^x e^{-t^2} dt$	
Characteristic function: $\varphi(u) = \exp\left(i\mu u - \frac{\sigma^2}{2} u^2\right)$	
Expected value, median, mode, center of symmetry: μ	
Variance: σ^2	Mean abs. deviation: $\sqrt{2/\pi} \sigma \approx 0.798\sigma$
Interquartile range: 1.348σ	Point of inflection of f : $\mu \pm \sigma$
Full width at half maximum (FWHM): $2\sqrt{2 \ln 2} \sigma \approx 2.355\sigma$	

■ Fig. 9.16

Comparison of the error function (erf) with the density function (f_{01}) and the distribution function (F_{01}) of the $N(0, 1)$ standard normal distribution. The intervals 0 ± 1 , 0 ± 2 , and 0 ± 3 correspond to the error limits $\mu \pm \sigma$, $\mu \pm 2\sigma$, and $\mu \pm 3\sigma$, respectively. The normal probabilities for deviations from the mean ($\mu \pm d\sigma$) can be found in ► Table 9.3

■ Fig. 9.17

The $\chi^2(k)$ distribution can be fairly well approximated with the $N(k, 2k)$ distribution for as low a degree of freedom as $k = 50$

■ Fig. 9.18

The density function of the $C(0, 1)$ Cauchy distribution (*thick red line*, also called Lorentzian curve) compared with different Gaussians. The green and turquoise curves indicate normal density functions (the area under each curve is 1). In one case the height (h_C), in the other case the width (γ_C) is fixed to be equal with that of the Lorentzian. The thicker blue curve shows a Gaussian having the same height and width as the Lorentzian (γ_C, h_C). (With both parameters fixed, the Gaussian could not be normalized. Thus the area under the curve is 0.678 this time.) The difference between the distributions is quite obvious here: the Lorentzian approaches 0 much more slowly than the Gaussian, which is in accordance with the nonexistence of the expected value and the variance in the case of the Cauchy distribution

In the above expressions f_{01} and F_{01} are the $N(0, 1)$ standard normal density function and distribution function, respectively (see Fig. 9.16). In physics and engineering normal distribution is often called Gaussian distribution. However, the expression Gaussian curve will only be used here meaning an un-normalized normal distribution function as shown in Fig. 9.18.

Interpretation. Let X be any random variable with existing expected value (μ) and variance (σ^2). Let X_i denote the random variable representing the outcome of the i th ($i = 1, 2, \dots, n$) independent experiment to observe the value of X . (The random variables X_i are obviously independent and have the same distribution as X .) Then the sample mean $\bar{X} \equiv (X_1 + X_2 + \dots + X_n)/n$ is asymptotically normal with $N(\mu, \sigma^2/n)$ distribution.

(#46) The above interpretation is the Lindberg–Lévy version of the central limit theorem. The $[N(np, npq)]$ normal distribution could also be interpreted as the limiting case of the $B(n, p)$ binomial distribution (De Moivre–Laplace theorem), but that is only a special case of the general theorem phrased for sums when the limiting distribution in general is $N(n\mu, n\sigma^2)$ normal.

(#47) When the normal distribution is referred to as the limiting case of an integral valued ($x = 0, 1, 2, \dots$) discrete distribution (e.g., Poisson or binomial distribution), then the continuous density function $f(x)$ is actually a substitute for the mass function p_x . This is so,

because the latter can be considered as a step function jumping at integral values. Therefore, since $\Delta x = 1$, one can write $p_x \approx f(x)\Delta x \equiv f(x)$ whenever x is an integer.

9.4.6.1 Properties

Standardization. Shifting and/or rescaling a normal random variable will result in another normally distributed random variable. Therefore, the standardization of the $N(\mu, \sigma^2)$ normal random variable X will result in an $N(0, 1)$ standard normal random variable Y :

$$Y = \frac{X - \mu}{\sigma}. \quad (9.95)$$

(#48) The random numbers produced by common calculators usually have a uniform distribution between 0 and 1. However, such $U(0, 1)$ random numbers can be easily converted to normally distributed random numbers by summing them n at a time (see remark (#46)). Considering large enough values for n , the summation will result in random numbers with an $N(n/2, n/12)$ distribution (see remark (#8)). Thus, for $n = 12$, an $N(6, 1)$ distribution is obtained. In this case, the result can be easily converted to $N(0, 1)$ standard normal distribution by subtracting 6 from the sum.

(#49) The $N(0, 1)$ random numbers simulated according to the above remark can be used, e.g., for the simulation of nuclear spectra. Nuclear spectrum points (see in [Sect. 9.6](#)) have $N(\mu_i, \mu_i)$ distribution. If the μ_i values are calculated from the fitting function and R_i is an $N(0, 1)$ random number, then the formula $Y_i \equiv \mu_i + \sqrt{\mu_i}R_i$ defines a random number with $N(\mu_i, \mu_i)$ distribution as required.

Addition theorem. If X_1 and X_2 are independent random variables with $N(\mu_1, \sigma_1^2)$, and $N(\mu_2, \sigma_2^2)$ normal distribution, respectively, then the random variable $X \equiv X_1 + X_2$ has an $N(\mu_1 + \mu_2, \sigma_1^2 + \sigma_2^2)$ normal distribution.

Bernoulli sampling. Suppose that the aim of an experiment is to observe certain objects (e.g., all the “visible” photons belonging to a light pulse that was produced as a result of the detection of a single radiation particle in the scintillator). Suppose that the number of these objects is a random variable with $N(\mu, \sigma^2)$ distribution. The objects are taken one by one and either “accepted” with probability η or “discarded” with probability $1 - \eta$. In other words: a $B(1, \eta)$ Bernoulli sampling is applied to them. (Returning to the above example, η can represent the probability that a “visible” photon will produce a photoelectron due to its interaction with the photocathode of the multiplier.) The question is, how many objects have been accepted altogether in the experiment, i.e., how many objects have passed the test of Bernoulli sampling (e.g., how many photoelectrons have formed on the photocathode as a result of the detection of a single radiation particle) and how these accepted numbers are distributed if a whole series of like experiments is considered. The $N(\mu, \sigma^2)$ distribution mentioned above is, of course, the integral-valued “discrete” version of normal distribution, for which the substitution values $f(n)$ of the density function act as mass function at the integral values of the x -axis. Therefore the question can be answered by reversing the De Moivre–Laplace theorem, i.e., if $\mu > \sigma^2$ and $\mu \gg 1$, then there is a $B(n, p)$ binomial distribution, which provides a fair approximation for the $N(\mu, \sigma^2)$ distribution. In the case of the binomial distribution, it has been shown that the result of Bernoulli sampling is a $B(n, p\eta)$ distribution. Thus one only needs to find the $N(\mu_\eta, \sigma_\eta^2)$ distribution that approximates this Bernoulli-sampled binomial distribution according to

the De Moivre–Laplace theorem. It is easy to show that the parameters of the “sampled” and “un-sampled” normal distributions are related as follows:

$$\mu_\eta = \eta\mu; \quad \sigma_\eta^2 = \eta^2\sigma^2 + \eta(1-\eta)\mu; \quad \frac{\sigma_\eta}{\mu_\eta} = \frac{\sigma}{\mu} \sqrt{1 + \frac{1-\eta}{\eta} \frac{\mu}{\sigma^2}}. \quad (9.96)$$

(#50) According to the above formula, the normal distribution can broaden considerably as a result of Bernoulli sampling. Referring to the above example, this means that the resolution of scintillation detectors is limited (among others) by the fact that typically only 1 “visible” photon out of 10 produces a photoelectron at the photocathode. In the case of the NaI(Tl) scintillator, moreover, there is also a previous Bernoulli sampling, i.e., only one excitation out of three will produce a photon that is suitable for the production of photoelectrons at all. The fact that the number of excitations (occurring, e.g., due to the absorption of a gamma photon) has a normal distribution will be shown in the frame of the renewal process.

9.4.7 The χ^2 Distribution: $\chi^2(k)$

Density function: $f_k(x) = \begin{cases} \frac{x^{k/2-1} e^{-x/2}}{2^{k/2} \Gamma(k/2)} & \text{if } x > 0 \\ 0 & \text{if } x \leq 0 \end{cases}$	
Characteristic function: $\varphi(u) = (1 - 2iu)^{-k/2}$	
Expected value: k	Mode: $k-2$
Variance: $2k$	Relative deviation: $\sqrt{\frac{2}{k}}$

Interpretation. Let Z_1, Z_2, \dots, Z_k be a sequence of independent $N(0, 1)$ random variables. Then the sum of squares $Z_1^2 + Z_2^2 + \dots + Z_k^2$ produces a random variable having a χ^2 distribution with k degrees of freedom – in short: $\chi^2(k)$ distribution.

(#51) If Y_1, Y_2, \dots, Y_k are a sequence of independent random variables having the same $N(\mu, \sigma^2)$ distribution with exactly known expected value and variance, then the sum of squares of the standardized variables will have a $\chi^2(k)$ distribution.

(#52) Continuing from the previous remark, the following conclusion can be drawn: If μ is not known, and therefore it is replaced by the average $\bar{Y} = (Y_1 + Y_2 + \dots + Y_k)/k$ when forming the standardized variables, then the sum of squares of the standardized variables will have a $\chi^2(k-1)$ distribution.

(#53) If Y_1, Y_2, \dots, Y_k are a sequence of independent random variables, which have $N(\mu_i, \sigma_i^2)$ normal distributions ($i = 1, 2, \dots, k$) with known expected values and variances, then the sum of squares of the standardized variables will have a $\chi^2(k)$ distribution.

(#54) Continuing from the previous remark, the following conclusion can be drawn: Suppose that there is a model function $\mu(x) = \mu(x; b_1, b_2, \dots, b_n)$, which is linear in all of its n parameters (b_1, b_2, \dots, b_n) and that model function (now: fitting function) produces the expected values $\mu_i (i = 1, 2, \dots, k)$ whenever the parameter vector \mathbf{b} is set to the value $\mathbf{b} = \mathbf{a}$:

$$\mu_i = \mu(x_i; a_1, a_2, \dots, a_n). \quad (9.97)$$

Consider now the sum of squares

$$S_k = \sum_{i=1}^k \left(\frac{Y_i - \mu(x_i; b_1, b_2, \dots, b_n)}{\sigma_i} \right)^2. \quad (9.98)$$

Suppose that the parameter values $\hat{a}_1, \hat{a}_2, \dots, \hat{a}_n$ minimize the above sum. Then the minimized sum of squares

$$\hat{S}_k = \sum_{i=1}^k \left(\frac{Y_i - \mu(x_i; \hat{a}_1, \hat{a}_2, \dots, \hat{a}_n)}{\sigma_i} \right)^2 \quad (9.99)$$

has a $\chi^2(k - n)$ distribution (Press et al. 1999).

(#55) Continuing from the previous remark, the following conclusion can be drawn: According to remark (#53), the sum of squares taken at the parameter values a_1, a_2, \dots, a_n would have a $\chi^2(k)$ distribution because in this case the “exact” expected values (μ_i) would show up in the sum. It is important to stress this, because it will be shown in the section on the evaluation of nuclear spectra that the values $\hat{a}_1, \hat{a}_2, \dots, \hat{a}_n$ are the maximum likelihood estimates of the “exact” values a_1, a_2, \dots, a_n . Therefore, one might expect that the relation of \hat{a} to the concrete measured spectrum is the same as that of the parameter vector \mathbf{a} that it estimates. Well, the decrease of the degree of freedom indicates that this assumption is false. The reason is that minimization tends to divert the estimated values from the “exact” parameter values so that they can attribute the largest possible likelihood to the concrete spectrum. And this will be so even if the concrete spectrum has a rather low likelihood when calculated with the “exact” values of the parameters.

(#56) The symbol $\Gamma(k/2)$ showing up in the density function denotes the complete gamma function. This is not by chance because the χ^2 distribution is actually a special case of the gamma distribution. (Looking at the density function f_k , one can easily recognize it as the density function of the $\gamma(k/2, 1/2)$ gamma distribution. The characteristic functions are still easier to compare.

(#57) Note that when the degree of freedom (k) is large, then the expected value is practically equal to the mode, i.e., the expected value doubles as the “most probable” value. (The reason for the quotation marks is that with continuous distributions any x value has 0 for probability. What this statement really means is that the probability $dP = f(x)dx$ is at its maximum if dx is considered constant.) When evaluating nuclear spectra, χ^2 distributions with about 2,000 degrees of freedom quite often occur (2,048-channel spectra). In such cases the relative deviation is about 3%, i.e., the value of the $\chi^2(2,000)$ random variable is most probably $2,000 \pm 3\%$ ($2,000 \pm 60$). For more detail, see the next remark. (The p -quantiles for χ^2 distributions $\chi^2(k)$ with degree of freedom $1 \leq k \leq 30$ can be found in [Table 9.4](#).)

9.4.7.1 Properties

Normal approximation. It follows from the interpretation as well as from the central limit theorem that for large enough values of k (i.e. $k \geq 30$) the $\chi^2(k)$ distribution can be approximated with the $N(k, 2k)$ normal distribution (see [Fig. 9.17](#)).

(#58) Continuing from the previous remark, the following conclusion can be drawn: According to the properties of the normal distribution (see [Table 9.3](#)), the value of the $\chi^2(2,000)$ random variable will be $2,000 \pm 3\%$ ($2,000 \pm 60$) in 68% of the cases, $2,000 \pm 6\%$ ($2,000 \pm 120$) in 95% of the cases, and $2,000 \pm 9\%$ ($2,000 \pm 180$) in 99.7% of the cases (i.e., nearly always).

(#59) The relative χ^2 is the scaled-down version of the $\chi^2(k)$ random variable with the scaling factor $1/k$. Consequently, both the expected value and the standard deviation decrease by the same factor $1/k$ resulting in $\mu_{\text{rel}} = 1$ and $\sigma_{\text{rel}} = \sqrt{2/k}$, respectively. Continuing from the previous remark the following conclusion can be drawn: This means that the value of the relative χ^2 will be 1 ± 0.03 in 68% of the cases, 1 ± 0.06 in 95% of the cases, and 1 ± 0.09 in 99.7% of the cases (i.e., nearly always). Relative χ^2 values out of this range are to be considered therefore with suspicion. (Of course, if k is smaller, then the error range is broader.)

Addition theorem. If X_1 and X_2 are independent random variables having χ^2 distributions with k_1 and k_2 degrees of freedom, respectively, then the sum $X = X_1 + X_2$ has a χ^2 distribution with $k_1 + k_2$ degrees of freedom.

9.4.8 Cauchy Distribution: $C(m, \gamma)$

Density function: $f(x) = \frac{1}{\pi\gamma} \frac{1}{1 + \left(\frac{x-m}{\gamma}\right)^2}$
Distribution function: $F(x) = \frac{1}{2} + \frac{1}{\pi} \arctan \frac{x-m}{\gamma}$
Characteristic function: $\varphi(u) = \exp(imu - \gamma u)$
Expected value, variance, standard deviation: do not exist
Median, mode, center of symmetry: m
Full width at half maximum (FWHM), interquartile range: 2γ
Point of inflection of the density function: $m \pm \gamma/\sqrt{3}$

All of the distributions mentioned so far lie within the range of attraction of normal distribution, i.e., the central limit theorem is valid for distributions that are quite dissimilar to the normal distribution such as the discrete Bernoulli distribution and the asymmetric exponential distribution. The Cauchy distribution presented below is, on the contrary, very similar in shape to the normal distribution (see [Fig. 9.18](#)), but it has neither an expected value, nor a (finite) variance, and therefore is exempt from the rule.

Interpretation. Let Θ be a random variable uniformly distributed in the interval $(-\pi/2, \pi/2)$. Then the random variable

$$Y = m + \gamma \tan \Theta \quad (9.100)$$

has a $C(m, \gamma)$ Cauchy distribution. In other words: consider the xy -plane and two lines – one (line 1) passing through the origin and another (line 2) parallel to the y -axis and intersecting the x -axis at the point $x = 1$. Now spin line 1 around the origin at constant angular velocity. Measure the y -coordinate of the intersection of lines 1 and 2 at random moments. The Y values obtained in this way will have a $C(0, 1)$ distribution (Hogg and Tanis 1988).

(#60) Using the above interpretation, it is easy to convert uniformly distributed $U(-\pi/2, \pi/2)$ random numbers to random numbers with Cauchy distribution. Such a simulated sequence (200 data) is shown in [Fig. 9.19](#), together with as many normally distributed random numbers having the same FWHM. Note that all of the normal random numbers lie within a few FWHMs from the origin. The Cauchy-type random numbers, on the other hand, behave in a much more disorderly way, i.e., there are quite a number of points that are way out of the same range.

(#61) Another possibility for interpretation (and simulation) is provided by the formula $X = Y_0/Y_1$, where Y_0 and Y_1 are independent random numbers/variables with $N(0, 1)$ distribution. This transformation results in $C(0, 1)$ distribution. The recipe is based on the

■ Fig. 9.19

Comparison of normal random numbers with random numbers having Cauchy distribution. Both distributions have the same halfwidth (FWHM = 2). Note that some of the Cauchy-type random numbers are as large as 500 in this particular sequence. On the other hand, all of the normal random numbers lie in the narrow range of $6\sigma = 5$ determined by the $0 \pm 3\sigma$ limits

fact that the Cauchy distribution can be considered as a special case of the (Student's) t distribution (not discussed here).

(#62) In Mössbauer spectroscopy (see ▶ Chap. 25 in Vol. 3), the density function of Cauchy distribution is called a Lorentzian curve. In nuclear physics, the same function is also called the Breit–Wigner curve (Lyons 1986). (See also ▶ Chap. 2 in this Volume.) This curve is characteristic of the energy uncertainty of excited (nuclear) states, which follows from the fact that excited states have exponential distribution with a finite mean life τ . The natural linewidth Γ , i.e., the FWHM of the Lorentzian energy density, is twice of the parameter γ ($\Gamma = 2\gamma$).

(#63) The lack of expected value and variance can be quite a shock for those who had been familiar with the physical meaning of the Lorentzian curve but learned about this mathematical “defectiveness” at a later date. (The confrontation with this defectiveness often fails to occur. For instance, Bevington, in his often-cited work (Bevington 1969), writes about Cauchy distribution as if it had an expected value.) This is so, because the nonexistence of these parameters makes them believe that the distribution is hopelessly smeared over the energy axis. However, this is not the case, which is quite clear from the viewpoint of physics, because otherwise no sharp spectrum lines could exist. The expected value (and the variance built on that) fails, because the “central tendency” of the distribution is simply not sufficient for the convergence of the respective formula(s). Note that the density function is asymptotically proportional to x^{-2} , and therefore the integrand in the expected value formula is proportional to x^{-1} , hence the integral itself ($\sim \ln x$) is boundless. Other parameters describing the “location” and “dispersion” of the distribution (mode, interquartile range, etc.) still may and actually *do* work.

■ Fig. 9.20

Fine structure of the detector signal of 0.1 mm NaI(Tl) scintillator at gamma energy of 14.4 keV. The high time resolution of the digital oscilloscope helps to visualize the elementary processes that make up the signal. The steep rise of the pulse is an indication of the promptness of the formation of the excited states. The individual “hairs” sticking out from the fuzzy contour represent photoelectrons (or rather the results of cascades started by these in the multiplier) produced by individual visible photons at the photocathode. The multitude of partly merging elementary pulses outlines the exponential law of the “decay” of excited states

(#64) Continuing from remarks (#62)–(#63), the following conclusion can be drawn: The formula $\tau \Gamma = \hbar$ is often used for the estimation of the natural linewidth. This formula is sometimes interpreted as the time–energy equivalent of the Heisenberg relation, where τ is the uncertainty (standard deviation) of the lifetime and Γ (FWHM) is that of the energy state. It should be stressed, however, that while τ can play the assigned role (because the standard deviation is equal to the expected value in the case of the exponential distribution), the quantity Γ cannot be interpreted as standard deviation, since the Cauchy distribution does not have any.

Nevertheless, the formula works not only in theory but also in practice as is proven for the 30 or so nuclides for which the values of Γ and τ have been determined by independent methods (Belgys et al. 1993).

9.4.8.1 Properties

Standardization. The rescaling and shifting of Cauchy distribution results in another Cauchy distribution. Therefore the following transformation of the random variable X having a $C(m, \gamma)$ Cauchy distribution

■ Fig. 9.21

Distributions of the multiplication by a “photomultiplier” calculated for 1, 2, 3, and 4 dynodes

$$Y = \frac{X - m}{\gamma} \quad (9.101)$$

generates a random variable Y with $C(0, 1)$ Cauchy distribution.

(#65) Note that in the above formula, the “substitutes” of the expected value and standard deviation appear as location and dispersion parameters.

Addition theorem. If X_1 and X_2 are independent random variables with $C(m_1, \gamma_1)$ and $C(m_2, \gamma_2)$ Cauchy distribution, respectively, then the random variable $X = X_1 + X_2$ has a $C(m_1 + m_2, \gamma_1 + \gamma_2)$ Cauchy distribution.

(#66) In Mössbauer spectroscopy, the peak-shape of the transmission spectrum (measured with a thin absorber, see ▶ Fig. 9.22) is described as the convolution of the Lorentzians characteristic of the source and the absorber. According to the addition theorem, the result of such a convolution will be another Lorentzian with a halfwidth equal to the sum of both halfwidths. In other words, in this case, the FWHM is twice of the natural linewidth Γ .

(#67) Note that in the case of the Cauchy distribution, the scaling-up of the random variable with the factor 2 leads to the same result as the addition of two independent random variables with the same distribution (i.e., both parameters m and γ will double). In the case of distributions “more normal” than the Cauchy distribution, on the other hand, the width will only increase by the factor $\sqrt{2}$ when two like (although independent) variables are added up.

■ Fig. 9.22

An example for a nuclear spectrum. The main graph shows a single-peak Mössbauer spectrum “measured” at transmission geometry. Such a spectrum can be fitted with a Lorentzian curve (blue line), whose shape is identical with the density function of a Cauchy distribution. Due to standardization, the tick distance on the horizontal axis is half of the full width at half maximum (FWHM) of the Lorentzian (γ). As mentioned in remark (#66), $\text{FWHM}/2 = \gamma$ gives the natural line width Γ provided that the absorber is ideally thin. On the other hand, the vertical scattering of the counts (red dots) is characterized by the normal distribution. The colored graph on the left, e.g., shows the normal density function belonging to the baseline (μ_∞). The color code is explained by ► Fig. 9.2. On the vertical axis the distance between the ticks equals to σ

As shown before, this is due to the “Pythagorean theorem” of the standard deviations, which means that it is the variances that add up rather than the standard deviations themselves.

9.5 Applications of Stochastic Processes

In this section, a few examples will be given to show the applicability of stochastic processes in nuclear science. It should be stressed that the aim is to present *illustrations* rather than to derive formulas that serve as the final solutions for the problems cited. Reading the next couple of pages can hopefully help to arouse interest in this field (See for more detail in Karlin and Taylor 1975, 1984).

9.5.1 Renewal Processes

The “prototype” of the renewal process is the following. Consider a part of equipment the lifetime of which, T_1 is a random variable with expected value μ and variance σ^2 . The first such part started to work at time 0. Having broken down at time T_1 , it was promptly replaced with a

new part, which was working for a period T_2 , i.e., it broke down at time $T_1 + T_2$, and so on. The n th renewal took place at time: $S_n = T_1 + \dots + T_n$. The renewal process N_t counts the number of renewals occurring in the time interval $[0, t]$, i.e.,

$$N_t = n, \quad \text{if } S_n \leq t < S_{n+1}, \quad \text{where } n = 0, 1, 2, \dots \quad (9.102)$$

The following theorems are very important as regards the above process:

Renewal theorem. $E(N_t) \approx t/\mu$, if t is large enough. (This is in agreement with the expectation based on common sense: If a part works for a period μ on an average, then about t/μ parts will be needed over the total operating period t .)

Central limit theorem for renewals. N_t is asymptotically normal with $N(t/\mu, t\sigma^2/\mu^3)$ distribution.

9.5.1.1 The Poisson Process as Renewal

It is not difficult to recognize the renewal process in the Poisson process discussed earlier, where the random variable T had a $\gamma(1, \nu)$ exponential distribution, as a consequence of which N_t (or, with the earlier notation: X) turned out to have a $\Pi(\nu t)$ Poisson distribution. The Poisson process represents one of the few cases where the distribution of the renewal process is known for any value of t . The importance of the central limit theorem for renewals lies in the very fact that, for large enough values of t , one can count on normal distribution even if the exact distribution of N_t is unknown. The validity of the theorem can be easily checked in this particular case, since by substitution one gets the well-known result that for large enough μ the approximation $\Pi(\mu) \approx N(\mu, \mu)$ can be used.

(#68) The fact that the Poisson process can be interpreted as a renewal makes it possible to generate random numbers with Poisson distribution using exponentially distributed random numbers (Goodman 1988; Lux and Koblinger 1991). (For the generation of exponentially distributed random numbers see remark (#30).) If, namely, T_1, T_2, \dots are a sequence of random numbers/variables with a $\gamma(1, \nu)$ exponential distribution, then the random number/variable N determined by the condition

$$T_1 + T_2 + \dots + T_N \leq t < T_1 + T_2 + \dots + T_N + T_{N+1} \quad (9.103)$$

will have a $\Pi(\nu t)$ Poisson distribution according to inequality (9.102).

(#69) The discrete equivalent of the Poisson process is related to a series of Bernoulli trials, in which case the individual trials (e.g., coin tosses) can be assigned to individual discrete moments (i.e., to the serial number of the toss, n). It is clear that the process $X(n)$ has a $B(n, p)$ binomial distribution – the distribution characteristic of the number of heads turning up in a series of n tosses.

9.5.1.2 Consideration of Dead Time

The Poisson process is connected with a (nonexistent) type of particle/signal detection, when the detecting system is promptly able to deal with a new signal after having received the previous one. In reality, however, any detecting system can only deal with a new signal after a certain period of time Θ_i called the dead time. During this period (which should be treated as a random variable in general), the detecting system is recovering (e.g., GM counter), or it is busy

with signal processing (e.g., pulse height analysis). The dead time is followed by the waiting time T_i having exponential distribution, the same as the one discussed at the Poisson process (see ▶ Eq. (9.89)), with the same mean frequency ν . (This is the consequence of the memorylessness of the exponential distribution.) The total waiting time (including the dead time) connected with the i th (actually detected) signal therefore is $Z_i = \Theta_i + T_i$. Thus the n th signal is detected at the moment $S_n = Z_1 + \dots + Z_n$.

Considering the independence of Θ_i and T_i , as well as that the distributions of both Θ_i and T_i are concentrated to the half-line $t > 0$, the distribution function of Z_i is given by the following convolution (see ▶ Eq. (9.51)):

$$F(z) = G * h(z) = \int_0^z G(z-x)h(x)dx = \int_0^z G(z-x)\nu e^{-\nu x}dx$$

where G is the distribution function of Θ_i , and h is the (exponential) density function of T_i . The subscripts have been omitted, because the Θ_i s have the same distribution and so do the T_i s (separately). The density function of $Z_i(f)$ can be obtained by differentiation. The density function of $S_n(f_n)$ can be obtained by forming the n th convolution power of $f = F'$:

$$f_n(z) = f * \dots * f(z)$$

In particular, if the dead time is constant (θ), then $f = \nu \exp[-\nu(t - \theta)]$, which is the exponential density function shifted to $\theta(t > \theta)$. Therefore, S_n has a shifted gamma distribution with the following density function:

$$f_n(t) = \frac{[\nu(t - n\theta)]^{n-1}}{(n-1)!} \nu e^{-\nu(t-n\theta)} \quad (t > n\theta).$$

The following results hold even if the concrete distribution of the process N_t is unknown:

$$\mu \equiv E(Z) = E(\Theta) + E(T) = \theta + \frac{1}{\nu} \quad (9.104)$$

$$\sigma^2 \equiv D^2(Z) = D^2(\Theta) + D^2(T) = D^2(\Theta) + \frac{1}{\nu^2} \quad (9.105)$$

where θ is the mean dead time, and ν is the mean signal frequency (mean count rate with zero dead time). If the dead time is constant, the latter equation becomes simpler:

$$\sigma^2 = \frac{1}{\nu^2}. \quad (9.106)$$

The mean count rate in the case of constant dead time θ is

$$\nu_\theta = \frac{1}{\mu} = \frac{\nu}{1 + \theta\nu}. \quad (9.107)$$

Using this, one can easily calculate the mean signal frequency ν (i.e., the mean count rate without dead time) from the measured value of the mean count rate ν_θ (i.e., the apparent mean signal frequency) provided that θ is known:

$$\nu = \frac{\nu_\theta}{1 - \theta\nu_\theta}. \quad (9.108)$$

According to the central limit theorem for renewals, N_t is asymptotically $N(t/\mu, t\sigma^2/\mu^3)$ normal. In the case of long enough counting times and constant dead time, therefore, the expected value and the variance of the counts are

$$E(N_t) = \frac{v}{1 + \theta v} t = v_\theta t, \quad (9.109)$$

$$D^2(N_t) = \frac{v}{(1 + \theta v)^3} t = (1 - \theta v_\theta)^2 v_\theta t. \quad (9.110)$$

(#70) It follows from above result that

$$D^2(N_t) = (1 - \theta v_\theta)^2 E(N_t) \leq E(N_t) \quad (9.111)$$

where the equals sign only holds for $\theta v_\theta \ll 1$. Thus, in the case of measured counts, the Poisson approximation (when the variance is taken to be equal to the expected value) tends to overestimate the actual standard deviation.

(#71) The product θv_θ represents the fraction of the counting time t that is “covered” by the dead-time intervals associated with the individual measured signals. The percentage of dead time displayed by some detecting systems is therefore equal to $100\theta v_\theta$.

9.5.1.3 The “Primeval” Shape of the Photoelectric Peak

The initial stage of the detection is the transferring of the energy of a radiation particle – or a gamma photon – to the substance of the detector. Owing to this process ionized/excited states are produced, the number of which is proportional to the absorbed energy, serving as a basis for the energy determination of the detected particle.

The renewal story can also be recounted with the following exchange of roles: $t \Leftrightarrow E$, $N_t \Leftrightarrow N_E$, $T_i \Leftrightarrow \varepsilon_i$, $\mu \Leftrightarrow \varepsilon$, $\sigma \Leftrightarrow \sigma_\varepsilon$. Consider, therefore, a gamma photon, the energy (E) of which breaks up to random portions (ε_i) while it is transferred to the detector crystal following photoelectric effect. The renewal process N_E now counts the number of portions – a random variable – to which the energy of the photon has happened to split. Each energy portion is spent on the production of one charge carrier (or one excited state relevant from the viewpoint of detection). Therefore, N_E also means the number of charge carriers produced by the detected photon, which – assuming linear amplification – will be proportional to the pulse height. If further statistical effects can be neglected, then the density function of N_E will be characteristic of the pulse height distribution as well, which has a Gaussian shape according to experience.

The distribution of the ε_i -values is concentrated to the energy range (V, E), where V is the minimum of energy (ionization potential), which is just enough for the production of one charge carrier in the given detector substance. Further characteristic parameters of the distribution are $\varepsilon \equiv \langle \varepsilon_i \rangle$, the mean energy spent on the production of one charge carrier/excited state, as well as σ_{rel} , the relative deviation of the ε_i -values.

According to the central limit theorem of renewals, N_E will be asymptotically normal with the following parameters:

$$N\left(\frac{E}{\varepsilon}, \sigma_{\text{rel}}^2 \frac{E}{\varepsilon}\right). \quad (9.112)$$

The shape of the photoelectric peak is therefore determined by the density function of the above normal distribution (i.e., by a Gaussian curve), the mode/expected value (MAX) and halfwidth (FWHM) of which are

$$\text{MAX} = \frac{E}{\varepsilon}; \quad \text{FWHM} = 2\sqrt{2 \ln 2} \sigma_{\text{rel},\varepsilon} \sqrt{\frac{E}{\varepsilon}}. \quad (9.113)$$

Thus the position of the maximum is proportional to the photon energy E , and the low-energy peaks are narrower than the high-energy peaks. Hence, the relative peak width turns out to be inversely proportional to the square root of the energy:

$$\text{FWHM}_{\text{rel}} \equiv \frac{\text{FWHM}}{\text{MAX}} = 2\sqrt{2 \ln 2} \sigma_{\text{rel},\varepsilon} \sqrt{\frac{E}{\varepsilon}}. \quad (9.114)$$

The above formulas show that this simple stochastic model not only explains the shape of the photoelectric peak, but also predicts that the smaller is the average energy spent on the production of one charge carrier/excited state in a detector, the better is its energy resolution.

9.5.1.4 Statistical Effects Smearing the Photoelectric Peak

It has been assumed above that there are no statistical effects at later stages of pulse formation that could change the shape of the photoelectric peak. However, such effects *do* exist. Consider the scintillation detectors, for instance, which waste much of the potential of energy resolution hidden in the “primeval” shape of the photoelectric peak.

In the case of scintillation detectors, the production of excited states is practically instantaneous in comparison with the time scale of de-excitation. The excited states are characterized by the same exponential-type lifetime distribution as the radioactive atoms. A large number of excited states start to “decay” at the same moment ($t = 0$), as a result of which visible photons are formed (see [Fig. 9.20](#)).

The temporal density of photons as a function of time – in other words, the shape of the light pulse – shows the characteristic features of the exponential law of decay. If the electronics does not mix up the elementary processes too much, then the shape of the light pulse will be reflected in the shape of the voltage pulse as well, the latter being the object of pulse height analysis. All in all, the pulse height of the detector signal will be determined by the number of photons emitted between $t = 0$ (the moment when the excited states were formed) and a moment a little later: $t = 0 + \Delta t = \Delta t$. (The length of Δt depends on the details of the signal processing/pulse height analysis, however it is surely shorter than the mean life τ of the excited states.) The number of photons responsible for the pulse height is determined therefore by the $B(N_E, \exp(-\Delta t/\tau))$ binomial distribution for any value of N_E . Since the “primeval” shape is very narrow, N_E can be replaced by its expected value (MAX). If the binomial expected value $\text{MAX} \times \exp(-\Delta t/\tau)$ and the variance $\text{MAX} \times \exp(-\Delta t/\tau) \times [1 - \exp(-\Delta t/\tau)]$ are not too small, then the binomial distribution can be approximated with normal.

Hence, the number of photons determining the pulse height is normally distributed:

$$N\left(A \frac{E}{\varepsilon}, B \frac{E}{\varepsilon}\right) \quad (9.115)$$

where A and B are constants. Note that the result is another Gaussian that is considerably broader than the “primeval” one, but otherwise has the same properties, the most important being the proportionality between pulse height (Ampl.) and energy:

$$\text{pulse height} \equiv \text{Ampl.} \propto \frac{E}{\varepsilon}. \quad (9.116)$$

From now on, only the fate of those photons will be followed that are characterized by the above distribution. The production of photoelectrons at the photocathode can be described by Bernoulli sampling (see at the normal distribution). Bernoulli sampling will broaden the distribution (in the relative sense); however, it will not lead out from the family of normal distributions:

$$N\left(\eta A \frac{E}{\varepsilon}, \eta[(1 - \eta)A + \eta B] \frac{E}{\varepsilon}\right) = N\left(a \frac{E}{\varepsilon}, b \frac{E}{\varepsilon}\right). \quad (9.117)$$

The electron multiplier will further modify the shape of the peak (see at the branching processes), but, fortunately, the proportionality between pulse height and energy will not suffer.

9.5.2 Markov Chains

A Markov chain is a stochastic process defined by the condition

$$P(a < X_n \leq b | X_1 = x_1, X_2 = x_2, \dots, X_{n-1} = x_{n-1}) = P(a < X_n \leq b | X_{n-1} = x_{n-1}) \quad (9.118)$$

which means that the current outlook of such a process is determined by the latest information to such an extent that no earlier information can add anything to it.

9.5.2.1 Branching Processes

The story of the branching processes is the following. Consider an entity (0th generation), which produces X_1 identical offspring in one single reproductive cycle (1st generation). The offspring of the n th generation constitute the $(n + 1)$ th generation. The entities belonging to each generation proliferate independently of each other and of their predecessors according to the same distribution. The aim is to follow X_n , the population of the subsequent generations of entities. Such entities can be, e.g., neutrons multiplied by a chain reaction or electrons “breeding” on the dynodes of a multiplier.

The X_1 is a discrete random variable that can assume the values $k = 0, 1, 2, \dots$ with different probabilities $P(X_1 = k) = p_k$. Let μ denote the expected value, and σ^2 the variance of the distribution. Let $G(s) \equiv G_1(s)$ be the generating function of the distribution

$$G(s) \equiv \sum_{k=1}^{\infty} p_k s^k. \quad (9.119)$$

Then, the generating functions of the subsequent generations can be calculated from the following recursion formula (Feller 1968):

$$G_{n+1}(s) = G(G_n(s)). \quad (9.120)$$

The expected value and the variance of the branching process are (Feller 1968)

$$E(X_n) = \mu^n; \quad D^2(X_n) = (\mu^{2n-2} + \mu^{2n-3} + \dots + \mu^{n-1})\sigma^2. \quad (9.121)$$

Note that the result obtained for the expected value is in accordance with the common-sense expectation.

(#72)  *Figure 9.21* shows a sequence of distributions resulted from such a calculation. The model can represent, e.g., a photomultiplier, the dynodes of which “double” the incident electrons with a probability of 50%, i.e., half of the electrons have 2 offspring, while the other

half only 1. Thus the mean multiplication factor of the dynodes is $\mu = 3/2$, with a standard deviation of $\sigma = 1/2$.

According to [Eq. \(9.121\)](#), the relative deviation of multiplication is

$$\sigma_{\text{rel}}(X_n) \equiv \frac{D(X_n)}{E(X_n)} = \frac{\sigma}{\mu} \sqrt{1 + \mu^{-1} + \mu^{-2} + \dots + \mu^{-n+1}}. \quad (9.122)$$

For a large number of dynodes, the relative deviation approaches the following limit:

$$\sigma_{\text{rel}}(X_{\infty}) = \frac{\sigma}{\mu} \frac{1}{\sqrt{1 - \mu^{-1}}} = \frac{\sigma}{\sqrt{\mu(\mu - 1)}}. \quad (9.123)$$

(#73) Continuing from the previous remark, the following conclusion can be drawn: In the case of one stage, the relative deviation is about 33%. By increasing the number of dynodes, the relative deviation increases asymptotically to about 58%. The above formula reveals, however, that by increasing the (mean) multiplication factor of the dynode (μ), the relative deviation becomes smaller (for the same σ). If, e.g., the dynodes triple/quadruple the incident electron with equal probability instead of doubling it (i.e., σ remains $1/2$, while μ increases from $3/2$ to $7/2$), then the asymptotic value of the relative deviation will decrease to about 17%.

(#74) Note that multiplication goes by electrons. When, e.g., the photocathode emits N electrons as a result of a light pulse, then each electron will be multiplied to a different extent by the dynodes. The total number of electrons collected by the anode is obtained by summation

$$\Sigma_N = \sum_{i=1}^N X_{n,i}. \quad (9.124)$$

Note that the above equation shows a random sum. According to the results discussed at renewals (see [Eq. \(9.117\)](#)), the random variable N is asymptotically normal with the following parameters:

$$N \left(a \frac{E}{\varepsilon}, b \frac{E}{\varepsilon} \right). \quad (9.125)$$

According to [Eq. \(9.55\)](#), the expected value and the variance of Σ_N are as follows:

$$E(\Sigma_N) = \mu^n a \frac{E}{\varepsilon} \propto \frac{E}{\varepsilon}, \quad (9.126)$$

$$D^2(\Sigma_N) = [b\mu^{2n} + a\sigma^2(\mu^{2n-2} + \mu^{2n-3} + \dots + \mu^{n-1})] \frac{E}{\varepsilon} \propto \frac{E}{\varepsilon}. \quad (9.127)$$

Thus the expected value of the pulse height remains proportional to the energy even after the photomultiplier. (The peak-width also remains proportional to the square root of the energy.)

9.6 Fitting Nuclear Spectra

In this section, the evaluation of certain parameterized data sequences called nuclear spectra will be discussed. For a more general treatment of similar problems, see Press et al. (1999).

9.6.1 Spectra, Fitting, Model Functions

Spectrum. A spectrum is a set of data pairs (spectrum points)

$$(x_i, Y_i) \quad i = 1, 2, \dots, k \quad (9.128)$$

where x_i is the exact value of some independent variable x (one of a number of set values chosen by the spectroscopist), and the corresponding value of the dependent variable Y_i is considered as a random variable. It will be assumed that the expected value μ_i of Y_i is provided by the appropriate member of a parameterized family of functions

$$\{\mu(x; \mathbf{b})\}_{\mathbf{b}} \quad (9.129)$$

called the model functions. (The subscript above is to remind that there is an element in the set of functions $\{\dots\}_{\mathbf{b}}$ for each different value of \mathbf{b} .)

The vector

$$\mathbf{b} \equiv (b_1, b_2, \dots, b_n) \quad (9.130)$$

is called the vector of the fitting parameters. (See the example mentioned in remark (#35).)

Let \mathbf{a} denote that particular choice of the parameter vector \mathbf{b} at which the fitting actually takes place, i.e., for which

$$E(Y_i) \equiv \mu_i = \mu(x_i; \mathbf{a}) \quad i = 1, 2, \dots, k. \quad (9.131)$$

The function determined by \mathbf{a} :

$$\mu(x) = \mu(x; \mathbf{a}) \quad (9.132)$$

will be referred to as the fitting function. The purpose of fitting is to give the best possible estimate for the parameter vector \mathbf{a} on the basis of the concrete spectrum. The estimate of \mathbf{a} will be denoted by $\hat{\mathbf{a}}$.

Nuclear spectra. Before sketching out the solution for the fitting problem in general, a special class of spectra called nuclear spectra will be considered, in the case of which the Y_i s are counts, for which the Poisson approximation and the normal approximation equally hold. In other words, for the spectra considered, the Y_i -values have $N(\mu_i, \sigma_i^2)$ distributions with $\sigma_i^2 = \mu_i$ as a heritage of the Poisson distribution. (See [Fig. 9.22](#))

9.6.2 The Maximum Likelihood Principle

The maximum likelihood principle is based on the following train of thought. Suppose that the shape of the model function is exactly known (in principle), but the exact value of the parameter vector \mathbf{a} (providing the fitting function common to all spectra that could be measured under the given conditions) remains hidden from the experimenter. One can only state with certainty (because of physical considerations) that such a parameter vector *does* exist. The measured spectrum

$$S_0(\mathbf{a}) \equiv \{(x_i, Y_i)_{i=1, 2, \dots, k}\} \quad (9.133)$$

can therefore be considered as a concrete member – realized by a concrete measurement – of the manifold of spectra $\{S_{\mathbf{a}}(\mathbf{a})\}_{\mathbf{a}}$ the elements of which are characterized by the same “exact” parameter vector \mathbf{a} . The different elements of $\{S_{\mathbf{a}}(\mathbf{a})\}_{\mathbf{a}}$ are not equally likely to occur in an actual measurement. Since the spectrum points have normal distribution and they represent independent random variables, the following “probability” – or rather: likelihood – can be assigned to the different spectra

$$P(\mathbf{a}; \mathbf{a}) \Leftrightarrow \prod_{i=1}^k \left[\frac{1}{\sqrt{2\pi}\sigma_i} \exp\left(-\frac{1}{2} \left(\frac{Y_i - \mu(x_i; \mathbf{a})}{\sigma_i}\right)^2\right) \Delta Y \right] = L(Y_i; \mathbf{a})(\Delta Y)^k \quad (9.134)$$

where $\mathcal{L}(Y_i; \mathbf{a})$ is called the likelihood function that can be considered as a k -dimensional density function characterizing the “probability” of the spectrum in question (Orear 1987)

$$\mathcal{L}(Y_i; \mathbf{a}) = \frac{1}{\prod_{i=1}^k \sqrt{2\pi}\sigma_i} \exp\left(-\frac{1}{2} \sum_{i=1}^k \left(\frac{Y_i - \mu(x_i; \mathbf{a})}{\sigma_i}\right)^2\right). \quad (9.135)$$

Note that the factor ΔY was needed in [Eq. \(9.134\)](#) so that the normal density function could be converted to probability. Now if one has to take a guess at the “position” of the measured spectrum $S_0(\mathbf{a})$ in the manifold $\{S_\alpha(\mathbf{a})\}_\alpha$, then the most sensible thing to do would be to look for it around the maximum of the above likelihood. In other words – like all experimenters – one should *trust* that the single result of that particular measurement (the spectrum measured maybe for several days) exemplifies a typical case rather than a rare and extreme one

$$P(0; \mathbf{a}) \approx \max_\alpha P(\alpha; \mathbf{a}). \quad (9.136)$$

Laying this down, one can continue arguing like this. Since one would like to *believe* that the measured spectrum $S_0(\mathbf{a})$ is a likely realization associated with the “real” – alas, unknown – parameter vector \mathbf{a} , the best thing that one can do is select the estimate $\hat{\mathbf{a}}$ so that it (of all the possible values of the parameter vector \mathbf{b}) assigns the greatest likelihood to the measured spectrum

$$P(0; \hat{\mathbf{a}}) \approx \max_{\mathbf{b}} P(0; \mathbf{b}). \quad (9.137)$$

The above maximum condition is an expression of the maximum likelihood principle. Note that the maximum likelihood principle – rationality aside – does not provide a guarantee that the “real” \mathbf{a} will be found, since it is based on belief rather than on strict mathematical foundations. However, the results shown below can be interpreted mathematically as well, speaking for the “strength” of the principle.

9.6.3 Weighted Least Squares as a Maximum Likelihood Method

Because of the monotony of the logarithmic function, the above maximum condition can be converted to the following minimum condition:

$$-\log P(0; \hat{\mathbf{a}}) \approx \min_{\mathbf{b}} (-\log P(0; \mathbf{b})). \quad (9.138)$$

In the concrete situation this condition provides the estimate $\hat{\mathbf{a}}$ as the solution of the following minimization:

$$\chi^2 \equiv \sum_{i=1}^k \left(\frac{Y_i - \mu(x_i; \hat{\mathbf{a}})}{\sigma_i}\right)^2 \Rightarrow \text{minimum} \quad (9.139)$$

Note that the above sum of squares is proportional to the weighted average of the squared deviation from the expected value as defined by [Eq. \(9.36\)](#).

There are commercial programs for solving the above type of minimization. They provide not only the estimates of the unknown parameters but also their variances and the correlation coefficients between them. Instead of going into details of such evaluations, only a couple of remarks will be made concerning the minimum of χ^2 that is characteristic of the goodness of fit.

(#75) The notation χ^2 is not accidental. It was pointed out at the χ^2 distribution that when the model function is linear in the fitting parameters, then the minimized sum of squares has a $\chi^2(k - n)$ distribution, i.e., the goodness of fit can be judged accordingly.

(#76) If the model function is not linear in all of the parameters, then, perhaps, it can be linearized by a transformation or using a power series. After linearization, the sum of squares will certainly have a χ^2 distribution with *some* degree of freedom. In order to find the minimum, however, the model function need not be linearized (Press et al. 1999). The possibility of linearization is only necessary for the declaration of the “competence” of the χ^2 distribution as a goodness-of-fit measure, as well as for finding the value of n pointing to the concrete χ^2 distribution “in charge.” Considering that the value of k can be as large as several thousand in the case of nuclear spectra, the value of n (which is much less than k) does not matter too much, because the sum of squares will approximately have a $\chi^2(k - n) \approx \chi^2(k) \approx N(k, 2k)$ distribution anyway.

(#77) Some types of linearization require the (nonlinear) transformation of the measured spectrum. As an example, one can mention the logarithmic conversion of decay data for the determination of the decay constant. Logarithmic conversion spoils the initially normal distribution of the spectrum points, thus breaking the connection with the χ^2 distribution as a goodness-of-fit measure.

9.6.4 Weighted Least Squares Method in Nuclear Spectroscopy

It has not yet been made use of the fact that $\sigma_i^2 = \mu_i$ for nuclear spectra. Before including this relationship in the least squares method, a very simple nuclear spectrum will be considered consisting of the counts measured with a long-lived radionuclide for equal periods of time. The model function is obviously very simple in this case. It only contains one single parameter representing the common expected value of the measured counts. The minimization problem therefore can be expressed like this

$$\chi^2 \equiv \sum_{i=1}^k \left(\frac{Y_i - \hat{a}}{\sigma_i} \right)^2 \Rightarrow \text{minimum} \quad (9.140)$$

where \hat{a} is the estimate of the constant $\mu = E(Y_i)$. In this particular case there are three – equally sensible – choices for giving the value of σ_i^2 . The question is, whether or not they lead to the same estimate.

Case 1: $\sigma_i^2 = \sigma^2 = \text{constant}$. The only constraint is that the points have the same variance

$$\chi^2 \equiv \sum_{i=1}^k \left(\frac{Y_i - \hat{a}}{\sigma} \right)^2 \Rightarrow \text{minimum.} \quad (9.141)$$

Case 2: $\sigma_i^2 = \sigma^2 = \mu \approx \hat{a}$. It is also utilized here that the data come from nuclear measurement, and also that \hat{a} is the estimate of μ :

$$\chi^2 \equiv \sum_{i=1}^k \frac{(Y_i - \hat{a})^2}{\hat{a}} \Rightarrow \text{minimum.} \quad (9.142)$$

Case 3: $\sigma_i^2 = \sigma^2 = \mu \approx Y_i$. It is utilized that the data come from nuclear measurement, and also that, in the case of Poisson distribution, a single measured value is a fair estimate of the

expected value (see remark (#24)), provided that the measured (and thus the expected) value is large enough

$$\chi^2 \equiv \sum_{i=1}^k \frac{(Y_i - \hat{a})^2}{Y_i} \Rightarrow \text{minimum.} \quad (9.143)$$

Differentiating the above expressions with respect to \hat{a} , one can see that each minimum problem has a different solution. The result will always be some type of an average of the Y_i -values, however, in case 1 it is the arithmetical mean (i.e., the sample mean, see [Eq. \(9.29\)](#)), in case 2 the harmonic mean (see [Eq. \(9.19\)](#)), while in case 3 the root mean square (see [Eq. \(9.17\)](#)), which provides the concrete solution.

Consider now the problem in general. However tempting case 1 seems to be (note that it proved to be related to the sample mean that is both the unbiased estimate of the expected value and, as shown before, its maximum likelihood estimate), it cannot serve as a general model, because the model function is not usually constant and therefore [Eq. \(9.141\)](#) does not represent a maximum likelihood condition in general.

Although case 2 conveys the nuclear character of the spectra quite accurately, it has two major drawbacks. First, the derivatives are more complicated and, second, the statistical interpretation is more difficult. Consider, e.g., that all the advantages of a linear model function disappear as soon as that same model function appears in the denominator as well (see [Eq. \(9.142\)](#)).

In case 3, the nuclear character is only expressed approximately, but the approximates (Y_i) can be considered as constants from the viewpoint of differentiation and therefore the following minimum condition/merit function is accepted in the practice of spectrum evaluation

$$\chi^2 \equiv \sum_{i=1}^k \frac{(Y_i - \mu(x_i; \hat{a}))^2}{Y_i} \Rightarrow \text{minimum} \quad (9.144)$$

As regards the relationship between χ^2 -values and confidence intervals, see the excellent literature available (Press et al. 1999). Only a few general remarks will be made below.

(#78) For rather obvious reasons, the following relationships hold between the above-mentioned means:

$$\text{harmonic mean} \leq \text{sample mean} \leq \text{root mean square} \quad (9.145)$$

It is reassuring, however, that in the case of the Poisson distribution the actual difference between the above “averages” is relatively small. It is easy to check (e.g., with random numbers of $\Pi(\mu)$ distribution) that the difference – varying μ between 10^2 – 10^6 and “averaging” ten data at a time – does not usually exceed 1. On the other hand, for $\mu = 10^2$, 10^4 , and 10^6 the standard deviations are 10, 100, and 1,000, respectively, showing that the three methods of “averaging” are practically equivalent, because the standard deviations are much larger than the difference between them.

(#79) In spite of the fact that the χ^2 -value is the result of minimization, the same “protocol” should be followed as usual, i.e., when the confidence/acceptability of an estimate is judged by using any other distribution as a measure. Therefore, the fit giving the smallest χ^2 -value is not necessarily the best. The best fit is the one whose χ^2 -value is nearest to the expected value (determined by the degrees of freedom) of the corresponding χ^2 distribution. It is true, however, that in 99 cases out of 100 the spectroscopist is unsatisfied with the fit because he or she finds the χ^2 -value too large.

One possible reason for this can be that the model function used is unsatisfactory. It is a serious error, e.g., when the dimension of the vector \mathbf{b} is taken too small (this happens, e.g., when a Mössbauer spectrum is fitted with fewer peaks than it actually contains). Another source of such error can be that the shape of the elementary model function is imperfect (e.g., the peaks of a Mössbauer spectrum cannot always be described perfectly by Lorentzians).

Spectrum points that are way out of range (mainly “dropped” points) can also lead astray the fitting process.

(#80) If the relative χ^2 is too small, it can be an indication that the fitting program tends to overestimate the degrees of freedom. This can happen, e.g., when the model function is not linear in each of the parameters, and the degree of freedom is calculated (according to the general practice) simply by subtracting the number of fitted parameters from the number of spectrum points.

Too small (i.e., too good) a χ^2 can be obtained, when the dead time is so large that the Poisson approximation built into the merit function of ▶ Eq. (9.144) overestimates the variance in the denominator. In such a case, a more realistic result is obtained, if – on the basis of ▶ Eq. (9.111) – the calculated χ^2 -value is divided by $(1 - \theta v_0)^2$, where θv_0 is the percentage of dead time divided by 100.

9.7 Summarizing Tables

■ Table 9.1

Addition theorems. The addition theorems summarized below are only valid if the random variables X_1 and X_2 are independent of each other

Distribution of X_1	Distribution of X_2	Distribution of $X_1 + X_2$
$B(n_1, p)$	$B(n_2, p)$	$B(n_1 + n_2, p)$
$\Pi(\mu_1)$	$\Pi(\mu_2)$	$\Pi(\mu_1 + \mu_2)$
$\gamma(r_1, v)$	$\gamma(r_2, v)$	$\gamma(r_1 + r_2, v)$
$N(\mu_1, \sigma_1^2)$	$N(\mu_2, \sigma_2^2)$	$N(\mu_1 + \mu_2, \sigma_1^2 + \sigma_2^2)$
$\chi^2(k_1)$	$\chi^2(k_2)$	$\chi^2(k_1 + k_2)$
$C(m_1, \gamma_1)$	$C(m_2, \gamma_2)$	$C(m_1 + m_2, \gamma_1 + \gamma_2)$

■ Table 9.2

Limiting distributions. The conditions given below are practical substitutes for the exact limits (such as $p \rightarrow 0$ and $n \rightarrow \infty$ in the case of the first row). Under the practical conditions given in the middle column, the limiting distribution given in the third column gives a fair approximation of the distribution given in the first column

Distribution of X	Conditions	Limiting distribution of X
$B(n, p)$	$p \leq 0.1, n \geq 20$	$\Pi(np)$
$B(n, p)$	$npq \geq 6, q \equiv (1 - p)$	$N(np, npq)$
$\Pi(\mu)$	$\mu \geq 20$	$N(\mu, \mu)$
$\gamma(r, v)$	$k \geq 30$	$N(r/v, r/v^2)$
$\chi^2(k)$	$k \geq 50$	$N(k, 2k)$

■ **Table 9.3**

Normal distribution. Probabilities expressed in percentage for deviations from the mean higher than $\mu \pm d\sigma$ for the random variable X having $N(\mu, \sigma^2)$ normal distribution

d	$100 \times P(X - \mu \geq d\sigma)$	d	$100 \times P(X - \mu \geq d\sigma)$

Abstract: The present experimental evidence seems to support the Standard Model of elementary particles, which interprets the world as consisting of 12 basic fermions: six quarks and six leptons with their antiparticles, 13 bosons mediating the strong, electromagnetic and weak interactions, and the mysterious Higgs boson. This chapter attempts to overview the basic features of the Standard Model with a minimal mathematical apparatus.

