Abstract: Chemical and physical radiation dosimetry methods, used for the measurement of absorbed dose mainly during the practical use of ionizing radiation, are discussed with respect to their characteristics and fields of application.

49.1 Introduction

The ionizing radiation quantity, absorbed dose (D) needs to be measured in many applications, and several effective dosimetry systems have been developed over the past century. The main purposes are measurement of (1) the energy imparted in a given mass of a specific material at a certain point of interest, namely dose, in units gray (Gy) where $1 \text{ Gy} = 1 \text{ J/kg}$; (2) absorbed dose rate; (3) the dose distribution over a specified material volume. Dose measurement is of basic significance especially in radiation processing, radiation protection, and in medicine, and the physical and chemical concepts developed for dosimetry are equally relevant for these applications. Although some of these methods are described in other chapters, dosimetry systems used mainly in radiation processing are discussed here, and when dealing with certain groups of dosimeters, other applications characteristic of that group, are also described briefly.

49.2 Role of Dosimetry

The most important practical applications of ionizing radiation in industry have been discussed in Vol. 3 (🔗 Chap. 23, “Radiation Chemistry”) describing the basic characteristics of the various processes. Some of these applications do not need exact doses, but many require knowledge of the dose applied in order to carry out uniform and accurate irradiation to achieve the necessary effect, i.e., the desired property of the product, e.g., sterility of medical devices or pasteurization of certain foods, while avoiding damage to the product. The exact measurement of absorbed dose in the course of the radiation process is critical, since it is used to document the successful execution of the irradiation process. Thus, dosimetry is also important in routine quality control as an independent, inexpensive, and reliable tool to measure and document whether the process was carried out according to specifications. Dosimetry then plays an important role in the transfer of the irradiation process from the laboratory to the industrial stage and in the quality control of radiation processing.

The main application fields of dosimetry in radiation processing include installation, operational and performance qualification, and routine process control. The selection of suitable routine dosimetry systems depends on the actual measurement to be carried out. Various characteristics should be considered, such as accurate and reproducible response, dose and dose rate range, energy of radiation, environmental effects on the response, stability before, during, and after irradiation, and method of evaluation.

In practical radiation processing, i.e., during installation, operational and performance qualification exercises, the selection of the most suitable dosimetry systems requires special care and the use of previous experiences. Some suggestions concerning the applicable dosimetry systems are given below.

Radiation sterilization is radiation process with the most detailed regulations, and the international standard for radiation sterilization, ISO 11137 (2006) specifies the measurements to be carried out in connection with validation of a radiation sterilization process. These requirements can also be applied to other radiation processes. In *installation qualification* (IQ)

of gamma facilities there are no specific dosimetry requirements to verify operation of the plant within specifications, i.e., no dosimetry exercises are needed. In the case of electron irradiation facilities, however, the beam characteristics like the electron energy, the width, and homogeneity of the scanned beam and the beam spot – in the case of pulsed electron accelerators – must be measured.

In the case of *operational qualification* (OQ) exercises like (1) determination of relationship between irradiation time and dose, (2) measurement of dose distribution in reference material, (3) measurement of effects of process interruption, and (4) measurement of beam characteristics have to be performed.

In case (1) in gamma facilities the dose vs. irradiation time (in plants with no product transport system) or the dwell time (in plants with product transport system) can be measured by using different reference standard, transfer standard, or routine dosimeters. In EB facilities, the dose vs. conveyor speed relationship can be measured mainly with process calorimeters, but other dosimetry systems with quick dose evaluation capabilities after irradiation can also be used for this purpose.

The measurement of dose distribution (2) in reference material can be carried out with various liquid or solid phase dosimeters in gamma plants, while mainly with film dosimeters in EB plants taking into account the specific spatial resolution requirements.

The measurement of beam characteristics can be performed the same way as described in the case of IQ exercises.

The basic procedure in *performance qualification* (PQ) exercises is the measurement of dose distribution in real products. In gamma processing, similar dosimetry systems can be applied like in OQ exercises. In electron processing, usually film dosimeters are suggested for use with the restriction of the application of only thin film dosimeters for dose mapping in inhomogeneous products.