10.1 Elementary Particles

A traditional way of studying Nature is to dig deeper and deeper in the structure of matter ever increasing the spatial resolution, i.e., studying smaller and smaller objects. In this process each major step resulted in a new set of particles believed to be *elementary*: the four atoms of Democritus (*a-tom* means indivisible), the elements, atoms of Dalton and Mendeleev, the atomic nucleus of Rutherford, and the so-called elementary particles of which the electron, the proton and the neutron are the most common, constituting most of the visible world. It will be shown that, in fact, the proton and the neutron are also composite particles.

In this review the present knowledge of particle physics is summarized on a popular level, with no attempt to go into the very difficult mathematical formalism involved. If the reader is confused, it is the fault of the author and not of the physical theory: that is very precisely elaborated and its predictions beautifully agree with the experimental observations, as shown in some detail at the end of this review. All present-day experimental evidence is summarized in the biennial *Particle Physics Review* of the Particle Data Group (Amsler et al. 2008); for a theoretical introduction the textbooks of Halzen and Martin (1984) and Perkins (2000) are recommended; the latter provides a nice glance at the experimental evidence as well.

The elementary particles can be categorized from various points of view. The most important property is their intrinsic angular momentum or *spin*. It cannot be connected to a rotation of the particle, but it is additive to the other, ordinary angular momenta like the orbital momentum. Its unit is the reduced Planck constant, $\hbar = h/(2\pi)$. The **fermions**, the particles with half-integer spin ($S = 1/2, 3/2, 5/2, \dots$), and the **bosons**, those with integer spin ($S = 0, 1, 2, \dots$) have very different symmetries and other properties. Fermions follow *Fermi–Dirac statistics* whereas bosons follow *Bose–Einstein* one: that is the origin of their names. The fermion number is conserved whereas bosons can be created and absorbed: a lamp can irradiate any number of photons ($S = 1$) and an antenna can absorb them, provided that the energy, momentum, etc. are conserved. At the same time the electrons ($S = 1/2$), in order to illuminate the cathode tube of one’s TV set, have to be brought there and then conducted away. Another very important difference is that any number of bosons, but only one fermion, can be put in any particular quantum state. This restriction concerning fermions is called **Pauli’s exclusion principle** (Pauli 1926). That is why the electrons of the atom fill discrete energy levels and that is the underlying force that prevents the atoms of matter and the nucleons in the nucleus from penetrating each other; this principle provides macroscopic forms for the material objects.

Another way to classify the particles is by the interaction they participate in. The four basic forms of interaction are **gravitational**, **electromagnetic**, **weak**, and **strong** interaction. Gravity affects all particles, but it is negligibly weak under laboratory conditions (although can be very strong in astronomy) and so it will be ignored. All fermions are exposed to the weak interaction, and the particles having an electric charge or magnetic moment also to **electromagnetism**. The composite particles that partake in the strong interaction are called **hadrons**,

among them the **baryons** are fermions and the **mesons** are bosons. The **leptons** are fermions that are not influenced by strong interactions. These names are coming from the masses of the first observed particles of each type: the first leptons (the electron and its neutrino) are light particles, the first mesons (the pion, $m_\pi \approx 139$ MeV is 273 times heavier than the electron) have intermediate masses and the baryons (like the proton and the neutron) are much heavier ($m_p = 938$ MeV $\approx 1,836$ m_e). According to Einstein's mass equation $E = mc^2$ the mass is expressed with energy. The correct notation would be $m_p = 938$ MeV/ c^2 , where m_p means the rest mass of the proton. However, particle physicists prefer to use a “natural” unit system where $\{c\} = 1$ and $\{\hbar\} = 1$ and everything (including time and distance) is measured in energy units.

10.2 Symmetries

Symmetries in particle physics are even more important than in chemistry or solid-state physics. Just like in any theory of matter, the inner structure of the composite particles is described by symmetries, but in particle physics everything is deduced from the symmetries (or invariance properties) of the physical phenomena or from their violation: the conservation laws, the interactions, and even the masses of the particles, as it will be shown later.

The conservation laws are related to symmetries: the conservation of momentum and energy are deduced from the translational invariance of space–time: the physical laws do not depend upon where one places the zero point of the coordinate system or time measurement; and the fact that one is free to rotate the coordinate axes at any angle is the origin of angular momentum conservation.

The symmetry properties of particles with half-integer spin (fermions) differ from those with integer spin (bosons). The wave function describing a system of fermions changes sign when two identical fermions are exchanged, whereas in the case of bosons there is no change; all other differences can be deduced from this property. The spin is also strange: the spin of the electron is added to its orbital momentum, but it has two eigenstates only: it is either left or right polarized (i.e., points either up or down) in any coordinate system. Thus, it is characterized by two independent quantities in three dimensions: by its length and one of its vector components.

The characteristic symmetries of the particles are described in terms of **group theory** (Wigner 1939). The language of physics is mathematics: the difference between theory and speculation is established via the mathematical formalism with the use of which one gets numerical predictions for measurable quantities. In most of the cases the symmetries can be expressed in terms of coordinate transformations and the mathematical apparatus is chosen that way. A simple example, the rotation of a two-dimensional coordinate system by angle Θ is shown in  Fig. 10.1.

The new coordinates (x', y') of point P are obtained from the old ones (x, y) with the well-known transformation

$$x' = a + b = x \cos \Theta + y \sin \Theta, \quad (10.1)$$

$$y' = y'' - c = y \cos \Theta - x \sin \Theta, \quad (10.2)$$

or, in vector/matrix formalism,

$$\begin{pmatrix} x' \\ y' \end{pmatrix} = \begin{pmatrix} x \cos \Theta + y \sin \Theta \\ -x \sin \Theta + y \cos \Theta \end{pmatrix} = \begin{pmatrix} \cos \Theta & \sin \Theta \\ -\sin \Theta & \cos \Theta \end{pmatrix} \begin{pmatrix} x \\ y \end{pmatrix}. \quad (10.3)$$

■ Fig. 10.1

Rotation of a coordinate system in two dimensions: the $[X', Y']$ system is obtained by rotating $[X, Y]$ by angle Θ

An important property of these rotation transformations is that they do not change the length of vector \mathbf{P} (its absolute value) as

$$x'^2 + y'^2 = (x^2 + y^2)(\cos^2 \Theta + \sin^2 \Theta) = x^2 + y^2. \quad (10.4)$$

Particle physics, however, works with complex quantities of the form $x = a + ib$, where i is the imaginary unit, $i^2 = -1$. The measurable physical quantities are always real, so they contain the absolute values of the complex numbers,

$$x^2 = x^* x = (a - ib)(a + ib) = a^2 + b^2 \quad (10.5)$$

where x^* is the complex conjugate of x . In the case of complex matrices, conjugation must be accompanied by the transposition of its elements around the diagonal, thus the requirement that a rotation whose matrix is \mathbf{U} does not change the lengths of vectors demands that the matrix be *unitary*, i.e., $\mathbf{U}^\dagger \mathbf{U} = \mathbf{I}$ where \mathbf{I} is the unit matrix. In the case of the above matrix this is of course fulfilled:

$$\mathbf{U}^\dagger \mathbf{U} = \begin{pmatrix} U_{11}^* & U_{21}^* \\ U_{12}^* & U_{22}^* \end{pmatrix} \begin{pmatrix} U_{11} & U_{12} \\ U_{21} & U_{22} \end{pmatrix} = \begin{pmatrix} |U_{11}|^2 + |U_{21}|^2 & U_{11}^* U_{12} + U_{21}^* U_{22} \\ U_{12}^* U_{11} + U_{22}^* U_{21} & |U_{12}|^2 + |U_{22}|^2 \end{pmatrix} = \begin{pmatrix} 1 & 0 \\ 0 & 1 \end{pmatrix}. \quad (10.6)$$

Rotations of the above type have the following properties:

- They are additive: consecutive rotations by angles Θ_1 and Θ_2 are equivalent to a rotation by $\Theta = \Theta_1 + \Theta_2$.
- The addition is associative: $(\Theta_1 + \Theta_2) + \Theta_3 = \Theta_1 + (\Theta_2 + \Theta_3)$.
- They have a unit element as rotation with angle $\Theta = 0$ does not do anything.

Sets consisting of objects of such properties constitute a *group*, in the given case the **rotation group**. This particular group in two dimensions is commutative as well: $\Theta_1 + \Theta_2 = \Theta_2 + \Theta_1$.

Being an angular momentum, the spin should be associated with the symmetry of the rotation group. Thus the rotation group can be described by Special (their *determinant* is 1) Unitary 2×2 matrices and so this group is called SU(2). The determinant of matrix **A** is unity if

$$\text{Det} \begin{pmatrix} A_{11} & A_{12} \\ A_{21} & A_{22} \end{pmatrix} = A_{11}A_{22} - A_{12}A_{21} = 1. \quad (10.7)$$

The SU(2) symmetry group describes not only the spin, but any quantity of similar symmetry properties. Such an example, that of **isospin**, will be shown later.

When the degree of freedom is increased, one gets higher symmetry groups of similar properties. The next one, SU(3), which will be used later, is the symmetry group of Special Unitary 3×3 matrices. It can be visualized the following way. A half-spin particle has two possible fundamental states (two *eigenstates*), spin up and spin down. In the case of the SU(3) symmetry group there are three eigenstates with an SU(2) symmetry between any two of them.

One can also *decrease* the degrees of freedom and get the U(1) group of unitary 1×1 matrices, which are simply complex numbers of unit absolute values. This is the symmetry group of the **gauge transformations** of electromagnetism. This **gauge symmetry** means, e.g., in the case of electricity a free choice of potential zero: as it is demonstrated by the birds sitting on high-voltage electric wires, the *potential difference* is the meaningful physical quantity, not the potential itself. The U(1) symmetry of Maxwell's equations leads to the conservation of the electric charge and, in the more general case, the U(1) symmetry of the Dirac equation (Dirac 1928), the general equation describing the movement of a fermion, causes the conservation of the number of fermions (Halzen and Martin 1984).

10.3 Antiparticles and CPT Invariance

All fermions have **antiparticles**, anti-fermions that have identical properties with charges and some quantum numbers of the opposite sign. The interaction of a particle with its antiparticle leads to *annihilation*. When an anti-electron, the **positron**, annihilates with an electron, they produce two or three photons depending on their relative spin states, whereas the annihilation of an **antiproton** with a proton releases so much energy that half a dozen various particles can be emitted. The different abundance of particles and antiparticles in the Universe is one of the mysteries of astrophysics: apparently there is no antimatter in the Universe in significant quantities (see, e.g., Cohen et al. 1998). If there were **antimatter galaxies** they would radiate antiparticles and one would see zones of strong radiation at their borders with matter galaxies, but the astronomers do not see such a phenomenon anywhere.

An extremely interesting property of free *antiparticles* is that they can be treated mathematically as if they were *particles* of the same mass and of oppositely signed charge of the same absolute value *going backward in space and time*. This is the consequence of one of the most important symmetries of Nature: **CPT invariance** (Kostelecký 2002). It states that the following three operations:

- Charge conjugation (i.e., changing particles into antiparticles), $C\psi(\mathbf{r}, t) = \bar{\psi}(\mathbf{r}, t)$,
- Space reflection, $P\psi(\mathbf{r}, t) = \psi(-\mathbf{r}, t)$, and
- Time reversal, $T\psi(\mathbf{r}, t) = \psi(\mathbf{r}, -t)$

when done together, i.e., $\text{CPT}\psi(r, t) = \bar{\psi}(-r, -t)$, do not change the measurable physical properties of the system.

This means that, e.g., the annihilation of a positron with an electron can be described as if an electron came to the point of collision, emitted two or three photons and then went out backwards in space–time. In field theory such incoming and outgoing particles are described as **particle currents** in (some) analogy with the electric current; in the above example the incoming electron and positron constitute a lepton current.

A simple particle collision is described as a particle current exchanging an **interaction boson** with another similar current. The appearance of an extra boson is made possible by the **uncertainty principle** of Heisenberg which implies that for sufficiently short times and distances the conservation laws of energy and momentum can be violated: $\Delta E \Delta t \geq \hbar/2$ and $\Delta p \Delta x \geq \hbar/2$, where ΔA means a small uncertainty or deviation in A ($A = E, p, t, x$), E and p are the energy and momentum of the particle, t and x are time and spatial coordinates. The smallness of the reduced (sometimes called *rationalized*) Planck constant, $\hbar = 1.055 \times 10^{-34}$ Js ensures that in the macroworld the conservation laws are exactly fulfilled. The exchanged boson may be *real* or *virtual* depending on whether or not the conservation laws are fulfilled for its creation; if it is real, then it is emitted and so it can be detected; if it is virtual, then it is absorbed and one can see the result of the boson exchange only, i.e., the effect of the interaction on the motion of the particles involved.

CPT invariance is so far fully supported by the available experimental evidence and it is absolutely fundamental in field theory. Nevertheless, there are many experiments trying to test it. The simplest way to do that is to compare the mass or charge of particles and antiparticles. The most precise measurement of this type is that of the relative mass difference between the neutral K meson and its antiparticle that has so far been found to be less than 10^{-18} (Amsler et al. 2008). In 1999, an *Antiproton Decelerator* facility (CERN 2009) was constructed at the European Particle Physics Laboratory, CERN, in order to test the CPT invariance by comparing the spectra of hydrogen and antihydrogen, the latter being the bound state of an antiproton and a positron (see [Chap. 28 in Vol. 3](#)).

10.4 The Quark Model

The similarity of the proton and neutron was one of the earliest observations indicating a possible compositeness of the *elementary* particles: they have almost identical masses and – in spite of the fact that the proton has electric charge and the neutron has none – they have very similar potentials in the nuclear field. The concept of the *nucleon* was introduced with two eigenstates, neutron and proton, and a quantum number, the **isospin**. Its only similarity to spin is that it belongs to the same symmetry group, SU(2). *Iso* stands for *isobaric*: isobars are a set of nuclei of the same mass number but different charge and they can be identified using the isospin quantum number.

As the technique of experiments improved, more and more hadrons (strongly interacting particles) were discovered and all of them had isospin, i.e., they could be grouped into *isospin multiplets* of very similar properties. The nucleon has an isospin $I = 1/2$ with two eigenstates, so, in analogy with the spin, the third isospin component can take two values, $I_3 = \pm 1/2$; the upward state, $I_3 = +1/2$, is assigned to the proton and the downward one, $I_3 = -1/2$, to the neutron. (In nuclear physics often a converse convention is used, so that $I_3 = +1/2$ is associated with the neutron.)

The lightest hadron, the π meson or *pion* has isospin $I = 1$ and, correspondingly, the three possible isospin states are characterized by $I_3 = -1, 0, +1$ and it has three charge states, positive, neutral and negative. Thus the isospin became a basic quantum number in the classification of particles.

When a new quantum number, called **strangeness**, was discovered, which could be combined with isospin, producing new and new hadrons, Gell-Mann (1964) and Zweig (1964) suggested the **quark model** of hadrons. All observed hadrons could be described as consisting of three quarks. The first two quarks carry the isospin and so the $I_3 = +1/2$ quark is called *up* (u) and the $I_3 = -1/2$ quark *down* (d) quark. The third quark's quantum number is the strangeness, so that is the *strange* (s) quark. The quark model postulates that for some reason the quarks can combine in two ways only: three quarks make a baryon (and of course three antiquarks an antibaryon) and the mesons are quark–antiquark bound states. The quarks have spin $1/2$, they are fermions, and so the baryons are also fermions, whereas the mesons have integer spins, i.e., they are bosons. The quarks have fractional charges: $+2/3$ and $-1/3$ (► Table 10.1) of that of the electron, thus, e.g., the charge of the proton, $p = (uud)$ is 1 and that of the neutron $n = (udd)$ is 0. That is why a unit increase of the isospin's third component increases the charge of the particle: a d quark is replaced by a u quark with a charge increase of $+2/3 - (-1/3) = 1$. The quarks in the baryons and mesons fill states with various spin states and orbital momenta just like the electrons in the atoms, and that explains the series of excited states observed for the hadrons.

The quark model, although very successful in explaining particle properties, had serious inconsistencies. Nobody understood, for instance, why only those two combinations exist, why there are no free quarks in Nature, and why there could be more than one quark in a particle in exactly the same quantum state in spite of the Pauli principle. An excellent example for the latter is the Δ^{++} particle: it has double charge and spin $3/2$ and so it consists of three u quarks in the same spin state. In the course of the history of particle physics, whenever some new unexplained behavior was observed, new quantum numbers were introduced. In order to explain the magic combination of three identical quarks, a new quantum number was suggested: **color**, in analogy with the three basic colors seen by the eye, with three possible values, *red* (R), *green* (G), and *blue* (B). Color solves the above-mentioned problem: the new quantum number makes each quark state in the observed particles specific, and so the Pauli principle is fulfilled. Moreover, color is considered to play the same role for the strong quark–quark interaction as the electric charge does in electrodynamics: it is the **strong charge**. The existence of all observed particles is consistent with the assumption that only colorless particles are allowed to exist in unbound states in Nature. The condition of colorlessness accounts for

► Table 10.1

Leptons and quarks, the three families of basic fermions. T_3 is the third component of the weak isospin, the rest of the notation is explained in the text step by step. The meaning of the subscript L and the apostrophe after some of the symbols is explained in ► Sect. 8

	Family 1	Family 2	Family 3	Charge	T_3
Leptons	$\begin{pmatrix} \nu_e \\ e \end{pmatrix}_L$	$\begin{pmatrix} \nu_\mu \\ \mu \end{pmatrix}_L$	$\begin{pmatrix} \nu_\tau \\ \tau \end{pmatrix}_L$	0 −1	$+\frac{1}{2}$ $-\frac{1}{2}$
Quarks	$\begin{pmatrix} u \\ d' \end{pmatrix}_L$	$\begin{pmatrix} c \\ s' \end{pmatrix}_L$	$\begin{pmatrix} t \\ b' \end{pmatrix}_L$	$+\frac{2}{3}$ $-\frac{1}{3}$	$+\frac{1}{2}$ $-\frac{1}{2}$

the nonexistence of free quarks (*quark confinement*). In other words, only combinations of color + anticolor (i.e., the complementary color) or that of all three colors (R + G + B corresponding to white in the perception of the eye) are allowed to exist.

10.5 The Three Families of Fermions

A great step from the simple quark model to the Standard Model of particle physics was made by Glashow et al. (1970) by introducing what became known as the **GIM mechanism**. On the basis of various experimental observations they postulated that the quarks and leptons exist in pairs and they predicted the existence of a fourth quark, the *charm* (c) quark (► Table 10.1) with a charge of $+2/3$. In 1974 two groups (Aubert et al. 1974; Augustin et al. 1974) succeeded at the same time in discovering the $(c\bar{c})$ bound state (they named it differently and so it is now called **J/ψ meson**, a combination of the two names originally given). For the discovery, Richter and Ting received the Nobel Prize in 1976. (In the large collaborations of high-energy physics the authors usually appear in alphabetical order, so it is not necessarily the first author who is awarded the Nobel Prize.)

According to the GIM mechanism there should be as many lepton pairs as quark pairs (these groups are called *families*), because in order to prevent the theory from having anomalies, the sum of charges of all particles has to be zero. This is fulfilled for each family (► Table 10.1) as the charge sum from the top down is $0 - 1 + 3(2/3 - 1/3) = 0$, where the factor 3 stands for the number of colors. Of course, as soon as Perl's group (Perl et al. 1975) observed a third lepton, the τ (discovery in 1976, Nobel Prize in 1995) another pair of quarks was immediately predicted and later discovered. Thus, one has the menagerie of basic fermions listed in ► Table 10.1. The place of a fermion in the table is determined by its *weak isospin* (T) introduced by analogy with the isospin: for the upper particles its third component has an eigenvalue of $T_3 = +1/2$, for the lower ones it is $T_3 = -1/2$ and the pairs are **weak isospin doublets**. Note that the weak isospin is quite different from isospin: the isospin is a property of the two lightest quarks only, whereas all fermions have a weak isospin. Moreover, the isospin is a quantum number of the strong interaction, and the weak isospin is a characteristic of the weak interaction.

At this point one could ask how many more such families are hidden by Nature at higher energies. The answer was given by experiments performed on the high-energy electron-positron **colliders** (ordinary accelerators hit standing targets with fast particles; colliders can achieve much higher energies by accelerating two beams in opposite direction for collision, see also ► Chap. 50 in Vol. 5 on "Particle Accelerators") of CERN and Stanford: none, there are three families only. The proof is that the Z boson produced by the above machines can decay in various ways and the Standard Model quantitatively describes all of them; detecting all products the only unknown is the number of different neutrinos which cannot be seen there. By comparing the total decay lifetime with that of the detected modes one can deduce the contribution of the invisible ones. It turned out that there are just three kinds of light neutrinos, ν_e , ν_μ and ν_τ , and so there are three families only. A possible heavy neutrino would not carry a charged lepton and quarks, because those should have been observed already from their low-energy effects.

Thus, according to the present knowledge, ► Table 10.1 contains all basic fermions allowed by the Standard Model. The reader should not be frightened by the extraordinary caution of the above statement. Theoretically, the Standard Model was extended in numerous ways and all

those extensions predicted numerous hypothetical new basic particles (Collins et al. 1989). Although up to now no real evidence was found against the Standard Model, there are many possible extensions which do not contradict the present experimental data and so one cannot *a priori* exclude their validity.

10.6 Interactions

As mentioned before, ignoring gravity, there are three fundamental interactions in particle physics. Their basic properties are summarized in [Table 10.2](#).

According to the Standard Model, the interactions are deducible from local symmetries, their source is some “charge” and they are mediated by bosons characteristic of the given interaction. These bosons are real particles in the sense that they exist not only as virtual particles mediating interactions, but they can also be emitted and observed experimentally. A fermion enters into an interaction if it possesses the corresponding charge; the weak interaction operates on all fermions, the electromagnetic one on those having electric charges or magnetic moments and the strong interaction on the colored fermions, i.e., on the quarks.

The photon (γ) mediates the electromagnetic interaction, and the three weak bosons (W^+ , W^- , and Z^0) the weak interaction. In the strong interaction of two quarks they exchange color so the mediating boson, the **gluon** (from glue) should carry a color and an anticolor. This means eight different gluons: the $3 \times 3 = 9$ combinations has one less degree of freedom as the combination $R\bar{R} + G\bar{G} + B\bar{B}$ changes white to white and so does not carry color.

The pion decay provides an excellent example for comparison of the strengths of the electromagnetic and weak interactions. The decay of the neutral pion to two photons, $\pi^0 \rightarrow \gamma\gamma$, is a typical electromagnetic reaction with a mean lifetime of 8×10^{-17} s. The charged pion can decay via the weak interaction to a muon and its neutrino: $\pi^- \rightarrow \mu^- + \bar{\nu}_\mu$ and its lifetime is 26 ns = 2.6×10^{-8} s, eight orders of magnitude longer than that of its neutral partner. Note that in the above reaction a boson disappeared and a lepton was created together with an anti-lepton: the fermion number is conserved, whereas the boson number is not.

The properties of the electromagnetic interaction have been well known for a long time: its source is the electric charge, its mediator is the photon, and it originates from the local form of

Table 10.2

The fundamental interactions. In column 3, r is the distance from the source and R is the range of interaction. In column 4 the mean lifetime of a particle that decays due to the interaction specified is presented in parentheses. The last column gives the rest masses of the mediating bosons

Interaction	Relative strength	Potential	Mean life	Mediating boson	M (GeV/ c^2)
Strong (color)	1	$\propto r$	10^{-23} s	8 gluons	0
			($\Delta \rightarrow p\pi$)		
Electromagnetic	10^{-2}	$\propto \frac{1}{r}$	10^{-20} – 10^{-16} s	Photon	0
			($\pi^0 \rightarrow \gamma\gamma$)		
Weak	10^{-7}	$\propto \frac{1}{r} \exp(-\frac{r}{R})$	$>10^{-12}$ s	W^+, W^-	80
		$R \approx \frac{\hbar}{M_w c}$	($\pi^- \rightarrow \mu^- \bar{\nu}$)	Z^0	91

the $U(1)$ gauge symmetry of Maxwell's equations. Their global $U(1)$ gauge symmetry, a particular demonstration of which is the arbitrariness of potential zero, leads to the conservation of the electric charge. The requirement of local symmetry means that the equation of motion has to be invariant under a gauge transformation with an arbitrary space–time function: that function will give rise to the interaction field after some mathematical manipulations. It can be shown that the range of the interaction is inversely proportional to the mass of the mediating boson. As the photon has mass zero the electromagnetic interaction has an infinite range and its *Coulomb* potential is inversely proportional to the distance. Freely propagating photons are detected by the eyes (visible light) or by the TV sets (radio waves) and so their real existence and their ability to propagate to infinity are evident.

Similarly to the role of the electric charge in the electromagnetic interaction, the source of strong interaction is the **color charge**. It is mediated by the eight gluons and, according to the three colors, its origin is the local $SU(3)$ symmetry. The mass of the gluons is also zero and so the range of color interaction is also infinite; its potential at short distances is of the Coulomb form, but at long distances it is roughly proportional to the distance of the colored objects. This is the consequence of the fact that – as opposed to the photons which are not charged – the gluons themselves carry color, the charge of the interaction, and so they interact with each other. When one tries to separate two quarks, the energy of the field will grow with the distance as the gluons will produce more gluons and quark–antiquark pairs, and the quarks will combine into hadrons until only colorless objects remain: that is how **quark confinement** works.

Nonetheless, one can see quarks experimentally in the form of hadron showers, *jets*, many hadrons going into the same direction, produced in high-energy particle collisions. In a high-energy electron–positron collision, e.g., quark–antiquark pairs are produced (▶ Fig. 10.2, upper left), which are emitted back-to-back in the center-of-mass system. As they are moving away from each other, they exchange color and many hadrons are produced, 10–20 particles per jet; such a reaction cannot be interpreted in any other way. The actual existence of gluons is proven by the observation of events with three jets: the third one has to originate from a gluon emitted by one of the quarks as conservation laws prohibit all other explanations (▶ Fig. 10.2, upper right).

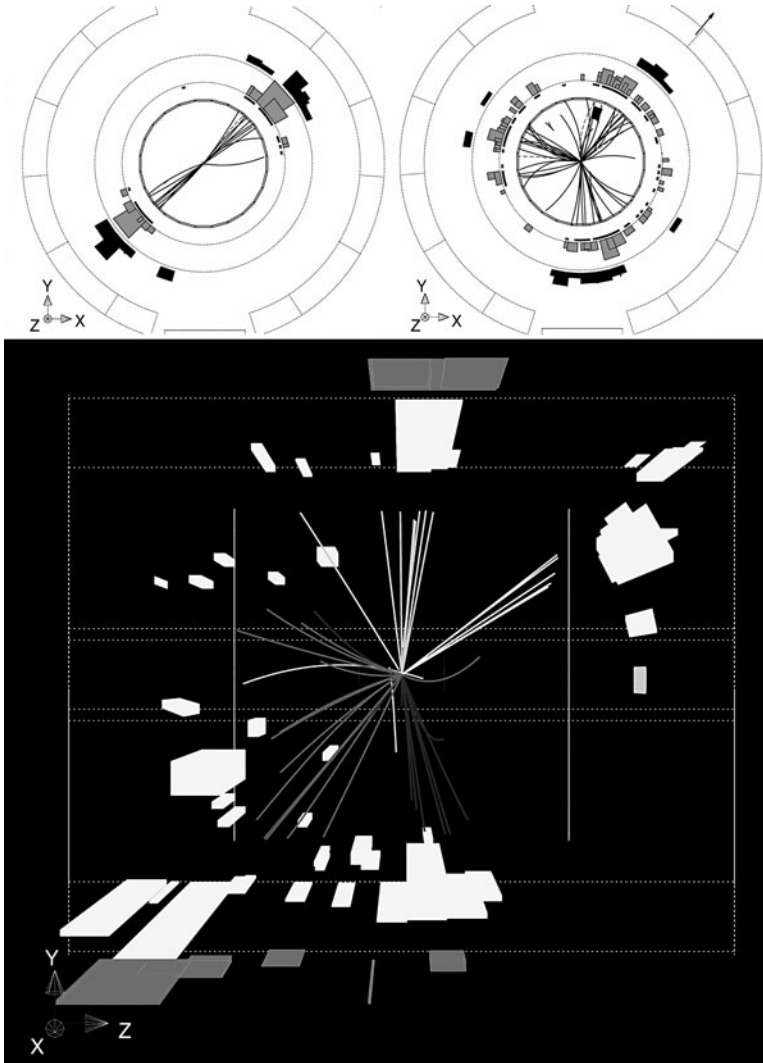

As a result of quark confinement, the observed range of the strong interaction between two hadrons is quite limited, it is about $1 \text{ fm} = 10^{-15} \text{ m}$, close to the size of the atomic nucleus. That means that the nuclear force binding the nucleus is the relatively weak *tail* of the color interaction appearing outside the nucleons, similarly to the chemical bond or to the van der Waals forces acting among neutral molecules or atoms, due to the Coulomb interaction within the atom.

10.7 The Higgs Mechanism

It seems to be quite natural to deduce the weak interaction from local $SU(2)$ symmetry as that is the symmetry group of the weak isospin. There are, however, several problems. First, such a theory predicts zero mass for the *weak bosons*, W^+ , W^- , and Z^0 , mediating the weak interaction, although from the short range of the interaction it follows that they should be quite heavy. As mentioned before, Heisenberg's uncertainty principle allows a particle of mass M to violate energy conservation for a time $\sim \hbar/(2Mc^2)$; that is how the W^- boson with a mass of 80 GeV can transfer, e.g., the 1.3 MeV (five orders of magnitude smaller!) energy released

■ Fig. 10.2

Hadron showers (jets) from quarks and gluons produced in the decay of weak bosons as detected in high-energy electron–positron collisions by the OPAL Collaboration (OPAL 2003) at the Large Electron Positron Collider at CERN. *Upper left:* the decay of a Z boson to a quark and an antiquark, $e^- + e^+ \rightarrow Z \rightarrow q + \bar{q}$ (two jets). *Upper right:* a Z boson decays to a pair of b quarks (as identified by jet properties) and one of them emits a gluon, $e^- + e^+ \rightarrow Z \rightarrow b + \bar{b} + g$ (three jets). *Below:* a W^+W^- pair decays to two quark–antiquark pairs (four jets). The sizes of boxes indicate the particle energies deposited in the detector elements

at the decay of the neutron. Neutron decay, $n \rightarrow p + e^- + \bar{\nu}_e$, is described at quark level as $d \rightarrow u + W^-$; $W^- \rightarrow e^- + \bar{\nu}_e$. The range of the weak interaction is $R = \hbar/(M_W c) \approx 2 \times 10^{-3}$ fm, about three orders of magnitude smaller than the nuclear radius. A problem occurs when calculating cross sections (or probabilities) of reactions involving the weak interaction: infinite

integrals come in which cannot be eliminated. Yet another problem is how to give mass to the fermions: the local SU(2) symmetry does not allow for that.

All of these problems are solved by the theory of **spontaneous symmetry breaking** which is called *Higgs mechanism* after its inventor (Higgs 1964a, b). It assumes the existence of a four-component field (complex isospin doublet) that is added to the fermion function as if it moved in that field. The fermions gain their mass in interaction with this Higgs field similarly to the additional inertia of a charged particle moving in a polarizable liquid as compared to vacuum. The Higgs field violates the local SU(2) symmetry and so – similarly to the quasi-particles of solid-state physics – it produces four new states; three of them are absorbed by the weak bosons, whereby the three weak bosons gain masses, and the fourth state, as a by-product, creates a heavy, neutral, spinless particle, the **Higgs boson**. The latter takes care of the divergences of the theory mentioned above, i.e., helps to eliminate the infinite integrals.

At the time of writing this review, the Higgs boson has not yet been found experimentally. In [Fig. 10.3](#) the goodness of fit of the Standard Model parameters is presented against the mass of a hypothetical Higgs boson. The fit is made by the LEP Electroweak Working Group and it combines the results of the four LEP experiments with those of several other major particle physics experiments. The place of the minimum implies a light Higgs boson around 100 GeV/c², whereas the direct LEP searches excluded, at a confidence level of 95%, all possible

Fig. 10.3

Search for the Higgs boson of the Standard Model: Goodness of fit of the Standard Model parameters against the mass of a hypothetical Higgs boson (LEP Electroweak Working Group 2009). The minimum implies a light Higgs boson with a mass around 100 GeV/c² whereas the LEP experiments excluded at a confidence level of 95% all possible Standard Model Higgs bosons with masses below 114.4 GeV/c² (shaded area) (LEP Working Group for Higgs Boson Searches 2003). The various curves and the shaded band around one illustrate the possible theoretical deviations ($\Delta\alpha_{\text{had}}^{(5)}$); NuTeV is one of the experiments involved. (The horizontal arrow at the level $\Delta\chi^2 = 1$ represents the $\pm\sigma$ limits. The 95% level of significance corresponds to $\pm 1.64\sigma$)

Standard Model Higgs bosons with masses below $114.4 \text{ GeV}/c^2$ as shown by the shaded area (LEP Working Group for Higgs Boson Searches 2003). A combination of all this information indicates that the Higgs boson mass should be between 114 and $250 \text{ GeV}/c^2$.

10.8 The Peculiarities of the Weak Interaction

In  [Table 10.1](#) there is a subscript L at the doublets and an apostrophe at the quark symbols. They indicate peculiarities of the weak interaction.

10.8.1 Parity and CP Violation

If one builds a clock looking at its design in a mirror, it should work properly except that its hands will rotate the opposite way and the lettering will be inverted. The laws governing the work of the clock are invariant under space inversion. In a system obeying such laws the **parity** of the wave function is conserved. Most physicists thought that physics has perfect mirror symmetry, until the experiment of Madame Wu (Wu et al. 1957) who has shown that a decaying cobalt nucleus emits its beta electron in a direction opposite to its spin. Since the spin direction is not reversed at mirror reflection, the mirror image of this decay process cannot take place, which amounts to a **violation of the mirror symmetry of Nature**. Thus, the weak interaction does not conserve parity.

The other two interactions *do* conserve the *parity* of a system, i.e., remember which way a particle was polarized before the interaction, whereas the weak interaction “maximally” violates it. This maximal violation manifests itself in the fact that the particles emitted in weak interaction tend to be polarized left (their spin pointing preferentially against the direction of the momentum) and the antiparticles polarized right (spin and momentum having the same direction) independently of any former polarization; this is indicated by the symbol L for *left* at the weak isospin doublets of the particles. The case of the neutrino is extreme: in the limit of zero mass the neutrino can only exist left-polarized and the antineutrino only right-polarized.

After the discovery of parity violation the CP symmetry, i.e., the invariance of the physical laws against the simultaneous transformation of charge and space reflection, was still assumed to be exact. However, in 1964 Cronin and Fitch (Nobel Prize 1980) discovered (Christenson et al. 1964) that the weak interaction violates that as well, although this violation is tiny, not maximal, like that of the P invariance. **CP violation** makes it possible to differentiate between a world and an antiworld and may be related to the matter – antimatter asymmetry.

As stated before, CPT invariance is still assumed to be absolute. Returning to the example of the clock, a P reflection means switching left to right, a C transformation means changing the matter of the clock to antimatter, and the time reversal T that one plays the video recording of the movement of the clock backward.

10.8.2 State Mixing

As opposed to the other two interactions, the weak interaction does not respect the kind of the quark (called *flavor*) either: heavy quarks can decay into lighter ones via emitting a W^+ or

W^- boson. This is interpreted as a signature that the weak interaction *mixes* the quark states. It is sufficient to assume that either the upper or the lower quark states are mixed. The lower quark states are taken to be mixed, and that is indicated by the apostrophes in [Table 10.1](#) on the symbols of the lower quarks. There is experimental evidence, neutrino oscillations, for the neutrinos also having a tiny little mass (Fukuda and et al. 1998); then of course the lepton states will be mixed as well for the weak interaction (Maki et al. 1962).

This mixing is described by *mixing angles*. If the three lower quark states correspond to the three axes of a rectangular coordinate system, then one needs three angles to describe any possible quark mixing. From those three angles one can get the **Cabibbo–Kobayashi–Maskawa (CKM) mixing matrix**, which transforms a (d,s,b) vector into (d',s',b') . The CP violation can be quantitatively described by simply bringing a complex phase as a fourth parameter into this matrix (Cabibbo 1963; Kobayashi and Maskawa 1973, Nobel Prize in 2008).

Another famous mixing is the **weak mixing** that emerged when the electromagnetic and weak interactions were united by Glashow, Weinberg, and Salam (Nobel Prize 1979) under the name of **electroweak interaction** (Glashow and Weinberg 1968; Weinberg 1967; Salam 1968). Generally, if two states can be mixed in the microworld (i.e., mixing is not prohibited by conservation laws or different quantum numbers), then they surely will; that means that the states observed in the experiment will be mixtures of the primary ones. This is what happens between the neutral currents of the weak and electromagnetic interaction (the concept of current is used here as defined in [Sect. 3](#)). This mixing, which yields the photon and the Z boson is described by an angle, the *Weinberg* or *weak mixing* angle, Θ_w . The Weinberg angle (Weinberg 1972) provides information about the relative strengths of weak and electromagnetic interactions and so it can be considered to be the *coupling constant* associated with the weak interaction, similarly to the *fine structure constant*, α , of the electromagnetic interaction.

All these mixing angles are free parameters of the Standard Model and so, together with the fermion masses, have to be determined using the experimental data.

10.9 The Present and Future of the Standard Model

The Standard Model assumes the existence of three fermion families and three local gauge symmetries, which create the three particle interactions and the $3 + 1 + 8$ **gauge bosons** mediating them. In order to create the masses and to eliminate the divergences of the theory one also needs the Higgs mechanism that produces the **Higgs boson** as well.

The Standard Model has 19 parameters. Each of the three interactions has a strength or coupling constant: the strong coupling, the fine structure constant, and the Weinberg angle. Free parameters are the nine fermion masses (those of the neutrinos can be generally neglected in the calculations), plus the mass of the Higgs boson and the four elements of the CKM matrix. Two more parameters are added by the Higgs potential (Halzen and Martin 1984) and by the theory of strong interaction, **quantum chromodynamics** (Greiner et al. 2002). If one wants to include the neutrino masses one needs three more masses and three or four additional mixing matrix elements (Maki et al. 1962).

All experimental evidence seems to support the validity of the Standard Model. Right at its birth it predicted the masses of the weak bosons and their other properties that were nicely verified experimentally by Arnison et al. (1983, UA1 Collaboration) (C. Rubbia, Nobel Prize 1984). Since its conception, experiment has reproduced every prediction of the Standard

Model quantitatively, and there is not a single observation that would contradict it. Some of the recent experimental data are compared with the predictions of the Standard Model in [Table 10.3](#), and the agreement is generally very good. Note the high precision of both the measurements and the predictions, the latter being usually even more precise. From time to time, as both experiment and theory developed, significant deviations occurred and later proved to be errors in theory or experiment. As the table shows, at present there are two such deviations: the forward–backward asymmetry observed in fermion pair production at electron–positron scattering and the anomalous magnetic moment of the muon represent some small disagreement between theory and experiment. Although these differences are in the range of 2–3 standard deviations only, they cause significant activities in both theory and experiment.

■ **Table 10.3**

Comparison of quantities observable in electron–positron collisions of energies near the Z mass with the predictions of the Standard Model of elementary particles (Amsler et al. 2008). Note the high precision of the calculations and the good agreement between theory and experiment. At present the largest deviation is in the electron–positron forward–backward asymmetry and the anomalous magnetic moment of the muon. If a measured quantity has two uncertainties, the first one is the statistical and the second the systematic error

Group	Quantity	Experiment	Prediction
Top quark	Mass [GeV]	$170.9 \pm 1.8 \pm 0.6$	171.1 ± 1.9
W boson	Mass [GeV]	$80.428 \pm 0.039(\text{pp})$	80.375 ± 0.015
		$80.376 \pm 0.033(e^-e^+)$	
Z boson	Mass [GeV]	91.1876 ± 0.0021	91.1874 ± 0.0021
Z decay	σ_{hadrons}	41.541 ± 0.037	41.466 ± 0.009
	Width Γ_{total} [GeV]	2.4952 ± 0.023	2.4968 ± 0.0010
	Γ_{hadrons} [GeV]	1.7444 ± 0.020	1.7434 ± 0.0010
	Γ_{leptons} [MeV]	83.984 ± 0.086	83.988 ± 0.016
	$\Gamma_{\text{neutrinos}}$ [MeV]	499.0 ± 1.5	501.59 ± 0.08
Z-width ratios	Hadrons/ e^-e^+	20.804 ± 0.050	20.758 ± 0.011
	Hadrons/ $\mu^-\mu^+$	20.785 ± 0.033	20.758 ± 0.011
	Hadrons/ $\tau^-\tau^+$	20.764 ± 0.045	20.803 ± 0.011
	$b\bar{b}/\text{hadrons}$	0.21629 ± 0.00066	0.21584 ± 0.00006
	$c\bar{c}/\text{hadrons}$	0.1721 ± 0.0030	0.17228 ± 0.00004
Forward–backward asymmetry A_{FB}	$e^-e^+ \rightarrow e^-e^+$	0.0145 ± 0.0025	0.01627 ± 0.0023
	$e^-e^+ \rightarrow \mu^-\mu^+$	0.0169 ± 0.0013	0.01627 ± 0.0023
	$e^-e^+ \rightarrow \tau^-\tau^+$	0.0188 ± 0.0017	0.01627 ± 0.0023
	$e^-e^+ \rightarrow b\bar{b}$	0.0992 ± 0.0016	0.1033 ± 0.0007
	$e^-e^+ \rightarrow c\bar{c}$	0.0707 ± 0.0035	0.0738 ± 0.0006
	$e^-e^+ \rightarrow s\bar{s}$	0.0976 ± 0.0114	0.1034 ± 0.0007
Weak mixing	$\sin^2\theta_w(A_{\text{FB}}^{\text{had}})$	0.2324 ± 0.0012	0.23149 ± 0.0013
Muon g-factor	$\frac{1}{2}(g_\mu - 2 - \frac{\alpha}{\pi}) \times 10^9$	4511.07 ± 0.74	4509.08 ± 0.10

Thus, every constituent of the Standard Model has been observed and studied experimentally except the Higgs boson, and Nature seems to faithfully follow its predictions. Even the observation of the (very small) mass of the neutrinos (Fukuda et al. 1998) is easily accommodated in the framework of the Standard Model.

One may ask why there is a need for those expensive accelerators and particle physicists at all if one has finally arrived at this theory describing everything correctly. The answer is contained in the name of what this chapter is about: it is just a model, not a comprehensive theory, and it is not really understood why it functions so well.

One took three different gauge theories, supplied them with some free parameters, added an *ad hoc* Higgs mechanism to make it work, and the result seems to function properly. It is not known exactly why those three symmetries create the three interactions although the $U(1)$ symmetry is clearly related to the electromagnetic charge, the $SU(2)$ to the weak isospin, and $SU(3)$ to the three colors. It is not clear why there are exactly three fermion families and how the fermions of a family are related to each other (apart from the sum of their charges). It is not known why there is no antimatter in the Universe, and there is the deep mystery of **dark matter**: astronomical observations indicate that about 90% of the mass of the Universe is invisible, probably non-baryonic matter that cannot be explained within the framework of the Standard Model (Amsler et al. 2008).

Furthermore, there are indications that there may be a unified, deeper theory behind the Standard Model. The coupling constants of the three interactions have different energy dependencies, but the three converge to the same value at very high energies, as if they were different facets of the same interaction. There are also several theoretical inconsistencies and peculiarities of the Standard Model, which are too involved to discuss here (Collins et al. 1989).

In order to resolve the problems a great number of extensions of the Standard Model have been proposed in the last three decades and much further experimental and theoretical work is needed to see whether any one of them is viable. Most of those models have been disproved with growing experimental information, but one class of them, the **supersymmetric models** (Nilles 1984), persists, although so far no direct evidence is available either for or against it. Such models postulate a symmetry between fermions and bosons assuming that each particle has a *supersymmetric partner* of the other kind. Thus, in this model the quarks and leptons of half spin ($S = 1/2$) have $S = 0$ boson partners called **sleptons** (selectron, smuon, stau, and sneutrinos) and **squarks** (“s” stands for scalar), whereas the $S = 1$ gauge bosons (photon, W^\pm , Z^0 , and the 8 gluons) have $S = 1/2$ fermion partners (*photino*, *wino*, *zino*, *gluinos*), even the Higgs boson has a partner, the *higgsino*. The simplest model of this family, the **Minimal Supersymmetric Standard Model**, solves all theoretical problems of the Standard Model in a very elegant way but at a high price. In addition to the many new particles it has many new free parameters as well, so many indeed that the total set of all available experimental data is not sufficient to determine them. One has to make rather rough approximations in order to reduce their number. The lightest, neutral supersymmetric particle could make the missing part of the dark matter as it interacts with ordinary particles very weakly, and thus it can be “seen” through its gravitational effects only. Although much effort has been made to observe these new particles, none of them has been successful. These experiments are nevertheless useful to help to confine the parameter space of the models. For further references see, e.g., the proceedings of the latest conference on supersymmetry (SUSY 2009).

The greatest question is of course the Higgs boson: whether it exists and its properties agree with the predictions of the Standard Model. It is expected that the Large Hadron Collider

(LHC 2009), the 14 TeV proton–proton collider accelerator of CERN that started to work in late 2009, will answer these questions.

11.1 The International System of Units (SI)

G. L. Molnár · R. B. Firestone

The modern metric system of measurement has become the standard in scientific practice. The official name is *International System of Units*, abbreviated *SI* from the French *Le Système International d'Unités*. The SI was established in 1960 by the 11th General Conference on Weights and Measures. The defining document, commonly called the SI Brochure, has been published by the International Bureau of Weights and Measures (BIPM) in French original and in English translation (BIPM 1991). It has been complemented with a series of international consensus standards to promote international uniformity in the practical use of the SI in science and technology (ISO 1993). Several national standards organizations have prepared practical guides to promote the implementation and practical use of the SI in their country. This chapter is mainly based on the guide prepared by the National Institute of Standards and Technology (NIST), USA (Taylor 1995), which is also available electronically on the NIST Web site on constants, units, and uncertainty (NIST 2003).

11.1.1 The SI Units of Measurement

There are two classes of SI units: base units and derived units. The system is founded on seven base units for seven base quantities, which are assumed to be mutually independent. They are given in ▶ Table 11.1. The definition of the *SI base units* can be found in the aforementioned documents. All other SI units can be expressed in terms of the base units via a system of quantity equations; hence, they are named derived units. Examples of SI derived units are listed in ▶ Table 11.2, using standard notations.

Several *SI derived units* have special names and symbols. They are listed in ▶ Table 11.3 with their definitions in terms of other SI units. Examples of SI derived units without special names can be found in ▶ Table 11.4.

■ Table 11.1

The base units of SI

Base quantity	Standard notation	Name	Symbol
Length	l	meter	m
Mass	m	kilogram	kg
Time	t	second	s
Electric current	I	ampere	A
Thermodynamic temperature	T	kelvin	K
Amount of substance	n	mole	mol
Luminous intensity		candela	cd

■ **Table 11.2**

Examples of SI derived units

Derived quantity	Definition	Name	Symbol
Area	$A = l^2$	Square meter	m^2
Volume	$V = l^3$	Cubic meter	m^3
Molar volume	$V_m = V/n$	Cubic meter per mole	m^3/mol
Specific volume	$v = V/m$	Cubic meter per kilogram	m^3/kg
Volume fraction ^a	$\varphi_B = x_B \cdot V_{m,B} / \sum (x_A \cdot V_{m,A})$	Cubic meter per cubic meter	$m^3/m^3 = 1$
Speed, velocity	$v = l/t$	Meter per second	m/s
Acceleration	$a = l/t^2$	Meter per second squared	m/s^2
Wave number	$k = 1/\lambda$	Reciprocal meter	m^{-1}
Mass density (density)	$\rho = m/V$	Kilogram per cubic meter	kg/m^3
Molar mass	$M = m/n$	Kilogram per mole	kg/mol
Mass fraction ^a	$w_B = m_B/m$	Kilogram per kilogram	$\text{kg}/\text{kg} = 1$
Amount-of-substance Concentration ^a	$c_B = n_B/V$	Mole per cubic meter	mol/m^3
Amount-of-substance fraction ^a (mole fraction)	$x_B = n_B/n$	Mole per mole	$\text{mol}/\text{mol} = 1$
Molality ^b	$b_B = n_B/m_A$	Mole per kilogram	mol/kg
Current density		Ampere per square meter	A/m^2
Magnetic field strength		Ampere per meter	A/m
Luminance		Candela per square meter	cd/m^2

^aOf substance B, for a mixture of substances A, B, C, . . .

^bOf solute B in a solution, divided by the mass of solvent A.

11.1.1.1 Units Outside the SI

There are several traditional units, which are so important for everyday life or for a certain field that they have been accepted for use with the SI. The *accepted units* are listed in ▶ [Table 11.5](#), together with their value in SI units. It is noteworthy that two of them – the *unified atomic mass unit* and the *electronvolt energy unit* – do not have an exact equivalent in SI units. Their values are fundamental constants, which are obtained experimentally (Mohr 1999, 2000). There are some other traditional units, which have been accepted only temporarily, as shown in ▶ [Table 11.6](#).

In basic science, the values of quantities are expressed in terms of *fundamental constants* of nature or so-called “natural units.” In theoretical atomic physics and chemistry, the customarily called “atomic units” have been widely used. Both classes are permissible when their use is absolutely necessary. Examples of physical quantities used as natural and atomic units are given in ▶ [Tables 11.7](#) and ▶ [11.8](#), respectively (Mohr 1999, 2000). More about fundamental constants can be found in ▶ [Section 11.2](#).

Table 11.3
SI derived units with special names and symbols

Derived quantity	Name	Symbol	Expression in terms of other SI units	Expression in terms of SI base units
Plane angle	Radian	rad		$\text{m}\cdot\text{m}^{-1} = 1$
Solid angle	Steradian	sr		$\text{m}^2\cdot\text{m}^{-2} = 1$
Frequency	Hertz	Hz		s^{-1}
Force	Newton	N		$\text{m}\cdot\text{kg}\cdot\text{s}^{-2}$
Pressure, stress	Pascal	Pa	N/m^2	$\text{m}^{-1}\cdot\text{kg}\cdot\text{s}^{-2}$
Energy, work, quantity of heat	Joule	J	$\text{N}\cdot\text{m}$	$\text{m}^2\cdot\text{kg}\cdot\text{s}^{-2}$
Power, radiant flux	Watt	W	J/s	$\text{m}^2\cdot\text{kg}\cdot\text{s}^{-3}$
Electric charge	Coulomb	C		$\text{s}\cdot\text{A}$
Electric potential	Volt	V	W/A	$\text{m}^2\cdot\text{kg}\cdot\text{s}^{-3}\cdot\text{A}^{-1}$
Capacitance	Farad	F	C/V	$\text{m}^{-2}\cdot\text{kg}^{-1}\cdot\text{s}^4\cdot\text{A}^2$
Electric resistance	Ohm	Ω	V/A	$\text{m}^2\cdot\text{kg}\cdot\text{s}^{-3}\cdot\text{A}^{-2}$
Electric conductance	Siemens	S	A/V	$\text{m}^{-2}\cdot\text{kg}^{-1}\cdot\text{s}^3\cdot\text{A}^2$
Magnetic flux	Weber	Wb	$\text{V}\cdot\text{s}$	$\text{m}^2\cdot\text{kg}\cdot\text{s}^{-2}\cdot\text{A}^{-1}$
Magnetic flux density	Tesla	T	Wb/m^2	$\text{kg}\cdot\text{s}^{-2}\cdot\text{A}^{-1}$
Inductance	Henry	H	Wb/A	$\text{m}^2\cdot\text{kg}\cdot\text{s}^{-2}\cdot\text{A}^{-2}$
Celsius temperature	Degree Celsius	$^{\circ}\text{C}$		K
Luminous flux	Lumen	lm	$\text{cd}\cdot\text{sr}$	$\text{cd}\cdot\text{m}^2\cdot\text{m}^{-2}$
Illuminance	Lux	lx	lm/m^2	$\text{cd}\cdot\text{m}^2\cdot\text{m}^{-4}$
Activity (of a radionuclide)	Becquerel	Bq		s^{-1}
Absorbed dose ^a	Gray	Gy	J/kg	$\text{m}^2\cdot\text{s}^{-2}$
Dose equivalent ^b	Sievert	Sv	J/kg	$\text{m}^2\cdot\text{s}^{-2}$

^aAlso specific energy (imparted), kerma.
^bAlso ambient dose equivalent, directional dose equivalent, personal dose equivalent, organ dose equivalent.

11.1.2 Decimal Multiples and Submultiples of SI Units

It is often necessary to form decimal multiples and submultiples of the SI unit, in order to avoid very large or very small numbers, respectively. These multiples, called *SI prefixes*, are summarized in Table 11.9, where the standard notations are also given. A prefix attaches directly to the name of the unit, and a prefix symbol attaches directly to the symbol for a unit. For example, one kilometer (symbol: 1 km) is equal to one thousand meters, symbol: 1,000 m or 10³ m.

■ Table 11.4

Some SI derived units expressed with units having special names and symbols

Derived quantity	Name	Symbol	Expression in terms of SI base units
Heat capacity, entropy	Joule per kelvin	J/K	$\text{m}^2 \cdot \text{kg} \cdot \text{s}^{-2} \cdot \text{K}^{-1}$
Specific heat capacity, specific entropy	Joule per kilogram per kelvin	J/(kg·K)	$\text{m}^2 \cdot \text{s}^{-2} \cdot \text{K}^{-1}$
Specific energy	Joule per kilogram	J/kg	$\text{m}^{-1} \cdot \text{s}^{-2}$
Energy density	Joule per cubic meter	J/m ³	$\text{m}^{-1} \cdot \text{kg} \cdot \text{s}^{-2}$
Molar energy	Joule per mole	J/mol	$\text{m}^2 \cdot \text{kg} \cdot \text{s}^{-2} \cdot \text{mol}^{-1}$
Molar entropy, molar heat capacity	Joule per mole kelvin	J/(mol·K)	$\text{m}^2 \cdot \text{kg} \cdot \text{s}^{-2} \cdot \text{mol}^{-1} \text{K}^{-1}$
Exposure (X and γ rays)	Coulomb per kilogram	C/kg	$\text{kg}^{-1} \cdot \text{s} \cdot \text{A}$
Absorbed dose rate	Gray per second	Gy/s	$\text{m}^2 \cdot \text{s}^{-3}$

■ Table 11.5

Units accepted for use with the SI

	Name	Symbol	Value in SI units
Time	Minute	min	1 min = 60 s
	Hour	h	1 h = 60 min = 3,600 s
	Day	d	1 d = 24 h = 86,400 s
Plane angle	Degree	°	1° = ($\pi/180$) rad
	Minute	'	1' = (1/60)° = ($\pi/10,800$) rad
	Second	"	1" = (1/60)' = ($\pi/648,000$) rad
Volume	Liter	l, L	1 L = 1 dm ³ = 10 ⁻³ m ³
Mass	Metric ton	t	1 t = 10 ³ kg
	Unified atomic mass unit ^a	u	1 u = 1.66053873(13) × 10 ⁻²⁷ kg
Energy	Electronvolt ^b	eV	1.602176462(63) × 10 ⁻¹⁹ J

^aThe unified atomic mass unit is equal to 1/12 of the mass of an atom of the nuclide ¹²C.^bThe electronvolt is the kinetic energy acquired by an electron in passing through a potential difference of 1 V in vacuum.

Table 11.6

Some units temporarily accepted for use with the SI

Quantity	Name	Symbol	Value in SI units
Length	Ångström	Å	1 Å = 0.1 nm = 10 ⁻¹⁰ m
Cross section	Barn	b	1 b = 100 fm ² = 10 ⁻²⁸ m ²
Pressure	Bar	bar	1 bar = 0.1 Mpa = 100 kPa = 1,000 hPa = 10 ⁵ Pa
Activity	Curie	Ci	1 Ci = 3.7 × 10 ¹⁰ Bq
Absorbed dose	Roentgen	R	1 R = 2.58 × 10 ⁻⁴ C/kg
	Rad	rad ^a	1 rad = 1 cGy = 10 ⁻² Gy
Dose equivalent	Rem	rem	1 rem = 1 cSv = 10 ⁻² Sv

^aWhen there is risk of confusion with the symbol for the radian, rd may be used as the symbol for rad.

11.2 Fundamental Physical Constants

G. L. Molnár

Basic physical theories and their application to other fields of science and technology always involve certain fundamental invariant quantities, called briefly *fundamental constants*. Well-known examples of such constants are the speed of light in vacuum, the elementary charge (electron charge), the mass of the electron, and so on. It is important to know the numerical values of the fundamental constants with the highest possible accuracy, because the attained accuracy determines the accuracy of the quantitative predictions of fundamental theories. Moreover, the accurate numerical values of the fundamental constants test the overall consistency and correctness of those theories.

The Committee on Data for Science and Technology (CODATA) was established in 1966 as an interdisciplinary committee of the International Council of Science and Technology (ICSU). The CODATA Task Group on Fundamental Constants was established in 1969, with the aim to provide internationally accepted values of the fundamental physical and chemical constants and related conversion factors. The first such CODATA set was established in 1973, while the latest one in 1998 (Mohr and Taylor 1999, 2000). The latest recommended values of the fundamental constants are also available on an Internet page (CODATA 2003), on which the following presentation is based. Those interested in all recommended values or in the earlier versions of the CODATA set are referred to that Internet page.

11.2.1 Frequently Used Constants

In this section, an arbitrarily selected subset of constants is presented in tabular form. The first category is the most fundamental quantities, listed in [Table 11.10](#) together with their relative

■ **Table 11.10**

Selected fundamental constants

Quantity	Symbol	Value	Unit	Relative std. uncert.
<i>Universal constants</i>				
Speed of light in vacuum	c, c_0	299,792,458	$\text{m}\cdot\text{s}^{-1}$	Exact
Magnetic constant	μ_0	$4\pi \times 10^{-7} = 12.566370614\dots \times 10^{-7}$	$\text{N}\cdot\text{A}^{-2}$	Exact
Electric constant $1/\mu_0 c^2$	ϵ_0	$8.854187817\dots \times 10^{-12}$	$\text{F}\cdot\text{m}^{-1}$	Exact
Characteristic impedance of vacuum $\sqrt{\mu_0/\epsilon_0} = \mu_0 c$	Z_0	376.730313461...	Ω	Exact
Newtonian constant of gravitation	G	$6.673(10) \times 10^{-11}$	$\text{m}^3\cdot\text{kg}^{-1}\cdot\text{s}^{-2}$	1.5×10^{-3}
Planck constant	h	$6.62606876(52) \times 10^{-34}$	$\text{J}\cdot\text{s}$	7.8×10^{-8}
		$4.13566727(16) \times 10^{-15}$	$\text{eV}\cdot\text{s}$	3.9×10^{-8}
Reduced Planck constant $\hbar/2\pi$	\hbar	$1.054571596(82) \times 10^{-34}$	$\text{J}\cdot\text{s}$	7.8×10^{-8}
		$6.58211889(26) \times 10^{-16}$	$\text{eV}\cdot\text{s}$	3.9×10^{-8}
<i>Adopted constants</i>				
Molar mass of ^{12}C	$M(^{12}\text{C})$	12×10^{-3}	$\text{kg}\cdot\text{mol}^{-1}$	Exact
Molar mass constant $M(^{12}\text{C})/12$	M_{u}	1×10^{-3}	$\text{kg}\cdot\text{mol}^{-1}$	Exact
Conventional value of Josephson constant ^a	$K_{\text{J-90}}$	483,597.9	GHz V^{-1}	Exact
Conventional value of von Klitzing constant ^b	$R_{\text{K-90}}$	25,812.807	Ω	Exact
Standard atmosphere		101,325	Pa	Exact
Standard acceleration of gravity	g_{n}	9.80665	$\text{m}\cdot\text{s}^{-2}$	Exact

^aValue of $2e/h$ adopted internationally for realizing representations of the volt using the Josephson effect.

^bAdopted internationally for realizing representations of the ohm using the quantum Hall effect.

standard uncertainty. Some of the *universal constants*, such as the speed of light in vacuum, form the basis of the SI system of measurement, hence their established value is considered exact. There are other constants, such as the basis of the atomic mass unit, which are not fundamental in nature but play an important practical role. Therefore, their value has also been adopted as exact.

The rest of the constants presented are grouped according to the scientific field where they belong. Physicochemical constants are given in ▶ [Table 11.11](#), followed by atomic and nuclear constants in ▶ [Tables 11.12](#) and ▶ [11.13](#), respectively.

Table 11.11

11.2.2 Conversion Factors

It is often necessary to convert the adopted value of a fundamental constant to another (SI or non-SI) unit. Useful *conversion factors for energy equivalent quantities* can be derived using the following relations:

$$E = mc^2 = hc/\lambda = h\nu = kT$$

$$1 \text{ eV} = (e/CJ)$$

$$1 \text{ u} = m_u = (1/12) m(^{12}\text{C}) = 10^{-3} \text{ kg mol}^{-1} / N_A$$

These equations allow, for example, expressing the energy in temperature units or energy-equivalent mass units. During the conversion, however, the precision inherent in the values of the fundamental constants involved must be kept as much as possible and care should be taken of the correlation of uncertainties. For this reason, the safest procedure is to use the set of

Table 11.14
Energy equivalents

	J	kg	m ⁻¹	Hz	K	eV	u
1 J	(1 J) = 1	$1.112650056 \times 10^{-17}$	$5.03411762(39) \times 10^{-24}$	$(1 \text{ J})/h = 1.50919050(12) \times 10^{-33}$	$(1 \text{ J})/k = 7.242964(13) \times 10^{22}$	$(1 \text{ J}) = 6.24150974(24) \times 10^{18}$	$(1 \text{ J})/c^2 = 6.70053662(53) \times 10^9$

1 eV	$(1 \text{ eV}) = 1.602176462(63) \times 10^{-19}$	$(1 \text{ eV})/c^2 = 1.782661731(70) \times 10^{-36}$	$(1 \text{ eV})/hc = 8.065544477(32) \times 10^5$	$(1 \text{ eV})/h = 2.417989491(95) \times 10^{14}$	$(1 \text{ eV})/k = 1.1604506(20) \times 10^4$	$(1 \text{ eV}) = 1$	$(1 \text{ eV})/c^2 = 1.073544206(43) \times 10^{-9}$
1 u	$(1 \text{ u}) c^2 = 1.49241778(12) \times 10^{-10}$	$(1 \text{ u}) = 1.66053873(13) \times 10^{-27}$	$(1 \text{ u}) c/h = 7.513006658(57) \times 10^{14}$	$(1 \text{ u}) c^2/h = 2.252342733(17) \times 10^{23}$	$(1 \text{ u}) c^2/k = 1.0809528(19) \times 10^{13}$	$(1 \text{ u}) c^2 = 931.494013(37)$	$(1 \text{ u}) = 1$

energy equivalent conversion factors, provided in [Table 11.14](#). Those who prefer to perform unit conversions online can do that using the CODATA Internet page (CODATA 2003).

11.3 Elements and Isotopes

G. L. Molnár

11.3.1 Chemical Elements and Their Properties

The chemical elements are uniquely distinguished by their *atomic number*, Z , which is the number of protons in an atom. According to the IUPAC terminology, the atom is the smallest part of an element with no net electric charge, which can enter into chemical combinations. Each neutral atom contains as many electrons as protons in its nucleus. Atoms of the same element with the same atomic number, but different number of neutrons are called *isotopes*. The *isotopic abundance* (isotope abundance or atom abundance) is the relative number of atoms of a particular isotope in a mixture of the isotopes of a chemical element, expressed as a fraction (%) of all the atoms of the element. The isotopic abundances of the elements vary depending on the source of materials. The *natural isotopic abundance* is the isotopic abundance in the element as found on Earth. Because of natural radioactivity, this quantity may not be well defined for some isotopes.

The *mass number*, A , of an isotope of a given element is defined by the sum of the number of protons, Z , and neutrons, N , in its nucleus. Elements have more than one isotope with varying numbers of neutrons. For example, there are two common isotopes of carbon, ^{12}C and ^{13}C , which have six and seven neutrons, respectively. The *atomic mass* is primarily determined by the number of protons and neutrons in the nucleus. The average atomic mass of an element is called *atomic weight*, see [Sect. 3.2](#).

The chemical properties of an element are determined by the *electron configuration*: the distribution of electrons according to the energy sublevels (subshells) in uncharged atoms. The known elements, their basic physical parameters and electron configurations are listed in [Table 11.15](#) after Hanukoglu (2003). The noble gas shown in square brackets (e.g., [He]), marks that all the subshells associated with that element are fully occupied by electrons. More about the properties of elements and compounds formed by them can be found in numerous handbooks (Lide 2003; Dean 1992; Kaye and Laby 1993). A convenient on-line source of chemical and physical properties of the elements is WebElements (Winter 2003).

The elements can be arranged into a periodic table according to their chemical likeliness. The periodic table of elements is shown in [Fig. 11.1](#), in the form recommended by the IUPAC Commission on the Nomenclature of Inorganic Chemistry (Moss 2003). The atomic weights in [Table 11.15](#) and [Fig. 11.1](#) are approximate. See [Sect. 3.2](#) for the precise values and the standard uncertainties. The temporary names for *superheavy elements* are given separately, in [Table 11.16](#). At the end of 2009 the discovery of the element with $Z = 112$ was also accepted by IUPAC.

11.3.2 Atomic Weights and Isotopic Compositions

The *relative atomic mass* is the atomic mass divided by the unified atomic mass unit. This unit is defined as 1/12 of the mass of a ^{12}C neutral atom in its nuclear and electronic ground state,

^aSymbol of element; the elements marked with an asterisk have no stable isotopes.

^bDensity of elements with boiling points below 0°C is given in g/l.

and its value in SI units is given in ► Table 11.5. Hence, the relative atomic mass of isotope X of element E is given by:

$$A_r(X) = \frac{m(X)}{m(^{12}\text{C})/12}$$

where m is the mass of isotope X. The *atomic weight*, $A_r(E)$, of element E can be determined by averaging the relative atomic masses of the isotopes of that element, using the *isotopic abundances* as weighting factors. The isotopic masses and abundances are determined experimentally. As the isotopic composition depends on the origin and treatment of the material used in the experiment, regional and other variations have to be taken into account when deducing universally applicable values for atomic weights.

The IUPAC Commission on Atomic Weights and Isotopic Abundances reviews the experimental data and updates the recommended set of atomic weights and isotopic compositions biennially. The latest recommended set of atomic weights of the elements is from the year 2007

Periodic table of the elements

^b Actinide series	89 Ac*	90 Th	91 Pa*	92 U	93 Np*	94 Pu*	95 Am*	96 Cm*	97 Bk*	98 Cf*	99 Es*	100 Fm*	101 Md*	102 No*	103 Lr*
------------------------------	-----------	----------	-----------	---------	-----------	-----------	-----------	-----------	-----------	-----------	-----------	------------	------------	------------	------------

The temporary names of possible superheavy elements. Note that the discovery of element 112 was already accepted by IUPAC at the end of 2009, but the name and the chemical symbol were only proposals at that time

Z	Name	Symbol
110	Darmstadtium	Ds
111	Roentgenium	Rg
112	Copernicium	Cn
114	Ununquadium	Uuq
116	Ununhexium	Uuh
118	Ununoctium	Uuo

The IUPAC recommended values for *standard atomic weights* and the related quantities used for their derivation are presented in [Table 11.17](#) for element 1 through 116 according to the Internet page by Coursey et al. (2001), which combines data from Coplen (2001), Rosman and Taylor (1998a), and Audi and Wapstra (1995). The relative atomic masses are given in atomic mass units according to the above equation, while the representative *isotopic*

■ Table 11.17

^aThe value and its standard uncertainty were derived not from purely experimental data, but at least partly from systematic trends

compositions (mole fractions of the various isotopes) are shown in percentages. The derived standard atomic weight is included at the end of the isotopic list for each element, in italics. For elements not found in nature, brackets [] indicate the mass number of the most stable isotope. The standard uncertainties are given as numbers in parentheses after the least significant digits, i.e., 99.9885(70)% means $(99.9885 \pm 0.0070)\%$. These uncertainties reflect the accuracy of measurement and the terrestrial and other variabilities as well.

11.4 Atomic Data

R. B. Firestone

11.4.1 Atomic-Electron Binding Energies

Tables 11.18–11.20 list the *atomic-electron binding energies* (Larkins 1977) for elements with $Z = 1\text{--}104$. These binding energies are referenced to the Fermi level for solid systems, except for Ne, Cl, Ar, Br, Kr, Xe, and Rn, which are vapor phase systems where the binding energy is referenced to the vacuum level. The binding energy uncertainties are 1–2 eV for most subshells in the lighter elements or outer orbitals in the heavier elements, but may be 10–20 eV for the

■ **Table 11.18**

inner orbitals of heavy elements. Significant atomic-electron binding energy shifts for the non-valence shells may occur with changes of chemical state (Shirley et al. 1977).

11.4.2 X-Ray Energies and Intensities

The X-ray transitions between the inner K atomic shell and the subshells of higher lying shells have been classified by Siegbahn according to ➤ [Table 11.21](#). Due to the

■ Table 11.21

Siegbahn notation for X-ray transitions

Siegbahn Notation	Transition
$K_{\alpha 1}$	$K-L_1$
$K_{\alpha 2}$	$K-L_2$
$K_{\beta 1}$	$K-M_3$
$K_{\beta 2}$	$K-N_{2+3}$
$K_{\beta 3}$	$K-M_2$
$K_{\beta 4}$	$K-N_{4+5}$
$K_{\beta 5}$	$K-M_{4+5}$

unmeasurably small energy differences, it is practical to group together certain K_{β} transitions as:

$$\begin{aligned} K_{\beta 1}' &\rightarrow K_{\beta 1} + K_{\beta 3} + K_{\beta 5} \\ K_{\beta 2}' &\rightarrow K_{\beta 2} + K_{\beta 4} + \dots \end{aligned}$$

➤ **Table 11.22** lists the energies E and intensities I (with the latter in parentheses) of the most prominent K X-rays defined according to ➤ **Table 11.21** and the above equations. The X-ray energies have been determined from the differences in the corresponding atomic shell binding energies (Bearden and Burr 1967). The energies of complex X-ray transitions, e.g., $K-N_{2+3}$, are intensity-weighted averages of the single-line components.

The X-ray intensities have been determined from the experimental relative emission probabilities of Salem et al. (1974) and the atomic yields of Krause (1979). Theoretical emission probabilities (Scofield 1974) were used when experimental values were not available.

■ **Fig. 11.2**
Theoretical total internal conversion coefficients for electric (E) and magnetic (M) multipole transitions in the energy range 10 keV to 1 MeV for the atomic number 10

Fig. 11.3

Theoretical total internal conversion coefficients for electric (E) and magnetic (M) multipole transitions in the energy range 10 keV to 1 MeV for the atomic number 30

The relative intensities of X-rays from the same initial atomic shells are independent of the processes creating the shell vacancies. They are normalized to $I(K_{\alpha 1}) = 100$ in [Table 11.22](#). The ω_K fluorescence yields are from a polynomial fit of experimental data (Bambynek 1984).

11.4.3 Internal Conversion Coefficients

The *internal conversion coefficient (ICC)* of a transition between nuclear levels is defined as the ratio of conversion electron emission intensity to γ -ray emission intensity. For the innermost shell, the K shell, this is:

$$\alpha_K = \frac{I_e}{I_\gamma}$$

The total conversion coefficient α or α_{tot} is the sum of all subshell coefficients.

■ Fig. 11.4

Theoretical total internal conversion coefficients for electric (E) and magnetic (M) multipole transitions in the energy range 10 keV to 1 MeV for the atomic number 50

Recently new ICCs have been obtained from relativistic self-consistent-field Dirac-Fock (DF) calculations for each Z between 10 and 126, for K , L_1 , L_2 , and L_3 atomic shells for nuclear-transition multipolarities $E1$ – $E5$ and $M1$ – $M5$, and for nuclear-transition energies from 1 keV above the L_1 threshold to 2,000 keV (Band et al. 2002). The *total ICC* values were calculated from the sum of partial ICC values from all atomic shells. The calculated K and total values are, on average, about 3% lower than the theoretical relativistic Hartree-Fock-Slater values, and agree better with the most accurate experimental ICC values. A selection of total ICCs is plotted in ► Figs. 11.2–11.7, for atomic numbers $Z = 10, 30, 50, 70, 90$, and 110. The full set of tables and graphs can be found in the original publication.

11.5 Absorption of Radiation in Matter

G. L. Molnár

11.5.1 X- and γ -ray Attenuation Coefficients

When penetrating a matter of thickness d , a collimated beam of X-rays or γ -rays with initial intensity I_0 is attenuated exponentially:

$$I = I_0 \exp(-\mu d) = I_0 \exp(-\ln 2 d / d_{1/2})$$

Here μ is the γ -ray *linear attenuation coefficient*, usually measured in cm^{-1} units. It is a sum of the interaction terms described in [Chap. 6](#) in this Volume, hence it is also called total attenuation coefficient. Its inverse is called the *mean free path*, while the thickness reducing the photon beam by half is the *half-thickness* $d_{1/2}$; both are measured in cm. Frequently the *mass attenuation coefficient* μ/ρ is used, because it does not depend on the physical state of the material. Its dimension is cm^2/g if the density ρ is given in g/cm^3 units. Another important quantity is the *mass-energy absorption coefficient* μ_{en}/ρ , measured in the same units, which characterizes the energy deposition by photons. All these quantities, their units and usage have been defined by the International Commission on Radiation Units and Measurements (ICRU) in ICRU Report 33 (ICRU 1980), which has recently been superseded by two new ones (ICRU 1993c, 1998).

Tables and graphs of μ/ρ and μ_{en}/ρ were presented for elements with $Z = 1$ –92, and for 48 compounds and mixtures of radiological interest (ICRU 1989b) for the energy range of photons from 1 keV to 20 MeV, i.e., for X-rays, γ -rays and bremsstrahlung, by Hubbell and Seltzer (1995). This document is also available on the Internet (Hubbell and Seltzer 1997). A most comprehensive photon cross section database, extended to any element, compound or mixture (with $Z \leq 100$) and up to 100 GeV photon energy was constructed (Berger et al. 1999; Berger and Hubbell 1987) to calculate photon cross sections for coherent and incoherent scattering, photoelectric absorption and pair production, as well as total attenuation coefficients. Interpolation to arbitrary energy and data plotting is done by the computer program XCOM, which can be used online or downloaded for individual use (Berger et al. 1999).

Another useful program is the PC code XMuDat by Nowotny (1998) which is furnished with the databases of Hubbell and Seltzer (1995) and Boone and Chavez (1996). Total mass attenuation coefficients, mass-energy absorption coefficients and half-thicknesses of some representative elements and materials have been calculated with XMuDat and plotted in [Figs. 11.8–11.13](#) for illustration.

11.5.2 Stopping Power and Range of Charged Particles

The penetration of charged particles into matter is characterized by the *stopping power* S defined as the energy loss per unit path length. The most frequently used version is S/ρ , which is measured in $\text{MeV cm}^2/\text{g}$ units. A related quantity is the *range*, which is the path length traveled by a charged particle as it slows down to rest. The continuous-slowing-down approximation range, or *CSDA range*, is obtained by integrating the reciprocal of S with respect to energy from the initial value to zero. The *projected range* is the average value of the depth of

■ Fig. 11.8

Mass attenuation coefficients for light elements from 1 keV to 10 MeV photon energy

penetration, measured along the initial direction of the particle. The ratio of projected range to the CSDA range is called the detour factor, which is always smaller than unity due to multiple scattering effects. More about these definitions can be found in the ICRU Report 33 (ICRU 1980), and its successors (ICRU 1993c, 1998).

The total stopping power for *electrons* is the sum of collision and radiative stopping powers, as described in ► Chap. 6 in this Volume. These quantities have been tabulated in the ICRU Report 37 for electrons and positrons (ICRU 1989a). The total stopping power for *protons*, *alpha particles* (helium ions) and heavy ions is the sum of collision (atomic) and nuclear stopping powers, the latter being important only at low energies.

Stopping power data for protons and alpha particles have been tabulated in the ICRU Report 49 (ICRU 1993a). While at high energies the Bethe–Bloch theory is accurate to a few percent, at low energies sufficiently accurate values are obtained by fitting experimental data, and in the

■ Fig. 11.9

Mass attenuation coefficients for heavy elements against the photon energy

intermediate range interpolation is performed. The most comprehensive collection of such data has been provided by Ziegler et al. (1985). The extended version of this database is available on the Internet, and is used by the SRIM code (the successor of TRIM) to calculate stopping power and range for protons and heavy ions ($Z = 1-92$) in all elements for the energy range 1.1 eV to 2 GeV per nucleon (Ziegler 2003). The deviation of SRIM values from experiment for more than 25,000 data points has been reduced to 4.6% in the most recent version.

A convenient package of computer codes, consisting of ESTAR for electrons, PSTAR for protons and ASTAR for alpha particles is available for online use and downloading (Berger et al. 2000). They are based on the ICRU data (ICRU 1989, 1993). ESTAR calculates total, collision and radiative stopping powers, CSDA range and *radiation yield* (fraction of kinetic energy converted into bremsstrahlung) for over 250 common materials and any user-specified material in the energy range 10 keV to 10 GeV. The smallest uncertainties are 1–2% above 100 keV for collision stopping powers, and 2% above 50 MeV for radiative stopping powers. PSTAR and ASTAR calculate total, electronic (collision) and nuclear stopping powers, as

well as CSDA and projected ranges for 74 materials (26 elements, 48 compounds and mixtures) in the energy range 1 keV to 10 GeV (protons) or 1 GeV (helium ions). An extension is the MSTAR code (Paul and Schinner 2003), which is applicable to ions with $Z = 3\text{--}18$. In [Figs. 11.14–11.26](#) representative results are plotted for electrons, protons and helium ions, as obtained using the online versions of ESTAR, PSTAR and ASTAR, respectively.

11.6 Nuclear Masses and Separation Energies

G. L. Molnár

With very few exceptions, data on masses of nuclei refer to “atomic” masses or to masses of singly ionized atoms. The *nuclear mass* of an isotope with mass number A of element Z can be calculated from the atomic mass as:

$$M_N(A, Z) = M_A(A, Z) - Zm_e + B_e(Z) \quad (11.1)$$

where m_e is the electron mass, and B_e is the total atomic binding energy. The atomic masses are usually given in *atomic mass units* as relative atomic masses A_r (see [Section 11.3](#)) and the derived quantities in energy units. The electronvolt (eV) maintained in standard laboratories by using the internationally adopted value for the ratio of frequency and voltage in the Josephson effect ([Section 11.2, Table 11.10](#)) was introduced by Audi and Wapstra in 1993 (Audi and Wapstra 1993a) for the atomic mass evaluation, because at that time it gave more consistent and accurate values than the international volt. Their adopted mass–energy conversion constant (Audi et al. 1993)

$$1 \text{ u} = 931, 493.86 \pm 0.07 \text{ keV} \quad (11.2)$$

is smaller by a factor of only 1.6×10^{-7} than the most recent international value given in [Section 11.2](#). Therefore, the evaluated data remain practically unaffected.

The quantity most frequently tabulated is the *mass excess*:

$$D = M_A - A \quad (11.3)$$

i.e., the difference between the atomic mass and the mass number A (Audi and Wapstra 1995). The total *binding energy* of the atom is:

$$B = Z D(\text{H}) + N D(\text{n}) - D \quad (11.4)$$

where $D(\text{H})$ and $D(\text{n})$ denote the mass excess for the hydrogen atom and the neutron, respectively.

Other important derived quantities are the characteristic energies or Q -values for beta decay and alpha decay, and the neutron and proton *separation energies* $S(\text{n})$ and $S(\text{p})$, respectively:

$$\begin{aligned} Q(\beta^-) &= M(A, Z) - M(A, Z + 1) \\ Q(\beta^+) &= M(A, Z) - M(A, Z - 1) \\ S(\text{n}) &= -M(A, Z) + M(A - 1, Z) + M(\text{n}) \\ S(\text{p}) &= -M(A, Z) + M(A - 1, Z - 1) + M(^1\text{H}) \end{aligned} \quad (11.5)$$

Here the subscript A has been omitted for brevity. The Q -values for more complex nuclear reactions can be derived from the related atomic masses in a similar manner (Audi and Wapstra 1993b).

■ Table 11.23

In ► Table 11.23 the *mass excesses* in keV units are given for 2,931 nuclides in their ground states according to the 1995 update to the atomic mass evaluation (Audi and Wapstra 1995), also available in electronic form (AME 1995). The deduced beta and alpha *decay energies*, as well as the *neutron separation energy* and the *proton separation energy* have been added after rounding the uncertainties from the original data files (AME 1995) in a similar manner as it was done by the authors for the masses. For those nuclides exhibiting β^+ /EC decay the Q -value is given as the $Q(\beta^-)$ of the preceding isobar. Reaction energies for more complex reactions can be retrieved from the original computer files at the Atomic Mass Data Center (AME 1995).

Abstract: This chapter provides the necessary background from astrophysics, nuclear, and particle physics to understand the cosmic origin of the chemical elements. It reflects the year 2008 state of the art in this extremely quickly developing interdisciplinary research direction. The discussion summarizes the nucleosynthetic processes in the course of the evolution of the Universe and the galaxies contained within, including primordial nucleosynthesis, stellar evolution, and explosive nucleosynthesis in single and binary systems.

12.1 Introduction

Chemical elements are central for the existence of life and the richness and variety of our environment. Therefore, one of the basic questions concerns the origin of the chemical elements. The answer is complex because it relies on dynamical processes from elementary particles and nuclei to stars and galaxies. An interdisciplinary effort of various fields of science achieved considerable progress in this direction of research. This chapter summarizes the state of knowledge obtained mainly from particle and nuclear physics, astrophysics, and astronomy.

➤ Sections 12.2 and ➤ 12.3 concentrate on the two most important information sources concerning the earliest history of the Universe, i.e., the cosmic microwave background radiation and the primordial synthesis of the nuclei of the lightest chemical elements. The aim is to describe, in the simplest qualitative terms, the empirical facts and the way their interpretation is connected with the physics of the epoch immediately following the Big Bang. It should become clear that the structures observed today on the largest distance scales reflect the nature of the quantum fluctuations of the earliest period. Moreover, nuclear physics combined with the basic facts of cosmology provide a perfect account of the primordial abundance of the lightest nuclei. In ➤ Sect. 12.4, the production mechanism of the elements will be discussed as they occur in the different stages of stellar evolution. Explosive events occurring in binary stellar systems and their roles in nucleosynthesis are discussed in ➤ Sect. 12.5. The concluding part – ➤ Sect. 12.6 is devoted to the description and the interpretation of the abundance of chemical elements in the Sun and in the Galaxy. This includes abundance determinations from astronomical observations as well as from the analysis of presolar grains. The experimental methods to determine abundances and to study the nuclear physics relevant to nucleosynthesis processes are outlined. Finally, the basic ideas of galactic chemical evolution are laid out, which combine all the knowledge concerning production and distribution of nuclides to a grander picture. The chapter is completed by a list of references, where textbooks and review articles appear alongside the relevant original publications.

12.2 Creation and Early Evolution of Matter in the Universe

12.2.1 Evolution of the Energy Density in the Early Universe

The basic question addressed when investigating the history of the Universe as a whole in the framework of modern physics is the following: Why do we see something instead of detecting nothing? It originates from the common wisdom that any isolated system after long enough evolution will reach thermal equilibrium, characterized by a homogeneous structureless

distribution of its energy. Nearly 14 billion years after the Big Bang, one observes the presence of complicated hierarchical structures on all scales, starting from the subnuclear world, through chemical elements, and up to the scale of galaxy clusters. This section will review our present understanding of how the structured evolution of the Universe could be sustained for a time more than 60 orders of magnitude longer than the characteristic timescale of the particle physics processes present at the moment of its “birth.”

The information concerning the constitution of the early Universe has increased tremendously during the past decade, mainly due to improved observations of the cosmic microwave background radiation (CMBR). The most important cosmological parameters (the total energy density, the part contained in baryonic matter, the part of nonbaryonic dark matter (DM), other components, etc.) have been determined with percent level accuracy as a result of projects completed in the first decade of the twenty-first century and now appear in tables of fundamental physical data (Amsler et al. 2008).

12.2.1.1 Observations of CMBR

The existence of CMBR was predicted by Alpher et al. (1948) as a direct consequence of the Hot Big Bang Universe of Gamow (Lamarre and Puget 2001). It was discovered by Penzias and Wilson (1965). It originates from the combination of the once free electrons and protons into neutral atoms when the temperature of the Universe dropped below $kT = 13.6$ eV (the ionization energy of the H-atom, i.e., $T = 1.58 \times 10^5$ K) to nearly 1 eV (1.16×10^4 K). (Note that in certain branches of physics it is customary to express temperature in eV units through the equation $E = kT$. The conversion is given by 1 eV corresponds to 1.16045×10^4 K.) After the recombination, the Universe became transparent to this radiation, which at present reaches the detectors with a redshift determined by the kinematics of the expansion of the Universe (Lamarre and Puget 2001). It appears to be a perfect thermal radiation with Planckian power distribution over more than three decimal orders of magnitude of frequency, having a temperature of $T = 2.725 \pm 0.001$ K.

The first quantitative evidence for the temperature anisotropy of CMBR was provided by the COBE (Cosmic Background Explorer) satellite in 1992. The angular resolution of its detectors was 7° . This enabled the collaboration to determine the first 20 multipole moments of the fluctuating part of CMBR beyond its isotropic component. It has been established that the degree of anisotropy of CMBR is one part in one hundred thousand (10^{-5}). There are two questions of extreme importance related to this anisotropy:

1. Is this anisotropy the origin of the hierarchical structure one observes today in the Universe?
2. What is the (micro)physical process behind this anisotropy?

► **Section 12.2.4** returns to the answer to the first question. To the second question, the answer will be briefly outlined below.

Following the success of the COBE mission several more refined (ground based and balloon) measurements of the CMBR fluctuations were performed between 1998 and 2001. An angular resolution of about 1° has been achieved, which was further refined to the arc-minute level by the satellite mission Wilkinson Microwave Anisotropy Probe (WMAP). The combined efforts of these investigations allowed the determination of the multipole projection of CMBR on the sky up to angular moments $l = 2,000$. The fluctuation information extracted

■ Fig. 12.1

Multipole fluctuation strength of the cosmic microwave background radiation as a function of the spherical harmonic index l . The location and the height of the first minimum favors a spatially flat Universe, while the level of the fluctuations in the higher multipoles ($l > 400$) indicates the presence of a low-density baryonic component ($< 5\%$). The measurements cover already the damping region ($l > 1,000$). Wilkinson Microwave Anisotropy Probe (WMAP) data are displayed together with results of earlier balloon observations (Reprinted from Nolte et al. 2009 with kind permission of the first author, the WMAP Science Team, and AAS)

until 2007 is presented in Fig. 12.1 with $l_{\max} = 2,000$. One easily recognizes the presence of three pronounced maxima in this figure (possible additional, weaker maxima are discussed further below).

Another important characteristic of the CMBR anisotropy is its spectral power distribution. The measured distribution is nearly scale invariant; it is the so-called Zel'dovich–Harrison spectrum (see Peebles 1993). This means that every unit in the logarithm of the wave number contributes almost equally to the total power.

The small-amplitude and almost scale-invariant nature of the fluctuation spectra, described above, reflects the very early fluctuations of the gravitational field. First of all, one has to emphasize that the coupled electron–proton–photon plasma near recombination was oscillating in a varying gravitational field (Hu 2001). Where the energy density was higher the plasma experienced the effect of a potential well, and the radiation emerging from this region was hotter than average. On the contrary, diminutions of the energy density led to a colder emission. Still, an observer located far from the sources detects lower temperature from denser sources due to the Sachs–Wolfe effect (Peebles 1993). In any case, the CMBR anisotropy actually traces the inhomogeneity of the gravitational potential (or total energy density) in the era of recombination.

Thomson scattering of the anisotropic CMBR on the ionized hot matter of galaxy clusters and galaxies results in roughly 5% linear polarization of CMBR. Its presence in CMBR was first detected by the Degree Angular Scale Interferometer (DASI) experiment (Kovac et al. 2002). Starting from 2003, the WMAP experiment also measured the temperature–polarization cross

correlation jointly with the temperature–temperature correlation. The significance of this type of measurement is obvious since the presence of ionized gases corresponds to the beginning of the epoch of star formation.

12.2.1.2 Inflationary Interpretation of the CMBR

A unique particle physics framework has been proposed, which can account for the energy density fluctuations with the characteristics found in CMBR. One conjectures that the large-scale homogeneity of the Universe is due to a very early period of exponential inflation in its scale (Peebles 1993).

One assumes that during the first era after the Big Bang the size of the causally connected regions (the horizon) remained constant, while the global scale of the Universe increased exponentially. This is called inflationary epoch. The wavelength of any physical object is redshifted in proportion with the global scale. Therefore, at a certain moment, fluctuations with a wavelength bigger than the horizon were “felt” as constant fields and did not influence anymore the gravitational evolution of the matter and radiation at smaller length scale.

The inflationary period in the evolution of the Universe ended at about 10^{-32} s after the Big Bang. At this moment, the constant ordered potential energy density driving the inflation decayed into the particles observed today. Some of them may have belonged to a more exotic class, which can contribute to the violation of the matter–antimatter symmetry if they exhibit sufficiently long lifetimes (see ▶ Sect. 12.2.2). The rate of expansion of the horizon in the subsequent radiation- and matter-dominated eras was always faster than the global expansion of the Universe (see ▶ Fig. 12.2). Radiation-dominated means

■ Fig. 12.2

Variation of the characteristic length scales during the history of the Universe. On both axes the logarithm of the corresponding length is measured. The wavelengths of physical phenomena (full lines) grow linearly with the scale parameter of the Universe. The size of the causally connected domains (dot-dashed line) stagnates during the exponential growth (inflation), whereas it increases faster than the length scale of the Universe later, i.e., quadratically in the radiation era and with 3/2 power under matter domination

that the main contribution to the energy density comes from massless and nearly massless particles with much lower rest energy than the actual average kinetic energy. Therefore, the long-wavelength fluctuations having left during inflation continuously reentered the horizon and their gravitational action was “felt” again by the plasma oscillations. The first maximum of the CMBR multipole moments corresponds to the largest wavelength fluctuations that were just entering the horizon in the moment of the emission of CMBR.

Since during its evolution beyond the horizon, any dynamical change in the fluctuation spectra was causally forbidden, the fluctuating gravitational field experienced by the recombining hydrogen atoms was directly related to the fluctuation spectra of the inflationary epoch, determined by the quantum fluctuations of the field(s) of that era. This observation leads promptly to the conclusion that the spectra should be very close to the Zel’dovich–Harrison spectra. Detailed features of the power spectra seem to effectively rule out some of the concurrent inflationary models.

Also the simplest version of the field-theoretical realization of inflation predicts a total energy density very close to the critical density ρ_c , which separates the parameter region of a recollapsing Universe from the region where a non-accelerating expansion continues forever. Such a Universe is spatially flat. In the apparently relevant case of accelerated expansion, the borderline is shifted and universes somewhat above the critical densities might expand with no return. It is customary to measure the density of a specific constituent of the Universe in proportion to the critical density: $\Omega_i = \rho_i/\rho_c$.

An important prediction of the inflationary scenario for the origin of CMBR anisotropy is a sequence of maxima in the multipole spectrum (Hu 2001). The latest results (see [Fig. 12.1](#)) confirm the existence of at least two further maxima, in addition to the main maximum known before. The new satellite-based CMBR observations by the European satellite PLANCK launched in May 2009 will improve the accuracy of the deduced cosmological parameters to 0.5% and determine the multipole projection of the anisotropy up to angular momentum $l \sim 2,500$.

The positions and the relative heights of these maxima allow the determination of the relative density of baryonic constituents among the energy carriers. The increased level of accuracy leads to the conclusion that the baryonic matter (building up also the nuclei of all chemical elements) constitutes no more than 5% of the energy content of the Universe. This conclusion agrees very convincingly with the results of the investigation of the primordial abundance of the light chemical elements to be described in detail in [Sect. 12.3](#). These facts lead us to the unavoidable conclusion that about 95% of the energy content of the Universe is carried by some sort of nonbaryonic matter. (More accurate numbers will be given at the end of this section). The discovery of its constituents and the exploration of its extremely weak interaction with ordinary matter is one of the greatest challenges for the scientific research in the twenty-first century.

12.2.1.3 Dark Matter: Indications, Candidates, and Signals

Beyond CMBR, growing evidence is gathered on a very wide scale for the existence of an unknown massive constituent of galaxies and galaxy clusters. It is tempting to follow a unified approach describing the “missing gravitating mass” from the galactic to cosmological scale (i.e., from a few tens of kpc to Mpc, with $1 \text{ pc} = 3.26 \text{ light-years} = 3.0856 \times 10^{13} \text{ km}$). In this

subsection the main evidence already found and the ongoing experimental particle physics efforts for direct detection of the dark matter (DM) constituents are shortly reviewed.

First hints of some sort of gravitating Dark Matter below the cosmological scale came from galactic rotation curves (some tens of kpc), then from gravitational lensing (up to 200 kpc), and from the existence of hot gas in galaxy clusters. The anomalous flattening of the rotation curves of galaxies was discovered in the 1970s. Following Kepler's law, one expects a decrease of the orbiting velocity of all objects (stars as well as gas particles) with increasing distance from the galactic center. Instead, without exception a tendency for saturation in the velocity of bright objects in all studied galaxies is observed. The simplest explanation is the existence of an enormous dark matter halo. Since velocity measurements are based on the 21 cm hydrogen hyperfine radiation, they cannot trace the galactic gravitational potential farther than a few tens of kiloparsecs. Therefore, with this technique only the rise of the galactic dark matter (DM) haloes can be detected but one cannot find their extension.

Dark supermassive objects of galactic cluster size are observable by the lensing effect exerted on the light of farther objects located along their line of sight. According to general relativity the light of distant bright objects (galaxies, quasars, γ ray bursts (GRBs)) will be bent by massive matter located between the light source and the observer along the line of sight. Multiple and/or distorted images arise, which allow an estimate of the lensing mass. The magnitude of this effect, as measured in the Milky Way, requires even more DM out to larger distances than it was called for by the rotation curves (Adelmann-McCarthy et al. 2006).

The large-scale geometry of the galactic DM profile semiquantitatively agrees with results of Newtonian many-body simulations, though there are definite discrepancies between the simulated and observed gravitating densities at shorter distances. Interesting propositions were put forward by Milgrom to cure the shorter-scale deviations with a modified Newtonian dynamics (MOND) (reviewed by Milgrom 2008).

Gravitational lensing combined with X-ray astronomy can trace the separation of bright and dark matter, occurring when two smaller galaxies collide. The motion of the radiating matter is slowed down more than that of the DM components. As a consequence, the centers of the lensing and X-ray images are shifted relative to each other. A recent picture taken by the Chandra X-ray Telescope is considered as the first direct evidence for the existence of DM on the scale of galaxy clusters (Clowe et al. 2006).

Another way to estimate the strength of the gravitational potential in the bulk of large galaxy clusters is offered by measuring spectroscopically the average kinetic energy (e.g., the temperature) of the gas. One can relate the very high temperature values (about 10^8 K) to the depth of the gravitational potential assuming the validity of the virial theorem for the motion of the intergalactic gas particles. Without the DM contribution to the binding potential the hot gas would have evaporated long ago.

Three most popular DM candidates could contribute to the explanation of the above wealth of observations. Historically, faint stars/planetary objects constituted of baryonic matter were invoked first, with masses smaller than 0.1 solar mass (this is the mass limit minimally needed for nuclear burning and the subsequent electromagnetic radiation). The search for massive compact halo objects (MACHOs) was initiated in the early 1990s based on the so-called microlensing effect – a temporary variation of the brightness of a star when a MACHO crosses the line of sight between the star and the observer. This effect is sensitive to all kind of dark matter, baryonic or nonbaryonic. The very conservative combined conclusion from these observations and some theoretical considerations is that at most 20% of the galactic halo can be made up of stellar remnants (Alcock et al. 2000).

Complementary to this astronomy-based proposition elementary particle physics suggests two distinct nonbaryonic “species,” which originate from the extreme hot period of the Universe and therefore could be present nearly homogeneously on all scales. *Axions* are hypothetical particles of small ($10^{-(3-6)}$ eV/ c^2) rest energy. They were introduced (Peccei and Quinn 1977) for the theoretical explanation of the strict validity of the symmetry of strong interactions (QCD) under the combined application of space- and charge reflections (CP-invariance). Although they are very light, their kinetic energy is negligible, since they are produced in nonthermal processes. This way they represent the class of cold dark matter. The parameter space was and is thoroughly searched for axions in all particle physics experiments of the last 2 decades. The presently allowed mass range is close to the limit of the astrophysical significance of these particles.

The most natural DM candidates from particle physics are weakly interacting massive particles (WIMPs). Assuming that the thermal abundance of the WIMPs is determined by the annihilation and pair-production processes with themselves, one can estimate their present density as a function of the annihilation cross section. It is quite remarkable (even qualified sometimes as “WIMP miracle”) that, using cross sections typical of the supersymmetric extension of the standard particle physics model, just the gravitating density missing on the cosmological scale is found. By this coincidence, one identifies WIMPs with the lightest stable supersymmetric particle (called neutralino). The neutralino’s mass is on the scale of heavy nuclei; usually one assumes it to equal the mass of the tungsten atom. It would constitute pressureless cold dark matter, with a density calculable by analyzing its decoupling from thermal equilibrium.

An important milestone in the WIMP-story will be reached once the Large Hadron Collider (LHC) at CERN begins working. The available energy covers the expected mass range of the most popular variants of supersymmetric extensions. Currently, extensive strategies are worked out for the identification of prospective new massive particles to be observed at LHC, along with their cosmologically motivated counterparts (Baltz et al. 2006).

A positive identification at CERN would give new impetus to the underground direct searches for WIMPs. Such research is based on looking for heat deposition by particles arriving from the nearest galactic neighborhood into cryogenic detectors, well isolated from any other type of heat exchange. At present, only a single such experiment, i.e., the Dark Matter (DAMA) experiment in Gran Sasso, Italy, has reported a positive signal in the DM particle search. For more than 5 years now, a seasonal variation in the heat deposition rate is observed, which may be caused by the DM particle flux variation along the orbit of the Earth (Bernabei et al. 2003).

Although the analysis of CMBR excludes the domination of hot dark matter, i.e., relativistic weakly interacting particles, like light neutrinos, there still exists a plethora of more exotic propositions for the constituents of dark matter, not yet accessible for experimental verification, like primordial black holes, nonthermal WIMPzillas, and the so-called Kaluza–Klein excitations of higher-dimensional theories.

12.2.1.4 Dark Energy, the Accelerating Universe, and the Problem of Distance Measurements

The expansion of the Universe is conventionally characterized by the Hubble law, stating that cosmological objects uniformly recede from the observer with a velocity proportional to their distance. The proportionality factor H has not remained constant during the

evolution of the Universe, the rate of change being characterized by the deceleration parameter $q_0 = dH^{-1}/dt - 1$ (Peebles 1993).

The deceleration can be probed by distance measurements using type Ia supernovae. As explained in ▶ Sect. 12.5.3 these very energetic cosmic events occur in a rather narrow mass range of compact objects, with a minimal scatter in their energy output or *luminosity* L , which determines also the energy flux F reaching the observer at distance d_L called *luminosity distance*. Therefore, type Ia supernovae are standardizable light sources (standard candles), their light curves can be transformed into a universal form.

Standard candles are important tools to measure astronomical distances. Knowing the luminosity (i.e., energy output) of an object, it is straightforward to calculate its distance by the observed brightness, which drops with the inverse square of the distance $1/r^2$. The advantage of using SN Ia is that they are outshining all the stars in a regular galaxy and thus can be seen and studied over vast distances.

More recently, the method of measuring distances with SN Ia has acquired some fame by showing that the Universe is expanding faster at large distances than expected by the standard cosmological model (Perlmutter et al. 1999; Riess et al. 1998; Leibundgut 2001a, b).

The luminosities of 42 SN Ia were analyzed in these pioneering publications as a function of their redshift. The survey comprised objects with redshift $z \leq 1$, which corresponds to an age ≤ 10 Ga (gigayears). Assuming that the absolute magnitude of these objects is independent of the distance (excluding evolution effects) the apparent luminosities were detected on an average 60% fainter than expected in a Universe, whose energy density is dominated by nonrelativistic matter. A number of data points with $z \leq 0.7$ are displayed in ▶ Fig. 12.3, all having positive deviation for the difference of the apparent and absolute luminosities, $m - M$

■ Fig. 12.3

Variation of the difference of the observed (m) and absolute (M) luminosity for the SN Ia with redshift z , measured in a special astronomical unit, called *magnitude*. The zero level corresponds to supernovae in an empty ($\Omega = 0$) Universe. A positive difference signals sources that are fainter than expected. A brighter (negative) value is naturally interpreted as the decelerating action of the gravitational force exerted on the source by a nonzero rest energy ($\Omega_M \neq 0$). See text for models corresponding to the different curves possibly producing positive values (Reprinted from Riess et al. 2001 with kind permission of the first author and AAS)

(note that the fainter is a source the larger is its magnitude). The simplest interpretation is to assume the scattering of the light on its way from the source by some sort of “dust” (full line) leading to objects that are fainter than foreseen. A less conventional interpretation is to assume positive acceleration of the global expansion. (An accelerating source is located farther away, and will appear to be fainter at a certain z than expected in standard cosmology.)

The quantitative argument is based on relating the measurements to the deceleration parameter defined above. In fact the luminosity distance of an object at redshift z can be expressed as an integral of an expression of the varying Hubble-parameter $H(z)$ on the interval $(0, z)$, where $z = 0$ corresponds to the observer’s position today. When the redshift is not too large, one can expand this integral into a series of z and arrive in the first approximation at a simple linear relation expressing Hubble’s law of the dependence of the luminosity distance on the redshift. Its first nonlinear correction involves the deceleration parameter: $d_L = (c/H_0)z[1 + (1 - q_0)z/2 + \dots]$. Dust absorption diminishes the source brightness irrespective of the value of z . On the other hand, the presence of both matter and a cosmological constant will change the sign of the deceleration parameter with z .

In the past decade several projects contributed to the luminosity distance measurements and by now (i.e., as of 2009) the list includes over 200 events. Specifically with the help of the Hubble telescope 13 new Sn Ia were found with spectroscopically confirmed redshifts exceeding $z = 1$ and at present the full sample contains already 23 $z > 1$ objects (Riess et al. 2007). Such objects most strongly influence the value of the deceleration parameter. A combined analysis of all Sn Ia data yields a deceleration parameter value of -0.7 ± 0.1 (Kowalski et al. 2008). Its negative value signals an accelerating expansion rate at distance scales comparable to the size of the Universe.

A nonzero cosmological constant Λ in the equations describing the dynamics of the Universe can account for such an acceleration. The cosmological constant is related to a vacuum energy density (ρ) characterized by negative pressure (equation of state $p = w\rho$, with $w = -1$). Nowadays, the more general term “dark energy” is used for the hypothetical agent of such an accelerating effect (acceleration requires $w < -1/3$).

The fraction of the total energy density stored in Λ is not constant in time. Although Λ is constant by definition, the energy densities in the radiation and matter components are varying respectively as quartic and cubic inverse powers of the distance scale of the Universe. The early Universe until the decoupling of the photons is radiation-dominated and the Λ energy density is negligible. Initially, the matter density (including nonbaryonic dark matter) is dominating after decoupling, exerting a conventional decelerating effect on the motion of cosmological objects. Because of the reduction of the matter density with the expansion of the Universe, its contribution to the total energy density (and total $\Omega = \Omega_M + \Omega_\Lambda$) may become smaller than the one of Λ at a given point in time. How early this crossover happens depends on the absolute value of Λ , which is not constrained by any current theory. From this point of view, it is remarkable that Ω_M and Ω_Λ are of the same order of magnitude in the Universe at present. Because of this and the rather small value of Λ its impact on the cosmic expansion can only be detected over large distances, i.e., when studying distances of objects with large redshift z . In the distant future, the repulsive action of a nonzero Λ will more and more dominate. Without any additional effect, this leads to a “Big Rip” scenario in which smaller and smaller volumes become causally isolated because the repulsion will be pushing everything apart faster than the speed of light.

The different fits in  Fig. 12.3 correspond to different matter – dark energy compositions. Without cosmological constant, the deviation is always negative but its rate of decrease

depends on Ω_M . The two lower curves show cases ($\Omega_M = 0.35$ and 1.00 , respectively), which do not fit the measurements at all. Evidently, if the measurements are correct, some sort of dust or dark energy will be needed.

Because of the important consequences of these observations on cosmology, astronomers seriously investigate possible alternatives or data biases, such as possible effects of the evolution of SN Ia objects (deviation from the “standard candle” behavior at low metallicity), effects of light absorption by the galaxy clusters hosting the supernovae, and by the intergalactic dust, lensing effects, etc. Although the actual dust content in the line of sight is not well determined, dust is not a problem in recent observations because astronomers make use of an empirical relation between the width of the SN Ia lightcurve (between rise and decay) and its absolute magnitude. By studying samples of closer SN Ia it was found that more energetic, brighter explosions also lead to a wider lightcurve. This is called the Phillips relation. It is not affected by dust absorption and the only assumption entering is that it is universally valid for all SN Ia. Thus, knowing the easily determinable lightcurve width, the absolute magnitude can be derived and the distance calculated by comparison to the observed relative magnitude of the explosion.

The best fit rather indicates the presence of dark energy. This conclusion was largely determined by the object with largest z observed to date. In 2001, a SN Ia with $z = 1.6$ was reported with larger apparent luminosity than expected in a matter dominated or in an empty Universe (Riess et al. 2001, see [Fig. 12.3](#)). It can be reconciled with the small z observations by assuming that it exploded in an epoch when the matter part of the energy density was still dominant and the rate of the expansion was decreasing. Quantitatively, the fit led to $\Omega_M = 0.35$, $\Omega_A = 0.65$.

The important question to be addressed in this context is the one regarding alternatives concerning the nature of the repulsive force. A cosmological constant implies an equation-of-state with $w = -1$ but any $w < -1/3$ yields repulsion. An additional, previously unknown, form of energy has been postulated as an alternative to the cosmological constant: Quintessence (Caldwell et al. 1998; Armendariz-Picon et al. 2000). It has repulsive properties but $w \neq -1$. Therefore, it can be time-dependent and even have different values at different spatial points, contrary to a cosmological constant. Detailed SN Ia investigations try to put bounds not just on the size of the acceleration but also on the type of dark energy, i.e., the equation-of-state of the Universe.

The most recent analyses (Riess et al. 2007; Wood-Vasey et al. 2007) employing much larger data sets than before are all compatible with the cosmological constant ($w = -1$) interpretation of the data and give $\Omega_M = 0.274$ with 20% statistical error. A final conclusion concerning the acceleration driven by a substantial cosmological constant might be reached by the proposed Supernova Acceleration Probe space mission. The project aims at the observation of around 2,000 SN Ia up to a redshift $z \leq 1.2$. Its launch is tentatively scheduled for 2013.

The results of 5 years of WMAP satellite mission were published and their cosmological interpretation was studied (Komatsu et al. 2009), taking into account the effect of the above-listed investigations. The results were interpreted by assuming that our Universe is flat and its energy content is a mixture of ordinary matter, gravitating dark matter, and dark energy. The most important cosmological parameters were determined with unprecedented accuracy. The accuracy was substantially increased by combining the WMAP CMBR data, type Ia supernova luminosity distance measurements, and the largest scale components of the 2dF galaxy cluster catalogue (Percival et al. 2007). The supernova data are sensitive to the energy density component of cosmological constant type, while the galaxy clusters represent the

aggregates of the gravitating (mainly dark) matter. The analysis results in a value of the Hubble parameter H at present time of $(70.1 \pm 1.3) \text{ km s}^{-1} \text{ Mpc}^{-1}$. The ordinary matter content is $(4.62 \pm 0.15)\%$, the cold (nonrelativistic) dark matter represents $(23.3 \pm 1.3)\%$, the part of the dark energy in the full energy density is $72.1 \pm 1.5\%$. The projection of the motion of such a Universe back in time leads to a highly accurate estimate of its age: 13.73 ± 0.12 billion years.

Concluding, it becomes a more and more established fact that the chemical elements formed from baryonic matter contribute less than 5% to the total energy density of the present Universe. In view of the complete symmetry of laws governing matter and antimatter in our present-day Universe it is actually a rather nontrivial fact that baryonic matter did not completely annihilate into radiation in the hot Universe directly after the inflationary epoch and also that the original energy density was transformed into a high-temperature gas of ordinary elementary particles.

12.2.2 Origin of the Matter–Antimatter Asymmetry

On the interface of neighboring domains of baryonic and antibaryonic matter, quark–antiquark (proton–antiproton) annihilation would lead to the emission of hard X-rays. The absence of this signal makes it highly probable that even if antibaryons were present in the early, hot Universe they had disappeared before the CMBR was emitted. Therefore, the observed baryonic density actually proves the presence of a matter–antimatter asymmetry within the present horizon in our Universe (Rubakov and Shaposhnikov 1996; Riotto and Trodden 1999).

In 1967, Sakharov analyzed the conditions that might lead to this asymmetry dynamically, instead of simply assuming it to be fixed by some initial conditions (Sakharov 1967). If, in a certain moment,

1. The elementary interactions violate the symmetry under the combined transformation consisting of spatial reflection (P) followed by charge conjugation (C) – the so-called CP symmetry,
2. The elementary interactions violate the baryon-antibaryon symmetry,
3. The Universe is out of thermal equilibrium,

then a matter–antimatter density difference is produced. One can deduce the actual amount of asymmetry with detailed quantitative calculations.