Note: The dosimetry systems applicable in gamma processing can also be used in X-ray processing according to the present knowledge.

Reliable dosimetry requires the knowledge of the level of accuracy and precision of the dosimetry system used. All dosimeters need calibration in order to establish measurement traceability. This can be achieved by carrying out suitable calibration procedures – traceable to an appropriate national standard – with respect to both the dosimeter system and the instrumentation used for evaluation. The main aim of dosimeter calibration is to determine the relationship between the response of the dosimeter and the dose absorbed in it. This relationship depends on a number of external factors with respect to irradiation conditions, and therefore calibration procedures should be selected to minimize the effect of these influence factors (e.g., environmental conditions affecting the dosimeter response), thus improving the accuracy of the dose measurement. It can be done by using calibration in-plant (i.e., under processing conditions) whenever possible. The other option is to calibrate dosimeters in a calibration laboratory applying correction factors (e.g., irradiation temperature coefficient), which is followed by calibration verification in the irradiation plant (ASTM 51261, Sharpe and Miller 1999). The calibration of routine dosimeters is usually carried out by irradiating routine dosimeters together with reference or transfer standard dosimeters. Both the reference and transfer standard dosimeter systems require calibration and this is often done by comparison with dosimeters of higher quality. Such systems are categorized as primary-, secondary reference, or transfer standard dosimeters of higher metrological characteristics, namely high accuracy and reproducibility ($\pm 1\text{--}2\%$, $k = 2$), long-term stability and limited – but known – environmental effects on their response (ASTM 2628, McLaughlin et al. 1989).

Uncertainties are usually reported based on either a 95% or a 99% probability that the correct value is within the range. The accurate calculation of such values according to the current practice is to report standard uncertainties multiplied by a coverage factor (k) of either 2 or 3. For most situations, a coverage factor of 2 is very close to a 95% confidence interval, and a coverage factor of 3 is very close to a 99% confidence interval (Sharpe and Miller 1999).

The ASTM Subcommittee E10.01 on “Radiation Processing: Dosimetry and Applications” has under its jurisdiction approximately 30 standard practices and standard guides, collectively known as the E10.01 standards on radiation processing. These practices and guides describe the dosimetry systems most commonly used in radiation processing, and the dose measurements that are required in the validation and routine monitoring of the radiation processes. The development, validation, and routine control of a radiation process comprises a number of activities, most of which rely on the ability to measure the delivered dose accurately. It is therefore necessary that dose is measured with traceability to national standards, and the uncertainty is known, including the effect of influence quantities. The E10.01 standards on radiation processing dosimetry serve to fulfill these requirements.

The scientific basis and historical development of many of the dosimetry systems used in radiation processing can be found in the recently published ICRU Report 80 (ICRU 2008).

49.3 Chemical Methods of Dosimetry

49.3.1 Liquid Systems

The most significant liquid dosimetry systems used in high-dose dosimetry are aqueous solutions of inorganic solutes, but a few organic systems (i.e., organic solvents containing organic solutes) are also of importance. Most of these systems consist of a bulk liquid component – in which practically all the energy imparted by the ionizing radiation is absorbed – and a solute that reacts with the radiation-induced species formed upon the interaction of the solvent with the ionizing radiation. The radiation chemistry of both components is well documented, and the main processes used for dosimetry are based on a carefully selected chemical change, i.e., the appearance or disappearance of a product or component of the system.

49.3.1.1 Aqueous Chemical Dosimeters

Ferrous Sulfate (Fricke) Dosimeter

The best-known liquid chemical dosimeter, the Fricke dosimeter, is based on the radiation-induced oxidation of ferrous ions, Fe(II), to ferric ions, Fe(III), in acidic media (Sehested 1970). The standard Fricke solution consists of $0.001 \text{ mol dm}^{-3}$ ferrous ammonium sulfate (Mohr's salt: $\text{Fe}(\text{NH}_4)_2(\text{SO}_4)_2 \cdot 6\text{H}_2\text{O}$) or ferrous sulfate ($\text{FeSO}_4 \cdot 7\text{H}_2\text{O}$) and 0.4 mol dm^{-3} H_2SO_4 in aerated aqueous solution. Organic impurities are to be carefully removed since they facilitate excess Fe^{3+} ion formation. Sometimes $0.001 \text{ mol dm}^{-3}$ NaCl is also added to the solution in order to reduce the effect of trace organic impurities (ASTM E 1026-04). The Fe^{3+}

ions form in reactions of the intermediates of water radiolysis with the Fe^{2+} ions (water radiolysis is discussed in ► Sect. 23.6, Chap. 23, Vol. 1).