Without going into details, some of the scenarios proposed by theoretical particle physicists for the creation process of this fundamental asymmetry will be outlined below. For this, a short account of the Standard Model of elementary interactions (Perkins 2000) is given first. (See also [Chap. 10, Vol. 1.](#))

Known elementary constituents of matter are quarks and leptons (see [Table 12.1](#)). Three families have been discovered. In each family one has two flavors of quarks and one lepton with the associated neutrino. The decay of the free neutron observed in 1932 and described first by the Fermi theory of weak interactions is understood today as the decay of a d-quark (one of three quarks composing the neutron) into a u-quark (which forms the final proton with the unchanged other two quarks) and an electron plus its antineutrino. The particles participating in this process constitute the lightest (first) particle family of the Standard Model.

Three elementary interactions act among these particles. Each of them is mediated by vector particles. The electromagnetic quanta, the photons, bind nuclei and electrons into

■ Table 12.1

Elementary particles in the Standard Model. For each family, the first line in the center column refers to quark species of left- and right-handedness (L, R), the second line gives the same for the leptons, not participating in strong interaction processes. Those appearing in a bracket form a doublet with respect to $SU(2)_L$ transformations. The field quanta mediating strong, electromagnetic, and weak interactions are listed in the last column. They are not specific to any particle family

Particle families	Matter constituents (each has its own anti-particle)	Interaction vector particles
1st	$(u_L, d_L), u_R, d_R$	8 gluons
	$(e_L, \nu_{eL}), e_R$	
2nd	$(c_L, s_L), c_R, s_R$	Photon (γ)
	$(\mu_L, \nu_{\mu L}), \mu_R$	Weak quanta (Z^0, W^\pm)
3rd	$(t_L, b_L), t_R, b_R$	
	$(\tau_L, \nu_{\tau L}), \tau_R$	

atoms and molecules. Weak interactions are mediated by three vector fields, the W^\pm and the Z^0 , all discovered in 1983. Gluon fields bind the quarks into protons and neutrons. The strong interaction quanta come in eight different, so-called colored states and also each quark can appear in one of three different colored states.

It has been shown that the three Sakharov conditions might be fulfilled simultaneously in the Standard Model at high temperatures. The CP-violation, which allows the oscillation of the K^0 and of the B^0 mesons into their antiparticles and back, has been observed experimentally (in 1967 and 2001, respectively) and can be quantitatively understood with the present theory (Amsler et al. 2008).

On the other hand, no sign of baryon number violation has been observed to date in any elementary particle physics experiment. In the Standard Model, one cannot find any process that would involve the transformation of a proton into mesons or leptons. However, in the early 1970s, 't Hooft (1976) showed that in the presence of specific configurations of electro-weak vector fields, fermions (leptons and quarks) can be created or annihilated, but the difference of the baryon number and of lepton number ($B-L$) should stay constant (quarks and antiquarks actually carry $\pm 1/3$ unit of baryon charge, while the lepton charge of the known species is ± 1). Today the chance for such transitions to occur is negligible (the probability is estimated to about 10^{-170}). However, they must have occurred frequently when the temperature was of the order of 100 GeV (about 10^{15} K).

It is a very interesting coincidence that exactly at that temperature scale one expects the transformation of all elementary particles from massless quanta into the massive objects observed in today's experiments. The creation of the mass is due to the so-called Higgs effect. This consists of the condensation of an elementary scalar field (a close relativistic analogue of the Cooper-pairing in superconductivity). If this transformation had proceeded via a sufficiently strong first-order phase transition, the third of Sakharov's criteria had been also fulfilled by the behavior of the known elementary interactions in the very early Universe.

In a first-order phase transition, the low-temperature (massive) phase would appear via thermal nucleation, which is a truly far-from-equilibrium process. Inside the bubbles of the new phase the baryon number-violating processes are stopped. So the question is this: What is the net baryon concentration frozen?

Quarks and antiquarks traverse the phase boundaries, which represent a potential barrier for them. As a consequence of the complex CP-violating phase in the Hamiltonian describing weak interactions, the reflection and transmission amplitudes for matter and antimatter turn out to be different leading to an asymmetry in the constitution of matter and antimatter inside the bubbles.

The quantitative details of this beautiful scenario critically depend on a single parameter: the strength of the self-coupling of the so-called Higgs field, whose condensation determines the masses of all particles. This parameter is still unknown. The latest lower bound (Amsler et al. 2008) lies in a region where the phase transformation is actually continuous (beyond the end point of the first-order transition line). The situation could be different in supersymmetric extensions of the Standard Model. The one explored best is the electroweak phase transition within the so-called Minimal Supersymmetric Standard Model (Carena et al. 2009). One expects considerable guidance from measurements at the Large Hadron Collider in constraining the parameter space to search for the origin of baryon–antibaryon asymmetry. Another avenue could be the very late (low-energy density) exit from the inflationary period of evolution (Garcia-Bellido et al. 1999; Krauss and Trodden 1999; van Tent et al. 2004). If this energy scale coincides with the electroweak mass scale then the reheating of the Universe from its cold inflationary state would offer an out-of-equilibrium situation. This is the basis of the proposition of the cold baryogenesis scenario (Tranberg et al. 2007).

The resolution of the matter–antimatter asymmetry problem is an issue of central importance in particle physics in the twenty-first century.

12.2.3 Evolution of the Expanding Universe

The equilibrium in the hot particle “soup” is maintained through frequent elementary particle reactions mediated by the quanta of the three fundamental interactions. The expansion of the Universe dilutes the densities and, consequently, the reaction rates get gradually lower. The adiabatic expansion lowers monotonically also the temperature (the average energy density). (Actually, there is a one-to-one mapping between time and temperature.) The following milestones can be listed in the thermal history of the Universe (Kolb and Turner 1990).

First, the weak interaction quanta became massive at the temperature scale of 100 GeV. Since then, weak reactions have only occurred in contact interactions of the particles. At about the same time the *t*-quark and the Higgs quanta also decoupled from the “soup.” The same decoupling happened for the other heavy quark species (*b*-quark, *c*-quark) and for the heaviest of the leptons (τ -particle) in the range 1–5 GeV (a few times 10^{13} K) of the average energy density. The τ -neutrinos remain in thermal equilibrium via weak neutral interactions.

The strong interaction quanta, the gluons became extremely short ranged at around the temperature $kT \sim 100\text{--}200$ MeV (a few times 10^{12} K). Computer-aided quantum field theoretical investigations have demonstrated that quarks and gluons are confined to the interior of nucleons (protons and neutrons) and excited baryonic resonances below this temperature range (Petreczky 2007). This transformation was smooth for baryonic matter

densities characteristic of our Universe at that epoch and for the actual mass values of the light quarks, very similar to the process of atomic recombination.

At this stage no nuclear composite objects can be formed yet, since they would instantly disintegrate in collisions with hard electromagnetic quanta. The stabilization occurs for temperatures below 0.1 MeV. Primordial synthesis of light nuclei took place at that cooling stage of the Universe (► Sect. 12.3).

Below this temperature, light nuclei and electrons form a globally neutral plasma, in which thermal equilibrium is maintained exclusively by electromagnetic interactions. The gravitational attraction of the massive and electrically screened constituents of matter was balanced by the radiation pressure. This dynamical equilibrium is described by coupled fluid equations and results in acoustic oscillations modulating the essentially homogeneous distribution of the constituents (Hu 2001). The dominant wavelength of these oscillations is determined by those density fluctuation modes that left the horizon during inflation and are continuously reentering, since during the radiation-dominated period, the horizon expands faster than the global scale parameter of the Universe increases.

The last qualitative change occurred at the energy scale around 1 eV ($\sim 10^4$ K), when at the end of atomic recombinations the Universe became transparent to the propagation of electromagnetic radiation. At this moment the size of the Universe was about 1/1000 of its present radial scale. Today, the light emitted in the act of the last scattering is detected as cosmic microwave background radiation. A consistent interpretation of the details of its features represents (together with the primordial abundance of light nuclei) a unique test of all ideas concerning the earlier evolution of the Universe.

12.2.4 Gravitational Clustering of Matter

At the moment of the decoupling of light, the matter in the Universe became gravitationally unstable against density fluctuations. The key feature in understanding the emergence of a large-scale structure in the Universe is the statistical characterization of the density fluctuations at this moment. These fluctuations are determined by the spectra of the acoustic oscillations, which are in turn determined by the reentering density fluctuations of inflationary origin. This line of thought leads us to the hypothesis of the quantum origin of the largest-scale structures observed in the Universe.

Amplitudes of density fluctuations at different wavelengths follow independent Gaussian (also called normal) statistics (see ► Sect. 9.3.6, Chap. 9, Vol. 1), and their mean spectral power is distributed in an almost scale-invariant manner, described above. The absolute normalization was determined by the COBE satellite to be 1 part in 100,000. Their evolution can be analyzed initially with the help of the linearized gravitational equations. The classical analysis, originally performed by Jeans (1902), leads to the conclusion that fluctuations above the Jeans-scale are unstable and they are at the origin of the formation of the oldest structures (for a modern textbook on the subject, see Peacock 1999).

The nonlinear stage of the clustering process can only be followed by numerical integration of Newton's equations of motion for a very large number (typically 10^6 – 10^7) of equal-mass particles. The most interesting question studied in these N -body simulations concerns the mass distribution of the first galaxies. This feature determines the frequency of the occurrence of densities sufficiently high to start nuclear fusion reactions in these first gravitationally bound galactic objects.

The semiempirical theory (Press and Schechter 1974) assumes that this distribution is determined by the probability of matter fluctuations obeying a Gaussian distribution to exceed an empirically determined threshold value. This simple idea results in an $\sim M^{-2/3}$ power scaling for the statistics of the collapsed objects with different mass M . This means that the earliest collapsed gas clouds were small, about 10^5 solar masses, and had a temperature of a few hundred Kelvin. The thermal excitation of H_2 molecules provides the microscopic mechanism for the further radiative cooling, which might have led to the formation of the first minigalaxies and/or quasars. If sufficient quantities of H_2 molecules were present, then the first stars and black holes were born very early, at a redshift $z \sim 20$ i.e., some 12 billion years ago, when the characteristic size of the Universe was $z + 1$ times smaller than it is at present). If the dominant radiative cooling mechanism was the excitation of the atomic hydrogen, then the first objects with nearly 10^8 solar masses were formed at a temperature of 10^4 K. The first galaxies appeared in this case only for a redshift $z \sim 10$. One expects that astronomical surveys of the coming years will be able to reach the distance that can be calculated from the Hubble law $d = H/\nu$, where the Hubble parameter H was defined in [Sect. 12.2.1.4](#). The exploration of this distance scale should bring evidence for the existence of the first galaxies. According to the latest WMAP results (Komatsu et al. 2009) the first galaxies were formed at $z = 10.8 \pm 1.4$.

The Millenium simulation (Springel et al. 2005) is an N -body simulation tracing over 10 billion mass points, representing fractions of the primordial gas, from the time of the CMBR decoupling to the present-day Universe. This simulation showed that it was necessary to assume cold dark matter (consisting of slowly moving, heavy particles) to reproduce the large-scale structures found in galactic surveys. It was also able to show that bright quasars are formed already at very early stages, thus confirming the observational results from the Sloan Digital Sky Survey (Anderson et al. 2001; Abazajian et al. 2009) that challenged traditional models of structure formation.

The radiative cooling and further gravitational evolution of the collapsed clouds lead to the appearance of the first stars (see [Sect. 12.4.1.1](#)).

12.3 Primordial Nucleosynthesis

12.3.1 Weak Decoupling

Since the quark–hadron phase transition no free quarks or gluons exist anymore. The hot plasma is composed of neutrons, protons, electrons, positrons, photons, and the electron-, muon-, and tau-neutrinos and their antineutrinos. Basically, all particles with masses $2m < kT/c^2$ are present because the respective particle–antiparticle pairs can be created in photon collisions. Scattering reactions thermalize all plasma constituents to the same temperature and forward and reverse reactions are in equilibrium. For instance, protons can be converted into neutrons by electron capture $e^- + p \leftrightarrow n + \nu_e$, neutrons into protons by positron capture $e^+ + n \leftrightarrow p + \nu_e$. While all other constituents are highly relativistic, the nucleons are slower due to their large mass. Their kinetic energy exhibits a Maxwell–Boltzmann distribution appropriate for the given plasma temperature. Although formation and destruction reactions are in equilibrium, protons will be more abundant because of their lower mass. The ratio of neutron to proton number densities only depends on the temperature

and the mass difference Δm between the nucleons as long as the reaction equilibria apply (Börner 1988; Kolb and Turner 1990; Peacock 1999):

$$\frac{n_n}{n_p} = \exp\left(-\frac{\Delta mc^2}{kT}\right). \quad (12.1)$$

Once $kT \leq 1$ MeV (i.e., at about 10^{10} K), the electrons are not energetic enough anymore to overcome the mass difference between neutrons and protons in electron captures. Also, photons cannot produce positrons anymore in pair-production processes to support positron capture on neutrons. Such weak transitions will thus cease to exist. Since the neutrinos were produced in such reactions, thermal communication of the neutrinos with the other constituents comes to an end. This phase is called weak freeze-out and weak decoupling because the neutrinos become decoupled from the rest of the particles and can assume different temperatures. Since there is little, if any, interaction between this neutrino background and the remaining particles, its evolution is governed predominantly by the expansion rate of the Universe similar to the photon background radiation after electromagnetic decoupling that gives rise to the cosmic microwave background (see [Sect. 12.2.1.1](#)). Thus, in addition to the cosmic microwave background there is a cosmic neutrino background stemming from the era of weak decoupling. Its temperature is lower by a factor of 0.714 because of the heating of the photons by $e^+ - e^-$ annihilation after weak decoupling.

With the ceasing of electron and positron capture, the ratio of neutrons to protons gets frozen at the decoupling temperature, yielding a value of about 1/6. However, after the weak freeze-out, photons still dominate the total energy of the Universe and thus the temperature is decreasing as the inverse square root of the time, according to the law valid for a radiation-dominated Universe. The ratio between baryon and photon number densities $\eta = n_b/n_\gamma$ characterizes a particular solution of the equations for the expanding early Universe and, therefore, the solutions can be labeled by the parameter η (Kolb and Turner 1990; Coles and Lucchin 1996; Riotto and Trodden 1999). Assuming a globally valid η , the baryon density can be written as a function of temperature: $\rho_b = 3.376 \times 10^4 \eta T_9^3 \text{ g cm}^{-3}$ (T_9 is the temperature in units of 10^9 K.) In fact, η is inversely proportional to the total entropy of the Universe, which has to remain constant.

Together with the equation for the evolution of the temperature $T_9 = 13.336/t^{1/2}$, this sets the conditions for primordial nucleosynthesis. The strength of the standard Big Bang scenario is that only one free parameter – the above-introduced baryon-to-photon ratio η – must be specified to determine all of the primordial abundances ranging over 10 orders of magnitude.

The parameter η also depends on $\Omega_b = \rho_b / \rho_c$, i.e., the ratio of the baryon density to the critical density ρ_c needed for a flat Universe.

Thus, a fit of η to observed primordial abundances not only probes the conditions in the early Universe at the time of nucleosynthesis but can also reveal the curvature of the Universe, or at least the baryonic contribution to that curvature (Schramm and Turner 1998). Historically, primordial nucleosynthesis was the first tool for determining the geometry of the Universe. With the increased accuracy in the resolution of the angular multipole expansion of the CMBR temperature fluctuations delivered by WMAP, the total density of the Universe (and not just the baryonic one) can be determined independently now (see [Sect. 12.2.1](#)).

12.3.2 The Reaction Network and the Production Process of Nucleosynthesis

After the weak freeze-out, the baryonic matter part essentially consists of free neutrons and protons interacting with each other. Deuterium is constantly formed via neutron captures on

protons. However, due to the low binding energy of the deuteron the created deuterons will preferably be destroyed by photodisintegration as long as the (photon) temperature is higher than 10^9 K. Below that temperature, photodisintegration is no longer effective, and more heavy elements can be built up by further reactions on the deuterons. Thus, although free neutrons and protons had already existed earlier, the onset of further primordial nucleosynthesis is delayed until about 2 s after the Big Bang (Boesgaard and Steigman 1985; Bernstein et al. 1991).

Because free neutrons are not stable, but decay with a half-life of $T_{1/2} = (10.25 \pm 0.015)$ min, the neutron-to-proton ratio will change from 1/6 to 1/7 until the onset of primordial nucleosynthesis.

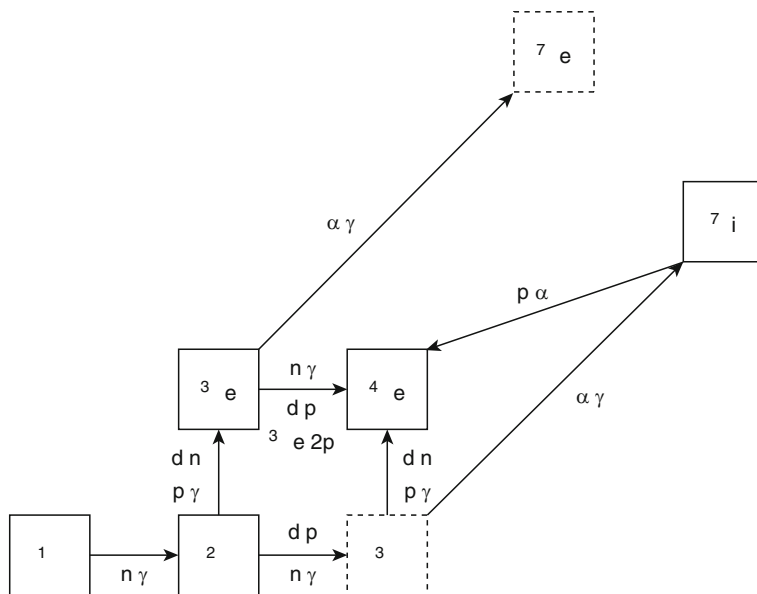

While the Universe expands further, it cools down and the decreased energy of the photons cannot prevent significant formation of deuterons anymore. Thereafter, heavier nuclides can be created by reactions involving protons, neutrons, and the newly formed nuclear species (Schramm and Turner 1998; Sarkar 1996). This is nothing else than a freeze-out from a high-temperature, low-density nuclear statistical equilibrium (NSE), similar to the one occurring in late and explosive phases of nucleosynthesis (see ▶ Sects. 12.4.4 and ▶ 12.4.5) but at different density. An NSE is defined by all reactions via the strong and electromagnetic forces being in equilibrium. The equilibrium abundances are then only determined by the (baryon) density, the temperature, and the binding energy of the nuclei, as well as by the initial composition of the material, i.e., the neutron-to-proton ratio. The latter is set by the weak freeze-out and the subsequent neutron decay. In a high-temperature NSE, all nuclei are completely dismantled into their constituents: the protons and neutrons. Assuming a quick freeze-out in such a manner that late-time nonequilibrium reactions will not significantly alter the NSE abundances, the resulting abundances can already be determined without detailed reaction network calculations. With decreasing temperature, simply the most strongly bound nuclei at the given neutron-to-proton ratio will be formed. Thus, mainly unprocessed protons and ^4He nuclei are expected to be present, which exhibit a high binding energy, with all neutrons having been incorporated into the ^4He nuclides. Formation of elements beyond He is hindered by the fact that there are no nuclei with mass numbers 5 and 8. The 3α reaction (see ▶ Sect. 12.4.3) could convert ^4He to ^{12}C but is not in equilibrium because it is strongly dependent on the density and too slow at the conditions in the early Universe. Nuclei close to ^4He are produced according to their binding energies.

The important reactions and the produced nuclear species are shown in ▶ Fig. 12.4. The conditions at the onset of and during the nucleosynthesis are given by the initial values and parameters discussed above, with η being a free parameter.

A typical result of a full network calculation for a specific η is shown in ▶ Fig. 12.5 (Tytler et al. 2000; Kolb and Turner 1990). As can be seen, practically no nucleosynthesis occurs during the first 2 s, the temperature remains above 10^{10} K, and no other nuclides than free nucleons are favored. Only after a sufficient drop in temperature, deuterons are formed, ^3H and ^3He nuclei are produced, quickly followed by ^4He . The neutron abundance is determined by slow β -decay in the early phase. During the formation of ^4He , the neutron abundance suddenly drops because most of the neutrons are incorporated into the α particles. Slightly delayed, traces of ^7Li and ^7Be nuclei are formed. During the decline of the temperature, charged particle reactions freeze out quickly and after about 15–30 min nucleosynthesis ceases. The very few free neutrons decay into protons, ^3H eventually also decays and so does ^7Be , which forms further ^7Li . Finally, by far the most abundant species are hydrogen (protons) and helium (^4He , i.e., α particles), which together give more than 99.9% of the baryonic material. Although this calculation did not assume NSE at all times, the resulting abundances are very close to the ones obtained from equilibrium abundances and fast freeze-out. Realizing the dominance of ^4He due to its high

■ Fig. 12.4

The reaction network of standard Big Bang nucleosynthesis. Unstable nuclear species are marked by dashed boxes. When all reactions are stopped, the unstable ${}^7\text{Be}$ decays to ${}^7\text{Li}$ and ${}^3\text{H}$ decays to ${}^3\text{He}$

binding energy, it is easy to understand that about 25% of the gas is made up of helium. The initial n/p ratio of $1/7$ translates into mass fractions $X_n = 0.125$ and $X_p = 0.875$ (i.e., 12.5% of the gas mass consists of neutrons). Assuming that all neutrons combine with protons to form ${}^4\text{He}$, the mass fraction of ${}^4\text{He}$ has to be $X_\alpha = 2X_n$ because it contains two neutrons and two protons. Thus, $X_\alpha = 0.25$, i.e., 25%.

An interesting result was obtained from the fact that the initial n/p ratio depends on the weak freeze-out (see above). The freeze-out time and temperature and thus also the resulting n/p ratio depends on the change in the degrees of freedom during freeze-out (Kolb and Turner 1990). Although only three neutrino families were known originally ($N_\nu = 3$), it remained an open question for a while whether there are more families containing light (nearly massless) neutrinos. Increasing the number of neutrino species increases the number of degrees of freedom and has a similar effect to that of a faster expansion resulting from larger pressure. Thus, a larger number of neutrino families would lead to an earlier weak decoupling at a still higher temperature. This results in a higher n/p ratio and consequently leads to more ${}^4\text{He}$.

Primordial nucleosynthesis calculations performed along these lines were able to put the limit $N_\nu \leq 3.3$, ruling out any further families long before any particle physics experiments. This was possible due to several facts: helium is very abundant and can be easily measured in astronomical observations; it is strongly bound and therefore robust during galactical chemical evolution; its abundance only weakly depends on η ; the primordial production reactions are well determined; and the half-life of the neutron (determining the change of the n/p ratio between weak freeze-out and onset of nucleosynthesis) is measured to high accuracy.

■ Fig. 12.5

Primordial abundances of different nuclear species as a function of time and temperature for a fixed ratio of baryon to proton number densities, $\eta = 5.1 \times 10^{-10}$ (Reprinted from Tytler et al. 2000 with kind permission of the first author and IOP)

This prediction on the number of neutrino species was later confirmed by experiments at CERN (see the article of D. Karlen in Hagiwara et al. 2002) directly measuring the decay widths of the Z^0 boson in the weak interaction.

The nuclear reaction rates (cross section) for the reactions specified in ► Fig. 12.4 are well determined, also at the interaction energies relevant to primordial nucleosynthesis, which are comparatively low by nuclear physics standards. Thus, once the initial conditions are determined, the evolution of the different species with time and the final abundances can be calculated with high accuracy. The only open parameter in the standard Big Bang nucleosynthesis model is η . Since the baryon density is proportional to η and the reaction rates are density dependent, the final abundances will also depend on the choice of η .

► Figure 12.6 shows this dependence for a typical range of the baryon density and equivalently its fraction of the critical density Ω_b . Immediately catching the eye is the difference between the density dependences of the different species: the ^4He fraction increases slightly with increasing density while the deuterium and ^3He fractions strongly decrease (note that the vertical scale of the upmost curve is linear, while those of the rest are logarithmic). The simple explanation is that a high density during the nucleosynthesis phase gives rise to a larger number of capture reactions on deuterium and ^3He , producing more ^4He but leaving less of the targets. ^7Li shows a more complex behavior with a pronounced minimum. At low densities ^7Li is produced by α -capture on ^3H but is preferably destroyed at higher densities by the reaction

■ Fig. 12.6

Primordial abundances as a function of baryon density ρ_b or fraction of critical density Ω_b (these two quantities are directly related to the baryon-to-photon ratio η , see text). The widths of the curves give the nuclear physics uncertainties. The boxes specify the ranges of abundances and densities constrained by observation (there is only an upper limit for ${}^3\text{He}$ from observation) as given in Burles et al. (1999, 2001). The shaded area marks the density range consistent with all observations (Burles et al. 1999, 2001). Symbol D represents deuterium, ${}^2\text{H}$ (Reprinted from Tytler et al. 2000 with kind permission of the first author and IOP)

${}^7\text{Li}(p,\alpha){}^4\text{He}$. However, at higher densities the production of ${}^7\text{Be}$ via ${}^3\text{He}(\alpha,\gamma){}^7\text{Be}$ also increases. This ${}^7\text{Be}$ is not destroyed by any further primordial process but eventually decays to ${}^7\text{Li}$ after nucleosynthesis has ceased. The different density dependences of the three main reactions involved give rise to the minimum shown in Fig. 12.6.

12.3.3 Comparison of Calculations and Observed Primordial Abundances

Except for helium, the abundances of the primordial isotopes change by orders of magnitude when varying the baryon density or η , respectively. On the other hand, ${}^4\text{He}$ is very abundant and thus it can be observed with high accuracy. Therefore, it is possible to determine η from

comparison with primordial abundances. As outlined above, this means nothing less than determining the total baryon density and thus the baryonic contribution to the curvature of our Universe! The allowed abundance range for each primordial species is shown in ▶ Fig. 12.6, combined with the calculated baryon density. It is reassuring that the independent observations for each species still permit a consistent range of η , i.e., all the observations are consistent with the same baryon density.

Serious complications arise from the fact that the calculations have to be compared to primordial abundances, not to the ones currently found in stars or the interstellar medium (Boesgaard and Steigman 1985; Olive et al. 2000; Tytler et al. 2000; Olive 2001; Steigman 2006). During the further evolution of the Universe, when stars are formed and destroyed, the abundances within a galaxy change with time (see ▶ Sect. 12.6.4) due to the stellar production and destruction processes (see ▶ Sect. 12.4). Thus, it is not trivial to determine the primordial values, especially those for isotopes that are weakly bound and therefore easily destroyed in stars such as deuterium, ^3He , or ^7Li nuclei. In order to trace the effects of chemical evolution, the standard practice is to correlate the abundance of the nuclide in question with the abundance of a nuclide, which becomes monotonically enriched in the interstellar medium during the course of the chemical evolution, e.g., oxygen. This other nuclide serves as a tracer of the metallicity of an object, i.e., the content of elements beyond hydrogen and helium (a technical term borrowed from astronomy). From the observation of different sites with different metallicities, one hopes to find trends that can be extrapolated to zero metallicity, i.e., to the primordial values. ▶ Figure 12.7 shows an example of such an extrapolation.

■ Fig. 12.7

Example of the extrapolation to primordial values. The primordial value of ^4He (Y_p) for zero metallicity (zero oxygen) is inferred from a series of observations (filled circles) (Olive 2001). For other primordial isotopes the slope of the interpolation would be steeper, for ^7Li there would be a steep rise at higher metallicities and a flat line with nearly constant abundance at low metallicity (Reprinted from Olive 2001 with permission by Springer)

The spectra of ^4He are easy to observe due to its high abundance. This He isotope can be identified in clouds of ionized interstellar gas around bright, young stars (HII regions). Although the abundance in an object can be determined with high precision, a large systematic uncertainty remains due to observations of different objects. On the other hand, the observation of ^3He is difficult and an extrapolation carries a large uncertainty because different stars both produce and destroy it effectively. Due to its weak lines it cannot be seen in low-metallicity stars. The chemical evolution of ^7Li is also complex but it can at least be seen in old stars. Such stars contain a factor of 0.03–0.0003 less “metals” (in astronomy: all elements except H and He) than the Sun. Studying such stars, a remarkable discovery was made: below a certain metallicity the content of ^7Li remains almost constant, i.e., a plateau appears in the abundance plots. The ^7Li -plateau was thought to give the primordial value. However, the question of possible depletion in early stars remains to be addressed (Korn et al. 2006) as well as the dependence of the data on the underlying assumptions, such as model atmospheres (Charbonnel and Primas 2005; Asplund et al. 2006a). These problems give rise to a large systematic uncertainty also for ^7Li . Until recently, deuterium was usually observed in the local interstellar medium. However, the situation has greatly improved in recent years. It became possible to observe ^2H absorption lines in quasar spectra (Tytler et al. 2000). Quasar light passes through clouds at high redshift, i.e., far away and at the same time far back in time, which contain (almost) primordial amounts of deuterium, ^2H . Because of the brightness of quasars such lines can still be identified although the photons have traveled a long distance. In summary, only upper limits can be given for primordial ^3He and the primordial values of ^4He and ^7Li have a smaller individual observational error compared to ^3He but a considerable systematic uncertainty in the observations. The averaged ^2H values from far objects seem to give the tightest constraint for Big Bang Nucleosynthesis (BBN) calculations (Steigman 2007).

The dependence of primordial abundances on Ω_b are shown in [Fig. 12.6](#). Using the available abundance information, it is found that it has to lie between about 0.038 and 0.048, also somewhat depending on the choice of the value of the Hubble constant (Schramm and Turner 1998; Burles et al. 2001; Steigman 2007). Most recently, an independent value for η_b was derived from the WMAP data of the CMBR (see Komatsu et al. 2009 for latest results). The CMBR value of $\eta_b = (6.11 \pm 0.2) \times 10^{-10}$ is in excellent agreement with the value derived from the BBN abundances for ^2H and ^3He . Depending on improvements in the observations and theoretical models of the evolution of ^4He and ^7Li with metallicity, their required η_b may or may not remain in agreement with the CMBR value. However, the BBN model still is in good standing when considering the CMBR data due to the large systematic uncertainties inherent in the observations of the latter isotopes (Steigman 2007).

Assuming only baryonic matter, the small value of $\Omega = \Omega_b$ would indicate an open Universe, i.e., one expanding forever. However, theory of inflation demands that $\Omega = 1$ (exactly) and thus a flat Universe (Kolb and Turner 1990; Peacock 1999). This is in agreement with the latest observations of the CMBR as discussed in [Sect. 12.2.1.2](#). Then the missing mass required to close the Universe must be nonbaryonic. Indeed, there are other indications (in the initial creation and later dynamics of galaxies) that there is more gravitational interaction than can be accounted for by standard baryonic matter. Of further interest is the value of the cosmological constant (see [Sect. 12.2.1.4](#)), which was found to be nonzero in recent distance measurements (Perlmutter et al. 1997; Schmidt et al. 1998; Perlmutter et al. 1999; Wood-Vasey et al. 2007; Riess et al. 2007), using type Ia supernovae as “standard candles” ([Sects. 12.2.1.4](#) and [12.5.3](#)). The cosmological constant Λ also provides a contribution Ω_Λ to the expansion of the Universe so that the new requirement reads $\Omega_M + \Omega_\Lambda = \Omega_b +$

$\Omega_s + \Omega_A = 1$, with Ω_s being the nonbaryonic contribution (Steigman et al. 2000). At the time of writing, it is not clear yet what constitutes the nonbaryonic mass. A quite general name for possible new, exotic particles is WIMP, an acronym for “weakly interacting massive particle” (see ► Sects. 12.2.1.3 and ► 12.2.1.4 for details).

12.4 Stellar Nucleosynthesis

12.4.1 Stellar Evolution

12.4.1.1 Birth of Stars

Stars are formed within molecular clouds, vast aggregations of molecules residing in the galactic disks. These clouds that often contain the mass of a million stars, are much denser and colder than the surrounding interstellar gas. Stars are born out of the collapse of small condensation areas that are scattered throughout the much larger volume of a molecular cloud. The collapse can occur due to random density fluctuations or be externally triggered, e.g., by shockwaves from supernovae or galaxy collisions. Soon after the collapse begins, a small pressure-supported protostar at the very center of the collapse flow develops. During the main collapse phase, the central protostar is surrounded by an inward flow of gas and dust. As the protostar evolves both the temperature and the density increase inside. Finally, the central core of the protostar heats up so much that nuclear “burning” is initiated and the star begins its energy production through nuclear fusion.

Star formation is a process complicated by the details of cloud fractionation, rotation, turbulence, and magnetic fields. While the formation of low-mass stars (below 8 solar masses) is thought to be understood and proceeding through an accretion disk, the mechanism to form more massive stars is not quite understood as well. Due to the larger radiation pressure of their emissions, the accretion disk would be blown away. The current model assumes, consistent with observations, the formation of a directed jet, transporting a small fraction of material but clearing a cavity through which most of the radiation can escape without interaction with the accretion disk (Bannerjee and Pudritz 2007). In this way, low-mass and high-mass stars could be formed in a similar manner. Other models assume coalescence of two or more light stars or competitive accretion of a low- and a high-mass star feeding from the same molecular cloud (Bonnell et al. 1997; Bonnell and Bate 2006).

The galactic mass distribution of the newborn stars is known as the initial mass function. To sustain nuclear burning in their interiors, stars must have at least 8% of the mass of the Sun. During their formation, stars with a smaller mass do not release sufficient gravitational binding energy to heat the gas to temperatures required for igniting nuclear fusion. These are called brown dwarfs. The lower-mass stars between about 8 and 40% of the mass of our Sun are called red dwarfs, because of their small size and their low surface temperature. At the other end of the mass range stars more than 100 times as massive as the Sun are highly unstable due to spontaneous pair production of electrons and positron from plasma interactions and therefore do not exist in our Universe. During their enormous life spans, stars produce energy through nuclear fusion and shine continuously over millions to billions of years. Lower-mass stars consume their fuel very quietly and survive for several billion years. Massive stars, on the other hand, burn out in a few millions of years.

12.4.1.2 Hertzsprung–Russell Diagram

Stars undergo drastic changes during their evolution. One of the best methods for charting the course of stellar evolution is the Hertzsprung–Russell (HR) diagram shown in ► Fig. 12.8, a particular type of graph developed in the early twentieth century by the astronomers Hertzsprung and Russell. In this diagram, the luminosity or energy output of a star is plotted on the vertical axis, and the surface temperature of the star on the horizontal axis. For historical reasons, the surface temperatures along the horizontal axis are plotted backward, so that they increase toward the left. In the HR diagram the various stars are then plotted according to their luminosity and surface temperature. As one can see, the stars are not distributed randomly in the HR diagram, but are rather grouped in certain areas.

Most of the stars line up along a well-defined band on the HR diagram known as the main sequence and are therefore also called main-sequence stars. This trend is no coincidence. Stars that lie along the main sequence have the proper internal configurations to support fusion of hydrogen to helium. Since stars spend most of their lifetime in this hydrogen burning state, most stars in the HR diagram are lying on the main-sequence band. Our Sun is also a typical main-sequence star.

After the hydrogen supply in the core of the star is exhausted and converted to helium, the central temperature is too low to fuse helium into heavier elements. Therefore, the core lacks an energy source and cannot support anymore the overlying bulk of the star. Through the gravitational pressure, the size of the core shrinks and the temperature of the central region

■ Fig. 12.8

The Hertzsprung–Russell (HR) diagram. In this schematic diagram, various stars are plotted according to their relative luminosity L/L_{\odot} (where L_{\odot} is the absolute luminosity of the Sun) and their surface temperature, T

increases accordingly. The heat released by the core increases steadily the luminosity of the star. Paradoxically, even though the helium core is shrinking, the radius of the star, determined by the outer hydrogen layer, increases by factors of 100 to 1,000. Through this expansion, the surface temperature drops by as much as 50% and the star becomes redder. Therefore, these stars are called red giants and are found in the HR diagram in the upper right corner.

When the core temperature of the red giant reaches about one hundred million degrees, a new sequence of nuclear reactions called helium burning begins in the core where helium nuclei fuse to carbon and oxygen. Our Sun has lived for 4.5 billion years and has already burnt half of its hydrogen in the core. After about another 5 billion years our Sun will also become a red giant and will thereby increase its size so much that the radius of the Sun will reach about the Earth's orbit.

The further evolution of a star and the nature of its stellar death depend on the initial mass. If the initial mass of a star is less than about 8 solar masses, it is burning He in an unstable way (see also [Sect. 12.4.3](#)) and the resulting pulsations lead to the loss of huge quantities of hot gases toward the end of its life. This cloud moving away from the star is called a planetary nebula. The central small and hot core of the star that is left over is a white dwarf and consists of the ashes of helium burning, i.e., carbon and oxygen. Even though the surface temperature of the white dwarf is still very hot its luminosity is small, because nuclear fusion has ceased. Therefore, the white dwarfs are found in the lower left corner of the HR diagram.

If the initial mass of a star is more than about 8 solar masses further burning phases will take place. These are called advanced burning phases and consist of carbon, neon, oxygen, and silicon burning, being named after the nuclei mainly destroyed in that phase. In these subsequent burning phases, heavier and heavier nuclei are built up, and the ashes of the preceding burning phases provide the fuel for the subsequent burning phases. However, in the outer and therefore cooler and less dense regions of the star the previous burning phases are still continuing. This leads to shell burning with distinct adjacent shells of different chemical compositions, in which different burning phases prevail. In the outermost shell of the star still hydrogen is burnt into helium (hydrogen burning), in the next shell helium to carbon and oxygen (helium burning), and finally, in the fully evolved star, there follow still carbon, oxygen, neon, and silicon burning shells ([Fig. 12.9](#)). In the core of the star significant amounts of iron are accumulating through silicon burning. A detailed discussion of the nuclear burning phases is given in [Sects. 12.4.2](#) through [12.4.4](#).

A detailed introduction to stellar evolution is given in the following books: Clayton ([1984](#)), Hansen and Kawaler ([1994](#)), Kippenhahn and Weigert ([1994](#)), Phillips ([1994](#)), Tayler ([1994](#)). Books and reviews discussing stellar nucleosynthesis are Rolfs and Rodney ([1988](#)), Arnett ([1996](#)), Thielemann et al. ([2001b](#)). Tables of nuclear reaction rates and cross sections can be found in Rauscher and Thielemann ([2000](#)).

12.4.1.3 Supernova Explosions

The endpoint in the evolution of stars with more than 8 solar masses is a type II supernova. One should not confuse novae with supernovae and even the two types (i.e., type I and type II) of supernovae are quite different. It will become evident in the following that the sites of these explosive events are only loosely related, despite the similarity in the name. There is a major difference in the underlying mechanism between type I (SN I) and type II supernovae (SN II). The confusing choice of names is, once again, historical. Astronomy is guided by observations

■ Fig. 12.9

Schematic structure of the different shells of a fully evolved massive star with their prominent constituents. At the bottom of each shell, different burning phases take place. The iron core in the center has been accumulated in silicon burning. The outer part of the star consists of a thick envelope of unburned hydrogen. Note that the relative thickness of the layers is not drawn to scale

and early astronomers did not have the equipment to investigate the objects in any detail. Obviously, even today, it is impossible to view the events in binary systems directly. Much more detail can be seen in light curves (i.e., brightness as a function of time) and spectra.

Historically, the comparatively frequent novae (see ▶ Sect. 12.5.2) were named first. Subsequently, much brighter eruptions of light were observed in the sky. Since they are brighter by more than a factor of 10^6 , they were appropriately termed supernovae. The light curve of a supernova is somewhat different from that of a nova: its rise time is only a few hours instead of days and it exponentially decays after having reached its peak. Closer investigations showed that several classes of supernovae can be found, according to features in their spectra: type I do not show hydrogen lines, whereas they are found in type II eruptions. This indicates whether the exploding object has an extended hydrogen envelope (such as massive stars). A more detailed classification scheme is shown in ▶ Table 12.2. Type Ia supernovae are further discussed in ▶ Sect. 12.5.3, while the unique scenario producing all other types (SN Ib,c; SN II) is shortly introduced in the following.

12.4.1.4 Core-Collapse Supernovae

When the stellar core becomes dominated by iron, the fusion into heavier elements does not lead to the release of energy, but rather requires absorption of energy. (See, e.g., ▶ Fig. 7.13 in Chap. 7, Vol. 1, showing the cross section of the stability valley of nuclei with iron at its lowest point.) Therefore, the core lacks an energy source and is unable to support itself against gravity anymore leading to a collapse of the star. In a single second the innermost regions are compressed to nuclear densities of about 10^{12} kg/m^3 and temperatures of about 10^{11} K . The iron nuclei, which have been synthesized just before in silicon burning are broken up again into protons and neutrons through the high-energy thermal radiation. The innermost regions are

■ **Table 12.2**

Supernova classification by observed properties. Different lines can be identified in the spectra. The assumed scenario causing the light burst is also given

Characteristic explosion energy (10^{44} J) and light curve				
No H lines			H lines	
Si lines	No Si lines		Exponential decay of light curve	Plateau feature in light curve
	He lines	No He lines		
White dwarf disruption	Core collapse (binary system?)	Core collapse (binary system?)	Core collapse	Core collapse
SN Ia	SN Ib	SN Ic	SN II L	SN II P

compressed so much that the core density becomes sufficiently high for electrons and protons to combine, producing neutrons and neutrinos. As the collapse continues, this giant ball of neutrons generally reaches a state of maximum density, and then bounces back. The bounce drives an extraordinarily powerful shock wave outward through the outer parts of the star. Investigations within the last 3 decades have made it clear that this prompt shock will not have enough energy to explode the remaining outer layers of the star. Only with the additional supply of energy through neutrino heating can the shock wave be supported to blow apart the star completely. This powerful explosion can explain supernovae of type II, but also of type Ib,c. At the center of the supernova explosion, the dense core of neutrons may be left behind as a neutron star. Alternatively, if the remaining core becomes heavier than a few solar masses through partial fallback of material, it can even collapse into a black hole. The dual explosion mechanism with prompt shock and delayed explosion by neutrinos is still not understood well. A proper treatment of the neutrino transport requires detailed three-dimensional hydrodynamic simulations, which are currently beyond the capability of modern computers and thus one has to refrain to approximations whose merits are debatable. For an overview, see, e.g., Janka et al. (2007).

The physics of the remaining compact objects after stellar death, e.g., white dwarfs, neutron stars, and black holes are discussed by Shapiro and Teukolsky (1983).

12.4.2 Hydrogen Burning: Proton–Proton Chain, CNO-Cycle

For nuclear reactions to take place in the interiors of stars, a temperature of at least 10 million degrees is necessary. This high temperature is needed because nuclei have positive charge and therefore repel each other through the Coulomb potential. The typical kinetic energy of nuclei in stellar interior range from between a few keV to a few 100 keV being much smaller than the typical height of a few MeV of the Coulomb barrier between reaction partners. Therefore, nuclear reactions in stars proceed mainly by barrier penetration exploiting the quantum mechanical tunnel effect. The cross sections decrease exponentially with the kinetic energies of the nuclei because of the decreasing penetration probability through the Coulomb barrier. The dependence on the relative kinetic energy E between interacting nuclei can be represented most simply by a formula in which a factor proportional to the inverse of the relative kinetic energy $1/E$ and the barrier penetration factor $G(E)$ is factored out from the cross

section: $\sigma(E) = (1/E) G(E) S(E)$. This leaves a function $S(E)$ called the astrophysical S -factor that varies smoothly with the kinetic energy E of the interacting nuclei in the absence of resonances. Neutron-induced reactions would not have to overcome the Coulomb barrier. However, neutrons are not very abundant in stellar interiors. They still play a major role for the nucleosynthesis of heavy nuclei through the so-called s - and r -processes, to be discussed in [Sect. 12.4.5](#).

The reaction rate, expressed as the number of reactions per volume and per time, is proportional to the astrophysical S -factor. At the temperatures and densities relevant to the stellar environments the interacting nuclei have a Maxwell distribution of speeds. This distribution has also to be taken into account when determining the reaction rate. An introduction to astrophysical S -factors and reaction rates can be found in many textbooks on nuclear astrophysics, e.g., Arnett (1996), Rolfs and Rodney (1988), Iliadis (2007), Boyd (2008).

Nuclear burning in late hydrostatic phases (see, e.g., silicon burning) and in different explosive scenarios proceeds at high temperatures and densities. This leads to equilibrium between forward and reverse reactions, e.g., capture and photodisintegration. It gives rise to equilibrium abundances depending only on the supply of free neutrons and protons and on certain nuclear properties. High temperatures favor the creation of light nuclei because photodisintegration processes dominate. High densities lead to heavy nuclei, and intermediate conditions yield the highest abundances for nuclei with high binding energies. Such an equilibrium can be established within a group of nuclear species where individual reactions link different groups. This is called quasi-statistical equilibrium (QSE). The full nuclear statistical equilibrium (NSE) is reached when all nuclei are equilibrated.

In the following, the different burning stages will be described one by one, starting with hydrogen burning, being the first burning stage of every star.

In hydrogen burning, occurring in the cores of main-sequence stars like our Sun, ordinary hydrogen nuclei (i.e., protons) are burnt through a chain or cycle of nuclear reactions into ^4He nuclei. In this stellar plasma there are two processes burning hydrogen: the proton–proton chain (pp-chain) ([Fig. 12.10](#)) and the carbon, nitrogen, and oxygen (CNO)-cycle ([Fig. 12.11](#)).

The pp-chain proceeds through a sequence of two-body reactions. The first reaction in the pp-chain is the exothermic fusion of two protons p into the deuteron d consisting of a proton p and a neutron n through the reaction

For this reaction to take place a proton p must be converted into a neutron n through $p \rightarrow n + e^+ + \nu$, releasing a positron e^+ and a neutrino ν . Such a conversion can only proceed through the weak interaction (see [Sect. 12.3.1](#)). Therefore, the rate of the reaction in [Eq. \(12.2\)](#) is very low, which makes the reaction the bottleneck of the pp-chain.

Once the deuteron d is formed, it very rapidly undergoes the reaction

There are two alternatives for the next step, leading to a branching of the pp-chain into the ppI- and ppII-chain. In the ppI-chain, occurring in 86% of the cases, two ${}^3\text{He}$ nuclei fuse to a final ${}^4\text{He}$ nucleus while two protons are released:

Fig. 12.10

The proton–proton chain of hydrogen burning

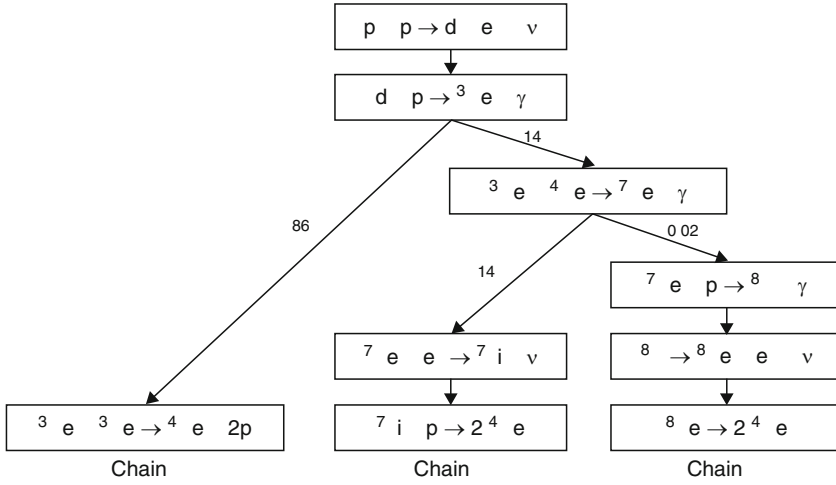

Fig. 12.11

The carbon, nitrogen, and oxygen (CNO)-cycle of hydrogen burning

In the ppII-chain, occurring in 14% of the cases, a ^3He nucleus fuses with a ^4He nucleus creating a ^7Be nucleus and thereby releasing a photon, γ :

In almost all cases, this reaction is followed by the capture of an electron and emission of a neutrino ν , thereby converting a ^7Be nucleus into ^7Li . This is followed by the capture of another proton, creating two ^4He nuclei:

Another branching into the ppIII-chain occurs in a very small percentage of cases with a total probability of only 0.02%. In this chain, reaction (12.5) is followed by the following sequence of reactions:

The net reaction of all three pp-chains

leads to a transformation of four protons into a ^4He nucleus releasing two positrons e^+ , two neutrinos ν and a total energy of 26.73 MeV. A fraction of this energy is carried away by the neutrinos, which leave the star practically unhindered due to their negligible interaction with the solar material.

Fusion of hydrogen into helium may also be achieved through another sequence called CNO-cycle (Fig. 12.11), which is notably different from the pp-chain:

In this sequence the C, N, and O nuclei only act as “catalysts” and the net reaction of the CNO-cycle is again given by Eq. (12.8).

For main-sequence stars lighter than about 2 solar masses, the pp-chain dominates in hydrogen burning, whereas the CNO-cycle is favored over the pp-chain in stars that are more than twice as massive as the Sun.

In our Sun the pp-chain dominates over the CNO-cycle, producing about 98% of the total energy. A prerequisite for CNO-cycles is, of course, the existence of the elements C, N, O in the stellar plasma. Stars formed early in the Galaxy (first-generation stars) contain only primordial elements and thus are not able to burn hydrogen through a CNO-cycle at all.

The Sun’s temperature in the core is about 1.5×10^7 K, whereas the surface temperature is only about 5,600 K. The Sun has already lived for 4.6 billion years, and will have enough hydrogen supply to live for about another 5 billion years. This leads to a long lifetime of about 10 billion years before its fuel is exhausted.

How can information be obtained from the Sun's core, where hydrogen burning takes place? The photons reaching us from the Sun are emitted from the solar surface. They have changed their energy enormously by many scattering processes on their way from the hot solar core to the relatively cool surface of the Sun. Therefore, in the visible region only the solar surface and not the solar interior can be observed. One possibility to obtain information about the Sun's core is helioseismology, i.e., by observing the vibration modes of the Sun. It was confirmed through helioseismology that our standard solar model is correct (Fiorentini and Ricci 2000; Bahcall et al. 2001a; Christensen-Dalsgaard 2001).

Another possibility is to observe the neutrinos that are set free in nuclear reactions of the pp-chain and CNO-cycle and reach the surface practically unhindered. Presently four neutrino detectors measuring solar neutrinos exist: HOMESTAKE (USA), GALLEX (Italy), (SUPER) KAMIOKANDÉ (Japan), and SNO (Canada). All these neutrino detectors are underground in order to shield out the cosmic rays that would give unwanted background signals in the neutrino detectors. The existing solar neutrino detectors measure only about 1/3 to 1/2 of the electron neutrino flux compared to the value calculated from the standard solar model (Bahcall 2000). This discrepancy is called the solar neutrino problem (Bahcall 1989, 1999). Possible problems both with the neutrino measurements and with our standard solar model have been ruled out. Recently, at SNO it was possible to observe not only the solar electron neutrinos, but also the μ - and τ -neutrinos in the same experiment (Heger 2001; SNO Collaboration et al. 2002a, b). The measured total neutrino flux agrees with the value expected from the standard solar model. The solution to the solar neutrino problem implies some new physics by the introduction of the so-called neutrino oscillations (see [Sect. 10.8.2 in Chap. 10, Vol. 1](#)). Through such oscillations, the electron neutrinos ν emitted in the solar core by the nuclear reactions given in [Eqs. \(12.2\)](#), [\(12.6\)](#), and [\(12.7\)](#) can change into other types of neutrinos. Thus, mainly μ -neutrinos emerge on their way from the core of the Sun to the detector. Experiments measuring electron neutrinos thus show a smaller flux than initially emitted in the solar core (Bahcall 2001; Bahcall et al. 2001b; Fiorentini et al. 2001). This physical picture is the culmination of about 40 years of solar neutrino detection and research.

Recently, these findings have been combined with the results of the so-called atmospheric neutrino anomaly, where μ -neutrinos generated in pion decays oscillate over into, mainly, τ -neutrinos. In addition, terrestrial experiments performed with neutrino fluxes (produced either at nuclear power plants or with accelerators) provide substantial information on the mixing pattern among the different neutrino species. Searches for possible oscillations into further light neutrino flavors, which would be of clear cosmological significance, have not yet provided a clear answer to the question of their existence. (See [Sect. 10.8.2 in Chap. 10, Vol. 1](#))

12.4.3 Helium Burning: Nucleosynthesis of Carbon and Oxygen

The fusion of protons into helium continues until the star has exhausted its hydrogen. When this happens, the star undergoes a gravitational collapse and the temperature rises to about a few times 10^8 K in the core of the star, which makes the fusion of helium into heavier nuclei possible. In the first reaction of helium burning, the fusion of two ^4He nuclei creates the ^8Be nucleus. However, the ^8Be nucleus has an extremely short mean life of only 10^{-16} s, before it

decays back again to two ${}^4\text{He}$ nuclei. This process is in equilibrium, where the rate of production equals the rate of destruction of the ${}^8\text{Be}$ nucleus:

The ${}^8\text{Be}$ just produced can, however, capture another ${}^4\text{He}$ nucleus creating the ${}^{12}\text{C}$ nucleus through the reaction

The reactions (12.10) and (12.11) are called the triple- α reaction, because three ${}^4\text{He}$ nuclei or α particles are necessary for the creation of ${}^{12}\text{C}$. This reaction can only create carbon in appreciable amounts because of the existence of a resonance in ${}^{12}\text{C}$ at the relevant energy for helium burning. Through this resonance, reaction (12.11) is enhanced by many orders of magnitude.

In helium burning, about half of the carbon nuclei produced are converted to oxygen nuclei ${}^{16}\text{O}$ by the capture of another ${}^4\text{He}$ nucleus:

Further captures of helium nuclei ${}^4\text{He}$ by oxygen nuclei ${}^{16}\text{O}$ occur only to a much lesser extent and therefore helium burning comes to an end after the creation of ${}^{12}\text{C}$ and ${}^{16}\text{O}$.

Carbon and oxygen are the two most important elements for carbon-based life. Carbon is needed for the complex nuclei of the DNA and proteins, whereas oxygen is needed even for water. Interestingly enough, these two elements are extremely fine-tuned with respect to the nuclear force. If the strength of this force were 0.5% larger or smaller, the average abundance of carbon or oxygen in our Universe would be reduced by more than two orders of magnitude. This would make the existence of carbon-based life in our Universe very improbable (Oberhummer et al. 2000; Schlattl et al. 2004).

Outside the stellar core burning helium, hydrogen burning continues in a shell around the core. If the initial mass of a star is less than about 8 solar masses no more burning phases will take place after helium burning and nuclear burning stops. A white dwarf with a surrounding expanding planetary nebula will be the endpoint of the star's life. Charbonnel et al. (1999) and Marigo (2001) review the chemical yields in light and intermediate-mass stars between 0.8 and 8 solar masses.

Two interesting effects happen in helium burning of low-mass stars. Firstly, stars with less than about 2 solar masses undergo a core He flash instead of igniting stable He burning after the H burning phase. This is because the cores of lower-mass stars are more dense than those of higher-mass stars. For stars with less than about 2 solar masses, the contracted He core is so dense that it cannot be described as an ideal gas. Rather, it is a degenerate gas, in which pressure is only depending on density but not on temperature. Once the triple- α reaction, being very efficient at high density, is ignited, a thermonuclear runaway ensues because the rising temperature does not raise the pressure and therefore does not cause an expansion of the burning zone. Thus, the usual self-regulation mechanism of hydrostatic burning is not working anymore and He burning proceeds quickly to high temperature. Very high temperatures lift the degeneracy of the gas and its equation-of-state becomes temperature dependent again very suddenly. This causes an explosive expansion of the outer core, also ejecting the outer layers of the star as a planetary nebula.

The second phenomenon occurs in stars between 2 and 8 solar masses, the so-called Asymptotic Giant Branch (AGB) stars. Regular He burning takes place in the core of these stars in their red giant phase. With the exhaustion of He in the center of the star, the burning zone moves outward and becomes a burning shell. Thus, there are two shells burning, a H-burning shell and a He-burning shell. The He-burning shell is very thin and does not generate sufficient energy to balance the mass layers on top of it through radiation pressure. This squashes the shell more and more. Because of the nonlinear dependence on density of the triple- α rate, which is actually two reactions one after another, the energy release will considerably increase but still not be enough to expand and self-regulate the shell against the pressure from the surrounding layers. Further contraction enhances the triple- α rate nonlinearly and so on. Although the gas is not degenerate, a similar thermonuclear runaway as in the degenerate case occurs. When a critical temperature is reached, enough energy is released to expand the shell explosively against its surroundings. This rapid expansion, the He-shell flash, is so strong that it also blows out the H-burning shell. Due to the expansion, the density drops and the triple- α reaction ceases. Quickly, the star contracts again, the outer material settles, and first the H-burning shell and then the He-burning shell is ignited again. This sets the stage for another such cycle. AGB stars undergo a large number of such pulses, where the thermonuclear runaway phase with the flash lasts only a few hundred years whereas the time between pulses is a hundred to a thousand times longer. Oscillations and vibrations are induced into the stellar plasma by these pulses, leading to increased mass loss from the surface of the star. AGB stars have strong stellar winds, which considerably decrease their total mass during their evolution. The shell flashes have another important impact: they cause large convection zones, mixing the plasma constituents across large distances within the star. This is important for the production of the s-process nuclei (see [Sect. 12.4.5.1](#)).

He-shell flashes only occur in low-mass stars because they are caused by thin He-burning shells and the size of the shells scale with the stellar mass.

12.4.4 Advanced Burning Stages

In a massive star with more than 8 solar masses, the next stage after helium burning is carbon burning. This starts when the carbon/oxygen core has shrunk so that the temperature at its center has reached about 5×10^8 K. Then two carbon nuclei fuse together creating ^{20}Ne or ^{23}Na nuclei:

The next stage is neon burning starting at 10^9 K, in which photons first disintegrate ^{20}Ne and liberate ^4He , which in turn reacts with the undissociated ^{20}Ne to build up ^{24}Mg and further nuclei:

Oxygen burning occurs when the temperature reaches 2×10^9 K, the most important reaction being the one producing ^{28}Si :

The final stage is reached at a temperature of 5×10^9 K, when silicon burning begins. At this high temperature, a series of reactions takes place beginning with the photodisintegration of ^{28}Si :

Then the released ^4He nuclei build up heavier nuclei by successive capture reactions

and so on. At such high temperatures, capture and photodisintegration reactions are in equilibrium. In this so-called nuclear statistical equilibrium (NSE) the knowledge of individual reactions or reaction rates is not important anymore to calculate the abundances. The produced abundances only depend on the temperature and density of the plasma and the nuclear binding energies (Iliadis 2007; Boyd 2008). The result of this series of photodisintegration and capture reactions is the steady buildup of heavier elements up to the elements grouped around iron (Hix and Thielemann 1998), with ^{56}Ni preferentially produced because it is the nucleus with the highest binding energy and having equal number of protons and neutrons.

The sequence of stellar burning is terminated when the core of the star is largely composed of elements in the mass region of nickel and iron, because no more energy is to be gained from further nuclear reactions. As soon as the energy produced is not enough to maintain the hydrostatic equilibrium, the core cannot support the outer layers anymore, and it begins to collapse due to its gravitation, leading to a core-collapse supernova (see [Sect. 12.4.1.3](#)).

In a core-collapse supernova explosive nucleosynthesis also takes place through the outward proceeding shock wave (Thielemann et al. 2001a), modifying the elemental abundance pattern of the outer layers of the pre-supernova star. This explosive burning of the C-, Ne-, O-, and Si-layers in the star mainly leads to modifications of the abundances in the region from Ca to Fe (Rauscher et al. 2002). Photodisintegration of heavy nuclei also leads to the production of proton-rich stable nuclides, the so-called p-nuclides (see also [Sect. 12.4.5.2](#)). The strong neutrino emission caused by the formation of a neutron star in the core collapse influences nucleosynthesis in the deepest, barely ejected layers of the star as well as in the outer layers ([Sects. 12.4.5.2 and 12.4.5.3](#)).

Nucleosynthesis of massive stars is reviewed by Rauscher et al. (2002), Woosley and Heger (2007). An overview of stellar nucleosynthesis including hydrogen, helium, neon, silicon, and explosive burning as well as the basics of the s- and r-process are given by Rauscher and Thielemann (2001). Explosive burning and the s- and r-processes are also introduced below.

12.4.5 Nucleosynthesis Beyond Fe

As it has been seen in the preceding sections, stellar burning phases only lead to the production of nuclei up to Fe. A review by National Research Council of the National Academies identified 11 key questions to be addressed in science in the next decade (Turner et al. 2003). Ranked three on the list is “How were the elements from Fe to U produced?” Although the ground to answer this question has been laid by Burbidge et al. (1957), Cameron (1957) and much progress has

been made since then, there remain a number of problems regarding the astrophysical sites of certain nucleosynthesis processes and also concerning the properties of certain, highly unstable nuclei in such processes. In the following subsections, a brief summary is given of the current knowledge of how elements beyond Fe were synthesized.

12.4.5.1 The Main and Weak s-Process Components

Due to the lack of a Coulomb barrier, the most likely process for the formation of elements heavier than those grouped around iron is neutron capture. If a supply of neutrons is available, they can accrete by sequential neutron captures on a “seed nucleus” in the region of iron to build up neutron-rich nuclei. As the neutron number of the nucleus increases, it will become unstable to β^- decay, transforming a neutron into a proton in the nucleus, and emitting an electron and an antineutrino. Successive neutron captures, interspersed by β^- decays build up many, but not all of the heavier stable nuclei.

There are two basic timescales in this scenario of heavy-element nucleosynthesis by neutron captures: (1) the β -decay lifetimes, and (2) the time intervals between successive captures that are inversely proportional to the neutron capture reaction rates and the neutron flux. If the rate of neutron capture is slow compared to the relevant β decays, the synthesis path will follow the bottom of the stability valley very closely. On the other hand, if the rate of neutron capture is faster than the relevant β^- decays, highly neutron-rich nuclei will be formed. After the neutron flux has ceased, those nuclei will be transformed to stable nuclei by a series of β^- decays. The above two processes are called s- and r-process, respectively, according to their slow or rapid rate of neutron capture. The observed abundances of nuclei in the solar system, especially in the regions of closed-shell nuclei, suggest that the s- and r-processes contributed more or less equally to the formation of the elements above the iron region (see [Fig. 12.12](#)).

Two important reactions provide neutrons for the s-process:

The reaction on ${}^{13}\text{C}$ is much more efficient in releasing neutrons because it is strongly exothermic, as opposed to the second reaction. However, ${}^{13}\text{C}$ normally does not occur in He-burning zones whereas ${}^{22}\text{Ne}$ does. This proved to be a longstanding problem in complete stellar simulations of s-process nucleosynthesis.

Early observations (see Burbidge et al. 1957) had already found Tc on the surface of AGB stars. Since Tc isotopes are short lived compared to the age of such a star, they had to be produced in that star and brought up to the surface. Only in recent years, sophisticated stellar models were able to follow the complicated convection and nucleosynthesis processes inside AGB stars with sufficient accuracy to confirm them as the production sites. He-shell flashes (see [Sect. 12.4.3](#)) and the mixing brought about by them turned out to be the key (Busso et al. 2001; Boothroyd 2006). Such a flash can mix down protons from the unburnt outer layer of the star, which can then be used to produce ${}^{13}\text{C}$ by proton capture on ${}^{12}\text{C}$ and subsequent β -decay of the resulting ${}^{13}\text{N}$. With this ${}^{13}\text{C}$ neutrons can be very sufficiently released even during the interpulse phase. Additionally, the reaction on ${}^{22}\text{Ne}$ can release further neutrons during the high temperature phase of the flash itself. Thus, the nuclides in the stellar plasma are irradiated with neutrons in bursts over millennia. The large convection zones appearing in the flash phase bring up the newly synthesized material to the surface.

■ Fig. 12.12

Contribution of s- and r-process to the solar abundances of the isobars for heavy elements (p-isotopes cannot be seen in this figure because of their very small abundances). Solar system abundances are measured (Anders and Grevesse 1989), s- and r-abundances are calculated. The peaks in the solar abundances around mass numbers $A = 88, 138, 208$ are formed in the s-process, whereas the broader companion peaks shifted to slightly lower mass number are r-process peaks

In the manner described above, AGB stars produce the majority of the s-process nuclei, the so-called main component. It was known for a long time that there must be a second site of s-processing, producing light s-nuclei. Because they exhibit smaller abundances than those of the main component, this was called the weak component. Such a weak s-process is found in massive stars (i.e., stars with more than 8 solar masses), where capture of ^4He by ^{22}Ne is the main neutron source. Massive stars reach higher temperatures than AGB stars already in their late evolution stages, which help to release neutrons. Even more neutrons can be released during explosive burning, when the temperature rises due to the supernova shock wave passing through the outer layers of the star. Because of the inefficiency of the ^{22}Ne neutron release and the short timescale, this mechanism cannot proceed much beyond Fe in massive stars.

For nucleosynthesis of the heavy elements through the s-process in both AGB and massive stars, there already must be nuclei present in the iron region, which were produced in previous generations of stars. Thus, the s-process will be stronger in stars formed more recently than in older stars containing less heavy elements.

12.4.5.2 Explosive Nucleosynthesis in the Outer Layers of a Massive Star

Since the buildup of nuclei in the s- (and r-) process follows the neutron-rich side of the stability valley (see, e.g., ► Fig. 7.13 in Chap. 7, Vol. 1), 32 proton-rich isotopes cannot be produced in either process. These so-called p-nuclides occur naturally but with abundances many orders of magnitude lower than the other nuclides. The hypothetical process synthesizing these nuclides was termed p-process and several models have been suggested. The commonly favored one is photodisintegration of preexisting nuclei in the Ne/O shells of massive stars. When a supernova shockfront is passing through these layers, the high temperatures of 2–4 GK enable photodisintegration, starting with γ -induced emission of several neutrons, leading to proton-rich nuclei. The photodisintegration path can branch when proton or α emission becomes more favorable than neutron emission in such proton-rich nuclei. The bulk of p-nuclides can be explained in such a model but some problems remain (Rauscher et al. 2002; Arnould and Goriely 2003; Boyd 2008). Especially the production of the light p-isotopes, in particular $^{92,94}\text{Mo}$ and $^{96,98}\text{Ru}$, is not understood. Among the p-nuclei they have by far the highest abundance but cannot be produced concurrently with the others. It remains an open question whether the stellar models have to be revised or an additional production mechanism has to be invoked for these light p-nuclei.

The neutrino flux of a core-collapse supernova is high enough to contribute to the nucleosynthesis of certain rare elements and isotopes, even in the outer layers of the star. In this so-called ν -process, inelastic scattering of a neutrino leads to formation of an excited daughter nuclide, which then decays by particle emission. This process can contribute significantly to the production of light (^{11}B , ^{19}F) and heavy (^{138}La , ^{180}Ta) nuclides (Woosley and Weaver 1995; Heger et al. 2005).

12.4.5.3 Explosive Burning in the Deep Layers of a Massive Star

In addition to s-process nucleosynthesis, about half of the nuclides beyond Fe are produced through rapid neutron captures on short timescales in the r-process. The site of the r-process is controversial. Mostly favored are core-collapse supernovae where appropriate r-process conditions are thought to be found close to the region of neutron star formation. These innermost layers, which are barely ejected, move outward within a strong neutrino flux, driving the material to become very neutron rich. With a high neutron density, neutron captures can proceed much faster than β -decays and produce very neutron-rich nuclei far from stability. Through simultaneously occurring captures, photodisintegrations with neutron emission, and β -decays, heavier elements are synthesized within a few seconds. When the ejected material cools down, those highly unstable nuclei decay back to stability, thus supplying the needed fraction of heavy elements. While the s-process is confined to the region up to Bi, the r-process is thought to also reach the region of fissionable nuclei and produce natural, long-lived elements such as U. The endpoint of the r-process path is highly debated since it depends on fission barriers of very neutron-rich, heavy nuclei, for which there is no consensus among theoretical models yet.

The conditions in those innermost regions of a core-collapse supernova are closely linked to the working of the explosion mechanism. Since the latter is not yet fully understood, it is not yet clear whether the required conditions can actually be established. Therefore, a number of alternative scenarios are still discussed, such as jet outflows from asymmetrically exploding stars. The search for the site of the r-process remains a major focus of research.

Recently, an additional nucleosynthesis process in the deep layers of the exploding star has been suggested (Fröhlich et al. 2006). It was discovered that the combined flux of neutrinos and antineutrinos from the emerging, hot neutron star initially creates very proton-rich conditions before the matter becomes neutron rich at later times and/or larger radii. The high temperature and density environment gives rise to rapid proton captures, thus synthesizing nuclei beyond Fe but on the proton-rich side of stability. A small number of neutrons are required to speed up the matter flow to heavier elements and these are produced by antineutrino captures on protons. The vp-process could perhaps explain the surprisingly high abundance of Sr, Y, and Zr found in very old stars (Travaglio et al. 2004; Frebel et al. 2005). Again, the details of this so-called vp-process (including the question of how efficiently it can produce elements beyond Fe) depend strongly on the conditions in the deep layers of the exploding star and the explosion mechanism. Among the suggested alternative scenarios are wind outflows from the accretion disks around black holes formed by core collapse of very massive stars (Surman et al. 2006). These are also thought to be the cause of so-called γ -ray bursts, which are the most energetic phenomena observed in our Universe today (MacFadyan and Woosley 1999; Mészáros 2006).

12.4.6 Nucleosynthesis by Spallation

The light and fragile elements lithium, beryllium, and boron (LiBeB) are not primarily produced in primordial or stellar nucleosynthesis. In fact, the abundance curve in [Fig. 12.13](#) shows a huge dip (almost a gap, actually) for the mass numbers 8–11, reflecting the scarcity of LiBeB-nuclei in the solar system. Only the nuclide ${}^7\text{Li}$ can be produced both in primordial (see [Sect. 12.3](#)) and in stellar nucleosynthesis (see [Sect. 12.4.2](#)), whereas the nuclides ${}^6\text{Li}$, ${}^9\text{Be}$, ${}^{10}\text{B}$, and ${}^{11}\text{B}$ are almost pure spallation products of heavier elements.

The high-energetic galactic cosmic rays (GCRs) originate probably from supernovae (Erlykin and Wolfendale 2001). GCRs consist mainly of fast-moving bare hydrogen and helium nuclei and, to a lesser amount, of carbon, nitrogen, and oxygen nuclei (CNO)-nuclei. Hydrogen and helium nuclei of interstellar clouds can spall the CNO-nuclei in flight of the fast GCRs. Therefore, the GCRs are by about a million times enriched in LiBeB-nuclei compared to the solar system abundance.

The most plausible origin of the main bulk of LiBeB-nuclei is that hydrogen and helium nuclei of GCRs hit and spall CNO-nuclei contained in interstellar clouds. However, this process alone seems unable to produce LiBeB at the observed level. Therefore, another production site of LiBeB-nuclei has been proposed. This invokes in-flight fragmentation of carbon and oxygen nuclei by collision with hydrogen and helium nuclei in interstellar clouds. The sites of this process are mainly the surroundings of massive stars, which are able to furnish freshly synthesized carbon and oxygen nuclei and accelerate them via shock waves. Finally, spallation through neutrinos in supernova explosions also produces the nuclides ${}^7\text{Li}$ and ${}^{11}\text{B}$ (Hartmann et al. 1999).

A review of nucleosynthesis by spallation is given by Vangioni-Flam et al. (2000).

12.5 Nucleosynthesis in Binary Star Systems

12.5.1 General Considerations

Observations reveal that more than half of the known stars are associated in binary or multiple systems. In many such systems, the stars are so well separated that there is negligible influence

■ Fig. 12.13

Relative solar abundances by mass number. Data are from Anders and Grevesse (1989). The abundances are arbitrarily renormalized to yield a value of 10^6 for silicon

on each other's evolution. However, when the constituents of such a system are close, a range of interesting physical phenomena can ensue. Mass can be transferred from one star to the other when the donating star becomes so large that its atmosphere extends beyond the limiting region where the gravitational attraction of the two stars is equal. Material is then escaping from the gravitational well of the donor and flowing into the attractive field of the other object. It can be shown that there is a single point of gravitational equilibrium between the two objects, through which the mass transfer will occur. The volume around a star enclosed by the equipotential surface containing this point is called the Roche lobe. A star can fill or exceed its Roche lobe when it either increases its radius in the normal course of evolution (e.g., by becoming a Red Giant), or when the orbital separation of the two objects is decreasing due to the emission of gravitational waves. The latter situation corresponds to shrinking their respective Roche lobes. The inflow onto the surface of the companion can alter its surface properties, which is manifested, for instance, in the observed spectra. The further evolution might even lead to powerful explosions. A broad review of such phenomena is given by Warner (1995).

From the point of view of nucleosynthesis, explosive burning in such binary systems proves to be especially important as nuclides created in such an environment can be injected into the interstellar medium by the explosion. Furthermore, the nucleosynthetic signature will be different from stellar hydrostatic and explosive scenarios due to the different initial and burning conditions. Thus, different isotopic ratios can be obtained and, in some cases, it is possible to synthesize nuclides not accessible in other sites. In the following, therefore the main focus is put on outlining only such scenarios, which might have an impact on the abundances

of elements observed in our Galaxy and the Universe. It has to be emphasized, however, that it is not yet possible to model all details of the explosive processes, due to the complexity of a multidimensional hydrodynamic problem including scales differing by many orders of magnitude. The problems are similar to those occurring in core-collapse supernova models. In scenarios where neutron stars are involved, additional uncertainties in the nuclear equation of state enter. As a result, a detailed, quantitative understanding of some of the processes is still lacking. Nevertheless, the basic features of all the processes can be described qualitatively in simplified models.

12.5.2 Novae

Historically, the Nova phenomenon is one of the oldest observed. Already astronomers of ancient civilizations were aware of sudden appearances of bright stars in the sky, at a position where no star had been observed before. This was termed “nova” as in “new star.” Modern astronomy was able to identify nova progenitors. These are faint stars (mostly undetectable by the naked eye), which suddenly increase their brightness by several stellar magnitudes (i.e., their energy output increases by a factor of 100–100,000) within a few days. The star returns to its initial brightness after several months. In rare cases, the same star experiences another nova outburst within several years. This is called a recurring nova. In general, classical novae reappear only every 100 to 10,000 years.

The modern explanation of the Nova phenomenon invokes a binary system with a regular star in its early burning phases and a white dwarf (Fujimoto 1982; Truran 1984; Gehrz et al. 1998; Starrfield 1999). The latter is too faint to be directly observed. Such a system can have originated from two low-mass stars, one of them slightly more massive than the other. More massive stars evolve faster and thus the heavier star already underwent its complete stellar evolution and left a white dwarf as a remnant, while the other star has not yet even completed its early phases. From the atmosphere of the main sequence or red giant star, hydrogen-rich material is flowing across the Roche surface. It is captured by the gravitation of the white dwarf forming an accretion disk around it. Subsequently, the gas is accreted on the surface of the companion, forming a thin layer. Close to the surface, the gas becomes degenerate, delaying the onset of hydrogen burning. As soon as the necessary density and temperature is reached, hydrogen burning ignites explosively, pushing outward and ejecting part of the outer accreted layer. With the sudden expansion, temperature and density are dropping again and the burning ceases. It can reoccur as soon as a sufficient amount of new material has been accreted, which usually takes several thousand years at typical accretion rates of less than 1 Earth mass per 10 years.

In terms of nucleosynthesis it should be obvious that nova ejecta are mainly hydrogen and that they more or less retain the surface composition of the accompanying star. However, it was found observationally that they are also strongly enriched in C, N, and O. This has been a puzzle for over 2 decades (Rosner et al. 2001). In the thermonuclear runaway triggered by hydrogen ignition the main reaction sequences are those of the CNO-cycles. However, they can account neither for the observed enrichment nor for the energy production required for a fast nova burst. Currently, it is thought that material from the surface of the white dwarf might be dredged up and efficiently mixed into the burning layer and the outer zones. This would increase the CNO energy production and also provide a mechanism for the enrichment. However, to date one-dimensional and multidimensional simulations have not been able to account for the observations (Starrfield et al. 2000; Kercek et al. 1999). Nevertheless, it seems

that novae are “digging up the ashes” of previous stars and distributing them throughout the Galaxy. They are considered to be the major sources of ^{15}N , ^{17}O , and ^{13}C , and to have minor contributions to a number of additional species, mainly ^7Li and ^{26}Al . For current reviews on the nucleosynthetic contribution of novae, see Jordi and Hernanz (2007, 2008).

12.5.3 Type Ia Supernovae

Given a binary system consisting of a white dwarf and a companion star as in the nova case, the accretion rate on the surface of the white dwarf is essential for further development. Low accretion rates lead to a nova as described above. When the accretion rate exceeds about 10^{-8} solar masses per year, hydrogen can be quiescently burned during accretion and the burning products will sediment on the surface of the white dwarf, forming a He layer. The details on the further fate of the object are complicated and have not been fully simulated yet. Basically, two ways of explosion can be envisioned. In the first, the ignition of the He layer leads to a thermonuclear runaway, this time mainly burning via the triple- α reaction, not depending on CNO elements, contrary to novae. Nevertheless, the resulting explosion would lead to an expulsion of the outer layers, like in a nova, only much more powerful. The second type of explosion occurs when the accretion rate is even higher, about 10^{-6} solar masses per year. The energy released by the accretion and by burning layers heats the C/O core of the white dwarf sufficiently to ignite core C burning. This is followed by a complete disruption of the white dwarf because the nuclear energy exceeds the gravitational binding energy (Leibundgut 2001a, b).

The latter is the currently most widely accepted scenario explaining SN Ia (Nomoto et al. 1984; Hillebrandt and Niemeyer 2000). It is encouraging that observations can confirm also the basic nucleosynthesis features expected. In each explosive event, a quantity of material of the order of 0.6–0.8 solar masses is produced in the ^{56}Ni region, which later decays to its stable isobars. Thus, the larger part of the Fe found in the solar system stems from SN Ia. In addition, some intermediate elements like Mg, Si, S, and Ca are also produced.

The details of the shockwave propagation and explosive burning are not fully understood yet. However, the total energy production remains robust due to the fact that the initial white dwarf mass is always close to the Chandrasekhar limit of 1.4 solar masses. This fact, in combination with the observational evidence that there are no compact central objects (i.e., neutron stars) found in SN Ia remnants, puts a strong constraint on the achieved explosion energy. This is why type Ia supernovae are thought to be excellent standard candles with very low variation in the effective energy output (Dominguez et al. 2001; Leibundgut 2001a, b). Type Ia supernovae as standard candles are important tools to measure astronomical distances although there is no firm theoretical grounding of the Phillips relation (see ► Sect. 12.2.1.4) yet.

12.5.4 X-ray Bursts and the rp-Process

Bursts have been observed not only in the optically visible frequency range of light. Powerful, brief bursts of X-rays are also observed throughout the Galaxy. A binary system is suggested to be responsible for one subclass of these bursts. Their duration is from several seconds up to minutes and they show a fast rise and a slowly decaying tail. In the assumed scenario, a main-sequence star and a neutron star are orbiting the common center of mass. As in the nova and SN Ia case, material is flowing from the atmosphere of the companion star and is accreted on

the surface of the compact object. Due to the increased gravitational field of the neutron star in comparison with a white dwarf, the thermonuclear runaway after ignition of hydrogen burning can proceed differently from the one in novae and supernovae (Taam et al. 1996; Schatz et al. 1998; Wiescher and Schatz 2000; Boyd 2008). Hydrogen and subsequently also helium, burn explosively at higher temperatures as before. First, the so-called hot CNO-cycle (also found in certain massive stars) is established, followed by further CNO-type cycles beyond Ne. The energy production from these cycles leads to a breakout to further CNO-type cycles beyond Ne at temperatures surpassing 4×10^8 K. The additional cycles generate additional energy, further increasing the temperature. In the next stage of the ignition process, He is also burned in the triple- α reaction. The CNO-type cycles break up toward more proton-rich nuclides by (α , p) and (p, γ) reactions.

Finally, the rp-process (rapid proton capture) sets in. In the rp-process, similar to the r-process for neutrons, proton captures and photodisintegrations are in equilibrium. Thus, the abundances within an isotonic chain are only determined by temperature, density, and the proton separation energy of a nucleus. The timescales of flows from one chain into the next are given by β -decay half-lives. The reaction path basically follows the proton dripline. The processing of matter is hampered at nuclides with long half-lives, the so-called waiting points, which determine the processing timescales. A final endpoint of the rp-process path was found in a closed reaction cycle in the Sn–Sb–Te region, due to increasing instability against α decay of heavy proton-rich nuclides (Schatz et al. 2001).

Time-dependent calculations showed that the structure of type I X-ray bursts can be explained by the energy generation of the proposed processes. Regarding nucleosynthesis, it is being discussed whether a fraction of or all light p-nuclei (see [Sect. 12.4.5.2](#)) originate from X-ray bursters. Since the rp-process synthesizes very proton-rich nuclei, they would decay to p-nuclei after the burning ceased. Since it proved to be problematic to synthesize the light p-nuclei with mass numbers $A < 110$ in the γ -process by photodisintegration ([Sect. 12.4.5.2](#)), the rp-process provides a compelling alternative to such models, especially after the discovery of its endpoint, preventing the production of nuclides with mass numbers $A > 110$. Although it was shown that the isotopes in question can be produced in large quantities, it is still speculative whether any of the material is ejected. There could be a very small fraction of material lost from the outer atmosphere of the accreted layer on the neutron star surface but the rp-process burning takes place further down. Therefore, some convection has to be invoked to bring the freshly produced nuclei to the outer layers. Comparatively small amounts of ejecta would be sufficient to explain solar p-abundances but detailed hydrodynamic studies of the burning, convection, and possible ejection are still needed.

12.5.5 Neutron Star Mergers

Another interesting binary system is that of two neutron stars. Such systems are known to exist; four have been detected by now. They can be created when two massive stars complete their stellar evolution and both explode in a core-collapse supernova, each leaving a neutron star behind. In such a configuration, the system loses angular momentum by emission of gravitational radiation (Taylor 1994) and the two neutron stars spiral inward. At timescales of 10^8 years or less, the objects collide at their center of mass. Such a merger can lead to the ejection of neutron-rich material (Rosswog et al. 1999; Ruffert and Janka 2001). Since this material is even more neutron rich than the deep, high-entropy layers thought to be a possible site of the

r-process in core-collapse supernovae, nucleosynthesis in decompressed neutron star matter could be a viable alternative site for the r-process (Freiburghaus et al. 1999). Detailed hydrodynamic calculations coupled to a complete r-process reaction network have not been undertaken yet, but parameterized r-process studies indicate the possibility that such mergers could even account for all heavy r-process matter in the Galaxy. However, detailed galactic chemical evolution models (Argast et al. 2004) show that neutron star mergers, occurring at late time in the life of a galaxy, cannot account for the r-process nuclei found in very old stars (Snedden et al. 2000; Cayrel et al. 2001; Frebel et al. 2005). Therefore, there may be several sites producing r-process nuclei, perhaps similar to the two components of the s-process (but occurring in different sites than the s-process, of course).

12.6 The Abundance of Elements in the Universe

12.6.1 Experiments and Observations

The essence of every science is the ability to validate theories by comparison to experiments. The ability to perform guided experiments is somewhat limited in astrophysics because of the large scales and extreme conditions involved. Nevertheless, there is a wealth of data to be exploited. Atomic transitions and certain nuclear reactions (Käppeler et al. 1998) can be studied in the laboratory with current methods.

Since the s-process (Sect. 12.4.5.1) involves mainly stable nuclei, an important experimental contribution is the one studying neutron capture at low energy. Special focus is put on reactions at s-process branchings. For the majority of unstable nuclei reached through the s-process, β -decays are much faster than the neutron captures. At several places in the nuclear chart, however, the s-process path encounters long-lived nuclei for which the decay rate becomes comparable to the neutron capture rate. This leads to a splitting of the path: a fraction of the s-process flow proceeds through neutron capture, the other through the decay, bypassing certain isotopes. A comparison of abundances of nuclei reached through one or the other branch provides information on the relation between decay and capture rate. Due to the different temperature dependence of capture and decay, the branching ratio is dependent on temperature, becoming a sensitive s-process “thermometer.” The capture rate also depends on the neutron density and thus such a branching can also be used as a neutron pycnometer. This yields detailed information on the conditions inside an AGB star. To be useful, neutron capture cross sections have to be known with an accuracy of better than 1% below about 50 keV neutron energy. This has been achieved for some target nuclei but remains a challenge for others. High-resolution time-of-flight experiments are most promising to give the required accuracy and provide cross sections within the required energy range. The cross sections have to be converted to reaction rates to be applied in astrophysical models. The Karlsruhe group (Käppeler et al. 1989) has had a leading role in directly determining rates by using a neutron spectrum created by the ${}^7\text{Li}(p, n){}^7\text{Be}$ reaction. Through this trick, the resulting energy distribution of the released neutrons is very similar to the one of neutrons in stellar plasma with thermal energy of 25 keV, coinciding with s-process conditions. The limitation of this technique is that it can only provide the spectrum at this energy.

The predictions of reaction models giving cross sections relevant to the production of p-nuclei and of the nuclear properties required in such calculations can also be tested by using neutron and charged particle reactions on stable targets (Descouvemont and Rauscher 2006).

Some of the accessible reactions are directly important in the nucleosynthetic processes while other experiments can only serve as tests of the theoretical approaches (Kiss et al. 2008). The reactions can either be studied in online beam experiments detecting directly emitted γ -rays or particles. Another important type of experiment is that of activation (see, e.g., Gyürky et al. 2006, and references therein). A material sample is activated by neutron, proton, or α beams at the energy of interest and the long-term radiation is counted over an extended period of time. Alternatively, the amount of the nuclei produced by the activation can be measured by the very sensitive accelerator mass spectrometry (AMS), which has become an important tool also for astrophysical measurements. It is especially well suited to study neutron-induced reactions producing different isotopes of the same element.

The advent of radioactive ion beam (RIB) facilities in nuclear physics allows studying the properties of and reactions with unstable nuclei (Käppeler et al. 1998; Thielemann et al. 2001b; Rauscher and Thielemann 2001). In addition to the few, already existing, smaller RIB facilities in Europe, Japan, and the USA, one large-scale facility is under construction at GSI Darmstadt, Germany, and another large-scale facility has recently been funded in the USA, the Facility for Rare Isotope Beams (FRIB) at Michigan State University. Both the GSI FAIR (Facility for Antiproton and Ion Research) and FRIB will allow producing highly unstable nuclides, both on the proton- and neutron-rich side of the chart of nuclides. For the first time, this will enable us to study nuclear properties of the p- and rp-processes directly, and also close to the r-process path. These investigations will largely improve the understanding of explosive nucleosynthetic processes.

Plasma physics experiments describe the properties of hot and thin plasmas. Utilizing data from laser-induced plasmas or nuclear testing allows drawing conclusions on the behavior of matter under conditions that are to a certain extent close to those found in stellar environments. Hydrodynamic simulations can also be validated against test cases drawn from experiments and terrestrial experience. However, large nuclear reaction networks involving highly unstable nuclei, extended stellar atmospheres with complicated mixing processes, or macroscopic amounts of matter at and beyond nuclear densities are only accessible by theoretical methods. The models have then to be tested ultimately against astronomical data. The latter have almost exclusively been observations in the electromagnetic spectrum, starting from the ancient observations of visible light coming from the Sun and the stars, to modern satellite observatories also exploring other frequency ranges and studying emissions of compact objects, faint galaxies, accretion disks, quasars, and the echo of the Big Bang, the cosmic microwave background. It is amazing how much has already been learned about the structure and history of the whole Universe by just examining the faint light reaching the surface of our tiny planet. The upcoming new missions of ground- and space-based observatories guarantee an increasing inflow of data, securing the development of the related fields and ensuring that this research field stays exciting and is still able to provide new insights.

In addition to the observation in the electromagnetic spectrum, other means of obtaining astrophysically relevant information become increasingly important. Among those are measurements of cosmic rays, on the surface and in the atmosphere of Earth, as well as in low-earth orbits (Westphal et al. 1998, 2001). Such investigations provide insights regarding the particle flux in our solar system, originating from the Sun and from galactic sources. In the future, it will be possible to study another type of radiation in addition to the electromagnetic one: gravitational waves emitted, e.g., by neutron star mergers, black hole formation, and other interactions between highly massive or relativistic objects (Sathyaprakash and Schutz 2009). Even more important for studying nucleosynthesis and stellar evolution are the isotopic ratios found in

certain meteoritic inclusions (Lugmair et al. 1983; Lewis et al. 1987; Hoppe and Zinner 2000). Using advanced chemical extraction methods, these data can be utilized to deduce the composition of the material in the early solar system. Because of its growing importance for nucleosynthesis studies, the field is introduced in a separate subsection (► Sect. 12.6.3).

12.6.2 Solar Abundances

As might have become evident from the previous sections, the origin of the elements can only be understood in detail when the physics of the nucleosynthesis sites is also understood. Complete simulations of nucleosynthetic events that account for all data are required, not just those giving details of elemental or isotopic abundances. Nevertheless, the determination of abundances remains central if one wants to study nucleosynthesis.

By inspection of the absorption lines in stellar spectra, it is possible to measure the contents of the stellar atmosphere. A theoretical model has to explain how many of those nuclides were inherited from the proto-cloud from which the star formed and what amount was produced in the central, nuclear burning regions of the star itself and brought up by convection.

Similar considerations apply to the observation of absorption and emission lines from other objects, such as supernova ejecta, planetary nebulae, and interstellar clouds. Some methods and results were already presented in ► Sect. 12.3.3.

On the way to understand the origin of elements on Earth, the abundances in the Sun have to be explained first because the planets and the Sun formed from the same interstellar cloud. Due to their low gravitation, the smaller planets subsequently lost those light elements that were not chemically bound in their crust whereas the Sun was able to retain more or less the original composition. In planets, physical and chemical fractionation processes then separated certain elements or isotopes and concentrated them in different regions, leading to the heterogeneous distribution found, e.g., in geological surveys. The solar composition is shown in ► Fig. 12.13. As an example of how the solar composition affects nucleosynthesis studies is shown in ► Fig. 12.12. In order to constrain the relative contributions of the s- and r-process, the solar abundances are used to represent the current composition of the local interstellar medium.

The accurate determination of solar abundances is, therefore, central to all investigations of nucleosynthesis. This is reflected in the recent commotion caused by a new study of solar abundances (Asplund et al. 2006a, b), revising the previously widely used tables of Anders and Grevesse (1989). The new abundances are based on modern three-dimensional model atmospheres (describing the region in the Sun where line absorption occurs). The content of elements beyond H and He was found to be lower by a factor of two compared to the previous study. This finding impacts all kinds of comparative nucleosynthesis studies but mainly those involving C, N, and O, which are the most abundant (apart from H and He). The new abundances resolved previous problems regarding the consistency of solar abundances and those of the solar neighborhood. On the other hand, they challenge current models of the solar interior, especially regarding the comparison of predictions of the local sound speed (which is also dependent on the abundances of C, N, O, Ne) and helioseismological results.

12.6.3 Meteoritic Inclusions

In addition to abundance determinations from stellar spectra, another way to obtain information about the composition of the early solar system as well as of environments that are

more distant has become increasingly important in the last years. Certain types of meteorites contain inclusions wherein the composition of the early presolar cloud is conserved. This also enables one to study some isotopic compositions that cannot be extracted from the solar spectrum. More surprisingly, some meteorites contain so-called presolar grains, which are supposed to have been formed from material of other stars. The grains traveled through interstellar space with their inherent speed at formation and were incorporated into the protosolar cloud from which the Sun and its planets formed. Some of them survived the formation of the solar system and also the fall as a meteorite. This requires that their host material never experienced temperature above about 1,000 K. Various types of meteorites, most prominently carbon-rich ones (carbonaceous chondrites) carry such nm- to μm -sized inclusions, which were incorporated into the presolar cloud and were since then shielded from any chemical or physical fractionation and mixing processes occurring during planet formation or in the Sun.

Literally being “stardust,” presolar grains provide information not just on the isotopic composition of other stars that cannot be determined through their spectra. Additionally, they may show the composition of different layers of a star depending on their formation process. There are a number of excellent reviews on the topic (e.g., Nittler 2003; Clayton and Nittler 2004; Zinner et al. 2006; and the book by Lugaro 2005). Therefore, here only a summary of the most important aspects regarding types and origins of presolar grains and the methods to analyze them (see also [Chap. 54 of Vol. 5](#)) is presented.

Presolar grains are foremost identified by their nonsolar isotopic composition. They are subsequently classified by the mineral phase carrying the isotopes and by the isotopic ratios of certain elements (mainly C, N, O, Si, Al, and Fe). Most abundant but the least understood are nanodiamonds. Best studied are the second most abundant SiC grains. Further phases include, in order of abundance, graphite, TiC, ZrC, MoC, RuC, FeC, Fe–Ni metal, Si_3N_4 , corundum, spinel, hibonite, and TiO_2 .

The well-studied SiC grains can be subdivided into different classes according to the isotopic anomalies (relative to solar) they exhibit. The bulk of 90% is made up of so-called mainstream grains, which are thought to originate from AGB stars, showing almost pure s-process isotopic ratios. They are inferred to have formed in the winds of AGB stars or planetary nebulae. Therefore, they are a snapshot of the surface composition of the star but AGB stars, contrary to other types of stars, have strong convection, carrying freshly synthesized nuclides from the burning zone deep inside the star to the surface ([Sect. 12.4.5.1](#)). Much of the recent progress on the nucleosynthetic details of the s-process in recent years is due to the analysis of presolar grains.

A small subclass of SiC grains, the so-called type X grains, contain a large $^{26}\text{Mg}/^{24}\text{Mg}$ ratio and large excess of ^{44}Ca , pointing to a core-collapse supernova origin. The radionuclides ^{26}Al and ^{44}Ti are concurrently produced only in such supernovae and decay to ^{26}Mg and ^{44}Ca , respectively. The SiC X grains are thought to be formed in supernova ejecta. As these consist of a large fraction of the progenitor star, grains can also condensate from material of inner layers or from a mixture of different layers of the star. There is some success in reproducing X grain compositions by mixing abundances predicted by current stellar models.

The origin of other types of grains is still debated and a unique identification with a site is not always possible. They could have been produced in supernovae, AGB stars, or novae.

The analysis of the content of a grain requires a combination of chemical and physical methods to separate the grain from the surrounding meteoritic material and to determine the isotopic abundances contained within. Luckily, mineral phases condensing in the vicinity of stars contain acid-resistant phases, which can be separated from the meteorite by essentially

dissolving everything else away. Until recently, this was the way to go but it has the disadvantage that other, less acid-resistant, presolar phases, e.g., silicates, may be lost in the process. Once the grain material has been isolated and concentrated, standard mass spectrometric methods (with AMS being the most sensitive) can be applied. A complete analysis of the presolar content, including more easily dissolvable materials, requires new analytic methods, currently under development. Among those is resonance ionization mass spectrometry (RIMS), which allows measuring ppm-level trace elements in μm -sized grains with elimination of isobaric interferences. Even more promising is the NanoSIMS, an ion microprobe with high sensitivity and high spatial resolution (Stadermann et al. 1999; Marhas et al. 2008). The NanoSIMS allows studying a grain in a slice of a meteorite to obtain isotopic abundances with information on their location within the sample. This enables studies of layered grains in their meteoritic matrix and also grains made up of easily dissolvable phases. This is superior to TEM (transmission electron microscope) analysis, which requires ultrathin samples cut with diamond knives and losing some depth information. Nevertheless, the TEM can sometimes be complementary to a NanoSIMS analysis.

Presolar grains open a new, promising window into the Universe by enabling us “hands on” analysis of nonsolar, stellar matter. With improved preparation and analysis methods, this line of research will remain important for many types of nucleosynthesis studies, even directly impacting the theory of stellar structure and evolution.

12.6.4 Galactical Chemical Evolution: Putting it all Together

Although the Sun is considered to exhibit a composition typical of the disk of the Galaxy, it has to be realized that its abundances are only a snapshot in time. As is evident from the discussion in the preceding sections, the Sun contains elements, which have been produced in other stars or galactic sites and the solar abundances (● Fig. 12.13) are only a snapshot of the composition of the interstellar medium. After the first stars in the galaxies lit up, numerous generations of stars have contributed to the elemental contents of the interstellar material from which new stars form. The current stars, on the other hand, are building up material that will be incorporated in future stellar generations. All this is illustrated by the fact that a gradient in metallicity is observed depending on the age of the star (see ● Sect. 12.3.3). Older stars contain less “metals,” i.e., elements other than H and He, because the interstellar medium from which they formed contained less. Therefore, it becomes obvious that the interstellar medium in a galaxy becomes enriched with elements over time. The general picture is that of a cycle of matter within a galaxy as shown in ● Fig. 12.14.

The primordial galactic material is processed and reprocessed in star-forming regions many times. Indeed, a general enrichment can actually be found when comparing galaxies of different ages.

We do not know how many generations of stars have contributed to the solar abundances and how well the products were mixed into the proto-solar cloud. Therefore, a comparison with abundances in old stars allows drawing conclusions on the relevant processes. For example, recent observations in stars found in the halo of the Galaxy show that the relative r-process abundances are very similar to the ones in the Sun, although very much depleted (Snedden et al. 2000; Cayrel et al. 2001; Frebel et al. 2005). This indicates that the r-process seems to be robust, i.e., occurring under almost the same conditions and giving almost the same elemental yield in each event.

■ Fig. 12.14

Schematic view of the cycle of matter in a galaxy

For a complete understanding of the chemical evolution of a galaxy it is necessary to integrate over the yields of all possible contributors. With the advent of advanced stellar models, galactic chemical evolution has become a field of its own, providing further constraints to the nucleosynthetic models. Many considerations enter, such as the amount and composition of ejecta per event, frequency of events, and mixing processes that distribute matter within a galaxy (Pagel 1997). Thus, all available knowledge is combined to reach an improved level of understanding. However, the young field of galactic chemical evolution still faces major difficulties due to the timescales involved, the limitations in observations and models, and the impossibility of accurately dating stars and galaxies. One of the big questions is how material is mixed and transported. Nevertheless, recent promising trends in modeling galactic evolution might even provide constraints, e.g., on individual supernova models rather than only on global properties of SN II and SN Ia. The reason for this possibility is the fact that there is no instantaneous mixing of ejecta with the interstellar medium, and therefore early phases of galactic evolution can present a connection between low metallicity star observations and a single supernova event (Argast et al. 2000).

To summarize, it is worth emphasizing again the tremendous achievements obtained over the last decades. Accurate and detailed studies made it possible that, coming from more simple observations of the Sun and nearby stars, one reached the stage where details of the origin of chemical elements and their isotopes on our planet as well as the evolution of their abundances in entire galaxies and in the early Universe can be studied. It is especially amazing that all this knowledge was gathered without really or just barely leaving the surface of our planet.

Future efforts in nuclear physics and astronomy ensure that the stream of data will not be cut off and will greatly improve our detailed knowledge not only of the origin of the elements but also of the position of our Galaxy, our planet, and ourselves within a vast, evolving Universe.

Abstract: Shell effects on nuclear stability have created an island of relative stability for nuclides near $A = 230$ – 240 and $Z = 90$ – 92 . Three nuclides, ^{232}Th , ^{238}U , and ^{235}U , have half-lives long enough for significant amounts to have survived since the heavy elements in the Earth's crust were created. When one of these nuclides decays, it starts a journey that ends with an isotope of lead ($Z = 82$, $A \approx 208$). The predominant steps in this journey are α and β decays, so that each of the long-lived parents heads a distinct chain. Each chain, as well as a fourth one that is extinct, is described.

13.1 Introduction

Radioactivity was discovered (1896) from observations of radioactivity occurring in natural radioactive chains. There are other instances of natural radioactivity, such as ^{14}C , ^{40}K , and ^{187}Re , but none of these nuclides leads to a radioactive product and therefore starts a chain. Note that many radionuclides occur in chains, e.g., $^{100}\text{Sn} \rightarrow 6 \text{ EC}/\beta^+ \rightarrow ^{100}\text{Ru}$, but early members of the chains have short half-lives and disappear before the chain is completed. The distinguishing characteristic of the natural chains is that they begin with a radionuclide with a long enough half-life that some of it has survived since the Earth was formed and leads to intermediate components with short – sometimes very short – half lives.

Details of the natural radioactive decay series are particularly important for several radioactive dating methods (🔗 Chap. 17 of this Volume). These methods depend on differences in chemical properties of chain components in a geological environment and on growth-and-decay among the components. See 🔗 Chap. 7 in Vol. 1.

There is considerable variety in the modes of decay of heavy elements; if spontaneous fission is considered a mode of radioactive decay, then there are many chains that meet this criterion of long-to-short. However, this chapter does not include fission except as a mechanism of terminating a chain.

The natural radioactive chains are represented in 🔗 Figs. 13.1–13.4. The relative intensities of various decay modes given in those figures do not show the full precision of current information. See the appendix “Table of Nuclides” by R. B. Firestone for current values.

The dominant steps in the chains are α and β decays, which either decrease the mass number by 4 (α decay) or leave it unchanged (β decay). Therefore, there are four chains (including one which is extinct on Earth) corresponding to mass numbers $A = 4n$ (^{232}Th and descendants) through $A = 4n + 3$ (^{235}U and descendants), where n is an integer. In the figures, rows correspond to elements, with atomic number increasing from the bottom to the top. Columns have constant $N-Z$; they contain nuclides that are related by α decay. For a given chain only half of the cells in such a row-and-column array are members of the given chain. (The other half corresponds to a chain differing by 2 mass numbers.) The components are in shaded boxes, and the chains progress two steps down (α decay) or one step up and to the left (β decay). The long-lived parent and the stable end-product have a deeper shade. For α decay of a particular nuclide, the percentage of decays that use that mode is given below it, followed (in italics) by the energies (in keV) of the most intense α groups. If there is no competing β decay, the α percentage is 100. If both α and β decay occur, the fraction of β decay is the complement of the α fraction. For example, in 🔗 Fig. 13.1 ^{212}Bi α decays 35.9% of the time, so 64.1% of the time β decays.

Many individual components in the series are referred to by names derived from their positions in the series and other details that are no longer of much interest except to reveal the history of discovery of structure of each series. The most common names of this type for the ^{232}Th series are given in Fig. 13.1. Since ^{228}Ra and ^{228}Ac are sandwiched between two isotopes of thorium, they were called mesothorium 1 and 2 (*meso*: intermediate or in the middle), with symbols MsTh_1 and MsTh_2 . ^{228}Th has higher specific activity (activity per unit mass) than ^{232}Th and was called radiothorium (RdTh). Tn (^{220}Rn) is short for thoron, the gaseous component similar to *radon* from *radium*. Relatively simple chemical procedures could show that there were three species following Tn, and these were named

ThA (^{216}Po), ThB (^{212}Pb), and ThC (^{212}Bi). Later it was determined that ^{212}Po (ThC') and ^{208}Tl (ThC'') are also involved.

Each of the chains could be extended (with many branches) to shorter-lived precursors. Although these precursors are not properly considered members of the natural chains, several

of them are included in the diagrams to show likely production paths of the chains in the nuclear fuel cycle. For example, neutron capture in ^{232}Th produces short-lived ^{233}Th , which decays to ^{233}Pa and then to ^{233}U (see Fig. 13.4), which can be used as reactor fuel.

13.1.1 $4n$ Chain

The chain is defined in Fig. 13.1. Because α decay changes mass number by 4, the overall loss of 24 mass numbers between ^{232}Th and ^{208}Pb requires six α 's. But six α 's would change atomic

Fig. 13.4
The $4n + 1$ (^{237}Np) chain

number by 12, and the overall change is only 8; there must be a net of four β decays (β decays less electron captures), each increasing atomic number by 1 without changing mass number. In fact there are no electron capture decays in any of the chains – for reasons related to general trends in nuclear stability – and there are exactly four β decays in this chain.

The parent of the $4n$ series, 1.405×10^{10} year ^{232}Th , is the longest-lived nuclide in the Th–U region. It is comparable to the age of the universe, so more than half of all of the ^{232}Th ever produced (and not consumed by nuclear reactions) is still present. Because of the long half-life, ^{232}Th has unusually low specific activity (rate of decay per unit mass). Little easily absorbed radiation, such as α particles and low-energy electrons and photons, escapes the necessarily thick samples of moderate activity.

The last steps in the chain are unusual; ^{212}Po has a remarkably short half-life (and high decay energy), and ^{208}Tl emits a high energy γ ray (2,615 keV). This γ ray is a distinctive feature of background spectra of most γ ray spectrometers (See [Fig. 13.7](#)).

13.1.2 $4n + 2$ Chain

The $4n + 2$ chain is very similar to the $4n$ chain. They both pass through two isotopes of the parent element and of the element two units below it. The outstanding feature of the $4n + 2$ chain is that it populates the longest-lived isotopes of radium (1,599 year ^{226}Ra) and radon (3.82 days ^{222}Rn).

13.1.3 $4n + 3$ Chain

The $4n + 3$ chain is the only one that (barely) includes every element from uranium to thallium. Although included, francium and especially astatine are very minor components. The parent, 704×10^6 year ^{235}U , has a half-life considerably smaller than the $\sim 4,500 \times 10^6$ year age of the Earth. It is long enough for significant amounts (0.720% of the atoms in natural uranium) to remain. The chain includes by far the longest-lived isotopes of protactinium (32.8×10^3 year ^{231}Pa) and actinium (21.77 year ^{227}Ac).

13.1.4 $4n + 1$ Chain

The $4n + 1$ series is extinct on Earth except (presumably) for vanishingly small amounts arising from capture of stray neutrons by ^{232}Th . Even the end-product ($\sim 2 \times 10^{19}$ year ^{209}Bi) appears to be slightly radioactive. The longest-lived member is ^{237}Np , but the most important is ^{233}U . This isotope of uranium has fission properties similar to ^{235}U (and ^{239}Pu). The mechanisms for large-scale production are similar to those for ^{239}Pu .

The following sections explain how the long-lived parents arise ([Sect. 13.2](#)), describe the growth and decay relations within the chains ([Sect. 13.3](#)), list the physical (i.e., nuclear physics) properties of members of the chains ([Sect. 13.4](#)), and indicate sources of information on the chemical properties of the elements in the chains ([Sect. 13.5](#)).

13.2 Island of Stability

The general trend in stability of various combinations of protons and neutrons can be understood in terms of the Weizsäcker formula, which is given as [Eq. \(2.3\)](#) in “Basic Properties of the Atomic Nucleus” ([Chap. 2](#) of Vol. 1). The first two terms of this semiempirical formula are related to the volume and surface of a nucleus; together they prefer large nuclei. The third term is proportional to the Coulomb energy of a charged sphere; it prefers a neutral nucleus. The fourth term has no classical interpretation, but it can be understood as arising from quantum mechanical exclusion; it prefers equal numbers of protons and neutrons. When these terms are combined, the lowest energy (most stable) combination of A nucleons is given by

$$Z_A(A) = \frac{A \left(2 - \frac{m_n - m_H}{a_s} \right)}{4 + \frac{a_c}{a_s} A^{2/3}} \quad (13.1)$$

where a_a is the asymmetry coefficient and a_c is the Coulomb coefficient. Note that Z_A is the minimum on the parabolic mass curve for mass number A . For small A the minimum corresponds to nearly equal numbers of protons and neutrons; the symmetry term dominates. For large A , Z is considerably less than N , e.g., ^{208}Pb with $N = 126$ and $Z = 82$. These general trends are displayed in N vs. Z plot, such as [▶ Fig. 2.7 in Chap. 2](#) of Vol. 1 on “Basic Properties of the Atomic Nucleus.” The main relevant feature of the figure is the distribution of stable nuclides in the vicinity of $A \approx 200$.

[▶ Figure 21.11 of Chap. 21](#), “Superheavy Elements,” gives a clearer picture of the nuclides beyond $A \approx 200$. There is an abrupt absence of nuclides with moderate much less long half-lives between ^{208}Pb and ^{232}Th . This is due to shell effects that are not included in the semiempirical equation. Of course shell effects are crucial for stabilizing the several “islands” of stability among heavy elements, which include the parents of the natural decay series as well as surprisingly stable isotopes of elements well beyond uranium.

[▶ Table 13.1](#) shows the α -decay energies of the $4n$ series and the energies predicted by the semiempirical equation without shell effects. The equation agrees with the facts near the middle — at ^{220}Rn . The predicted half-lives are too short in the Th–U region, and too long for Po (just above the shell). The Hg–Pb isotopes are predicted to have rather short half-lives for α decay. To be sure some of them are energetically unstable, but not enough that barrier penetration proceeds at an appreciable rate.

13.3 Time Dependence

The equations for growth and decay of genetically related radioactive materials were developed (Bateman 1910) in order to understand the complicated relations among the components of the natural decay chains. Time dependence remains important. First, it is of interest to

■ **Table 13.1**

Shell effects on α -decay energies (in MeV) and half-lives in the $4n$ chain. Note that for very rare α decays it is difficult to obtain experimental Q_α values. (In the case of ^{228}Ra nuclides, e.g., 19 ppb are only expected to undergo α decay, while the rest disintegrates by β decay according to

[▶ Fig. 13.1](#))

Nuclide	Q_α	Q from eqn.	α half-life	Half-life from mass eqn.
^{236}U	4.572	7.62	2.3×10^7 years	0.9 s
^{232}Th	4.083	6.92	1.4×10^{10} years	20 s
^{228}Ra	~ 4.1	6.21	$(3 \times 10^8 \text{ years})$	5×10^3 s
^{228}Th	5.520	7.63	1.911 years	0.02 s
^{224}Ra	5.789	6.95	3.66 days	5 s
^{220}Rn	6.405	6.25	56 s	150 s
^{216}Po	6.907	5.53	0.146 s	1 day
^{212}Pb	~ 3.1	4.80	(Not known)	3 years
^{212}Bi	6.207	5.56	2.8 h	5 h
^{212}Po	8.954	6.29	0.3 μs	10 s

anticipate how radioactivity will develop in freshly prepared samples. Second, processes such as weathering of waste deposits disturb the growth and decay relations, and analysis of the relative activities of the several components can indicate the rates and times of the disturbances. Third, the processes have been valuable in dating very old geological samples.

See ▶ Chap. 7 of Vol. 1 for information on the rates of genetically related radioactive materials and, in particular, the Bateman equations describing members of arbitrarily long chains. Note that each set of equations describes the components of a chain defined for particular branches. Different branches require different set of equations. These points are illustrated in the following sections.

The time dependence of a genetically related pair can be described as equilibrium (if the half-life of parent is longer than that of the descendant) or no equilibrium (half-life of parent shorter than that of the descendant). Cases involving equilibrium are further classified as secular (half-life of the parent is long compared to the descendant and to the time duration of interest) or transient (decay of parent must be considered); the distinction depends on one's criterion for change. In most cases it is difficult to measure rates with uncertainties less than 0.1%, so one might require that less than 0.1% of the parent decay and that the rate of decay of descendant be more than 99.9% of the initial activity of the parent. For these conditions to obtain, the half-life of the parent must be at least 7,000 times the half-life of the descendant.