The dosimeter containers are usually sealed glass ampoules of 2–5 cm³ capacities. Fe^{3+} ion concentration is measured in a spectrophotometer at the absorption maximum of these ions, at 304 nm. The dose is determined from the increase of optical absorbance, ΔA :

$$D = \frac{\Delta A}{G \varepsilon_m l \rho} \quad (49.8)$$

where l is the light path in the optical cell and ρ is the density. The molar linear absorption coefficient ε_m is 219 m² mol^{−1} at 25°C; it increases with the analysis temperature by 0.7% (°C)^{−1}. The response of the system is nearly independent of spectral energy of photon and electron radiation in the range of 0.5–16 MeV (Mattson and Johansson 1982).

The conventional Fricke dosimeter is applicable for measuring doses in the 40–400 Gy range; actually the consumption of oxygen determines the upper limit. For doses up to 2 kGy, the super Fricke dosimeter can be used, which contains higher Fe^{2+} concentration and is saturated with oxygen (Sehested et al. 1973).

The system is widely used for calibration purposes, but its routine application for irradiation process control is also well known. It is mainly used in gamma and X-ray fields, but the solution can also be used for electron dosimetry.

The calibration of the Fricke dosimeter must be verified by comparison with reference standard dosimeters in order to provide measurement traceability to national standards.

Ceric Sulfate (or Ceric-Cerous Sulfate) Dosimeter

The use of the ceric sulfate dosimeter solution is based on the radiolytic reduction of the ceric ions to cerous ions in an aqueous acidic solution (Weiss 1952).

The response of the dosimeter is based on the difference in ceric ion concentration before and after irradiation. The initial concentration of ceric sulfate (or ceric ammonium sulfate) can be varied between 2×10^{-4} and 5×10^{-2} mol dm^{−3} in an aqueous solution

containing 0.4 mol dm^{-3} sulfuric acid. This system can be used for dose measurement in the range of 1–200 kGy (ISO/ASTM 2002a). The evaluation of the irradiated solutions is carried out with spectrophotometry by measuring the change of absorbance of the ceric ions at 320 nm, which is approximately linear with dose. The molar linear absorption coefficient (ϵ_m) for the ceric ion is $561 \text{ m}^2 \text{ mol}^{-1}$ at 25°C (Matthews 1982).

The ceric sulfate dosimeter is sensitive to impurities, but this effect can be decreased by the addition of scavengers, e.g., cerous ions, or by preirradiation of the solution to a dose of approximately 1 kGy. Other unfavorable characteristics of the solution are its light sensitivity, energy dependence below 0.1 MeV, dose rate dependence above 10^6 Gy s^{-1} , and the need to dilute the irradiated solutions for the spectrophotometric evaluation. The temperature coefficient of the solution during irradiation is not significant in the range of $10\text{--}62^\circ\text{C}$ (Matthews 1982).

Since the addition of cerous ions to the ceric sulfate solution suppresses the effect of impurities, Matthews introduced the modified version of this dosimetry system by using a mixture of the ceric and cerous ions (Matthews 1982). Electrochemical potentiometry is applied to evaluate the irradiated solutions by measuring the redox potential difference between the unirradiated and irradiated solutions. This method can be applied in the dose ranges of 0.5–5 kGy or 5–50 kGy depending on the initial ceric ion concentration chosen. An important advantage of this method compared to spectrophotometry is that no dilution of the irradiated solution is needed.

This dosimetry system has been applied widely for dose mapping and routine process control, especially due to dedicated commercially available instruments such as potentiometric electrochemical cells.