13.3.1 Approach to Equilibrium

If one excludes the extinct $4n + 1$ series, the parents of all three natural series have decayed less than 0.1% during human history, and the smallest parent/descendant ratio of half-lives (18,000 for $4n + 2$) is greater than 7,000 (see above). Therefore they can be in secular equilibrium with their descendants. For geological time scales, the entire series will follow the decay curve of the parent within 0.1%.

Parts of chains, such as the important genetic pair ^{226}Ra – ^{222}Rn , may also demonstrate secular equilibrium. The growth and decay relations of radon isotopes are perhaps of greatest general interest. About half of the radiation exposure of the general population is due to ^{222}Rn and its descendants. Its immediate parent, ^{226}Ra , has a long half-life ($160,000 \times$ that of ^{222}Rn) and is often displaced from its Th and U ancestors. For example, Ra in groundwater might be absorbed on a deionizer column, while any associated Rn would pass through unless embedded in the support material by recoil. If there is no flow for a period of time, the Rn will build up and eventually (perhaps within a month) reach secular equilibrium. For any given shorter time, the radon activity A_{Rn} will follow the simple growth curve given by $(1 - e^{-\lambda t}) A_{\text{Ra}}$, where λ is the decay constant for radon and t is the time since radium was freed from radon. The case is represented in ▶ Fig. 7.9 of Chap. 7 in Vol. 1.

The decay of ^{227}Ac to ^{227}Th is an example of transient equilibrium. (See ▶ Fig. 13.3 for half-lives and branching ratios.) An initially pure sample of ^{227}Ac will have increasing amounts of ^{227}Th until the rate of decay of ^{227}Th is nearly the same as the rate of decay of ^{227}Ac to it. If the ^{227}Th were fed at a constant rate, it would reach 99.9% of that rate in 9.966×18.7 days ≈ 186.6 days. However, during that time the ^{227}Ac would decay by 1.61%. Therefore the proper Bateman equation must be used to include both growth of ^{227}Th and decay of ^{227}Ac . The maximum in the decay rate of ^{227}Th occurs when it is equal to the production rate, namely, 0.9858 of the initial rate of decay of ^{227}Ac to ^{227}Th at 3,930 h (164 days).

Note that the weak 1.38% branch from ^{227}Ac to ^{223}Fr has been ignored and only a genetically related pair has been considered. When these factors are included, the correct equations are essential.

13.3.2 Branching Decay

When one takes into consideration that only 98.62% of the decay of ^{227}Ac goes to ^{227}Th and that 1.38% goes to ^{223}Fr , one finds that the maximum fractional activities for ^{227}Th and ^{223}Fr are 0.975 and 0.0138, respectively. Note that the ^{223}Fr reaches maximum sooner (when the production rate is nearly equal to the initial production rate); it meets the criterion for secular equilibrium. A subtle point is that one must distinguish between total and partial decay constants. The total describes the rate of disappearance of a species, while the partial decay constants describe the rate of production of the product of a particular branch. These points are developed in more detail in the next section.

13.3.3 Multiple Step Series

Consider one more step in the series originating from ^{227}Ac , passing through the branches described above, and rejoining at ^{223}Ra . Separate equations are required for the separate branches.

One can consider the terms in the Bateman equations to have three parts: a product of λ 's in the numerator, a product of *differences* in λ 's in the denominator, and an exponential factor. For branched decay of component i , the λ_i in the numerator is the partial decay constant, and the λ_i 's in the denominator and the exponential for i are the total decay constants. Another way to view the use of partial decay constants in the numerator is to multiply the entire equation by the fraction for that particular branch. This is not a simplification, because chains with different branches have different numerators and some different exponential factors.

These calculations for $^{227}\text{Ac} \rightarrow ^{223}\text{Ra}$ for several times are given in [▶ Table 13.2](#) and [▶ Fig. 13.5](#). Note that the weak branch through 21.8 min ^{223}Fr produces ^{223}Ra more quickly, but eventually the main branch dominates. The total amount of ^{223}Ra at any time is the sum of the amounts coming through separate branches. If the calculations had been made for longer times, it would be clear that ^{223}Ra is in transient equilibrium with ^{227}Ac .

13.3.4 Multiple Separations

As a final example of time dependence, consider the effect of several chemical purifications on the relative amounts of Th and Ra components of the $4n$ (^{232}Th) series. Assume that these components initially are in secular equilibrium. This would *not* be the case if the sample consisted of thorium that had been isolated from an ore in modern times.

If the object is to obtain pure ^{228}Ra , isolation from the equilibrium chain does not suffice; an equal amount of ^{224}Ra will be obtained. Of course, aging the sample will improve purity, because the ^{224}Ra will decay more quickly than the ^{228}Ra . These trends are shown in [▶ Fig. 13.6](#). The amount of ^{228}Ra will decrease slowly, but that effect is ignored in this example. After about 22 days, the amount of ^{224}Ra growing from ^{228}Ra will be equal to the residual amount from the initial purification. If nothing is done, the sample will become progressively less pure. If the

■ Table 13.2

Calculations for the relative activities of ^{227}Ac , ^{227}Th , ^{223}Fr , and ^{223}Ra in aged samples of initially pure ^{227}Ac . The convention used for representing numbers is $aE \pm b \equiv a \times 10^{\pm b}$. The Ac activity is not given; the final rate is 0.99982 times the initial rate. The fractions of each nuclide's production rate are given in the body of the table. The actual activities, relative to the activity of Ac, are obtained by multiplying Th and the Ra growing from it by 0.986. For Fr and the Ra obtained from it, the factor is 0.0138

Growth of ^{223}Ra in initially pure ^{227}Ac as a fraction of the initial ^{227}Ac activity. The squares show the Ra produced through Fr, the diamonds through Th. The triangles show the sum, the actual amount of Ra produced by all available paths

■ Fig. 13.6

Growth and decay of ^{224}Ra after isolation of radium from $4n$ series at secular equilibrium. The top curve gives the decay of ^{224}Ra after the first isolation relative to the secular rate. The growth curve shows the time dependence of ^{224}Ra that comes from ^{228}Ra (via ^{228}Ac and ^{228}Th). The middle decay curve shows ^{224}Ra that decays (with the clock restarted) after thorium is removed when growth and decay are equal (about 22 days from $t = 0$). The bottom decay curve shows decay following a third purification (about 10 days after the second)

^{228}Th is removed, growth is interrupted and decay in the fraction of ^{224}Ra resumes. However, for this purer ^{228}Ra sample, growth and decay effects become equal sooner, in this case about 10 days. Seven days later the $^{224}\text{Ra}/^{228}\text{Ra}$ ratio will be about 0.006; if higher purity were needed, more (and more frequent) purifications would be required.

The thorium after the initial purification would have equal activities of ^{228}Th and ^{232}Th . If pure ^{232}Th were needed, a similar series of purifications would eventually (about 20 years for 99.9% ^{232}Th) suffice. Even without subsequent processing, it would take many decades for the ^{228}Th to return to equilibrium with ^{232}Th . Getting pure ^{228}Th would be easier; the thorium growing into the purified radium would be pure ^{228}Th .

13.4 Physical Properties

The most sensitive detection of natural radioactive materials is by α spectroscopy. However, to realize good resolution it is necessary to have thin sources, which requires radiochemical purification in most cases. Therefore, γ rays are most convenient for measuring the components in complex mixtures, but γ rays emphasize the β -decay steps.

In addition to β decay and γ -ray emission, the elements near and beyond Pb in the chart of nuclides are unstable with respect to breakup, such as emission of α particles or heavier nuclei. The α , β , and γ emissions preserve the $4n + x$ chains, but emission of heavy ions might not, and fission certainly will not preserve the chains.

13.4.1 Alpha Rays

The energies of the most intense α groups are given in [Figs. 13.1–13.4](#). The lower members of the chains emit the highest energy α particles, and the energies of different nuclides are generally quite different. A semiconductor detector can give ~ 20 keV resolution (full width at half maximum – FWHM) for α spectroscopy if thin sources are used. In the ^{232}Th chain, all of the intense α groups differ by more than 50 keV except the main group of ^{228}Th (5,423 keV, 71%) and the secondary group of ^{224}Ra (5,449 keV, 5%). Note that it would be difficult to obtain a thin source of a mixture of components without using chemical procedures, and chemistry would emphasize a few elements.

Similarly, the various isotopes of a given element isolated from a mixture of natural chains are likely to be resolvable. Radium occurs in all four chains, but ^{225}Ra in the $4n + 1$ chain is a nearly pure β emitter ([Table 13.3](#)).

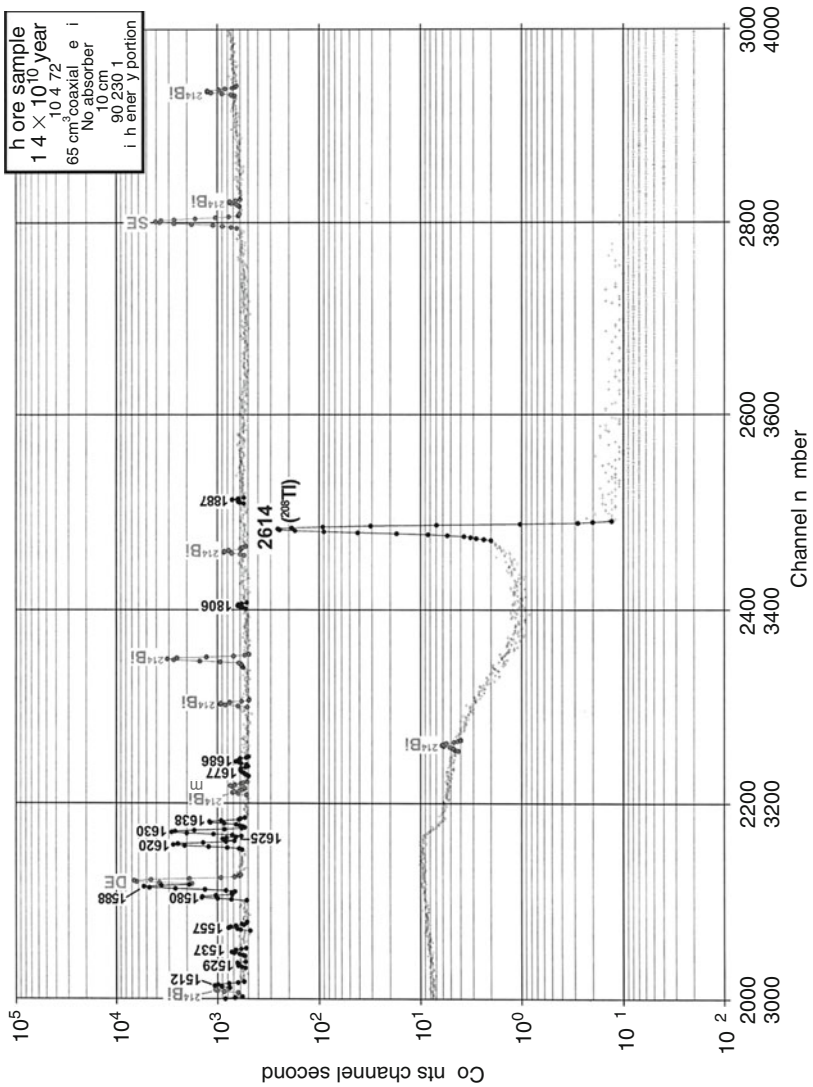

13.4.2 Gamma Rays

Most of the γ rays emitted in the decay chains are emitted following β decay. Most of the Q values for α decay are considerably larger than those for β decay, but β decay is much more likely to populate states that are just barely accessible energetically. Therefore, the use of γ -ray spectroscopy to measure the amounts of various components in a mixture emphasizes the β decays. [Figure 13.7](#) shows the γ -ray spectrum (Helmer et al. 1999) of a sample of thorium ore, i.e., a sample that has been undisturbed for long enough time that the chain is in secular equilibrium. [Table 13.4](#) lists the energies and intensities of the most intense γ rays emitted by components of the chain.

Table 13.3

Energies of α groups from Ra isotopes

Chain	Isotope	α energy/keV	Abundance/%
$4n$	^{224}Ra	5,685	94

Energies and intensities of γ rays in the $4n$ chain

Nuclide	γ -ray energy/keV	γ -ray intensity/%	Nuclide	γ -ray energy/keV	γ -ray intensity/%
^{232}Th	63.8	0.27	^{220}Rn	549.7	0.07
	410.88	0.018	^{216}Po	804.9	0.0018
^{228}Ra	13.5	14	^{212}Pb	238.6	43.6
^{228}Ac	911.2	29	^{212}Bi	727.3	6.7
	969.0	17.4	^{212}Po	None	
^{228}Th	84.9	1.21	^{208}Tl	583.0	86
	215.8	0.28		2614.4	100
^{224}Ra	240.8	3.9			

It is difficult under any circumstances to observe the γ rays emitted by ^{232}Th itself. The Q value for α decay is small and transition rates are very sensitive to small changes in the energy available for α decay. Because of the high atomic number of the daughter Ra , the transition from the excited state to the ground state mostly occurs via internal conversion rather than γ emission. Because of the long half-life and corresponding low specific activity, attenuation in the source material is serious. Finally, the detector used for ▶ Fig. 13.7 had a thick layer of “dead” Ge , which would limit the detection efficiency at energies as low as 64 keV.

It is easier to detect the γ rays emitted in α decay of ^{224}Ra . The Q value is higher (hence the shorter half-life) and less sensitive to high excitation energy of the 240 keV first excited state of ^{220}Rn . There is less competition from internal conversion. The peak due to the 240 keV γ ray is a shoulder (easily resolved by current detectors) on the 238 keV peak of ^{212}Pb .

The high excitation energy of the first excited state accessible by α decay of ^{220}Rn and ^{216}Po dominates the increase in Q , and the γ -ray intensities are low. The 549 keV peak is barely discernable, and the 804 keV peak is below the limit of detection in γ -ray singles.

The dominant features of the spectrum are the peaks at 238 (^{212}Pb) and 2,614 keV (^{208}Tl). The actual intensities are about the same (recall that only 36% of the chain passes through ^{208}Tl), but the detection efficiency for the lower-energy γ ray is higher. The 2,614 keV stands out for lack of spectral competition.

Many of the other γ rays are associated with the ^{228}Ac . Beta decays of both ^{228}Ac and ^{208}Tl have high Q values.

▶ Figure 13.8 shows the γ -ray spectrum of uranium ore (Helmer et al. 1999). The spectrum of recently purified uranium is considerably different; most of the high-energy γ rays emitted by the ore arise from decays of the chain members near the end (primarily ^{214}Bi). Their growth is slowed by long-lived intermediates, such as ^{230}Th and ^{231}Pa .

13.4.3 Recoil

The substantial energy imparted to the residual nucleus in α decay is important because, in the chains, the residual nucleus may itself be radioactive and its fate is observable. For example, in α decay of ^{228}Th to the ground state of ^{224}Ra , the α particle has 5,423 keV of energy. The ^{224}Ra “recoils” with an initial energy of 97 keV, which is large compared with the energy required

Fig. 13.8
Gamma-ray spectrum of U series (Helmer et al. 1999)

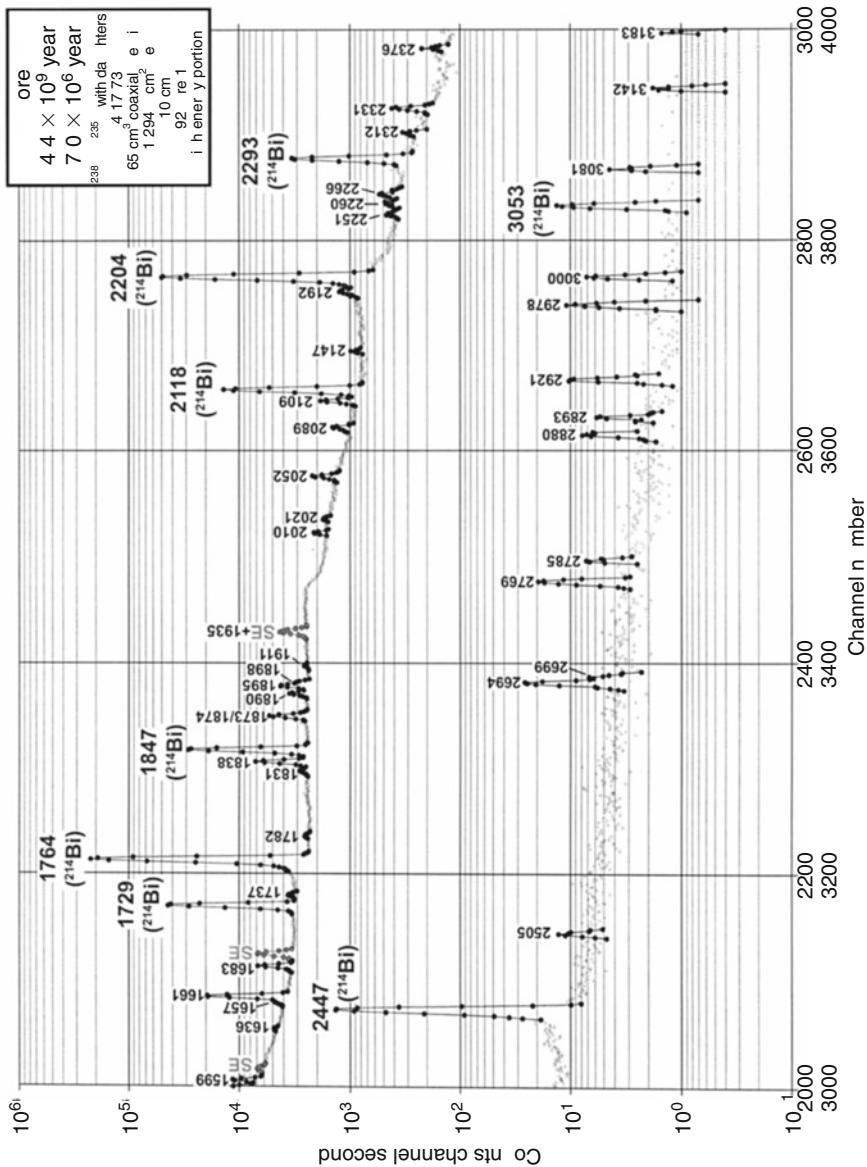

Fig. 13.8
(Continued)

to vaporize one atom of Ra. If the thorium is in a thin deposit in a vacuum, the recoil will move in a direct line (opposite the direction of the emission of the α particle) until it strikes an object.

The recoil can be used to prepare thin sources. The recoils can embed in a catcher, such as a metal disk, placed close to a thin deposit. Of course, the process can repeat; subsequent α decays can produce other recoils, but each such cycle eliminates one member of the chain in the catcher.

If the source is covered with a thin layer such as evaporated gold or a VYNS film, the recoils will be retained. It is important to do so in order to prevent contamination of an α detector, particularly a semiconductor spectrometer operated with a vacuum between the source and the detector.

If a radon atom decays in a gas, although the recoils will stop in the gas, they often will be charged and can be collected by electrostatic attraction to a charged plate.

Recoils can interfere with ordinary chemical processing. If a parent nuclide is adsorbed on a surface, such as a bead of ion-exchange resin or the surface of a container, the recoil can embed deep in the support material and not be in equilibrium with the external chemical environment.

13.4.4 Heavy Ion Emission

All of the members of the natural decay chains are unstable with respect to spontaneous fission, but the probabilities are small. The decay chains follow the side of the valley of stability where the fissionability parameter Z^2/A is relatively small. However, fission is such an extraordinary event that even a few events can be detected, as long as they can be distinguished from events such as muon-induced fission. For the natural chains ^{238}U has the highest fraction of decays by spontaneous fission, 5.4×10^{-7} . Although this leads to a multitude of natural decay chains consisting of fission followed by decays through fission product chains, the process will not be considered in this chapter.

Because fusion reactions such as $3\ ^4\text{He} \rightarrow\ ^{12}\text{C} + Q$ and $4\ ^4\text{He} \rightarrow\ ^{16}\text{O} + Q'$ are exothermic ($Q = 7.275\ \text{MeV}$ and $Q' = 11.16\ \text{MeV}$), when several α decays occur in sequence, the corresponding “crossover” decays can occur. For example, in the $4n$ chain the primary flow from ^{228}Th is a sequence of four α decays to ^{212}Pb . The crossover process would be $^{228}\text{Th} \rightarrow\ ^{16}\text{O} + ^{212}\text{Pb} + 39.06\ \text{MeV}$. In fact, the process $^{228}\text{Th} \rightarrow\ ^{20}\text{O} + ^{208}\text{Pb} + 44.72\ \text{MeV}$ is even more energetically favorable and is found to occur in $1.13 \times 10^{-11}\%$ of the decays of ^{228}Th . The low probability corresponds to the improbability of such a large particle as ^{20}O to tunnel through the Coulomb barrier. In this case the crossover does not lead to a product outside the chain. In some cases the mass number of the emitted heavy ion is not a multiple of 4 (e.g., ^{14}C), and the process crosses to another chain. Several known cases of heavy ion emission are listed in [Table 13.5](#). (A more complete list is given in [Chap. 18](#) in this Volume.) None is sufficiently probable as there are significant violations of the $4n + x$ rule for chains.

In some cases, heavy ion emission has been characterized in considerable detail. The structure in the ^{14}C emissions from ^{223}Ra has been observed. The energies are 29.8, 29.1, and 28.6 MeV, which populate ^{209}Pb levels at 0 (9/2+), 779 (11/2+), and 1,423 keV (spins and parities, in parenthesis) with relative intensities 15, 84, and 4, respectively.

The nuclides in the natural radioactive decay chains are not the most favorable candidates for heavy ion emission; they have unfavorable N/Z ratios. As shown in the example of emission of oxygen isotopes by ^{228}Th , emission of a $Z = N$ fragment leads to a product that is far from the center of β stability. Of course, emitting a fragment with $N > Z$ (e.g., ^{20}O) displaces the emitted

Table 13.5

Instances of heavy ion emission by members of the natural decay chains

Chain	Emitter	Heavy ion	Probability	Product	Q value	Partial $T_{1/2}$
$4n$	^{228}Th	^{20}O	1.13×10^{-13}	^{208}Pb	44.7 MeV	1.7×10^{13} years
	^{224}Ra	^{14}C	4.3×10^{-11}	^{210}Pb		2.3×10^8 years
$4n + 1$	^{225}Ac	^{14}C	6.4×10^{-12}	^{211}Bi		
	^{221}Ra	^{14}C	1.2×10^{-12}	^{207}Pb		
	^{221}Fr	^{14}C	8.8×10^{-13}	^{207}Tl		
$4n + 2$	^{234}U	Ne	9×10^{-12}	Pb		
	^{234}U	Mg	1.4×10^{-11}	Hg		
	^{230}Th	^{24}Ne	5.6×10^{-13}	^{206}Hg		
	^{226}Ra	^{14}C	3.2×10^{-11}	^{212}Pb	28.2 MeV	5×10^{13} y
	^{222}Ra	^{14}C	3.5×10^{-8}	^{208}Pb	33.0 MeV	34 years
$4n + 3$	^{235}U	^{20}Ne	8×10^{-12}	^{215}Pb		
	^{223}Ra	^{14}C	6×10^{-10}	^{209}Pb		

particle from β stability. If the emitter is on the proton excess side of stability, its decay benefits from extra “push” and can reach more stable products. The partial half-lives for heavy particle emission are very sensitive functions of the Q values. Although 38 s ^{222}Ra is not a member of a natural chain, it is included in the table to illustrate this point. Even though ^{222}Ra has a much shorter physical half-life than ^{226}Ra , the fraction of decays that involve ^{14}C emission is much higher — 3.5×10^{-8} versus 3.2×10^{-11} . The ratio of partial half-lives (see the last column of the table) is even more striking.

Heavy ion emission would be grouped with spontaneous fission and not considered in this chapter were it not for the convenience the chains afford as a source of radioactive materials with which to study the process. Products such as ^{222}Ra can be produced in charged-particle bombardments, but that implies the presence of energetic ions, which can complicate the detection of a few heavy ions from decay. The ranges of the heavy ions emitted by processes analogous to α decay are a few milligrams per square centimeter. Thin sources are needed, and the carrier-free materials that can be isolated from the chains serve this purpose well. It is likely that heavy particle emission will be found to be a decay mode for most heavy elements.

13.5 Chemical Properties

The most significant chemical property of most members of the chains is that each element is carrier-free — there are no inactive atoms to compete with the radioactive ones for chemical sites, such as ion-exchange sites on the inner surface of a container. In extreme cases, such as polonium in the ^{232}Th chain, there will be few if any atoms at a given time. The specific activity of ^{232}Th is 4,070 Bq/g. If 1 g of thorium is in equilibrium with its chain, the activities of 0.15 s ^{216}Po and 0.3 μs ^{212}Po will be 4,070 Bq and 2,609 Bq (64.1%), respectively. On average there will be 881 atoms of ^{216}Po present at any given time. Only 0.1% of the time is even one atom of ^{212}Po present. Francium is even more rare. It occurs only in the ^{235}U chain (and the extinct $4n + 1$), and then only in a 1.4% branch. There are only a few grams of Fr in the entire crust of the Earth.

■ **Table 13.6**

Chemistry of the chain elements. *Astatine and francium were discovered as the products of nuclear reactions. They are present in only one of the natural chains (^{235}U), and even then not in the main branch (see ► [Fig. 13.3](#)). The masses given in the last three columns refer to undisturbed (secular) equilibrium along the whole chain. See text for more details

Element	Oxidation state(s)	Monograph NAS-NS 30xx	Year of discovery	Mass/g of ^{232}Th	Mass/g of ^{238}U	Mass from ^{235}U /g of U
Thallium	1 3		1861	136 ag	0.1	82 ag
Lead	2 4	3040	Ancient	Various	Various	Various
Bismuth	3 5	3061	1753	7.6 fg	7.7 pg	38 ag
Polonium	2 4	3037	1898	0.3 ag	75 pg	~3 atoms
Astatine	–1 1 3 5 7	3012	1940*	–	–	<1atom
Radon	0	3025	1900	120 ag	2.2 pg	1.2 ag
Francium	1	3003	1939*	–	–	5.6 ag
Radium	2	3057	1898	0.4 ng	340 ng	303 fg
Actinium	3	3020	1899	49 fg	–	215 pg
Thorium	4	3004	1828	1 g	44 ng	1.2 pg
Protactinium	4 5	3016	1913		757 ag	332 ng
Uranium	3 4 5 6	3050	1789		1 g	7.2 mg

The chemical properties span a range similar to the representative elements in the first few rows of the periodic table. Francium and radium are certainly characteristic of alkali and alkaline earth elements. Both Fr and Ra have only one oxidation state in chemical combinations and have little tendency to form complexes. Thallium in the 1+ oxidation state has alkali-like properties, but it does form complexes and has extensive chemistry in its 3+ state. Similarly, lead can have alkaline earth characteristics, but differs from Ra in forming complexes and having a second, 4+, oxidation state. Bismuth and actinium form 3+ ions in solution and are similar to the lanthanides and heavy ($Z > 94$) actinides. Thorium also has a relatively simple chemistry, with similarities to zirconium and hafnium. Protactinium is famous for difficult solution chemistry; it tends to hydrolyze and deposit on surfaces unless stabilized (e.g., by $>6\text{ M}$ sulfuric acid). The chemistry of uranium as the uranyl ion UO_2^{2+} is fairly simple, but several other oxidation states are possible.

These properties and references for monographs giving detailed radiochemical characteristics (published by the U.S. National Academy of Sciences beginning in 1960 in a series NAS-NS 30xx, e.g., NAS-NS 3040 for lead) are given in ► [Table 13.6](#) (see also LANL [2004](#)).

Abstract: Technetium (Tc) ($Z = 43$) and promethium ($Z = 61$) are the only elements below bismuth ($Z = 83$) in atomic number that have no stable isotopes. The discovery of these unusual elements is described, and the physical factors leading to their instability are discussed.

14.1 Introduction

The last of the naturally occurring stable elements were discovered in 1923 ($_{72}\text{Hf}$) and 1925 ($_{75}\text{Re}$). This concluded over a century of rapid discovery of elements found in the earth's crust. Two holes among atomic numbers below $_{83}\text{Bi}$ remained: 43 and 61. Moseley's correlation of atomic number with the energies of transitions involving inner atomic electrons made it clear that the gaps were real.

The steps and missteps in the process of discovering new elements led to caution in accepting a previously unidentified spectroscopic feature as evidence for a new element (Boyd 1959). Chemical characterization was required. For example, "masurium" was proposed for element 43, and "illium" and "florentium" were proposed for element 61 based on atomic spectroscopy of extracts from minerals. In retrospect, it is clear that there was evidence for unusual conditions for these elements. For example, above $_{7}\text{N}$ the only mass numbers of stable isotopes of elements with odd atomic number are also odd, and there is only one stable isobar for each odd A . Molybdenum (Mo) has stable isotopes 92, 94–98, and 100. Ruthenium has 96, 98–102, and 104. Niobium has 93, and rhodium 103. Nothing is left for technetium, which would have the best chance for stability at mass numbers 97 and 99. Similarly, either neodymium or samarium has a β -stable isotope from 142 to 150; nothing is left for promethium.

There is little difference between protons and neutrons with respect to nuclear properties, but our interest in elements leads to an emphasis on atomic numbers. There are more missing neutron numbers (19, 35, 39, 45, 61, 89, 115, and 123).

The development of the cyclotron and, later, the fission reactor gave the means for a variety of artificial transmutations, but it often was difficult to identify the element and mass number of a radioactive product. In many cases, individual radionuclides could be characterized only by simple features, such as half-life or attenuation of radiations in absorbers, which did not allow discriminating the components of a complex mixture. Chemical evidence was required in order to make definite identification with a particular element.

Except when original observations are relevant, nuclear properties are taken from compilations (Browne et al. 1986; Firestone et al. 1996; Baum et al. 2002).

14.2 Discovery of Technetium

According to the periodic table, the missing element at atomic number 43 should be between manganese and rhenium with regard to chemical properties. The group that discovered rhenium in 1925 (Noddack et al. 1925) claimed to have detected element 43 ("masurium") in the same minerals. They subsequently were able to isolate weighable quantities of rhenium (more than a gram in 1928), but neither they nor others could confirm detection of element 43.

Technetium was finally discovered by Perrier and Segrè in 1937 (Perrier and Segrè 1937). E.O. Lawrence had bombarded a Mo plate with deuterons (and secondary neutrons) in the

Berkeley cyclotron for several months prior to shipping the plate to Segrè's group in Italy in late December, 1936. Perrier and Segrè began their radiochemical studies in late January, more than 6 weeks after the end of bombardment. On the surface exposed to the deuterons, they found "strong activity, chiefly due to very slow electrons" ascribed to "more than one substance of a half-value period of some months" in addition to ^{32}P (which they could not explain, but did not attribute to reactions with molybdenum).

Subsequent work (Cacciapuoti and Segrè 1937) revealed that most of the Tc activity arose from what are now known to be 61-day $^{95\text{m}}\text{Tc}$ and 90.1-day $^{97\text{m}}\text{Tc}$.

► **Table 14.1** shows a nuclide chart corresponding to charged particle reactions with Mo. Both (d,n) and (d,2n) reactions are energetically allowed (have energy requirements, Q , that are met by the bombarding particle) and lead directly to Tc. For example, the Q values for ^{95}Mo (d,n) ^{96}Tc and ^{95}Mo (d,2n) $^{95\text{m}}\text{Tc}$ are -3.25 and -4.74 MeV, respectively. The Q value for ^{97}Mo (d,2n) $^{97\text{m}}\text{Tc}$ is -3.42 MeV. In addition, (d,p) reactions with ^{98}Mo and ^{100}Mo produce Mo isotopes that subsequently decay to Tc. Therefore, the bombardments produced many different radioactive products, but after a few months 61-day $^{95\text{m}}\text{Tc}$ and 90.1-day $^{97\text{m}}\text{Tc}$ dominate the activity. Note that both of these are isomeric levels. One, $^{95\text{m}}\text{Tc}$, decays primarily (96%) by electron capture (EC) and subsequent γ -ray emission. The other, $^{97\text{m}}\text{Tc}$, decays by a highly converted 96.6 keV transition, which presumably produced the "slow electrons" reported (Perrier and Segrè 1937).

The chemical identification consisted of three parts: (1) removing ^{32}P , (2) showing that the remaining activity was not due to zirconium, niobium, or molybdenum, and (3) showing that the element was similar, but not identical, to rhenium.

Until recognized for what it was, the ^{32}P was very confusing. Once recognized, it was removed by precipitating magnesium ammonium phosphate.

Zirconium was isolated as a hydroxide, molybdenum as a sulfide, and niobium as sodium metaniobate. None carried a significant part of the activity.

In solutions containing inactive manganese and rhenium carriers as well as the activity under study, the activity generally followed rhenium. This is consistent with the greater chemical similarities of heavy members of a group in the periodic table as compared to differences among lighter members. However, Tc_2O_7 is more volatile than Re_2O_7 , and the chloride is less volatile. Other chemical properties of Tc are summarized in ► Sect. 14.5.

Stable isotopes are shaded and list natural abundances in percentage. When isomers exist and relative energies of the states are known, the half-life of the isomer is given above that of the ground state. See also ► **Table of Nuclides** in this volume's appendix (My = Ma, i.e., 10^6 years; ky = ka, i.e., 10^3 years).

14.3 Discovery of Promethium

In principle, $_{61}\text{Pm}$ could have been discovered by techniques similar to those used for $_{43}\text{Tc}$ – bombardment of $_{60}\text{Nd}$ with charged particles from a cyclotron and demonstration that some of the products were isotopes of element 61. Indeed the bombardments were done, and several radionuclides that might have been isotopes of element 61, for example, “cyclonium” (Pool and Quill 1938), were produced, but the essential chemical proof was lacking. Whereas technetium and its neighbors differ considerably in chemical properties, variations among neighboring rare earths are very slight. This chemical characterization was beyond the capabilities of the groups carrying out the bombardments.

Conventional chemistry is illustrated by the chemistry used to support the claim of “illinium” (Harris et al. 1926). This report is one (*Observations on the Rare Earths XXIII*) of a series of studies in which concentrates rich in one or more rare earths were studied by arc spectroscopy. Harris et al. chose a concentrate prepared by methods that were intermediate between those found to enhance $_{60}\text{Nd}$ and $_{62}\text{Sm}$. The visible and infrared emissions were found to have about 130 lines that were not unique to either Nd or Sm fractions. They found support for their claims in absorption spectra of solutions and L X-ray emission spectra associated with the concentrate.

The chart of the nuclides in the region of promethium is given in ▶ Table 14.2. It is obvious now that there is a negligible amount of promethium in natural materials, and if macroscopic amounts were present, the radioactivity would be intense. The isotope with the longest half-life is 17.7-year ^{145}Pm . If it were present at 1 ppm in a 1-g sample, the activity would be 6 MBq.

In order to separate adjacent elements and to isolate very small quantities, a new chemistry was needed. This chemistry, ion-exchange chromatography (see ▶ Chap. 51 in Vol. 5) with synthetic resins (Walton 1976), was developed during the Manhattan project in order to study the products of nuclear fission, which include several light rare earths. The technique was borrowed in order to identify element 61.

The columns contain isotones. The fission yields for ^{235}U are given for several mass chains (i.e., isobars situated along the lines shown by the slanted arrows). Stable isotopes are shaded and list natural abundances in percentage. (The upmost cells show the stable and primordial Sm isotopes.) See also ▶ Table of Nuclides in this volume’s appendix.

By mid-1945, over 30 fission products had been characterized as isotopes of yttrium or one of the lanthanides, but few could be definitely assigned by element and mass numbers. The work that ultimately identified element 61 began with a mixture of radioactive materials that concentrated elements between cerium and samarium. This mixture included a soft β emitter with a half-life of ~ 4 years and a γ emitter of ~ 11 days.

Marinsky, Glendenin, and Coryell reported their discovery of promethium in part as follows:

- In the comprehensive studies of the radioactive species produced in the fission of uranium it has been found that over thirty are members of the rare earth family (isotopes of yttrium and the group lanthanum through europium). The chemical and physical identification of these was an important part of the research program of the Manhattan Project. Standard oxidative separations and fractional precipitations and the use of radiochemical methods based on chain relations served to distinguish the activities of yttrium, lanthanum, cerium, and some of praseodymium, and those of samarium and europium. The characterization of the sequence praseodymium, neodymium, and element 61 presented very difficult problems that were solved only with the intensification of ion exchange methods originally developed by Boyd and co-workers and applied to the rare earth field by Cohn and co-workers. (Marinsky et al. 1947)

The ion-exchange medium was Amberlite IR-1, a sulfonated phenol-formaldehyde resin, and the eluting agent was 5% ammonium citrate at pH 2.75. The order of elution of the rare earths had been established in a series of experiments with radioactive cerium, lanthanum, europium, and yttrium produced by fission, and praseodymium and europium produced by neutron capture. The lanthanides elute in reverse order of atomic number, and yttrium precedes the fission-product lanthanides. Although the technique was a vast improvement over conventional chemical procedures, the physical form of the resin was quite inferior to modern, uniform beads. Resolution was barely better than the separation between adjacent elements, and there was considerable tailing. It is fortunate that the elution order puts low yield products before higher yield ones; this minimized the interference from tailing.

A sample of the praseodymium group (praseodymium, neodymium, and element 61; most of the cerium, samarium, europium, and yttrium fission products had been removed, cerium by ceric iodate precipitations and the others by potassium carbonate digestions) was absorbed on an Amberlite IR-1 column. The elution curve is shown in ► Fig. 14.1. The soft β emitter (now known to be 2.62-year ^{147}Pm ; see ► Table 14.2) appeared in the position expected (by interpolation) for element 61 and became the first isotope identified as the element subsequently named promethium. The ~ 11 -day γ emitter eluted in the position expected for neodymium (10.98-day ^{147}Nd). The praseodymium peak was primarily 13.6-day ^{143}Pr . The yttrium peak was primarily 58.5-day ^{91}Y ; the fission yields of ^{143}Pr and ^{91}Y were high, $\sim 6\%$, and the yttrium peak represented $\sim 0.001\%$ of the fission yield.

Subsequent experiments with neutron-activated neodymium, described in the same report, revealed a 1.7-h isotope of neodymium (too short to be isolated from fission with the available columns) and a 47-h isotope of element 61 (also detected in fission).

Mass number assignments were based on quantitative analysis of the chemically resolved fractions. Fission is known to produce primarily products with neutron/proton ratios similar to the fissioning nuclide (here ^{235}U , two to three neutrons less which accompany the fragments). For $A = 147$, the most likely products are 4-s ^{147}La and 56-s ^{147}Ce , which join their short-lived isobars by quickly cumulating in 11-day ^{147}Nd . Very little ^{147}Pm is produced as a primary fission product; just as in neutron activation of Nd, ^{147}Pm is a product of decay of ^{147}Nd .

■ Fig. 14.1

Elution curve for the praseodymium group of fission products from Amberlite IR-1 (Reprinted with permission from Marinsky et al. 1947. © 1947 American Chemical Society)

The general form of the mass-yield distribution was also known; the yield drops rapidly with increasing mass number above 144. By showing that the cumulative fission yield of the “~4-year” product was about twice that of the “48-h” product, combined with the results of activation measurements, ^{147}Pm and ^{149}Pm were identified by mass number as well as atomic number.

14.4 Why Do Tc and Pm Have No Stable Isotopes?

There is nothing remarkable about atomic numbers 43 and 61, except that they are odd integers and, in terms of nuclear stability, unlucky. In random assemblages of neutrons and protons, there are equal probabilities for even A versus odd A or even Z versus odd Z . However, far fewer odd- Z nuclides are stable. These generalizations can be understood in terms of the symmetry and pairing terms in the semiempirical mass equation (Choppin et al. 2002; Friedlander et al. 1981). The symmetry term is proportional to $(N-Z)^2$ and leads to a parabolic dependence on Z at constant A . The pairing term raises odd- Z odd- N nuclides and lowers even- Z even- N nuclides, producing two parabolas for even- A isobars. The effect is exemplified by the $A = 98$ isobars shown in Fig. 14.2. Both parabolas are centered on $Z = 43.0$, and they are separated by ~ 2.22 MeV; ^{98}Tc would be at the bottom and, therefore, stable, were it not for the pairing term.

For mass numbers above ~ 40 , and certainly by $A \sim 98$, Coulomb energies are significant, and stable nuclides have more neutrons than protons. The parabolic minima define $Z_A(A)$, which increases by ~ 0.45 per mass unit in the vicinity of Tc. Therefore, the minima should be $\sim 43.0 - 0.45 = 42.55$ at $A = 97$ and should be 43.45 at $A = 99$. Both of these are closer to 43 than to the adjacent atomic numbers. If masses were exactly parabolic, both ^{97}Tc and ^{99}Tc would be stable. These are the conditions that lead to two stable isotopes for some odd- Z elements.

Although the masses (energies) are nearly parabolic, as shown in Fig. 14.3, valence neutrons are slightly more stable than valence protons. According to the mass equation, energy

■ Fig. 14.2

Relative energies of the $A = 98$ isobars. The odd- Z and even- Z elements are represented by *squares* and *diamonds*, respectively. The lines are quadratic (parabolic) fits to the data of each type

■ Fig. 14.3

Relative energies of the $A = 97$ (top) and $A = 99$ (bottom) isobars

differences between adjacent isobars should be linear with atomic number. These energy differences are just the Q values for β decay (β^- and EC). These energy differences are shown in ▶ Fig. 14.4. The upper part gives EC energies for $A = 97$ isobars for comparison with ^{97}Tc , which decays by this mode. The lower part gives β^- energies for $A = 99$ for comparison with ^{99}Tc . In both parts, linear fits to odd- Z and even- Z elements are shown. For both chains, the small positive decay energy for Tc would disappear if the neutron–proton separation were removed.

The same analysis applies to promethium. ▶ Figure 14.5 shows the decay energies for isobars of ^{145}Pm (17.7-year EC decay) and ^{147}Pm (2.62-year β^- decay). Just as for technetium, the most favored isotopes of promethium just miss being stable because of small differences in neutron–proton stabilities.

Although these promethium isotopes have much shorter half-lives than the corresponding technetium isotopes, the decay energies for promethium are actually lower. Decay of the technetium isotopes is hindered by large angular momentum changes.

Because of a small difference in stability of valence neutrons and protons, combined with fortuitous combinations of symmetry and Coulomb energies, technetium and promethium have no stable isotopes.

■ Fig. 14.4

Q values for electron capture (EC) decay of $A = 97$ isobars (top) and β decay of $A = 99$ isobars (bottom)

■ Fig. 14.5

Q values for electron capture (EC) decay of $A = 145$ isobars (top) and β^- decay of $A = 147$ isobars (bottom)

Since Z_A increases ~ 0.4 per mass number, the neutron number must increase by ~ 0.6 per unit A . Therefore it is *expected* that all isotones for some odd N would be unstable. As pointed out in [Sect. 14.1](#), there are eight such neutron numbers.

14.5 Chemical and Physical Properties

Neither element is unusual except for the absence of stable isotopes. Of course this means that either pure element can have high specific activity; there are no nonradioactive forms to dilute the activity.

On the earth, the most likely source of macroscopic amounts for technetium and promethium is the reprocessing of irradiated uranium and plutonium from fission reactors. This mechanism produces only a few, and not the longest-lived, isotopes.

For technetium, most of the mass consists of 2.1×10^5 -year ^{99}Tc . Heavier isotopes are short lived, and lighter isotopes are “shielded” by stable isotopes of molybdenum (here “shielded” means not fed by chain decay). The cumulative fission yield of ^{99}Tc is $\sim 6\%$ for both ^{235}U and ^{239}Pu . Because of the long half-life, this isotope contributes little to the total activity of fission products for the first 100 years, but it is the dominant fission product after 1,000 years. There is little energetic γ emission; it is difficult to detect ^{99}Tc in impure matrices without chemical processing. The dominant mode of decay is 293.5-keV β^- decay to the ground state of ^{99}Ru . Only 0.0016% of the β^- decays goes to excited states. The only γ -ray is the $\sim 6 \times 10^{-4}\%$ 89.7-keV γ .

The most important isotope of technetium is 6.0-h $^{99\text{m}}\text{Tc}$. It is a valuable tool of medical diagnostics because of its chemical versatility and the energy of its γ -ray. This application is described in detail in ► Chap. 43 of Vol. 4.

For promethium, most of the mass in aged fission products consists of 2.62-year ^{147}Pm , which (except for half-life) has decay characteristics similar to ^{99}Tc . The dominant decay mode is 224-keV β decay to the ^{147}Sm ground state. Only 0.0057% of decays feeds excited states. The most intense γ -ray is the 0.0029% 121.2-keV γ -ray. Because of its high specific activity and the absence of penetrating radiation, ^{147}Pm has been used as a source of energy in thermoelectric converters for remote applications.

Anders (1960) summarized the chemical properties of technetium in his monograph on radiochemistry.

- In many respects, the analytical behavior of Tc is similar to that of Re. Both form stable XO_4^- anions that give insoluble salts with large cations; both form volatile heptoxides; and both form acid-insoluble heptasulfides. However, there are subtle differences between the two elements that can cause them to behave very differently under certain conditions. The vapor pressure of Tc_2O_7 is much higher than that of Re_2O_7 at low temperatures (e.g., 10^{-1} mm at 100°C , compared to $\sim 3 \times 10^{-5}$ mm for Re_2O_7). In contrast to rhenium, technetium (VII) is therefore easily lost upon evaporation of acid solutions unless a reducing agent is present or the evaporation is conducted at a very low temperature. Ignorance of these factors has led to a multitude of conflicting statements concerning the volatility of technetium.

The chemistry of promethium must be understood in terms of the trends in properties within the rare earth, or lanthanide, series. The radiochemistry of these elements (plus scandium and yttrium) has been described by Stevenson and Nervik (1961).

Abstract: Isotope effects, that is, differences brought about by isotopic substitution in the physical and chemical properties of atoms and molecules, are reviewed from the point of view of spectroscopy, chemical equilibria, phase equilibria, physicochemical properties, reaction kinetics, and biology. The theory of isotope effects is discussed in some detail.

15.1 Introduction

If naturally occurring water, containing deuterium in low concentration, evaporates then the concentration of deuterium in the liquid phase increases because H_2O is more volatile than HDO . (Note that deuterium ^2H will be denoted by D in this chapter, whereas protium ^1H , the common isotope of hydrogen, will be denoted by H , as customary in this field.) The viscosity of D_2O is higher than that of H_2O . The diffusion rate of ^{36}Ar is higher than that of the heavier argon isotope ^{40}Ar . The infrared spectrum of CH_4 is different from that of CD_4 . The reaction of an organic compound becomes substantially slower if, in the rate-determining step of the reaction, a $\text{C}-\text{D}$ bond is being broken instead of a $\text{C}-\text{H}$ bond. Other examples abound.

These differences brought about by isotopic substitution in the physical and chemical properties of atoms and molecules are called *isotope effects*. The differences in the characteristic parameters of nuclear transformations (half-life, energy of radiation, cross section) are not considered as isotope effects. The molecules that differ in their isotopic composition are usually called *isotopic molecules* in the literature. However, according to the IUPAC terminology, a molecular entity that differs solely in isotopic composition (number of isotopic substitutions), for example, CH_4 , CH_3D , CH_2D_2 , CD_4 , is called *isotopologue*. Isomers having the same number of each isotopic atom but differing in their positions are called *isotopomers* (the term is a contraction of “isotopic isomer”). Isotopomers can be either constitutional isomers (e.g., $\text{CH}_2\text{DCH}=\text{O}$ and $\text{CH}_3\text{CD}=\text{O}$) or isotopic stereoisomers (e.g., (*R*)- and (*S*)- CH_3CHDOH). The term isotopologue is preferable to the customary “isotopomer,” which ought to be restricted to species that are constitutionally or stereochemically isomeric because of isotopic substitution.

Isotope effects are usually based on the differences between the masses of the atoms and therefore they are referred to sometimes as “isotope-mass effects” (the so-called mass-independent isotope effects, for example, the “magnetic isotope effects,” which are due to the differences between the nuclear spins of isotopes, will be discussed in [Sect. 15.8](#)). The geometrical and electronic structures of isotopic molecules are much the same because isotopic nuclei differ only in the number of neutrons, while it is the number of protons that determines the nuclear charge and thus the electron distribution and molecular structure. This fact leads to a great simplification in theoretical calculations of isotope effects.

Isotope effects can be divided in two main groups: phenomena that are directly connected to the differences in the molecular mass (thermal motion, motion in gravitational, electric, and other fields) and those connected to different mass distributions within the molecule (isotope effects on molecular spectra, chemical equilibria, reaction rate, etc.). Isotope effects may also be classified according to the field in which they are observed: physics, chemistry, biology, geology, spectroscopy, etc. Isotope effects play an important role in the variation of stable isotope compositions in nature. The differences in chemical and physical properties of the isotopes form the basis of their separation from each other and make possible the production of enriched isotopes for industrial, military, medical, and research purposes (see [Chap. 51](#) in Vol. 5).

Extensive information about isotope effects can be found in a number of books, book chapters, and review papers (e.g., Brodsky 1961; Roginski 1962; Wolfsberg 1969c; Krumbiegel 1970; Rabinovich 1970; Collins and Bowman 1971; Wolfsberg 1972; Bigeleisen et al. 1973; Bigeleisen 1975, 1984; Vértés and Kiss 1987; Criss 1999).

15.2 Mechanical Effects

The average speed of gas molecules at a given temperature depends on their masses, therefore, in a gas made up of molecules containing different isotopic species, those molecules containing the light isotope will, on average, have speeds slightly higher than those that contain the heavy isotope. In the gaseous diffusion process used for the enrichment of ^{235}U isotope, the maximal theoretical separation that can be achieved is equal to the square-root of the ratio of the masses of the gas molecules. In the diffusion process, utilizing uranium hexafluoride, this ratio is 1.00429. Because this number is so close to unity, the degree of enrichment that can be achieved in a single diffusion stage is very small, but the effect can be multiplied by making use of a cascade consisting of a number of stages.

Isotope effects can also be observed in the concentration distribution of gaseous substances in mechanical fields. In the earth's gravitational field, the pressure decreases with increasing altitude, which can be described by the barometric formula

$$p_h = p_0 \exp\left(-\frac{Mgh}{RT}\right) \quad (15.1)$$

where p_h and p_0 are the pressures at altitude h , and at zero altitude, respectively, g is the gravitational acceleration, M is the molar mass, R is the gas constant, and T is the temperature. (It should be noted that during the derivation of Eq. (15.1), the h dependence of T and g has been neglected, therefore it is only a rough approximation to actual atmospheric pressures). As a consequence of Eq. (15.1), the ratio of the concentrations (c'_h/c_h) of two isotopic variants with molecular masses M' and M , respectively, changes with the altitude according to the following equation

$$\frac{c'_h}{c_h} = \frac{c'_0}{c_0} \exp\left(-\frac{(M - M')gh}{RT}\right). \quad (15.2)$$

Similarly, the ratio of the concentrations of the two isotopic species will be different at the axis of a gas centrifuge and at a distance r from the axis:

$$\frac{c'_r}{c_r} = \frac{c'_0}{c_0} \exp\left(-\frac{(M - M')(\omega r)^2}{2RT}\right) \quad (15.3)$$

where ω is the angular velocity of the centrifuge. This effect is utilized in the enrichment of ^{235}U isotope. The magnitude of the separation factor $\alpha = (c'_r/c_r)/(c'_0/c_0)$ in this case is the function of the absolute mass difference of the isotopic molecules, not of the relative mass difference, which is the case in the other processes. This fact is especially advantageous for isotope separation of heavier elements.

In electric and magnetic fields, the deflection of ions from the original direction of motion also depends on their mass m . The deflection (X) of an ion with velocity u and charge q in an electric field E can be given as

$$X \propto \frac{Eq}{mu^2}. \quad (15.4)$$

The magnitude of the deflection (Y) caused by a magnetic field strength H is

$$Y \propto \frac{qH}{mu}. \quad (15.5)$$

► Equations (15.4) and ► (15.5) show that the deflections of the ions of the lighter isotope are greater than those of the heavier isotope, provided that their velocities and charges are the same. The isotope analysis by mass spectrometry and the electromagnetic isotope separation method using large-scale mass spectrometers, called Calutrons because of their early development at the University of California Cyclotron Laboratory, are based on these effects.

The kinetic theory of gases yields theoretical expressions for the thermal conductivity and other transport properties of gases. For ideal gases around atmospheric pressure, where the mean free path is much less than the smallest dimension of the container, the ratio of the thermal conductivities of the isotopic molecules is inversely proportional to the ratio of the square-roots of their molecular masses. At lower pressures, where the mean free path becomes comparable to, or larger than the dimensions of the container, the thermal conductivity will be strongly pressure dependent. The isotope analysis of isotopic gas mixtures by using a catharometer is based on the fact that, to a first approximation, the relationship between the thermal conductivity and isotopic composition of the mixture is linear (Müller et al. 1969). The isotope ratio of the viscosities of gases is equal, to a first approximation, to the square-root of the molecular mass ratio.

On the basis of the mass dependence of the different forms of motions of isotopic molecules, one can expect isotope effects also in the rate of evaporation, condensation, dissolution, and crystallization as well as in electric mobilities of ions.

15.3 Isotope Effects in Spectroscopy

Isotope effects in atomic spectroscopy can be illustrated using the example of the visible spectra of hydrogen that led Urey et al. (1932) to the discovery of deuterium (the first public announcement of the discovery was made at the 1931 Christmas meeting of the American Association for the Advancement of Science in New Orleans). The spectral lines of the visible spectra of hydrogen (Balmer series) can be given by the Rydberg equation, which describes the energy change accompanying the jump of an electron from the n th orbital to the 2nd

$$\frac{1}{\lambda_H} = R \left(\frac{1}{2^2} - \frac{1}{n^2} \right), \quad (n > 2) \quad (15.6)$$

where λ_H is the wavelength of a spectral line, R is the Rydberg constant that depends on the mass of the nucleus; its values for hydrogen and deuterium are 109,677.58 and 109,707.42 cm^{-1} , respectively. Urey et al. (1932) observed weak satellites for four of the Balmer lines of hydrogen ($n = 3, \dots, 6$), which were shifted to shorter wavelengths and the magnitudes of these shifts were found to be in exact agreement with the predictions of ► Eq. (15.6) if one assumed the existence of a nucleus with a mass of “2.”

In a diatomic molecule isotope effects appear in the vibrational, rotational, and electronic spectra. Isotope effects on vibrational spectra can be interpreted within the framework of the *Born–Oppenheimer approximation*, which is the cornerstone of most theories dealing with the effects of isotopic substitution on molecular properties. In this approximation, the potential energy surface for the vibrational-rotational motions of a molecular system is taken as being independent of the masses of the nuclei. Thus, the nuclei of different masses move on the same potential surface because to good approximation the electronic structure is independent of isotopic substitution. Then, the harmonic vibrational frequencies of the two isotopic variants of a diatomic molecule (prime denotes the lighter molecule) can be given as

$$\frac{\omega'}{\omega} = \sqrt{\frac{\mu}{\mu'}} \quad (15.7)$$

where ω is the frequency and μ is the reduced mass ($= m_a m_b / (m_a + m_b)$), m_a and m_b are the atomic masses of the atoms in the diatomic molecule. Vibrational and rotational lines cannot always be observed separately; changes in the vibrational state are accompanied by changes of the rotational state and the rotational constant is dependent on the vibrational quantum number. It should also be noted that quite often the potential curve is significantly anharmonic.

The effect of isotopic substitution appears also in the electronic spectra of diatomic molecules that led to the discovery of ^{18}O , ^{17}O , ^{13}C , and ^{15}N by the methods of optical molecular spectroscopy in 1929 (see, e.g., Nash 1975).

Isotopic substitution plays an important role in the determination of vibrational force constants of small polyatomic molecules from observed vibrational frequencies.

In the general valence force field of an N -atomic nonlinear molecule, there are $\frac{1}{2}(3n - 6) \times (3n - 5)$ force constants, but maximum only $3n - 6$ vibrational frequencies may be observed. Isotope substitution changes the vibrational frequencies without changing the force constants (within the Born–Oppenheimer approximation) and thus increases the number of data from which the force constants can be determined.

If hydrogen is replaced by deuterium in one of the substituents connected to an asymmetric carbon atom, the optical activity may change by several per cent. Similar shifts can be observed when the solvent is changed for its deuterated variant. Isotopic substitution can create asymmetry in a molecule, for example, by replacing one of the hydrogen atoms in a compound of the type $\text{R}_1\text{-CH}_2\text{-R}_2$, and thereby induce optical activity. In this case, the molecular chirality arises solely from an isotopic substitution and the phenomenon can be well understood in terms of vibronic interactions that differ for isotopically substituted and parent molecules (Polavarapu et al. 1981). One example is the α -deuteroethyl benzene molecule in which one of the hydrogen atoms of the methylene group is replaced by deuterium and the optical activity of this compound is $\alpha_D^{25} = -0.30^\circ$. The replacement of H by D in the C–H bond will result in a shortening of the average length of the bond, while the rest of the molecule remains unchanged. This very small difference in the average bond lengths of C–H and C–D bonds renders the carbon atom of the methylene group asymmetric and is the principal cause of the optical activity (Dezentje and Dekkers 1976).

The isotope effects observed in different spectral regions are often used for isotopic analysis. For example, in a certain range of the emission spectra of nitrogen there is an isotopic shift of $3. \dots 8 \text{ \AA}$ between ^{14}N and ^{15}N isotopes, on the basis of which an analytical method was developed for ^{15}N -analysis. Emission molecular spectroscopy has also been used for isotope

analysis of hydrogen, lithium, boron, carbon, and oxygen (Müller et al. 1969). The IR absorption intensity of the OH-stretching vibration of HDO at $3,500\text{ cm}^{-1}$ makes possible the high precision deuterium analysis of heavy water. On the other hand, the intensity of the OD-stretching vibration of HDO at $2,510\text{ cm}^{-1}$ can be used for the determination of deuterium content of natural water samples (see, e.g., Fusch et al. 1993). Other interesting applications of spectroscopic isotope effects are described by Nash (1975).

There is a considerable difference between the values of the index of refraction of H_2O and D_2O , 1.33250 and 1.32796 (at 25°C , Na D-line), respectively. This difference can be used for a rapid, although not very precise (± 0.4 atom percent of D) deuterium analysis of water samples by means of a simple immersion refractometer (Müller et al. 1969).

15.4 Isotope Effects in Chemical Equilibria

One of the most characteristic manifestations of the chemical differences between isotopic molecules is the difference between the equilibrium constants for a given chemical reaction. Compare the following chemical equilibria:

where X and X' are different isotopes (the prime denotes the lighter isotope). The equilibrium constants can be written as

$$K'_A = \frac{[\text{BX}'][\text{AY}]}{[\text{AX}'][\text{BY}]} \quad (15.8)$$

$$K_A = \frac{[\text{BX}][\text{AY}]}{[\text{AX}][\text{BY}]} \quad (15.9)$$

where [] denotes the concentration. If there were no difference between the chemical properties of the isotopic molecules, then K'_A would be equal to K_A . However, the vibrational frequencies and, consequently, the zero-point energies and dissociation energies of isotopic molecules are different; therefore the equilibrium constants of the above reactions are also different. The deviation of K'_A/K_A from unity is the isotope effect on the equilibrium constant.

The isotope effect on chemical equilibria can be illustrated with the example of acid–base equilibria. Consider the ionization reactions of the weak acids HA and DA in water and heavy water, respectively

The isotope effect can be characterized by the ratio of the dissociation constants ($K_{\text{H}}/K_{\text{D}}$). For example, it was found experimentally that for OH-, NH-, SH-, and CH-acids K_{D} is less than K_{H} ($K_{\text{H}}/K_{\text{D}} \approx 2.5\text{--}3.9$), that is, the strength of these acids is less in D_2O than in H_2O and the weaker acids exhibit higher $K_{\text{H}}/K_{\text{D}}$ values.

For water and heavy water, the values of the ionization constant at 25°C are 1.00×10^{-14} and 1.38×10^{-15} , which correspond to pH and pD values of 7.0 and 7.43, respectively. This has a practical consequence in the determination of pD values by glass electrodes (Glasoe and Long 1960): if the pH meter is calibrated by using buffer solutions prepared with H_2O , then one must

add 0.40 to the value shown by the instrument (“pH meter reading”) in the case of a solution prepared with D₂O in order to obtain the value of pD (i.e., pD = pH meter reading + 0.40).

15.4.1 Isotope Exchange Equilibria

The ratio of the equilibrium constants K'_A and K_A (Eqs. (15.8) and (15.9))

$$K = \frac{K'_A}{K_A} = \frac{[AX][BX']}{[AX'][BX]} \quad (15.10)$$

gives the equilibrium constant of the isotope exchange reaction

K indicates how the two isotopes are distributed between the two chemical compounds. Instead of K , very often the elementary *separation factor* (fractionation factor) is used, which is defined by

$$\alpha = \left(\frac{N}{N'} \right)_{AX} / \left(\frac{N}{N'} \right)_{BX} \quad (15.11)$$

where N and N' are the atom fractions of the heavier and lighter isotopes in the compounds AX and BX. In general, α is defined in such a way that its value be larger than 1, that is, the compound in which the heavier isotope is enriched is in the numerator of Eq. (15.11). It should be noted that α is only equal to K , if one atom in each molecule takes place in the isotope exchange (the relationship between α and K for the general case is given, for example, by Criss 1999). A separation factor of 1.050 is often referred to as a 5% isotope effect. Some examples for isotope exchange reactions (the values of K for 25°C are given in parenthesis):

The equilibrium constants for isotope exchange reactions are functions of temperature, similarly to those of ordinary chemical reactions. However, contrary to expectations that the magnitudes of the equilibrium constants decrease monotonically with increasing temperature, their temperature dependences may show striking “anomalies,” such as maxima, minima, inflections, and single and multiple inversions (“cross-overs”) as shown by Stern et al. (1968). The temperature dependence of the separation factor constitutes the basis of the “dual temperature” processes used for the production of heavy water (Rae 1978). For example, in the water–hydrogen sulfide (Girdler–Spevack) exchange process, in the hot tower ($\alpha = 1.8$ at 138°C) deuterium passes from the liquid to the gas, whereas in the cold tower ($\alpha = 2.2$ at 30°C) the equilibrium of the exchange reaction shifts to the right, so in the net process deuterium passes from the gas to the liquid.

Isotope effects can also be readily detected in exchange reactions for other light elements. For example, the $^{15}\text{N}/^{14}\text{N}$ ratio is 3.5% higher in solution than in the NH_3 gas when ammonia gas and aqueous solutions of ammonium salts are in equilibrium. The heavier carbon isotope (^{13}C) enriches ($\sim 1\%$) in aqueous carbonate compared with gaseous carbon dioxide.

When stable isotopes are used, for example, as tracers for in vivo metabolic studies, typically the tracer flux is being measured and inferences are made about the flux of the material being traced (“tracee”). When there is no isotope fractionation, the flux of the heavy tracer is equal to the flux of the lighter major isotope and hence the tracee flux. However, when there is isotope fractionation the fluxes of the heavy tracer and tracee are not equal and thus the flux derived from the kinetic analysis of the tracer is not equal to that of the tracee. For example, ^{18}O is fractionated between water and carbon dioxide ($\alpha = 1.041$ at 25°C) thus the rate of removal of ^{18}O by CO_2 is 4.1% greater than the rate of ^{16}O removal. Because ^{16}O comprises 99.8% of the oxygen pool, the rate of CO_2 production is essentially equal to the rate of ^{16}O removal by CO_2 , which will be less by 4.1% than that measured from ^{18}O . Without taking this correction into account, the calculated tracee flux will be in error. On the other hand, the isotope effect becomes negligible in the distribution of the isotopes of heavier elements; therefore, no corrections are necessary in the tracer experiments.

The distribution of isotopes between isotopic molecules is a special case of isotope exchange reactions, for example,

It should be noted that the HDO molecules cannot be isolated from the liquid H_2O - D_2O mixture owing to the above disproportionation reaction (which is fast). The question arises how the isotopes are distributed between the different isotopic molecules. By assuming random isotope distribution, the mole fractions of the isotopic molecules AX_2 , AXX' , and AX_2' are $(1 - x)^2$, $2(1 - x)x$, and x^2 , respectively, where x is the atom fraction of the lighter isotope (X'). This means, for example, that in natural water that contains about 0.015 atom percent D (abbreviated as 0.015 at% D), practically all the deuterium atoms are in the form of HDO. In reality, however, isotope effects can be observed even in these reactions. The equilibrium constant for the above reaction is 3.75 at 25°C instead of 4 (which would correspond to the random distribution).

15.4.2 Calculation of the Equilibrium Constant

The statistical thermodynamic method used for the calculation of equilibrium constants of chemical reactions becomes considerably easier in the case of isotopic exchange reactions. The reason for this is that within the framework of the Born–Oppenheimer approximation, the zero of energy is the same for the isotopic molecules, thus ΔE of the reaction from the zero of energy of reactants to that of the products does not enter into the calculations. Consider the following isotope exchange reaction

the equilibrium constant (K) for this reaction can be written as

$$K = \frac{Q_{\text{A}_2}^a Q_{\text{B}_1}^b}{Q_{\text{A}_1}^a Q_{\text{B}_2}^b} = \left(\frac{Q_{\text{A}_2}}{Q_{\text{A}_1}} \right)^a \left(\frac{Q_{\text{B}_2}}{Q_{\text{B}_1}} \right)^b \quad (15.13)$$

where Q is the partition function of the molecule. It can be seen that the equilibrium constant can be expressed through the ratio of the partition functions of isotopic molecules. These have been calculated for many compounds and are available for different temperatures in the literature (e.g., Urey and Greiff 1935; Urey 1947; Richet et al. 1977; Knyazev et al. 2001).

The calculation of partition functions and of K is based on the following assumptions: the Born–Oppenheimer approximation is valid, that is, the electronic potential energy is independent of isotopic substitution; the partition function can be factored into contributions from translational, rotational, and vibrational motions; the translational and the rotational motions of the molecule can be treated in the classical approximation; the vibrations are harmonic. Corrections to the effect of anharmonicity and to the Born–Oppenheimer approximation on isotopic exchange equilibria have been discussed by Wolfsberg (1969a, b) and by Kleinman and Wolfsberg (1973, 1974), respectively.

In the calculation of equilibrium constants and in the theory of isotope effects, the so-called reduced partition function ratio (RPFR) introduced by Bigeleisen and Mayer (1947) plays an important role. The RPFR (f) is the quantum mechanical partition function divided by the classical partition function, and in the case of an ideal gas is given by the expression

$$f = \prod_i^{3n-6} \frac{u_i}{u'_i} \frac{1 - \exp(-u'_i)}{1 - \exp(-u_i)} \exp\left(\frac{u'_i - u_i}{2}\right) \quad (15.14)$$

where $u_i = h\nu_i/(kT)$ (ν_i is the harmonic frequency of mode i in cm^{-1}), $3n - 6$ is the number of vibrational modes if the number of atoms in the molecule is n . The equilibrium constant for the isotope exchange reaction (Eq. (15.12)) can be written in terms of the reduced partition function ratios as

$$K = \left(\frac{s_{A_1}}{s_{A_2}}\right)^a \left(\frac{s_{B_2}}{s_{B_1}}\right)^b \frac{f_A^a}{f_B^b} \quad (15.15)$$

where the s values are the symmetry numbers of the molecules. The ratio of the symmetry numbers corresponds to the random isotope distribution and to the equilibrium constant derived using classical statistical mechanics. For example, as the symmetry numbers for H_2O , D_2O , and HDO are 2, 2, and 1, respectively, the symmetry number ratios in Eq. (15.15) give a value of 4. The symmetry number factor leads to no fractionation of isotopes, the isotope effect is reflected by the RPFRs; in other words *any isotope separation by an isotopic exchange reaction must be a quantum effect*.

In terms of the RPFRs, some simple and practical relationships can be derived that help understand the direction and magnitude of isotope fractionation between different molecules (Vojta 1960, 1962; Bigeleisen 1961b):

1. At very high temperatures ($T \rightarrow \infty$) $f = 1$.
2. $f > 1$, since $u_i < u'_i$.
3. For pairs of isotopic molecules in which the substitution occurs at the same site by different isotopes of an element, $f - 1$ is roughly proportional to the isotopic mass difference. For example, $f - 1$ is twice as large for the molecule pair with ^{14}C and ^{12}C than for the molecule pair with ^{13}C and ^{12}C , thus, at 0°C

$$f\left(\frac{^{13}\text{CO}_2}{^{12}\text{CO}_2}\right) - 1 = 0.2199, \quad f\left(\frac{^{14}\text{CO}_2}{^{12}\text{CO}_2}\right) - 1 = 0.4469.$$

The following rule is also valid approximately: the larger the relative mass difference between the isotopes, the larger the isotope effect. For instance, H–D isotope effects are much larger than $^{235}\text{U} - ^{238}\text{U}$ isotope effects.

4. The larger isotope molecule has a larger f value because it has more vibrational degrees of freedom, for example, at 0°C

$$\left[f \left(\frac{(\text{S}^{18}\text{O}_3)^{2-}}{(\text{S}^{16}\text{O}_3)^{2-}} \right) \right]^{1/3} = 1.080, \quad \left[f \left(\frac{(\text{S}^{18}\text{O}_4)^{2-}}{(\text{S}^{16}\text{O}_4)^{2-}} \right) \right]^{1/4} = 1.100.$$

5. An atom with higher valency is characterized by a larger value of f , for example, the values of f for the $^{34}\text{S}/^{32}\text{S}$ isotope effects (at 0°C) in the molecule SO_2 , SO_3 , and $(\text{SO}_4)^{2-}$ are 1.053, 1.096, and 1.101, respectively.
6. For pairs of molecules with multiple isotopic substitution (with the exception of D and T substitution) f is independent of the isotopic composition of the other atoms in the molecule, for example, for carbon dioxide:

$$f \left(\frac{^{13}\text{C}^{16}\text{O}_2}{^{12}\text{C}^{16}\text{O}_2} \right) = f \left(\frac{^{13}\text{C}^{18}\text{O}_2}{^{12}\text{C}^{18}\text{O}_2} \right).$$

7. A useful rule of thumb is the following: the heavier isotope enriches in that isotopic molecule that has a larger f , in other words, *the heavier isotope accumulates where the binding is stronger*.

The value of the equilibrium constant for the isotope exchange reaction between real gases can be taken, to a good approximation, to be equal to that of ideal gases. For reactions taking place in the liquid phase, K can be obtained from its value in the gaseous phase and the vapor pressures of the isotopic compounds.

15.5 Isotope Effects on Phase Equilibria

15.5.1 Vapor Pressure Isotope Effects

The difference between the isotope distributions of two phases that are in thermodynamic equilibrium is a manifestation of the differences between the properties of isotopic molecules. The differences between the equilibrium isotope compositions of the condensed and gaseous phases, that is, the different volatilities of isotopic molecules, are called *vapor pressure isotope effects* (VPPIE) and they represent the most often and thoroughly investigated thermodynamic isotope effects (Rabinovich 1960; Van Hook 1968; Rabinovich 1970; Jancsó and Van Hook 1974). The direction and magnitude of the vapor pressure differences between isotopic molecules vary in a wide range. Some examples (in some cases, the magnitude of the relative vapor pressure difference is given in parenthesis): $p(^{20}\text{Ne}) > p(^{22}\text{Ne})$; $p(^{11}\text{BF}_3) > p(^{10}\text{BF}_3)$ (0.2–1.8%); $p(^{11}\text{BCl}_3) > p(^{10}\text{BCl}_3)$ (0.2–0.3%); $p(\text{B}^{35}\text{Cl}_3) > p(\text{B}^{37}\text{Cl}_3)$ (0.3%); $p(\text{H}_2\text{O}) > p(\text{D}_2\text{O})$, $p(\text{H}_2\text{O}) = p(\text{D}_2\text{O})$ at 220°C (“cross-over temperature”), and above this temperature $p(\text{H}_2\text{O}) < p(\text{D}_2\text{O})$; $p(\text{HT}) > p(\text{D}_2)$; $p(\text{o-dideuterobenzene}) < p(\text{p-dideuterobenzene}) < p(\text{m-dideuterobenzene})$ (0.003%!).

One can see from the above examples that the lighter isotopic molecule is usually more volatile than the heavier one (“normal vapor pressure isotope effect”). Sometimes, however, the heavier molecule has a higher vapor pressure (“inverse vapor pressure isotope effect”) and in some cases the direction of the isotope enrichment between the liquid and gaseous phases changes its direction with temperature at the “cross-over temperature.” There are very small, but still measurable differences between different diduterobenzenes.

The vapor pressure difference between isotopic compounds is usually expressed in terms of logarithm of the vapor pressure ratio, $\ln(p'/p)$ (the prime, as usual, denotes the lighter

molecule). The use of this quantity is very convenient because it expresses the relative difference in the vapor pressures for small differences, $\ln(p'/p) \approx \Delta p/p = (p' - p)/p$. The vapor pressure isotope effect is called normal if $\ln(p'/p) > 0$, that is, if the lighter isotopic molecule has a higher vapor pressure than the heavier one, and inverse if $\ln(p'/p) < 0$. The temperature at which the vapor pressures of the isotopic molecules are the same ($\ln(p'/p) = 0$) is called the cross-over temperature.

The best possible precision for the determination of VPIE can be obtained by measuring Δp and p simultaneously using a differential technique. Another and quite different approach to determine the VPIE involves a measurement of the separation factor (α) defined by the equilibrium between the liquid phase and its saturated vapor in a one-plate fractionation experiment

$$\alpha = (y'/y)/(x'/x) \quad (15.16)$$

where y and x are the concentrations in the vapor and liquid phase, respectively. The accuracy of this method is limited by the accuracy of the isotopic analysis of the two phases in equilibrium; an improvement can be achieved by multiplication of the elementary separation process, for example, by using distillation columns.

The relationship between α and the vapor pressures of the pure isotopic molecules is given to a good approximation by the equation (the exact relationship is given, e.g., in Jancsó and Van Hook 1974)

$$\ln \alpha \approx \ln \frac{p'}{p}. \quad (15.17)$$

The isotope separation factor can be expressed in terms of the equilibrium constant for the liquid–vapor phase equilibrium

$$X'_{\text{liq}} + X_{\text{vap}} = X_{\text{liq}} + X'_{\text{vap}} \quad (15.18)$$

where X and X' denote different isotope molecules.

The equilibrium constant K itself

$$K = \frac{[X_{\text{liq}}][X'_{\text{vap}}]}{[X'_{\text{liq}}][X_{\text{vap}}]} \quad (15.19)$$

is thus equal to the distillation separation factor. Consequently, α and the VPIE may be expressed in terms of the reduced partition function ratios (f) of the liquid phase and gas phase

$$K = \frac{f_{\text{liq}}}{f_{\text{vap}}} \approx \alpha \approx \frac{p'}{p}. \quad (15.20)$$

The theory of VPIE was worked out by Bigeleisen (1961a). In model calculations of f_{vap} it is often assumed that in the case of an ideal gas, the molecules are freely rotating and translating and the $3n - 6$ vibrational modes (n is the number of atoms in the molecule, $3n - 6$ is the number of internal degrees of freedom) can be treated as harmonic oscillators and f_{vap} is given by ► Eq. (15.14). In the liquid phase, the reduced partition function ratio for the “average” liquid-phase molecule (f_{liq}) will be calculated within the framework of a simplified cell model in which the molecule has $3n$ degrees of freedom, of these $3n - 6$ are similar to the vibrational modes of the gas-phase molecule (Stern et al. 1963). The other six external degrees of freedom correspond to the gas-phase translations and rotations, which have become bound (hindered) in the liquid phase. In this approximation,

$$f_{\text{liq}} = \prod_i^{3n} \frac{u_i}{u'_i} \frac{1 - \exp(-u'_i)}{1 - \exp(-u_i)} \exp\left(\frac{u'_i - u_i}{2}\right). \quad (15.21)$$

The most common approximation applied to the calculation of the VPIE makes use of the fact that very often the $3n$ molecular frequencies happen to fall neatly into two groups. The first group contains the low translational and rotational frequencies (ν_{ext}) of the molecule in the liquid phase, which are treated in the so-called first-order quantum correction (first term on the right-hand side of [Eq. \(15.22\)](#)). The second group contains the high frequencies, usually the internal vibrational frequencies, for which $u_i = h\nu_i/(kT) \gg 1$, these may be treated in the so-called zero-point energy approximation (second term on the right hand side of [Eq. \(15.22\)](#)).

$$\ln \alpha = \ln \frac{f_{\text{liq}}}{f_{\text{vap}}} \approx \frac{1}{24} \left(\frac{hc}{kT} \right)^2 \left[\sum_{\text{ext}} (\nu_{\text{ext}}'^2 - \nu_{\text{ext}}^2) \right] - \frac{1}{2} \frac{hc}{kT} \sum_{\text{int}} (\Delta \nu' - \Delta \nu) = \frac{A}{T^2} - \frac{B}{T} \quad (15.22)$$

where $\Delta \nu' = \nu_{\text{vap}}' - \nu_{\text{liq}}'$ and $\Delta \nu = \nu_{\text{vap}} - \nu_{\text{liq}}$.

[Equation \(15.22\)](#) makes it easier to understand the contributions of the different molecular motions to the vapor pressure isotope effect. One can see that the hindered translations and rotations will always work in the direction of a normal isotope effect, since in this case $\nu' > \nu$. Consequently, for monatomic substances, which have only translational degrees of freedom, always a normal VPIE is observed. For polyatomic molecules, the effect of intermolecular forces on the internal vibrations of the molecules must also be considered. The frequencies of the internal vibrations shift in most cases toward lower frequencies (“red shift”) when the molecule passes from the vapor phase to the liquid phase, and this leads in the direction of an inverse isotope effect. The observed VPIE is the result of the interplay between the normal isotope effect from hindered translations and rotations and the inverse isotope effect arising from the zero-point energy contribution of the internal vibrations. The temperature dependence of the effects is different: the normal isotope effect usually falls off more steeply with temperature (proportionally to T^{-2}) than does the inverse isotope effect (T^{-1}). With internal and external effects of opposite sign, each proportional to different powers of temperature, it is not surprising that VPIE can and often *does* cross from positive to negative (cross-over effect). A good example that illustrates the cross-over is the case of heavy water/light water: H_2O has a higher vapor pressure than D_2O up to 220°C , but above this temperature D_2O is more volatile than H_2O (Harvey and Lemmon [2002](#)). At yet higher temperatures, the inverse effect would decay to zero, but before the decay gets complete the critical point is reached, and the distinction between condensed and vapor phase vanishes, and the point becomes moot.

A frequently used relationship for the vapor pressure isotope effects is the “rule of the geometric mean” (Bigeleisen [1955](#)). For example, for the vapor pressures of H_2O , HDO , and D_2O

$$p_{\text{HDO}} = (p_{\text{H}_2\text{O}} p_{\text{D}_2\text{O}})^{1/2}. \quad (15.23)$$

The rule of the geometric mean is an exact one if the temperature dependence of the VPIE follows the A/T^2 rule (see [Eq. \(15.22\)](#)). For molecules with appreciable B/T terms, however, it is found that [Eq. \(15.23\)](#) is obeyed only approximately, and thus the exponent is $1/1.91$ for $\text{HOH}/\text{DOD}/\text{HOD}$ instead of $1/2$ (Van Hook [1972a, b](#)).

In order to calculate the VPIE within the framework of the above model, one has to know (1) the hindered translational and rotational frequencies of the molecule in the liquid phase and (2) the internal vibrational frequencies (and thus the vibrational force constants) of the molecule (at least of one of the isotopic species) in the vapor and liquid phase.

The theoretical analysis of experimentally observed VPIE data has furnished information, among others, (1) about the details of the intermolecular interactions in the liquid phase, (2) on the vibrational coupling between internal vibrations and molecular translations and/or rotations, which occurs in the condensed phase, (3) on the density dependence of the force constants, which govern the external molecular motions and internal vibrations in the liquid, (4) on changes in vibrational anharmonicity, which occur on condensation, as well as (5) on the magnitude of the “dielectric correction” to IR absorption peaks in condensed phases.

The statistical mechanical theory of the vapor pressure isotope effect can be applied to the interpretation of isotope effects on other phase equilibria (e.g., solid–liquid, liquid–liquid miscibility, solubility of gases in liquids, etc.).

An interesting question, which is closely related to the VPIE, is the deviation of *isotopic mixtures* from the ideal behavior. Isotopic mixtures, that is, mixtures of isotopic molecules (e.g., benzene and deuterated benzene), have long been considered as textbook examples of ideal solutions: “statistical theory predicts that mixtures of very similar species, in particular isotopes, will be ideal”; “the only truly ideal solutions would thus involve isotopic species”; “molecules which differ only by isotopic substitution... form ideal solutions”; “except for isotope mixtures, ideal solutions will occur rather rarely”; “we expect binary solutions to have ideal properties when the two components are isotopes of each other.”

The ideal behavior of isotopic mixtures is expected if one assumes that the intermolecular forces between pairs of like molecules of each type and between unlike molecules are all the same, and further assumes the isotopic molecules to have the same size. Both assumptions are reasonable to a first approximation. Highly precise vapor pressure measurements on isotopic mixtures have shown, however, that even these mixtures exhibit small, but still significant, deviations from ideal behavior (Jancsó et al. 1993, 1994). Theoretical analysis has demonstrated that the origin of nonideality is closely connected with the difference between the molar volumes of isotopic molecules (“molar volume isotope effect”).

15.5.2 Isotope Effects on Other Phase Equilibria

Ice–water equilibrium is a well-known example for the isotope effect on solid–liquid phase equilibrium. It has been found that both deuterium and ^{18}O enrich in the solid phase by 2.1 and 0.30%, respectively. This is in harmony with the rule of thumb (see “rule” (7) in ► Sect. 15.4.2), according to which the heavier isotope enriches in the phase where the bonding is stronger. The triple point temperatures (at the triple point solid, liquid, and vapor phases are in equilibrium) of the isotopic water molecules containing the heavier isotopes are also higher than that of ordinary water (3.82°C, 0.38°C, and 0.01°C for D_2O , H_2^{18}O , and H_2^{16}O , respectively). Isotope effects on triple points and melting temperatures of different compounds have been discussed by Van Hook (1994).

Whereas the differences in vapor pressure between isotopic substances have received much attention, relatively little is known about the isotope effects on the solubility of gases in liquids; the available experimental information has been recently reviewed by Jancsó (2002). The isotope effect is manifested in the isotope fractionation of natural gases, for example, in studies of the solubility of nitrogen and oxygen in water it was found that the heavier molecular species, $^{14}\text{N}^{15}\text{N}$ and $^{16}\text{O}^{18}\text{O}$ are more soluble in water than the respective lighter ones, $^{14}\text{N}_2$ and $^{16}\text{O}_2$, by 0.085% and 0.080%, respectively, at 0°C and both effects decrease to approximately 0.055% at 27°C. In general, the *solubility isotope effect* is normal, that is, the heavier isotopic

species is more soluble than the lighter one. The largest effect was observed for the solubilities of pure hydrogen and deuterium gases in water (8.6% at 5°C). The first inverse isotope effect (the lighter isotopic species is more soluble than the heavier one) on gas solubility was observed in the study of isotopic fractionation between gaseous carbon dioxide and the equilibrated aqueous solution of the gas between 0 and 60°C (Vogel et al. 1970). It was observed that $^{13}\text{C}^{16}\text{O}_2$ is slightly less soluble than $^{12}\text{C}^{16}\text{O}_2$ (by 0.012% at 0°C) while the oxygen isotopes exhibit a normal isotope effect ($^{12}\text{C}^{16}\text{O}^{18}\text{O}$ is about 0.08% more soluble than $^{12}\text{C}^{16}\text{O}_2$). Dang et al. (1989) demonstrated that the solubility isotope effect can be interpreted using the same theoretical framework as developed for vapor pressure isotope effects (see ▶ Sect. 15.5.1). For example, using available spectroscopic data Bacsik et al. (2002) were able to predict the order of magnitude of the inverse and normal solubility isotope effects of methane observed in water for H/D and $^{12}\text{C}/^{13}\text{C}$ substitution, respectively.

There are some differences (up to about 30%) between the solubilities of inorganic salts in ordinary and heavy water. In general, the solubilities of salts in D_2O are markedly less than in H_2O (e.g., at 20°C NaCl and KCl are 6.7% and 9.8% less soluble in D_2O than in H_2O , respectively), with the exception of LiF and LiCl-aq, which have higher solubilities (e.g., by 13% and 2% at 25°C) in heavy water. The magnitude of the isotope effect decreases with increasing temperature and the less soluble the salt, the larger the isotope effect.

The solubility of heavy water in different organic solvents is smaller than that of ordinary water. The differences in the solubility of H_2O and D_2O can be expressed as $100 (N_{\text{H}} - N_{\text{D}})/N_{\text{H}}$, where N_{H} and N_{D} are the solubilities of H_2O and D_2O in mole fractions. For example, at room temperature the solubility differences in triethylamine, carbon disulfide, benzene, chloroform, and diethylether are 30%, 21%, 17%, 15%, and 7%, respectively. The deuterium isotope effects in liquid–liquid phase diagrams have been reviewed by Rabinovich (1970) and Fenby et al. (1981). The experimental investigations showed that the replacement of H by D usually, but not always, leads to an enlargement of the domain of partial miscibility; the upper critical solution temperature usually increases, while the lower critical solution temperature always decreases. The study on the miscibility behavior of methanol–cyclohexane binary mixture revealed that whereas the replacement of hydrogen atoms involved in hydrogen bonding (OH group of methanol) leads to an increase of the miscibility gap, the replacement of hydrogen atoms not involved in hydrogen bonding (CH_3 , $\text{c-C}_6\text{H}_{12}$) by deuterium leads to a reduction of the miscibility gap (Schön et al. 1986). There are some even more striking isotope effects on miscibility behavior of liquids, for example, while 2-methylpyridine and 3-methylpyridine are completely miscible in all proportions at all temperatures with water, they are only partially miscible with heavy water. Isotope effects on coexistence curves, similarly to the vapor–liquid and gas–liquid solubility equilibria, can be interpreted in terms of the theory of condensed phase isotope effects, inasmuch as the necessary spectroscopic information for the two phases in equilibrium is available (Singh and Van Hook 1987).

The difference in the adsorption isotherms of isotopic molecules has long been known and it has been used for isotope separation and isotope analysis. For example, deuterium gas exhibits an enrichment factor of 40 (!) at 20 K on silica gel, but the enrichment factor decreases steeply with increasing temperature (Krumbiegel 1970). Another example is the behavior of CH_4/CD_4 system in a capillary column with activated glass surface: at 153 K the retention time of CH_4 is larger than that of CD_4 , at 130 K they are equal to each other and at lower temperatures CH_4 leaves earlier the column than CD_4 (Bruner et al. 1966). Similarly to the gas–solid chromatographic separations, gas–liquid separation techniques have also been widely used for isotopic separation and for rapid and convenient analysis of mixtures of

isotopic molecules. Isotopic fractionation of organic compounds observed in different chromatographic techniques has been reviewed by Filer (1999). The isotope effects observed in gas chromatography can be interpreted analogously to the vapor pressure isotope effect (Van Hook 1969). The VPIE is governed by the “solute–solute” interactions in the pure liquid state, whereas in the infinitely dilute solution “solvent–solute” (gas–liquid chromatography) and in the dilute surface-adsorbed state “surface-adsorbate” (gas–solid chromatography), intermolecular forces are operative.

Isotope effects in ion exchange chromatography and extraction chromatography have also been studied, with the aim of investigating the possibility of separation of ^6Li and ^7Li isotopes (Lee 1969). It was found that the lighter isotope enriches in the resin phase and the separation factor (in general, less than 1.005) is determined by the difference in the states of the ion in the solution and in the resin. With resin having monobenzo-15-crown-5 as a functional group, a single separation factor as high as 1.053 can be achieved for the separation of Li isotopes (Kim et al. 1991). A method for uranium isotope separation has been developed by Asahi Chemical Industries in Japan using redox ion exchange chromatography (see ▶ Sect. 51.6.2, Chap. 51, Vol. 5). The isotope separation factor anomalies observed in this process are discussed in ▶ Sect. 15.8.

15.6 Isotope Effects on Some Physicochemical Properties

Beside spectroscopic and thermodynamic isotope effects treated in the preceding sections, isotope effects related to the structure of the molecules manifest themselves in a variety of physical and physicochemical properties, such as density, permittivity, compressibility, dipole moment, surface tension, etc. It is not possible to give a comprehensive treatment of the subject here; useful reviews have been given among others by Rabinovich (1970) and Jancsó and Van Hook (1974). For illustration of the magnitude of the isotope effects, differences in various physical properties between water and *heavy water* are collected in ▶ Table 15.1.

The density difference between H_2O and D_2O can be used for the determination of the deuterium content of heavy water (Schattenstein 1960). It is interesting to note that the 10% difference in density is within 0.5% entirely due to the molecular weight difference. The molar volume of D_2O is *larger* only by 0.34% and that of H_2^{18}O is *smaller* by 0.15% than the molar volume of H_2^{16}O . The isotope effect on the dielectric constant and dipole moment is very small, which plays an important role in the interpretation of solvent isotope effects in aqueous systems (Van Hook 1975).

The compressibility of liquid water is anomalous in that it decreases with increasing temperature, passes through a minimum at 46°C , and then increases again. The compressibility of heavy water follows a similar pattern, but the minimum is about 3°C higher than for H_2O . The ratio of the viscosities of liquid D_2O and H_2O is 1.23 at 25°C , which is much larger than the ratio of the square-roots of the molecular masses (1.0544). However, according to Vedamuthu et al. (1996) the “thermal offset effect,” that is, the difference (6.498°C) between the temperatures of the maximum densities of H_2O (3.984°C) and D_2O (11.185°C) should be taken into account when one compares the different properties of the two liquids. Thus, for example, the viscosity of D_2O at 26.498°C would be the viscosity of H_2O at 20°C multiplied by 1.0544, the square-root of the mass ratio of the two isotopic molecules (Cho et al. 1999). This supports the view that the viscosity isotope effect on liquid water is not a rotational, but a translational mass effect. The concept of thermal offset effect can be used in correlating the various thermodynamic properties of liquid H_2O , D_2O , and T_2O .

■ Table 15.1

Some physical properties of water and heavy water

	H ₂ O	D ₂ O
Melting point (°C)	0.00	3.81
Triple point (°C)	0.01	3.82
Temperature of maximum density (°C)	3.984	11.185
Normal boiling point (°C)	100.00	101.42
Critical temperature (°C)	374.0	370.7
Critical pressure (MPa)	22.06	21.67
Critical volume (cm ³ /mol)	55.3	55.0
Density at 25°C (g/cm ³)	0.997048	1.104468
Heat of fusion at the melting point (J/mol)	6,008	6,339
C _p (liquid at 25°C) (J deg ⁻¹ mol ⁻¹)	75.27	84.35
C _v (liquid at 25°C) (J deg ⁻¹ mol ⁻¹)	74.48	83.7

Compressibility at 25°C (TPa ⁻¹)	447.0	459.5

Experimental measurements of the molar volumes of benzene, toluene, cyclohexane, and methylcyclohexane and their deuterated analogs have shown that the lighter species have a greater volume by about 0.3% (Bartell and Roskos 1966). This difference in molar volumes (*molar volume isotope effect*) arises from the fact that C–H bonds are longer than C–D bonds by about 0.005 Å. Whereas in the above case, the hindered translational motion of the molecules as a whole plays a negligible role, for small molecules (e.g., ethylene) the vibrations of the molecules give important contributions to the molar volume isotope effect (Menes et al. 1970). The volume dependence of the vibrational frequencies may also influence the molar volume isotope effect as was shown in the case of polyethylene (Lacks 1995).

The question sometimes arises whether the *deuterium bond* is stronger or weaker than the hydrogen bond. While the electronic contribution to the strength of the H-bond is unaffected by deuterium substitution since the H-bonded and D-bonded species have the same potential surface, some of the vibrational frequencies in the complex will be smaller because of the larger mass of deuterium (Buckingham and Fan-Chen 1981). Consequently, the zero-point vibrational energy of the D-bond will be lower than that of the H-bond, and thus the *D-bond can be considered stronger than the H-bond*. It was found from ab initio calculations, carried out on complexes containing H-bond forming organic functional groups (such as hydroxyl, carbonyl, carboxyl, and amide) and water molecules (Čuma and Scheiner 1997), that deuterium substitution increases the strength of the hydrogen bond by several tenths of a kcal/mol. In contrast

to the hydrogen bonds in complexes pairing neutral molecules, *in ionic complexes* (e.g., $\text{H}_2\text{O}\cdots\text{H}^+\cdots\text{OH}_2$) *the H-bond is stronger than the D-bond*.

Some interesting isotope effects in the solid phase include those on superconductivity and ferroelectricity. For simple metals like Hg, Pb, Sn, and Zn, the relationship between the characteristic temperature at which the metal becomes superconductor (T_c) and the mass of the isotope (m) can be given as $T_c \propto m^{-1/2}$. Very large isotope effects can be observed on ferroelectricity of crystals. A ferroelectric crystal exhibits a spontaneous electric dipole moment, that is, even in the absence of an applied electric field the center of the positive charges does not coincide with that of the negative charges. At the Curie temperature, the crystal changes from the polarized state to the unpolarized state. For example, the Curie temperature of KH_2PO_4 crystal is 123 K, whereas that of KD_2PO_4 is 213 K. In some crystals (e.g., Seignette salt, sodium potassium tartrate- $4\text{H}_2\text{O}$) there are two Curie points, an upper and a lower one, and between these temperatures the crystal is ferroelectric. In the Seignette salt, the lower Curie point decreases (by 4°C), while the upper one increases (by 11°C) when H_2O is replaced by D_2O in the crystal.

The differences between isotopic molecules in the majority of the physical properties are still awaiting interpretation on the molecular level.

15.7 Kinetic Isotope Effects

Isotopic molecules may react at different rates in the same chemical reaction and the effect of isotopic substitution on a rate constant is referred to as a *kinetic isotope effect*. For example, in the reaction

the effect of isotopic substitution in reactant A is expressed as the ratio of rate constants k'/k , where the superscripts with prime and without prime represent reactions in which the molecules A contain the light and heavy isotopes, respectively.

The phenomenon was first observed in the electrolysis of water when it was found that the decomposition rate of H_2O may be several times higher than that of D_2O . This observation led to the preparation of the first pure heavy water sample electrolytically and forms the basis of one of the methods of industrial production of heavy water. The study of isotope effects on reaction rates provides one of the most powerful and subtle methods for elucidation of reaction mechanisms and plays an important role in investigations using isotope labeling.

The experimental determination, theory, and application of kinetic isotope effects are treated in a number of excellent monographs and book chapters (Bigeleisen and Wolfsberg 1958; Melander 1960; Van Hook 1971; Wolfsberg 1972; Shiner 1975; Buddenbaum and Shiner 1977; Cleland et al. 1977; Melander and Saunders 1980; Willi 1983; Sims and Lewis 1984; Vértés and Kiss 1987).

15.7.1 Classification and Determination of Kinetic Isotope Effects

Kinetic isotope effects can be divided into different groups. The term *primary isotope effect* is used when in the rate-determining step of the reaction the bond to the isotope in question will be broken (or formed). *Secondary isotope effects* are those in which the bonds to the isotopically

substituted atom are not broken or formed in the course of the reaction. Secondary isotope effects are, in general, about one order of magnitude smaller than primary isotope effects. *Intermolecular isotope effect* causes the difference between the reaction rates of two isotopic molecules. The *intramolecular isotope effect* reflects the difference between the reaction rates of two functional groups of the same molecule, which differ only in their isotopic compositions. The different types of kinetic isotope effects can be illustrated by the following general reaction schemes (the prime refers to the lighter isotope).

Primary intermolecular isotope effect, k'/k , e.g.,

Primary intramolecular isotope effect, k'_i/k_i , e.g.,

Secondary intermolecular isotope effect, k'_s/k_s , e.g.,

As a rule, lighter isotope molecules react at a higher rate (*normal isotope effect*, $k'/k > 1$), however, there are some cases in which $k'/k < 1$ (*inverse isotope effect*).

The ratio of the rate of a reaction in light water to that in heavy water (or in $\text{H}_2\text{O}/\text{D}_2\text{O}$ mixtures) is referred to as a *solvent isotope effect*. For example, many enzymatic properties, including catalytic rates, differ when the enzyme is dissolved in D_2O rather than in H_2O . Solvent isotope effects including those on chemical equilibria have been reviewed, among others, by Arnett and McKelvey (1969), Laughton and Robertson (1969), Schowen (1977), and Conway (1981).

The simplest method of the experimental determination of kinetic isotope effects is to compare the reaction rates of the pure isotopic variants under the same experimental conditions. This technique is simple and does not require the isotope analysis of the reactants and products; however, it requires pure isotopic compounds. In addition to that, the reaction rate should be measured with an accuracy that is at least one order of magnitude higher than the difference between the reaction rates of the isotopic variants.

It is often more advantageous to use comparative methods, that is, to work with the mixture of the two compounds in the experiments, which ensures identical experimental conditions for the parallel reactions. The isotope competition method does not require pure isotopic compounds, it can be used even with compounds of natural isotopic composition, and thus it can be applied to the determination of ^{13}C , ^{15}N , and ^{18}O isotope effects. However, the isotopic composition must be measured with high accuracy, in the case of stable isotopes usually by mass spectrometry, in the case of radioisotopes by measuring the change in the specific activity. In order to obtain the kinetic isotope effect, one needs to determine the isotopic composition of the test compound, first at the start of the reaction then again after the reaction has taken place to a known extent. The isotope effect can also be obtained from the isotopic analysis of the reaction products. In the latter case, the method of the evaluation of k'/k from the experimental data can be found, for example, in the book of Vértés and Kiss (1987).

15.7.2 Theory of Kinetic Isotope Effects

The method of calculating the isotope effect on equilibrium constants was extended to the rates of chemical reactions by Bigeleisen (1949), and the formal theory of kinetic isotope effects was developed by Bigeleisen and Wolfsberg (1958) within the framework of transition-state theory.

According to the transition-state theory, reactions proceed through an activated or transition state (molecules in this state will be designated as “activated complexes”). The first step of the process is the formation of the activated complex and in the second step the activated complex dissociates to reaction products:

The reactants are considered to be in equilibrium with the activated complex.

The equilibrium constant (K) can be written as

$$K = \frac{[\text{A} \dots \text{X} \dots \text{B}]^*}{[\text{AX}][\text{B}]} \quad (15.24)$$

and can be expressed through the corresponding partition functions (Q)

$$K = \frac{Q_t^*}{Q_{\text{AX}} Q_{\text{B}}} \quad (15.25)$$

where Q_t^* is the total partition function of the activated complex. For the ratio of the rate constants of the reactions of AX and AX' (k'/k) one obtains

$$\frac{k'}{k} = \frac{\kappa'}{\kappa} \frac{\tau'}{\tau} \frac{Q^{*'}_{\text{AX}}}{Q^*_{\text{AX'}}} \quad (15.26)$$

where κ is the transmission coefficient, which expresses the probability that an activated system moving in the forward direction will cross to the product side; κ is assumed to be independent of isotopic substitution therefore the κ'/κ ratio in [Eq. \(15.26\)](#) cancels. The factor τ corresponds to the tunnel effect, which takes into account that according to quantum mechanics, it is possible for systems with insufficient energy to surmount the energy barrier to leak or to “tunnel” through. The tunnel effect is significant only for particles whose de Broglie wavelength is comparable to the thickness of the barrier that must be penetrated. Protons at ordinary temperatures have wavelengths of the order of 1–2 Å, which is similar to the width expected for an energy barrier to a proton reaction, therefore the tunnel effect should have some influence on the rate of proton transfer reactions. The tunnel corrections to kinetic isotope effects are discussed in detail by Weston (1975), Kresge (1977), and Bell (1980). Contrary to Q_t^* in [Eq. \(15.25\)](#), Q^* in [Eq. \(15.26\)](#) does not include the normal vibrational mode that corresponds to the transformation of the activated complex back to reactants or forward into products and has a zero or imaginary frequency (in the literature, this mode is referred to as the “reaction coordinate”). Therefore, in the calculation of Q^* one is supposed to use only $3n - 7$ real vibrational frequencies of the transition state (n is the number of atoms).

The expression for the isotope effect on the rate constant has the same form as the one for the equilibrium isotope effect (see [Eqs. \(15.14\)](#) and [Eq. \(15.15\)](#))

$$\frac{k'}{k} = \frac{u^{*'} }{u^*} \prod_i^{3n-7} \frac{u_i^{*'} }{u_i^*} \frac{1 - \exp(-u_i^*)}{1 - \exp(-u_i^{*'})} \exp\left(\frac{u_i^{*'} - u_i^*}{2}\right) \prod_i^{3n-6} \frac{u_i}{u_i^{*'}} \frac{1 - \exp(-u_i^{*'})}{1 - \exp(-u_i)} \exp\left(\frac{u_i' - u_i}{2}\right) \quad (15.27)$$

where u^* refers to the zero or imaginary frequency (ν^*) of the transition state and $u_i = h\nu_i/(kT)$. (ν_i is the harmonic frequency of mode i in cm^{-1} , T is the temperature.)

A straightforward conclusion that can be drawn (e.g., from [Eq. \(15.27\)](#)) is that isotope effects are determined almost entirely by the changes in vibrational force constants on going from the reactants to transition state.

Very often, one assumes that the vibrational frequencies in the reacting molecule are identical with those in the activated complex with the exception of the vibrational frequency corresponding to the rupture of the bond (ν_k). In this approximation, and at low temperatures or high vibrational frequency for the bond of interest, the logarithm of the isotopic rate ratio k'/k is given by

$$\ln \frac{k'}{k} = \frac{hc}{2kT} (\nu'_k - \nu_k). \quad (15.28)$$

Very often, isotope effects are dominated by zero-point energy differences and this contribution plays an important role in the qualitative discussions explaining isotope effects. [Equation \(15.28\)](#) can be used for the estimation of the primary kinetic isotope effect. For example, the zero-point energy of a typical C–H stretching vibration with $\nu = 3,000 \text{ cm}^{-1}$ is 18 kJ/mol; deuterium substitution reduces the frequency to $2,200 \text{ cm}^{-1}$ and the zero-point energy to 13.4 kJ/mol. The difference (4.6 kJ/mol) gives $k_{\text{H}}/k_{\text{D}} = 6.4$ for the primary kinetic isotope effect for C–H bond breaking at room temperature.

On the basis of [Eq. \(15.27\)](#), it is possible to estimate the maximal values of primary kinetic isotope effects for different isotopic substitutions. For example, at room temperature the maximal values of k'/k for some isotopes are as follows: $\text{H/D} = 18$, $\text{H/T} = 60$, $^{12}\text{C}/^{13}\text{C} = 1.25$, $^{12}\text{C}/^{14}\text{C} = 1.5$, $^{14}\text{N}/^{15}\text{N} = 1.14$, $^{16}\text{O}/^{18}\text{O} = 1.19$, $^{32}\text{S}/^{34}\text{S} = 1.05$, and $^{127}\text{I}/^{131}\text{I} = 1.02$ (see, e.g., Vértés and Kiss [1987](#)). Similarly, for the maximal secondary isotope effects one obtains for H/D isotope substitution in C–H and O–H bonds 1.74 and 2.02, respectively. For $^{12}\text{C}/^{13}\text{C}$ substitution in C–C bond one has $k'_s/k_s = 1.012$.

A very simple expression can be derived for the estimation of intramolecular isotope effects. In this case, the reacting molecules are identical and thus only the breaking bond of the activated complex may exhibit isotope effect, therefore

$$\frac{k'_{\text{intra}}}{k_{\text{intra}}} = \frac{\nu^{*'} }{\nu^*} = \sqrt{\frac{\mu}{\mu'}} \quad (15.29)$$

where μ is the reduced mass calculated from the masses of the two atoms joined by the bond being broken or from the masses of the molecular fragments to be separated in the reaction. It can be seen that the intramolecular isotope effect is independent of temperature, which is in agreement with the experimental observations.

Computer programs are available for the calculation of kinetic isotope effects within the framework of [Eq. \(15.27\)](#), which use as input data the geometry and force constants of reactants and transition states (Wolfsberg and Stern [1964](#)).

Melander and Saunders ([1980](#)) have given a comprehensive description of the development of methods of computer calculations of isotope effects on the kinetics of chemical reactions. Such techniques, originally proposed by Wolfsberg and Stern ([1964](#)), Shiner ([1975](#)), Buddenbaum and Shiner ([1977](#)), and Schowen ([1977](#)), marry the methods of Eyring's absolute rate (activated complex) theory with detailed modeling of molecular vibrational properties. Input parameters are a mix of spectroscopically determined or quantum mechanically calculated force constants and/or force constant shifts. The method has resulted in informative and detailed molecular description of the molecular changes that occur as the system proceeds from reactant to product along the reaction coordinate. As a result, kinetic isotope effect studies now constitute one of the most important methods employed in the development of detailed

models of the mechanisms of organic and enzymatic reactions (see, e.g., Francisco et al. 2002; Knapp et al. 2002).

15.8 Mass-Independent Isotope Effects

In the previous sections, it has been demonstrated that both equilibrium and kinetic isotope effects can be well understood in terms of mass differences between different isotopes. However, there are some isotope effects that either do not depend on mass or exhibit an anomalous mass-dependence.

Different isotopes may have different nuclear spins (e.g., H: 1/2, D: 1; ^{12}C : 0, ^{13}C : 1/2; ^{16}O , ^{18}O : 0, ^{17}O : 5/2), which may result in the so-called nuclear spin isotope effect (also called “magnetic isotope effect”). This type of isotope effect may be observed in chemical processes that involve triplet-singlet transition. The energy characterizing such transitions contains a term that depends on the interaction between the spins of electrons and nuclei. Thus, the probability of the chemical process is a function of hyperfine coupling describing the above interaction. Hence, in the case of elements that have isotopes with different nuclear spins, the reaction rates may be different, thus leading to the nuclear-spin isotope effect. The term “magnetic isotope effect” refers to the fact that the magnitude of the isotope effect can be influenced by the strength of the applied external magnetic field. The magnetic isotope effect was discovered in 1976 by Buchachenko et al. (1976) in the photolysis of dibenzyl ketone (DBK). During photolysis triplet pairs of acyl and benzyl radicals are formed as primary products. The fate of the pair depends on whether it carries magnetic (^{13}C) or nonmagnetic (^{12}C) nuclei. The magnetic radical pair (with, e.g., ^{13}C in the carbonyl position) undergoes a fast triplet-singlet conversion, induced by the hyperfine coupling between the unpaired electron and the magnetic nucleus ^{13}C , which is followed by the recombination into the starting DBK molecule. The nonmagnetic pair (with ^{12}C in the carbonyl group) predominantly dissociates and forms the reaction products (dibenzyl and carbon monoxide). Thus, the DBK regenerated is enriched in ^{13}C while the reaction products are depleted in it. Some characteristics of the nuclear spin isotope effects are as follows (Turro and Kraeutler 1984; Buchachenko 2001). The isotope effect increases with increasing value of the hyperfine coupling constant; its magnitude does not depend on temperature and the expression describing the isotope effect does not contain any mass-dependent term. The magnetic isotope effect can be used to separate ^{13}C from ^{12}C and also to separate the magnetic ^{17}O selectively from the nonmagnetic isotopes ^{16}O and ^{18}O . It is interesting to note that the efficiency of the separation of ^{13}C from ^{12}C by use of the magnetic isotope effect mechanism surpasses considerably the separation efficiencies possible via mechanisms involving conventional isotope mass effects.

Another type of “anomalous mass effect” resulting from the uneven charge distributions in the isotopic nuclei was discussed by Bigeleisen (1996a, b) in order to explain the anomalies revealed by the precise measurements of equilibrium separation factors for uranium isotopes during the U(IV)/U(VI) redox equilibrium carried out on an anion exchange resin (Fujii et al. 1989): (1) separation factors for all the uranium isotopes appeared to be unexpectedly high; (2) heavy isotopes are enriched in compounds characterized by the lower oxidation states; (3) the dependence of the logarithm of the separation factor ($\ln\alpha$) on the reciprocal of the isotopic masses exhibits distinct deviations from the expected linear pattern for odd masses. The experimental finding that in the redox exchange system of U(IV)–U(VI) α for the $^{238}\text{U}/^{235}\text{U}$ isotope pair did not fit the linear interpolation between $^{238}\text{U}/^{234}\text{U}$ and $^{238}\text{U}/^{236}\text{U}$ explains why the phenomenon is sometimes called the “even-odd effect” or “even-odd staggering

of the isotopes.” Bigeleisen suggested that the anomalies are the result of a nuclear field shift of the electronic energy levels; the differences in the size and shape of nuclei of different isotopes bring about a displacement of the ground-state electronic energy of the atom or molecule. The contribution of the field effect to the U(IV)–U(VI) isotope separation factors was found to be about three times that of the vibrational effect due to the mass differences between uranium isotopes and the two effects are opposite in sign. It was suggested later that there is a nuclear quadrupole (Knyazev et al. 1999) and a chemical type isotope effect contribution (Mioduski 1999) to the even-odd effect. The study of the fractionation of ytterbium isotopes (the rare earth ytterbium has five isotopes with even mass numbers and two with odd) in Yb(III)-acetate/Yb-amalgam system represents another example for the occurrence of the “even-odd effect” (Dembiński et al. 1998). The problems that occur during the numerical estimation of nuclear size equilibrium isotope effects have been reviewed by Knyazev and Myasoedov (2001).

In order to understand the *mass-independent isotope effect*, which was first observed by Thiemens and Heidenreich (1983) in a laboratory experiment, the so-called δ -notation will be introduced. In the mass spectrometric determination of isotopic abundances, the isotopic ratios are typically reported in terms of the delta value (δ), which is the relative difference between the isotope ratio of the sample and that of a standard with known isotopic composition:

$$\delta = \frac{R_{\text{sample}} - R_{\text{standard}}}{R_{\text{standard}}} \quad (15.30)$$

where R is the ratio of the concentrations (atom fractions) of the heavy and light isotopes (e.g., $^{18}\text{O}/^{16}\text{O}$ isotope concentration ratios). The value of δ depends on the standard chosen, and as the differences between the samples and the standard are usually quite small, it is convenient to express the δ values in parts per thousand (“per mil”) $\delta (\text{‰}) = \delta \times 1,000$ (the δ values are widely used to describe the variations of stable isotope ratios in nature). For the relative fractionation of ^{18}O and ^{17}O isotopes, the theory of “mass-dependent” isotope effects predicts (see [Eq. \(15.15\)](#) and “rule” (3) in [Sect. 15.4.2](#)) that $\delta ^{17}\text{O} \approx 0.52 \times \delta ^{18}\text{O}$. Thiemens and Heidenreich (1983) measured the oxygen isotope fractionation, which occurs during the formation of ozone by an electric discharge in molecular oxygen. They found quite unexpectedly that the ^{18}O and ^{17}O isotopes were approximately equally enriched in the ozone product and equally depleted in the residual oxygen, that is, ^{17}O and ^{18}O isotope effects were found to be nearly equal ($\delta ^{17}\text{O} \approx \delta ^{18}\text{O}$). Since then, a number of experiments have been carried out in different laboratories and the existence of the anomalous relationship between ^{17}O and ^{18}O isotope effects was confirmed; see the critical reviews of the field published by Krankowsky and Mauersberger (1996), Weston (1999), and by Gao and Marcus (2001). The ozone isotope effect plays an important role in atmospheric processes (Mauersberger et al. 2001). Different models have been put forward to explain the observed experimental results (see, e.g., Janssen et al. 2001). According to the theory of Marcus and his coworkers (Gao and Marcus 2001, 2002; Gao et al. 2002), which is based on RRKM calculations of rate constants, the isotope effects can be regarded as “symmetry driven” and the calculations are consistent with most of the available experimental data.

15.9 Biochemical and Biological Isotope Effects

The sensitivity of living organisms to different isotopes of a given element is more difficult to explain than are physical and chemical isotope effects. After the discovery of deuterium in

1932, interest in the biological properties of deuterium was immediately aroused, however, early experimentation with deuterium was severely hindered by the extreme scarcity of the separated isotope (then produced by the electrolysis of water).

The first biological experiment with heavy water took place in 1933 in the laboratory of Urey where one of his assistants put few drops of deuterium-enriched water on his tongue and reported that it tasted the same as ordinary water (Rittenberg 1964). In another early experiment, Lewis, the famous physical chemist, administered 1 g of heavy water to a mouse; however, he was not able to draw any definite conclusion concerning the effect of deuterium, because he ran out of the supply of heavy water (Bigeleisen 1984). With the growth of nuclear technology, heavy water became readily available in the mid-1950s in quantities of hundred tons at a reasonable price. This circumstance greatly facilitated the research on the effects of deuterium in biological systems and the results obtained have been discussed in detail in monographs and review papers (Thomson 1963; Katz and Crespi 1971; Katz et al. 1975).

On the basis of isotope effects observed in physical and chemical properties, one can expect that *the replacement of hydrogen by deuterium in a living organism* may result in differences in the biological activity. Some of the factors that play an important role are the following. A significant part of a living organism consists of water and the properties of H_2O and D_2O differ from each other; the rate of reaction involving the breaking of a C–H bond is about six times faster than that of the C–D bond; deuterium bonds ($\text{OD} \cdots \text{O}$, $\text{ND} \cdots \text{O}$) are supposed to be stronger than hydrogen bonds ($\text{OH} \cdots \text{O}$, $\text{NH} \cdots \text{O}$); the substitution of D for H has a large effect on the rate of enzymatic reactions and on the three-dimensional structure of naturally occurring macromolecules, etc. It is very difficult to separate solvent isotope effects, primary and secondary isotope effects in living organisms and biochemical systems.

Since the metabolic rates of isotopically labeled compounds are different, variations in the concentration of the stable isotopes in organic compounds can be expected to depend on their biosynthetic pathway. Some examples are given by Rittenberg (1964): the concentration of deuterium in fermentation alcohol is less by 33 ppm than that of tap water (150 ppm); stearic acid and cholesterol are 21 and 34 ppm “lighter” than tap water, glucose and mannose are enriched in deuterium by 11 and 15 ppm, respectively, with respect to tap water. The application of isotope separation occurring in biological systems to large-scale separation of isotopes has been also considered; however, the low efficiency of the biological processes does not make the method feasible (Syrett 1961).

15.9.1 Physiological Effects of Heavy Water

The effect of heavy water on various living organisms has been widely investigated and this section is based on the excellent review of Katz and Crespi (1971). Algae are autotrophic systems in which water represents the only source required for the biosynthesis of organic compounds. The early experiments indicated that the incorporation of deuterium into algae was incompatible with life, however, it turned out later that by gradually changing the deuterium concentration of water, algae can be fully adapted to grow in D_2O . It is interesting to note that the phenomena observed when organisms are transferred from H_2O to D_2O should not be ascribed to the toxicity of deuterium, since they occur under the reversed conditions as well, that is, H_2O is “toxic” to organisms grown in D_2O . Algae are cultivated in heavy water on a large scale and the fully deuterated algae produced are available on the market and used for isotope effect studies in biological systems. There are some striking effects of heavy

water on simple organisms. For example, the yeast *Torulopsis utilis* grows well in a medium containing glucose and inorganic salts; however, it can only grow in D₂O if the sulfur-containing vitamin thiamine is added to the medium. This indicates that the presence of deuterium hinders the ability of the yeast to biosynthesize thiamine. Another example is *Aspergillus niger* that grows well in media containing D₂O, but loses its ability to synthesize its characteristic black pigment and becomes alabaster-white.

Whereas simple organisms can be adapted to grow in D₂O, higher plants as well as animals resist full deuteration. Experiments carried out with mice showed that animals drinking 30% D₂O, and deuterated to about 25% in the body fluids, live normal life span; however, their reproductive capacity becomes severely impaired. When the deuterium content of drinking water is higher than 30%, the animals do not survive. Deuterium content of 15–20% in the body fluids was found to be the *threshold for toxicity* in animals. Since deuterium substitution results in a decrease of the rates of reactions, the question arose already at an early stage after the discovery of deuterium whether the growth of tumors could be inhibited by the administration of heavy water. Experiments carried out on mice with mammary cancer showed that although the administration of 40% D₂O decreased the growth rate of the tumors, the mice treated died more rapidly due to the toxic effects of deuterium.

It is an interesting question how toxic deuterium or heavy water is to humans. If it is accepted on the basis of animal experiments that the “critical” deuterium concentration (the double of which would cause severe physiological effects) is about 10%, then one can easily estimate that a person of 70 kg may drink 4.8 l heavy water or 1.2 l per day for 4 days without serious consequences (Förstel 1978). Thus, heavy water cannot be considered toxic to humans. This is an important conclusion, since stable isotopes (e.g., heavy water for the estimation of total body water) are widely used in clinical research and diagnosis (Krumbiegel 1991). In the literature, one can find also some more conservative estimates as far as the application risk of the deuterium in the form of heavy water is concerned, for example, Jones and Leatherdale (1991) suggest that the threshold for noticeable side-effects exists at the dosage between 70 and 140 g of 100% D₂O.

While the effect of increased deuterium concentration on various physiological processes has been extensively investigated in different biological systems, very little is known about the sensitivity of biological processes to *reduced deuterium concentrations*. It was demonstrated by Somlyai et al. (1993) that subnormal deuterium concentration leads to the inhibition of cell division in cultured proliferating animal cells, indicating that naturally occurring deuterium is essential for normal growth rate of cells.

15.9.2 Isotope Fractionation in Biological Processes

Natural differences in the stable isotope composition of biological compounds result from differences in a variety of predictable factors, such as kinetic isotope effects, fractionating via diffusion, enzyme selectivity, etc. Stable isotope studies have been extensively used for solving problems in geochemistry and cosmochemistry (Craig et al. 1964) for a long time. Applications of stable isotope analysis in biological and ecological sciences have been expanding rapidly during the past 20 years (Rundel et al. 1988; Gebauer et al. 1993; Ivlev 2001; Zarzycki et al. 2002).

One of the most extensively studied biological isotope fractionation process is the *photosynthetic carbon fixation* (O’Leary 1981; Rundel et al. 1988; Ivlev 2001). It was found that plants with C₃ (e.g., rice, beet, potatoes, wheat, barley, legumes), C₄ (e.g., corn, sugar cane, sorghum,

pearl millet), and CAM (Crassulacean acid metabolism: e.g., pineapple) photosynthetic pathways show different discriminations against ^{13}C during photosynthesis. For example, while atmospheric carbon dioxide contains ^{12}C and ^{13}C in the ratio 89:1, C_3 plants generally contain proportionally less ^{13}C than does the air, their $^{12}\text{C}:^{13}\text{C}$ ratio is typically 91:1. Photosynthesis leads to an enrichment of the lighter carbon isotope (^{12}C) in organic materials; in other words they are depleted in ^{13}C (C_4 plants and CAM plants are richer in ^{13}C than C_3 plants). The difference in isotopic composition has become one of the methods by which C_4 plants can be distinguished from C_3 plants. Isotope fractionation in the photosynthesis of C_3 plants is due to the carboxylating enzyme ribulose biphosphate (RuBP) carboxylase, which discriminates strongly against the heavier carbon isotope. In C_4 and CAM plants, diffusional processes and recarboxylation play an important role in determining the carbon isotope composition since phosphoenolpyruvate (PEP) carboxylase does not discriminate against ^{13}C .

In plant samples collected in a salt marsh and lagoon, Smith and Epstein (1970) observed that the organic hydrogen of the dried plants contained 5.5% less deuterium than the environmental water, and the lipid fraction of the plant was even more depleted in deuterium. Investigations with plants grown under controlled conditions indicated that photosynthesis is the major process in fractionating the stable hydrogen isotopes in plants (Estep and Hoering 1980, 1981). The relationship between hydrogen isotope fractionation processes in plant tissues and different photosynthetic pathways has been thoroughly studied and significant differences were observed in discrimination against deuterium (Ziegler et al. 1976; Ziegler 1989).

Further biological fractionation takes place in animals and the measurement of the animals' isotopic ratios can be used to study animal ecology (Rundel et al. 1988). Finally, the isotopic composition of humans may reflect the composition of their diets and the principle "we are what we eat" can be used in archeological research to reconstruct the diet of prehistoric humans (Chen and Orna 1996) and hominids that predate the genus *Homo* (Sponheimer and Lee-Thorp 1999).

Abstract: Paleotemperature scales were calculated by H. C. Urey and others in the 1950s to assess past temperatures, and later work using the stable isotopes of oxygen, hydrogen, and carbon employed standards such as Peedee belemnite (PDB) and Standard Mean Ocean Water (SMOW). Subsequently, subjects as diverse as ice volume and paleotemperatures, oceanic ice and sediment cores, Pleistocene/Holocene climatic changes, and isotope chronostratigraphy extending back to the Precambrian were investigated.

16.1 Urey and His Geologic Thermometer

Oxygen isotopes of masses 17 and 18 were discovered in atmospheric oxygen in 1929. Deuterium, the heavy stable isotope of hydrogen, was detected in 1931, and by 1938 the carbon dioxide–water exchange technique for the oxygen isotope analysis of water had been developed. By the end of the 1930s, the existence of variations in the hydrologic cycle of both hydrogen and oxygen had been elaborated. Isotope paleoclimatology started with H. C. Urey's researches both on the empirical and theoretical aspects of isotope chemistry that followed his award of the Nobel Prize in 1934. In that year, he had already examined oxygen isotopes in stony meteorites and terrestrial rocks and claimed that they are constant to 2.5%. Later refinements produced per mill (‰, parts per thousand) accuracies and, after his World War II involvement in the separation of uranium isotopes, he treated the thermodynamics of isotope equilibria, also geochemical and cosmic problems. A seminal paper on the thermodynamic properties of isotopic substances appeared in 1947 (Urey 1947).

A mass spectrometer was described for measuring the isotopic variations in gas samples with high accuracy (Nier 1947). Urey improved its precision and started taking the paleotemperatures of Cretaceous belemnites. He did this by assessing the oxygen isotope fractionation between ocean water and the calcium carbonate precipitated by these animals (Urey et al. 1951). This was probably one of the greatest developments in the earth sciences and spans a wide range of disciplines from biology through isotopic fractionation to the history of the Earth.

In 1958, Urey relocated from Chicago to California, where at the Scripps Institution of Oceanography a School of Chemistry was formed. H. A. Lowenstam and S. Epstein continued the examination of Mesozoic belemnites following development of a paleotemperature scale (later modified by H. Craig and others) that will be discussed below. Attempts were later made to use two other mineral phases, i.e., biogenic silica/water and biogenic phosphate/water. They were successful, but the difference in values of carbonate, silica and phosphate in equilibrium with water were constant. Thus, it proved impossible to use either silica or phosphate to assess the temperature and isotopic composition from the measurements of delta (δ) oxygen-18 values in pairs of biogenic carbonate, silica, and phosphate. Parenthetically, delta is a parameter defined in per mill as ‰. This is fully explained later in the text (see ► Table 16.1).

Additional and ongoing research has accelerated the accumulation of more knowledge about the climates of the past essentially based on what some physicists scornfully described as “Urey's plumbing” beside the Pacific Ocean at La Jolla at Urey's lunch table. As well as oxygen isotopes, the isotopes of hydrogen, carbon, and, to a lesser degree, nitrogen, strontium, sulfur, etc., have been investigated. And the further back in time, the less the reliability of the data, the scantier the available evidence. Almost all interesting information relates to the isotopic paleoclimatology of the period, which started about 66.5 million years ago at the

■ Table 16.1

A comparison of hydrogen, oxygen, and carbon isotopic standards

Element	Isotope	Natural abundance variation (%)	Standard	Abbreviation

			Vienna peedee belemnite	V-PDB

Cretaceous/Tertiary (K/T) Boundary. Significant topics include ice volume versus paleotemperatures, sediment core data from deep oceans, ice core information, and the extension of the paleotemperature scale from belemnites to other organisms such as foraminifera and brachiopods. Associated matters involve the missing carbon problem, the global carbon cycle, simulation of the ice age, modeling climatic response for the Pleistocene, climate forcing, quantifying isotopic chronostratigraphy, ice-free oceans, and geochemical changes possibly connected with mass extinctions.

16.1.1 The Paleotemperature Concept

In 1950, the phosphoric acid technique for obtaining carbon dioxide from carbonates for mass spectrometric analysis was described (McCrea 1950). An improved version of Nier's mass spectrometer was used to determine the temperatures of Cretaceous belemnites by assessing the oxygen isotope fractionation between ocean water and the carbonate precipitated by these extinct animals (Urey et al. 1951). An oxygen isotope scale for evaluating paleotemperatures was developed in the 1950s following Urey's realization that if calcium carbonate is slowly crystallized in the presence of water at 0°C , the ratio of the oxygen isotopes in it should be 1.026:500 if the ratio of the oxygen isotopes in the water is 1:500, that is to say that the oxygen-18 is very slightly concentrated in the calcium carbonate in relation to water. If the temperature is 25°C , the oxygen isotopes will be concentrated only to the extent of 1.022:500 compared to 1:500 in water. From these considerations, a slight temperature coefficient for the abundance of oxygen-18 in the calcium carbonate as compared to that in the water was inferred. The degree of this fractionation is so small that the atomic weight of oxygen in the calcium carbonate will be changed by only 0.0000007 atomic weight units as the temperature is changed by 1°C . Hence

it was calculated that a change in temperature from 0°C to 25°C entails a change in the atomic weight of the oxygen of a mere 0.00002 atomic weight units. In this way, Urey wrote that “*I suddenly found myself with a geologic thermometer on my hands.*” With his group, he went on to develop the PDB standard.

This standard is significant because of the **calcareous-shelled abundance of carbonates** in the geological record. Urey and others used constant temperature baths to grow marine animals at known temperatures and also collected at various places so as to solve what he called “*the toughest chemical problem I ever faced,*” that is to say setting up a paleotemperature scale. The following paleotemperature equations are based on empirical data either obtained through growth experiments under controlled conditions (Epstein et al. 1953) or by the inorganic precipitation of minerals (Tarutani et al. 1969).

16.1.2 First Carbonate/Water Paleotemperature Scale

The first carbonate/water paleotemperature scale was based on the fact that the isotopic composition of oxygen from calcium carbonate differs from that of the water and depends on the temperature when the carbonate in question is precipitated under equilibrium conditions. This difference arises from an isotope-exchange reaction that can be represented by the expression

As only two thirds of the oxygen reacts to carbon dioxide when carbonate is treated with phosphoric acid, it is necessary to know the relevant fractionation factor which is

$$K = \alpha = R_c/R_w \quad (16.2)$$

where R_c and R_w represent the oxygen-18/oxygen-16 ratios of carbonate and water respectively. In the system calcite/water, the fractionation factor found is 1.0286 at 25°C so that the calcite precipitated in equilibrium will be enriched in oxygen-18 to 2.86‰ or 28.6‰ in δ -notation. The fractionation is temperature-dependent with values near unity and carbonate can either be enriched or depleted in heavy oxygen isotopes. Of course, the isotopic composition of seawater is unaffected because the mass of this is larger by orders of magnitude than that of the CaCO_3 equilibrated with it.

The temperature dependence of oxygen isotope fractionation between water and the important carbonate phases was established, the fractionation being normalized to the form as follows: $\delta^{18}\text{O}$ (CaCO_3 versus PDB) – $\delta^{18}\text{O}$ (water versus SMOW). Details regarding PDB and SMOW follow below, see ► [Table 16.1](#).

One of several equations is

$$T/^{\circ}\text{C} = 16.0 - 4.14(\delta_c - \delta_w) + 0.13(\delta_c - \delta_w)^2, \quad (16.3)$$

later revised so that 16.0 became 16.9 and 4.14 became 4.2. A later relationship was proposed for the aragonite/water paleotemperature scale by Grossman and Ku (1986). This is as follows:

$$T/^{\circ}\text{C} = 21.8 - 4.69(\delta_{\text{aragonite}} - \delta_w). \quad (16.4)$$

In all these cases, T is the derived temperature in °C, δ_c is the $\delta^{18}\text{O}$ of carbon dioxide liberated by the reaction of carbonate with 100% phosphoric acid at 25°, and δ_w is the $\delta^{18}\text{O}$ of

carbon dioxide equilibrated at 25°C with the water in which the shell was precipitated. The second factor is a problem because it refers, in their cases, mostly to oceanic water in a paleo-ocean, the isotopic composition of which is not known precisely. Urey assumed a value of zero for it, but later work has refined this approach. Doubtless, changes in the isotopic composition of seawater occurred through geological time and affected the $\delta^{18}\text{O}$ and also the δD contents as well as some significantly dissolved constituents such as the $\delta^{13}\text{C}$ of bicarbonate and the $\delta^{34}\text{S}$ of sulfate.

16.1.3 Other Paleotemperature Scales

Epstein et al. (1953) determined empirically the temperature dependence of the oxygen-18 of calcite in equilibrium with water, the delta values of these being later modified by Craig (1965). The expression for the temperature (T in °C) is as follows:

$$T/^{\circ}\text{C} = 16.9 - 4.2(\delta_{\text{c}} - \delta_{\text{w}}) + 0.13(\delta_{\text{c}} - \delta_{\text{w}})^2, \quad (16.5)$$

where δ_{c} is the $\delta^{18}\text{O}$ of carbon dioxide obtained from a sample of carbonate by reaction with 100% H_3PO_4 with respect to the mass spectrometer standard working gas, and δ_{w} is the corrected oxygen-18 of carbon dioxide equilibrated isotopically at the same temperature with the water from which the carbonate was precipitated, again measured against the same mass spectrometer standard working gas. Subsequently, extended studies have been done taking into account the new information regarding the paleotemperature scales and problems arising from the further development of the method. The estimation of paleotemperatures by measuring the oxygen isotope ratios of calcium carbonate from marine fossils had great significance as regards interpreting the history of climatic changes in the past, although it must be admitted that paleotemperatures have to be interpreted carefully if reliable data are to result. Unrealistic results can derive from various factors such as salinity, diagenetic alteration of samples, ice volume effects, mixing with freshwater, life habits, biological fractionation, or the mineralogical structure of the calcium carbonate. Although these parameters might influence and limit the value of temperature determinations in the past, each one of them offers opportunities for obtaining more paleoecological information, particularly if comparable data gained through faunal or floral analyses are available.

Clearly, these considerations necessitated initial chemical work using appropriate standards and various isotopic geochemical laboratories employ different reference gases or working standards in order to measure relative isotopic ratios using mass spectrometers. In [Table 16.1](#) there is a list of the most important isotopes involved.

16.1.4 Working Standards (PDB, SMOW, SNOW, SLAP)

All the stable and relevant standards are listed starting with the lightest isotope and proceeding upward. As well as oxygen and hydrogen, carbon is included in the following [Table 16.1](#) because it has proved to be useful in paleotemperature and allied work, for instance in dating groundwater aquifers. Information as to how these standards were derived follows below. Some of them have now been exhausted and have had to be replaced and some details as to how this was accomplished follow below the table under the headings PDB and SMOW.

Measurement of these isotopes produces data expressible in units of delta, δ , a parameter defined as follows:

$$\delta = \delta_{\text{sample to standard}} = \frac{R_{\text{sample}} - R_{\text{standard}}}{R_{\text{standard}}} \times 10^3, \quad (16.6)$$

and stated in parts per mill (‰). R_{sample} can be D/H, $^{18}\text{O}/^{16}\text{O}$, $^{13}\text{C}/^{12}\text{C}$, etc., the subscript “sample” denoting isotope ratio in a sample and the subscript “standard” denoting that in an appropriate standard.

PDB refers to a standard derived from *Belemnitella americana* from the Cretaceous Peedee Formation, South Carolina, USA. This standard is exhausted but referred to in the literature, so isotope ratios are measured against other standards and related to PDB as follows:

$$\delta_{\text{sample to PDB}} = \delta_{\text{sample to standard}} \times \delta_{\text{standard to PDB}} + \delta_{\text{sample to standard}} + \delta_{\text{standard to PDB}}, \quad (16.7)$$

where the result is expressed in parts per thousand (per mill). Vienna-PDB (V-PDB) standard was introduced in 1985 with NBS-19 as a reference material.

SMOW is Standard Mean Ocean Water, and it is now exhausted. It was originally made from seawater distilled into fractions and measured for deuterium and oxygen-18. The fractions were so combined and adjusted as to produce $\delta^{18}\text{O} = 0\text{‰}$ relative to what was originally defined as SMOW relative to NBS standard water. The oxygen-18 value was exactly 0‰ (to $\pm 0.02\text{‰}$). The D/H delta was negative because of the effects of distillation, so heavy water was added to bring the D/H delta to 0‰ (to $\pm 0.02\text{‰}$). As regards SLAP, H. Craig proposed SNOW (Standard Non-Ocean Water) for the light water standard, a proposal which did not find favor with the International Atomic Energy Agency (IAEA) on the grounds that it could be confused with SMOW. Urey wrote:

- ▶ *the temperature coefficient for the abundance of the oxygen isotope in calcium carbonate makes possible a new thermometer of great durability which may have been buried in the rocks for hundreds of millions of years after recording the temperature of some past geological record and then having remained to the present.* (Urey 1948)

The oxygen isotope compositions of foraminiferal tests from oceanic cores are a function of two variables, namely the oceanic temperatures and the oxygen isotope composition of the waters in which these animals lived. It was calculated that almost 85% of the isotopic change between glacial and interglacial planktonic foraminifera resulted from oceanic temperature changes, the remaining 20% or so coming from changes in the isotopic composition of water in the oceans through this transition due to the expansion and contraction of continental ice sheets (Emiliani 1955). Such changes were expressed in terms of 16 isotope stages, odd numbered ones representing warmer periods of Earth history and even numbered ones colder periods. Broecker and Van Donk referred to the changes from cold to warm stages as “terminations” (🔗 Fig. 16.1); thus, Termination I is the transition between Stages 2 and 1, Termination II that between Stages 6 and 5, etc. (Broecker and Van Donk 1970).

16.2 Milankovitch, Ice, and Sediment Cores

Greenhouse states occurred throughout Earth history, and they were occasionally irregularly interrupted by icehouse states during glaciations (ice ages). There is probably a greenhouse effect at present and this is quite different from the situation prevailing through the rest of the

■ Fig. 16.1

The oceanic isotope record and the timescale of planetary orbital changes showing an accurate chronology of first-order climatic variations through the last 0–75 million years. It can be seen that the record is saw-toothed in shape. Data composed from Cores P6304-9 (275,000–730,000 years) show $\delta^{18}\text{O}_{\text{‰}}$ -values against Chicago PDB-1 of *Globigerinoides sacculifer* (with correction of 2‰ for the section from Core 280). Absolute timescales were based on age 0 for core top, 125,000 years for the peak of Stage 5, and 700,000 years for the peak of Stage 19 (representing the Brunhes/Matuyama Boundary). Interpolations were based on average stage thicknesses from the Caribbean (Stages 1–6) and on the thicknesses of Stage 6–20 in Core V28-238. *Upward pointing arrows* show obliquity maxima and vice versa. *Upward pointing triangles* show eccentricity maxima and vice versa. *Circles* show times of maximum eccentricity when the northern summer was at perihelion. SCT 1–4 are superclimatherms and an earlier fifth covers isotope Stages 21–25. The foregoing SCT6 is a Late Cenozoic climatic boundary connected with the first continental ice sheet glaciations of Europe and the maximum glaciations in North America and Patagonia. Transitions from cold to warm episodes are called “terminations.” The last was Termination I (TI) between Stage 2 and 1. It was preceded by Termination II (TII) between Stages 6 and 5 (After Emiliani 1955, 1978)

Holocene Epoch that commenced some 10,000 years ago. Prior to that, the Pleistocene was characterized by ice episodes comprising the last Ice Age. Large quantities of ice remain even today, and examination of ice cores and their oxygen isotope profiles have shown climatic variations through the past 100,000 years. The parameter $\delta^{18}\text{O}$ measured in the water molecules produces basic information in an ice core. The temperature at which ice crystals form clouds determines the $\delta^{18}\text{O}$ ratio of the ice deposited at the surface so that the $\delta^{18}\text{O}$ of an ice core provides a proxy record of precipitation temperatures. In 1987, Dansgaard recorded many abrupt climatic changes in the North Atlantic during the last ice-age and deep-sea sediment analyses have confirmed that the southern hemisphere was affected as well. Ocean sediment cores are also important in understanding past climates since they embody relevant data on timescales of 1,000–10,000 years at sample resolutions claimed to be in the range of 1,000–10,000 years. The Deep Sea Drilling Project (DSDP) sampled 600 sites and gave records up to tens of millions of years in age. The most interesting areas for sediment core studies is probably within 10° of the equator in mid- to high latitudes and along coastal margins. Such ice ages occurred irregularly throughout Earth history, and long-term climatic trends entail astronomical cycles of 100,000 years (eccentricity of the planetary orbit), 41,000 years (obliquity signal), and 23,000 and 19,000 years (Milankovitch 1930). **CLIMAP (Climate Long-Range Investigation and Mapping)** deep-sea ocean core stratigraphy and associated isotope analyses have been used to determine whether smaller fluctuations in an isotope curve correspond to

those predicted by Milankovitch theory. The history of the North Atlantic and North Pacific oceans during the Brunhes Epoch of normal magnetic polarity extends back to 690,000 years before the present. Brunhes himself noted that magnetization of lava flows and underlying baked clays indicated that the direction opposed that of the present field (Brunhes 1906). It became apparent that the Earth's magnetic field reversed itself during the past. A preceding reversed polarity time interval extended from 690,000 to 2.4 million years before the present and this is termed the Matuyama Epoch.

16.2.1 Basic Considerations

Damage to the ecosystem increases through acid rain, ozone depletion, and supernovae may well induce ozone drops through the emission of a proton burst that might add an equivalent of solar possible greenhouse effects. Some of these factors are beyond human control, e.g., it has been suggested that ionizing radiation to the terrestrial atmosphere can produce NO_x molecules capable of reducing the ozone layer to as little as 10% of its present concentration and that the Tunguska event of June 1908 actually caused a 40% drop in this layer, which probably entailed the release of a nitric oxide cloud. It has been proposed that the transition from an ice-free “greenhouse” Earth to a glacial cycle “icehouse” regime could be produced from a northern hemisphere ice sheet model if there was a slow general cooling on the continents perhaps due to plate tectonic shifting (Oerlemans 1984). Implications of the coral reef record from New Guinea in regard to the astronomical theory of ice ages may provide a means for quantitatively evaluating ice volume and the temperature factor from their oxygen isotope contents and sea-level changes. An even more startling application of isotopes to Pleistocene ice age events was an indication that detailed heavy isotope and dust concentration profiles from Greenland ice cores imply that the North Atlantic regional climate became milder and less stormy because of a rapid retreat of the sea ice cover occurring in less than 20 years. As regards mass extinctions, e.g., at the K/T Boundary, supportive records show a high $^{87}\text{Sr}/^{86}\text{Sr}$ ratio in some planktonic fossils, which could reflect continental-derived strontium. Curiously, at the K/T Boundary, there was a change in the carbon isotope ratios, but not in the sulfur ones. Lower values of the carbon ones may imply lowered oceanic productivity that eliminated the usual state between surface and deep waters to give “**Strangelove**” conditions. Later, higher values were restored with vigorous oceanic circulation. Productive oceans have a biologically mediated gradient in the carbon isotopes between surface and deep waters and it is this that disappeared at the K/T Boundary to initiate “Strangelove” conditions, i.e., a “Strangelove” ocean, one where the above-mentioned biologically mediated gradient in carbon isotopes between surface and deep waters characteristic of productive oceans disappears. A similar carbon drop was recorded for the largest mass extinction in the Phanerozoic era, namely that which took place at the Permo/Triassic (P/T) Boundary about 237.2 Ma ago. Several magnetic reversals around this time have been noted from core records and, curiously, the carbon record does not revert as rapidly back to normal as was the case in the wake of the K/T one. However, apparently global changes in the carbon cycle started in the Late Permian and continued smoothly across the stratigraphical P/T Boundary to culminate in the Early Triassic.

Greenland ice cores may record a milder and less stormy climate in the North Atlantic region because of a rapid retreat of the sea-ice cover occurring in less than 2 decades (Dansgaard et al. 1989). This produced a wide belt of open seawater of intermediate temperatures lying between tropical and polar water masses. In fact, it is feasible that a bi-stable

climatic regime existed there in the course of the glacial period and may have been connected to a flip-flop mechanism in the North Atlantic Ocean. This could perhaps be correlated with switching from “strong” to “weak” modes of deepwater production there, a process that could have been driven, at least to some extent, by an influx of cold freshwater from melting continental ice sheets. Isotopic data have been applied also to mass extinctions of which the best known is that occurring at the K/T Boundary about 66.5 Ma ago. This may have contributed to the extinction of the dinosaurs and other life-forms and could have resulted from the impact of an “extinction bolide” striking a shallow marine terrane on Earth or even an asteroid if the Chicxulub crater really is an impact relic.

16.2.2 Dole Effect and the Meteoric Water Line

Melting ice releases isotopically light water, that is to say water enriched in ^{16}O . Freezing has the opposite effect. Variation in oxygen-18 ocean contents between maximum and minimum glaciations might have been about 1.5‰, therefore glaciation can be more significant than temperature as regards the isotopic composition of marine carbonates, for instance in foraminifera in tropical oceans (Craig 1965). This is because their environmental temperatures will not vary much during glacial or interglacial episodes. And, while oxygen-18 temperature effects produce approximately 0.7‰ increase in the heavy stable isotope in precipitation for every 1°C rise in temperature, the isotopic difference between shells formed during maximum or minimum glaciation in equatorial surface waters in the Atlantic Ocean and in the Caribbean Sea is only about 1.6‰. From this, it may be inferred that freshwater systems respond far more to climatic changes than do marine ones.

Today atmospheric oxygen is not in isotopic equilibrium with ocean water (Dole effect) and there is a considerable oxygen-18 enrichment relative to V-SMOW, $\sim 23.5\text{‰}$, possibly accounted for by global respiratory processes. As for δD , the hydrosphere now has an overall value ranging from roughly zero relative to V-SMOW. Since magmatic water has values ranging from -50‰ to -90‰ relative to V-SMOW, it cannot have originated from the hydrosphere. Of course it is possible that the hydrogen isotope composition of the original sources of water on the surface of the Earth may have been different from that of those waters incorporated into the planetary interior.

Examination of the ranges of relative deuterium concentrations in various terrestrial and meteoric materials shows that seawater is on the heavy side of most samples, including those from carbonaceous chondrites. This may be due to a stepwise distillation process during which hydrogen moves faster than the heavier deuterium. It may be described by a modified Rayleigh equation and determines that precipitation falling furthest from its source will be isotopically enriched in the lighter stable isotopes hydrogen and oxygen-16. Also, natural waters in high latitudes and altitudes are isotopically light and those in subtropical regions with low rainfall are often heavier than seawater. A linear correlation exists between deuterium and oxygen-18 in meteoric waters and this can be expressed by the following relationship

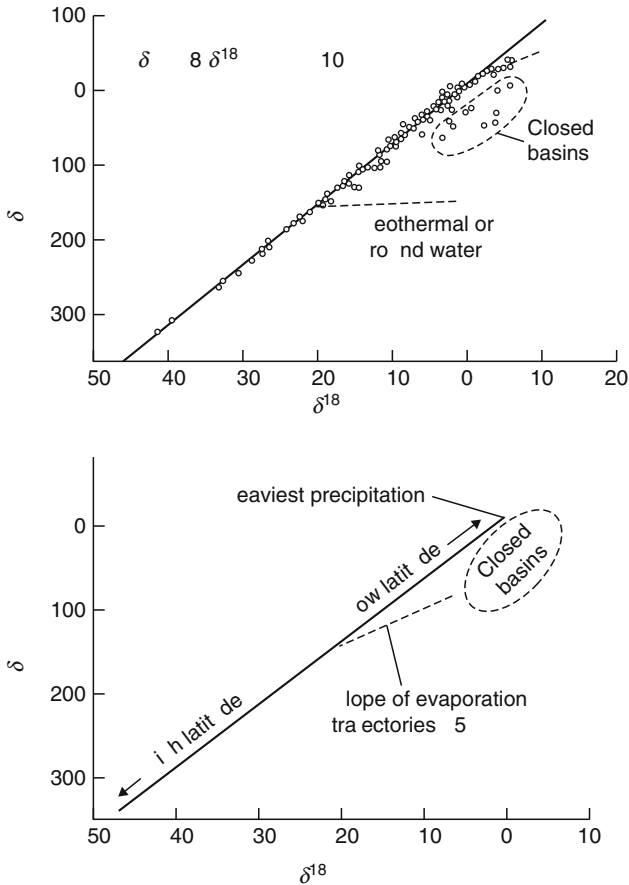

$$\delta\text{D} = 8 \delta^{18}\text{O} + 10 \quad (16.8)$$

which is called the “meteoric water line” (see upper graph in [Fig. 16.2](#)). Deviations occur in lakes and other enclosed water bodies undergoing extensive evaporation.

There are other effects to consider. They are temperature, altitude, and latitude. The above correlation confirms that atmospheric precipitation follows a Rayleigh distillation process at

■ Fig. 5.2

The relationship between δD and $\delta^{18}O$ in meteoric water. The linear relationship is the “meteoric water line”

liquid–vapor equilibrium and the slope of the meteoric water line roughly corresponds to the ratio of equilibrium fractionations at 25°C. Decreasing δD and $\delta^{18}O$ values along this line are connected to increasing altitude and latitude and decreasing mean annual temperature. As for groundwater, their isotopic compositions in temperate and humid regions resemble those of precipitation in their recharge areas. Another effect of evaporation may be a rise in salinity, but, if such a rise does not occur, the isotopic composition of the evaporating water body may increase monotonically to a steady-state condition.

16.2.3 Continental Glaciation

Continental glaciation exerts effects on the isotopic composition of the oceans arising from isotopic fractionation in the meteoric cycle. High-latitude precipitation is depleted in the heavy stable isotopes relative to ocean water so that when continental glaciers grow, the light

isotopic species are preferentially removed from seawater and the $\delta^{18}\text{O}$ and δD contents of the residual oceans increase. The reverse takes place when glaciers or ice sheets melt. Consequently, the advance and retreat of continental glaciers during the Pleistocene must have altered the $\delta^{18}\text{O}$ in seawater and this so-called ice volume effect is calculable. It must have been paralleled during earlier ice ages in Earth history, and notable $\delta^{18}\text{O}$ shifts in the records of Tertiary deep-sea carbonates may be due to the development of such continental glaciers.

16.3 Ice Volume Versus Paleotemperatures

A composite curve of isotopic variations for the past 700,000 years was constructed (Emiliani 1978). It implied that glacial/interglacial cycles have a periodicity of about 100,000 years. Fluctuations were saw-toothed in a pattern that suggested rapid change from one condition to the other. Subsequently, the original idea that ice effect was less than temperature was reversed and an improved timescale devised. Obtaining an improved timescale entailed deciding between one based on radiocarbon dating linked to a presumed fit to Milankovitch fluctuations and another based on the dating of raised coral reefs (Broecker and Van Donk 1970). The so-called Broecker scale was vindicated.

Continental glaciation exerts effects on the isotopic composition of the oceans arising from isotopic fractionation in the meteoric cycle. High-latitude precipitation is depleted in the heavy stable isotopes relative to ocean water so that when continental glaciers grow the light isotopic species are preferentially removed from seawater and the $\delta^{18}\text{O}$ and δD contents of the residual oceans increase. The reverse takes place when glaciers or ice sheets melt. Consequently, the advance and retreat of continental glaciers during the Pleistocene must have altered the $\delta^{18}\text{O}$ in seawater and this so-called ice volume effect is calculable. It must have been paralleled during earlier ice ages in Earth history and notable $\delta^{18}\text{O}$ shifts in the records of Tertiary deep-sea carbonates may be due to the development of such continental glaciers. Attempts to estimate variations in $\delta^{18}\text{O}$ in seawater through geological time could be improved by analyzing two mineral phases, both of which equilibrated with the seawater at the same temperature. Two independent equations could be constructed relating the δ -value of the water and the temperature, the latter then becoming determinable. Two such phases have been proposed, namely biogenic silica and phosphate, but unfortunately the slopes of lines drawn from derived equations parallel that of the calcium carbonate paleothermometer; therefore, the difference in the δ -values of carbonate and silica in equilibrium with water is constant and independent both of δ -values of the relevant water and also of the temperature. The situation between biogenic carbonate and biogenic phosphate is similar. Hence, it is not possible to use either approach for assessment of both temperature and the isotopic composition of water from measurements of $\delta^{18}\text{O}$ values in pairs of biogenic carbonate, silica, or phosphate.

Variations in the oxygen isotopic compositions of Quaternary foraminifera relate to paleoclimatic events, but the extent to which temperature changes and **ice volume** actually correlate is unclear. Oxygen isotope analysis of deep-sea cores implies that massive destruction of the Antarctic ice sheet occurred during glacial terminations I and II. It should be mentioned that although most references allude to marine environments, there are data regarding oxygen and carbon isotopes in freshwater shells, terrestrial plants, etc. If diagenetic changes have not taken place, there can be little doubt that the isotopic composition of fossil shells and limestones from freshwater deposits embody information showing much greater variability because of the large-scale fractionation of oxygen isotopes in the meteoric water cycle. Thus,

the oxygen isotopic composition of freshwater systems varies by a factor of 10 more than that of seawater and it is not directly applicable to paleotemperature determinations. The carbon-13 isotopic composition of fresh-water mollusks was studied and its distribution and that of oxygen-18 in such shells from Dutch estuaries showed no significant deviation from the isotopic equilibrium values expected, which implies that vital effects did not occur. The latter are disequilibrium fractionations shown by oxygen and carbon isotopic analyses of calcite shells or tests from certain organisms such as living benthic foraminifera like *Heterostegina depressa*. All recent species of planktonic foraminifera seem to be in isotopic disequilibrium with respect to the $\delta^{13}\text{C}$ of equilibrium calcite. The disequilibrium fractionation is species-specific and very large in small spinose species in the euphotic zone.

Various mechanisms have been proposed to explain vital effects. One is uptake of metabolic carbon dioxide calcification. A second is physiological changes with ontogeny, that is to say a possible physiological control being exerted on the carbon and oxygen isotope compositions of skeletons of some marine organisms such as echinoderms. A third is kinetic isotope effects in the transport of carbonate ions to the calcification sites. And where symbiotic algae are present, their photosynthetic activities may play a part also. Honestly, the fact of the matter is that such **vital effects** have been recorded, but so far not properly understood. An important fact is that isotope effects involving radiocarbon are greater than those for carbon-13 by a factor of about 2 and this offers a basis for correcting $\delta^{13}\text{C}$ values from organic matter. The total range of this is ca 30‰, hence 60‰ for radiocarbon. Hence, the measured age difference between an isotopically heavy and light wood would be almost 350 years. Resolving this is done conventionally by normalizing all radiocarbon dates to a $\delta^{13}\text{C} = 25\text{‰}$, which is a value close to the average for all terrestrial plants.

Deuterium has been sampled from organic matter for use as a paleoclimatological tool and, since the average ratio of hydrogen to this isotope is 6,419:1, only minuscule isotopic variations can be anticipated. However, because of the relatively enormous mass difference between the two stable isotopes of hydrogen, the isotopic effects are strongly accentuated. But the problem is that plants constitute complicated chemical systems and so isotopic differences between various chemical compounds in any particular plant could have a great influence on the recorded D/H ratio for the plant. To overcome this, cellulose was investigated and showed that two types of hydrogen are found in plants, and also that carbon-bound hydrogen in cellulose is not exchangeable in contrast to hydroxyl- and oxygen-bound hydrogen which are exchangeable. There is an excellent correlation between the D/H ratio in plants and that of the water available to them. Hence, since the δD of freshwater is dependent on climatic parameters, information from plants must relate to this as well. Obviously plants growing and living for centuries are optimal for study. Depletion in D and ^{18}O in growth rings points to lower temperatures, while enrichment in these isotopes shows higher overall temperatures and less fractionated rainwater or groundwater. The approach has been applied to fossil, but not decomposed, wood from the Pleistocene.

16.3.1 Isotopes and Ice Age Impacts

Four ice age episodes were recognized in the Pleistocene Epoch that commenced about 2 million years ago and ended about 10,000 years ago. Each was succeeded by warmer episodes and there were an estimated 22 ice episodes during this time interval. Numerous possible causes for this last ice age and earlier ones have been put forward. One is a decrease in solar energy output. Another is variations in the geometry of the Earth's orbit and precessional cycle,

which could have produced significant changes in the pattern of incident radiation on timescales from 10,000 to 400,000 years, such changes entailing three orbital parameters, namely eccentricity, obliquity (tilt), and the precession index. It has also been proposed that abrupt sliding of huge sections of the Antarctic ice sheet into the ocean might well have initiated climatic changes ending in an ice age. Another model envisaged an ice age starting when, for a short time, the Arctic Ocean is ice-free and open to warm currents from the North Atlantic (a state of affairs that looks likely to recur shortly if present trends continue). Evaporative increases added (or will add) excess water vapor to the overlying air, and this in turn gives greater snowfall on surrounding land areas. Escalating glaciation might trigger an ice age, deglaciation following when temperatures drop enough to permit the Arctic Ocean to refreeze. Later, with the moisture source removed, ice sheets would shrink, sea level would rise with its eustatic elevation inundating continental shelves, and warm North Atlantic Ocean currents could start melting Arctic ice once again. Since an historic sequence of events is involved, this should be recorded in Arctic Ocean sediments so that, in principle, the hypothesis can be tested. Such sediments ought to have fossils of organisms that colonized sunlit waters, but none has been found and also the sediments in question demonstrate that the Arctic Ocean has not been ice-free during the past several million years.

Another suggestion is that an ice age, however caused, could be terminated through postulated greenhouse conditions, which are worsening today because of fossil fuel burning and a correlated rise in carbon dioxide levels in the atmosphere. This gas comprises 0.033% of air and, while reasonably transparent to solar shortwave radiation, is rather opaque to reflected long-wave radiation and returns most of it to Earth as infrared light. This makes the atmosphere act like glass covering a greenhouse, hence the environment heats up through an accompanying entrapment of incoming incident radiant energy. Data from Antarctic ice cores show that over the past 160,000 years, ice ages indeed coincided with reduced carbon dioxide levels and warmer, interglacial periods were characterized by increased production of this gas.

16.3.2 The Geography of the Last Ice Age

In the 1960s, isotope analytical work was applied to a number of paleoclimatic problems and only then did it become possible to attempt to reconstruct conditions on Earth at the culmination of the last ice age. Ten years later, quantification followed and entailed the use of multivariate statistical methods using both biological and geological data. Transfer functions were integral to this approach and their use was based on the assumption that biological changes, for instance in the distribution of species, relate to climatic factors. Basically, they are regressive equations relating modern fauna and floral census information to oceanic characteristics such as the temperature of the sea surface. Further observations on them are included in [Sect. 16.6.1](#) below. They facilitate the estimating of past ocean properties from past census information (Imbrie and Kipp 1971). CLIMAP contributions were valuable because they involved the determination of oxygen isotope stratigraphy for hundreds of ocean cores in each of which the inferred maximum ice volume was estimated and correlated from one core to another. The climate 18,000 years ago was compared with that of today and this took into account relevant factors such as bioturbation, inaccurate stratigraphic correlation, and imprecise absolute dating – these could cause individual sampling points to have ages ranging from 15,000 to 20,000 years B.P. The main objective was to reconstruct the surface of the Earth during the last glacial maximum about 18,000 years ago and the final oceanic reconstruction

was based on 450 worldwide cores. The main conclusions were that during the last glacial maximum, there were several vast land-based ice sheets as much as 3 km thick in the northern hemisphere, while in the southern hemisphere there was much more sea ice than there is today. Global sea level dropped by at least 100 m and the average sea surface temperatures were about 1.7°C cooler in August and 1.4°C in February. The average surface albedo then was higher than now, and the ice age ocean was characterized by a steepening of thermal gradients along frontal systems as well as by an equatorial shift of subtropical convergences in the southern hemisphere and a displacement of the Gulf Stream which flowed east at 40°N. As for the last interglacial, it seems that it resembled current conditions to a great extent. However, there is evidence that the stable isotope record of the planktonic foraminifera from the Fram Strait and central Arctic Ocean could refine the response of that ocean to climatic change. Until 1988, the paleo-oceanography of the Fram Strait–Norwegian/Greenland seas was interpreted mainly from sediment core studies and only four isotope records were available. The longest was V28-56 and this was interpreted as reaching Isotope Stage II (about 420,000 years ago).

The opinion offered was that during the last glacial/interglacial transition about 10,000–18,000 years B.P., the North Atlantic Ocean responded to orbital-induced insolation changes which suggested that when glaciation sets in, the ice pack retreated to higher latitudes and allowed a northerly extension of the warm North Atlantic drift to reach higher latitudes (Broecker et al. 1985). There, heat emitted by this warm current would reach adjacent ice caps and leave residual surface water cold and dense. Actually, it would be dense enough to sink and form Norwegian/Greenland Sea Deep Water (**NGDW**).

Waning of ice caps could have produced a melt-water spike over huge areas of high-latitude seas to throw the climatic system back toward the glacial mode and the isotopic composition of planktonic foraminifera would record such changes. Since orbital positioning caused increased insolation to overwhelm the glacial pulse, the climatic system would have entered the now prevailing interglacial mode. This explains the “pulsed” nature of the isotope records from high-latitude seas, namely glacial toward interglacial then back to glacial and eventually to full interglacial. The explanation of the “pulsed” high-latitude isotopic records suggests that once in the interglacial phase of the climatic cycle the increased production of **NGDW** may induce spillage over the Iceland/Faroe Sill to produce **NADW** for most of the world’s ocean basins. Further light was shed on the subject through a claim that a comparison of stable isotope and textural records of sediment cores from the Fram Strait and central Arctic Ocean with low-latitude oceans showed that the Arctic/Mediterranean responded dynamically to climate change during the Pleistocene (Morris 1988). Core MG-123 from this strait had a minimum of four significantly low $\delta^{18}\text{O}$ intervals with low amounts of coarse sediments also. The association of high $\delta^{18}\text{O}$ values with high amounts of such sediments indicated increased glacial ice in the Fram Strait during the glacial phases of the climate cycle. Peaks within the low $\delta^{18}\text{O}$ intervals increased in size from oldest to youngest, implying a progressive intensification in the oceanographic response to glacial/interglacial transitions in the Fram Strait during the past 524,000 years. Time series spectral analyses suggested this age for the oldest sediment in core MG-123 that would then have had a rate of sedimentation of about 1.66 cm per 1,000 years. Isotope records support the established central Arctic Ocean lithostratigraphy, but coarse sediment deposition in the Arctic is not so clearly related to glacial conditions as it is in the Fram Strait. The oxygen isotope range of central Arctic Ocean records is accentuated relative to the global ice volume signal recorded from lower latitude cores, perhaps because of variations in salinity, temperature, and thickness of the low salinity surface area of the Arctic Ocean. Paleoceanographic responses to climatic changes recorded in the Fram Strait are

paralleled in the central Arctic Ocean, but with decreased resolution due to the great difference in the rates of sedimentation between the two. All this and other work led to a new outlook on the Earth during the ice age. Earlier studies were based on terrestrial data, mostly from midlatitudes, and they showed the growth of ice sheets and accompanying equatorial compression of climate zones. However, data from ocean cores also show a similar compression inwards towards the centers of subtropical oceanic gyres forming thermally and geographically stable parts of the climate system with areas of modest cooling around them, those with maximum effects being located in the higher latitudes.

16.4 The Quaternary Global Carbon Cycle

As regards recent natural events and CO₂ anomalies, increase of about 9 ppm between 1976 and 1982 suggested a mean global rate for the atmosphere of 1.5 ± 0.2 ppm annually. The total production of this gas from fossil fuel use and current manufacturing through this time interval was estimated at about 38×10^{13} g C (=16.8 ppm atmospheric equivalent). Such data facilitate understanding the response of the atmosphere/ocean/biosphere systematic anthropogenic perturbations. Trapped air bubbles in cores showed variations of up to 100 ppm in atmospheric carbon dioxide, which are thought to have taken place in periods as short as a century in the course of the last ice age. The cause might be rapid uptake or removal of enormous amounts of carbon from a reservoir (maybe the oceans) through some mechanism. Natural events such as the El Niño/Southern Oscillation (ENSO) may be involved. There is some evidence for this because, in 1993, it was shown that a slowing of the growth rate of atmospheric carbon dioxide due to anthropogenic emissions by more than in any preceding year in a 35-year record from samples from Mauna Loa correlated, after removing the long-term trend and seasonal signal, with huge changes in the oceanic and atmospheric circulation of just this oscillation. After such events, atmospheric carbon dioxide usually rises, but during them the ocean reduced its content. Aberrant results came from the eruption of Mt. Pinatubo in June 1991 and a “**Pinatubo carbon anomaly**” had reached Mauna Loa by May 1993. If this were applied globally in the northern hemisphere, a loss of 1.6 Pg (1.6×10^{15} g) of carbon would be entailed. An oceanic sink for it would give an oxygen/carbon dioxide ratio of between 2 and 8 and a terrestrial sink ratio of ca 1. La Jolla observations demonstrated a positive **Pinatubo eruption anomaly** approximately twice that of the negative carbon one. Hence, though a terrestrial sink may account for part of the anomaly, the oxygen data suggest that much is due to the oceans. The coincidence of the onset of carbon and oxygen anomalies with the Pinatubo eruption connotes a causal relationship, e.g., iron fertilization of the oceans since removal of over 1.6 Pg of carbon would need ca 10^5 t of iron.

16.4.1 Past Atmospheric Carbon Dioxide in Ice Cores

The history of such CO₂ was obtained from deep ice cores embodying continuous sequences formed up to 100,000 years ago. The preindustrial age concentration is believed to have been in the range 260–270 ppm. Basic information from an ice core derives from $\delta^{18}\text{O}$ measurements from water molecules, periods of high values (positive) recording warmer times and vice versa. At about 10,000 B.P. for Dye 3 1981, there was a marked shift paralleled at Camp Century 1967, both corresponding to the last warming from the Pleistocene into the Holocene. Both cores

recorded an earlier $\delta^{18}\text{O}$ increase around 13,000 B.P. Plotting these values against depth and carbon dioxide and beryllium-10 concentrations showed that the increase to higher values at the first warming transition around 13,000 B.P. occurred within 100 years. In fact, since data from ancient air compositions came from ice layers about a century older than those containing the oxygen-18 information, the two transitions took place during the same time interval within ± 100 years. Interestingly, at 1,890 m depth (corresponding to an estimated age of about 40,000 years), there is a relatively high carbon dioxide concentration coinciding with one of the high $\delta^{18}\text{O}$ periods during the Wisconsin glaciation. Further work on the $\text{CO}_2/\delta^{18}\text{O}$ relationship in the 30,000–40,000-years-old level of the Dye ice core showed that all rapid $\delta^{18}\text{O}$ oscillations are accompanied by simultaneous and well-correlated carbon dioxide oscillations. It was concluded that changes in both of these parameters took place at about the same time (phase shift $< \pm 100$ years). Therefore, the observed carbon dioxide concentrational changes in air occluded in ice may represent atmospheric carbon dioxide changes.

16.4.2 Carbon Cycle Changes

The average carbon-13/carbon-12 ratio on Earth is $\sim 1.12 \times 10^{-2}$, although it varies because the physicochemical properties of the molecules are mass-dependent, e.g., the carbon dioxide exchange between the atmosphere and the oceans causes a 9‰ lower $^{13}\text{C}/^{12}\text{C}$ ratio of atmospheric CO_2 relative to ocean bicarbonate. $^{13}\text{C}/^{12}\text{C}$ ratios are expressed as $\delta^{13}\text{C}$, this being the relative deviation from PDB standard in per mill.

Radiocarbon is present in atmospheric carbon dioxide with a $^{14}\text{C}/^{12}\text{C}$ ratio of about 10^{-12} and it is produced continuously in the stratosphere through interactions between thermal neutrons and nitrogen. For further details, see [Chap. 6](#). Precise radiocarbon determinations need large samples and long counting times. For instance, a typical tree ring counting precision of 1.5‰ was obtained at a Quaternary Isotope Laboratory for 6 g carbon samples counted for 4 days. The optimal material is dendrochronologically dated tree samples, the cellulose annually formed in each ring ceasing to exchange carbon thereafter. However, even when the removal is not 100% total, resultant errors in natural $\Delta^{14}\text{C}$ values are reducible to a few tenths per mill. The radiocarbon age is obtained from the ratio of residual sample activity to oxalic acid standard activity.

In 1989, Suess noted that measured carbon-14 values deviate consistently from those calculated from tree rings and the “wiggles” involved showed the existence of a geophysical parameter valid for the entire terrestrial atmosphere (Suess 1989). Fourier spectra showed the consistency of the results and supported the contention that secular variations of radiocarbon in atmospheric carbon dioxide are related to variations in solar activity. Using varve deposits, it is possible to extend the study of radiocarbon variations beyond dendrochronological limits. Some temperature regional lakes contain rhythmites, sedimentary successions of interbedded laminae, and such sediments in the Lake of the Clouds, Minnesota, have over 10,000 couplets. The problem is that varve chronologies assume that no duplication of annual couplets occurred, no parts are missing, and also that constant radiocarbon reservoir deficiency occurred. Obviously it would be valuable if agreement with radiocarbon tree ring data over the last 8,600 years or so up to as much as 9,200 years could be reached. But this has only been achieved at the Lake of the Clouds. Much less is known about atmospheric $\Delta^{14}\text{C}$ before 13,000 B.P., but a good agreement between carbon-14 and ionium dates in Searles Lake sediments showed that departures from the oxalic acid baseline are restricted to about 10%

between 23,000 and 32,000 years ago. Also, a comparison between carbon-14 and ionium dates of a stalagmite showed a 50% increase in $\Delta^{14}\text{C}$ about 18,000 B.P. and a roughly normal level near 29,000 B.P. These data imply carbon-14 levels one and a half to twice the present ones for the time interval between 35,000 and 40,000 years B.P.