Dichromate Dosimeter

This dosimeter relies on the radiolytic reduction of the dichromate ion $(\text{Cr}_2\text{O}_7)^{2-}$ to chromic ion in aqueous perchloric acid solution. In this aqueous solution the radiolytically produced hydrogen atoms reduce Cr(VI) , while the hydroxyl radicals oxidize Cr^{3+} . Matthews (1981) suggested adding silver ions to the solution, since these scavenge the oxidizing hydroxyl radicals.

The solution consists of $2 \times 10^{-3} \text{ mol dm}^{-3} \text{ K}_2\text{Cr}_2\text{O}_7$ and $5 \times 10^{-4} \text{ mol dm}^{-3} \text{ Ag}_2\text{Cr}_2\text{O}_7$ in 0.1 mol dm^{-3} perchloric acid. The decrease of dichromate ion concentration is almost linear with dose, which is determined by spectrophotometric measurement of the absorbance on the high wavelength shoulder of the radiation-induced absorption band at 440 nm (► Fig. 49.1). At this wavelength, however, both the dichromate and the chromic ion absorb; therefore, the net molar linear absorption coefficient ($44 \text{ m}^2 \text{ mol}^{-1}$ at 25°C) and the $G((\text{Cr}_2\text{O}_7)^{2-})$ ($0.0395 \times 10^{-6} \text{ mol J}^{-1}$) can be used to calculate the dose.

The dosimetry characteristics of the solution are quite favorable according to Sharpe et al. (1985), who have shown good reproducibility ($\pm 0.5\%$) and almost linear response in the dose range of 5–40 kGy. The irradiation temperature coefficient of the solution is $-0.2\% (^\circ\text{C})^{-1}$ in the temperature range of $25\text{--}50^\circ\text{C}$ (Sharpe et al. 1985). No significant photon and electron energy dependence (Miller 1985), dose rate effect (in the range of $0.7\text{--}500 \text{ Gy s}^{-1}$, Sharpe et al. 1985) or ambient light effect is observed on the response of the dosimeter solution.

By using lower concentration of $\text{Ag}_2\text{Cr}_2\text{O}_7$ ($5 \times 10^{-4} \text{ mol dm}^{-3}$) in 0.1 mol dm^{-3} perchloric acid solution doses down to about 2 kGy can be measured, but in this case the analysis has to be carried out at 350 nm, i.e., at the absorption maximum (Thomassen 1985).

■ Fig. 49.1

Optical absorption spectrum of dichromate ion (measurement wavelengths are shown with arrows)

The dichromate dosimeter solution is of importance mainly for radiation sterilization and food irradiation applications both for gamma and electron dosimetry. Due to its very good reproducibility, the system is classified as a reference standard system (ASTM E 2628-2009) in the 5–50 kGy dose range and used widely also as a transfer standard dosimeter.

Tetrazolium Dosimeter Solutions

Besides the well-established aqueous dosimeter solutions, new systems are also under development and test; and the introduction of the tetrazolium solutions for dose control in radiation processing is one example of these new dosimeter systems.

Tetrazolium salts are heterocyclic organic compounds (quaternary ammonium compounds) with a significant property of forming water-insoluble, highly colored formazans by reduction. Gierlach and Krebs (1949) observed the appearance of red color upon UV light exposure, as well as α - or X-ray radiation of its aqueous solutions and gelatin emulsions, and this can be utilized for dosimetry purposes. The radiolytic reduction of the tetrazolium salts (e.g., 2,3,5-triphenyltetrazolium chloride, ► Fig. 49.2) is a two-electron process, i.e., the reduction of each tetrazolium molecule needs two reducing species. In the first step a tetrazolinyl radical forms, which is then reduced further to formazan (Kovács et al. 1999). In the case of tetrazolium salts containing two tetrazolium rings (e.g., nitrotetrazolium blue) the formation of diformazan is a four-electron process involving the consecutive reactions of the formation of monotetrazolium radical, monoformazan, monoformazan radical, and the final diformazan product (Bielski et al 1980).

In aqueous solutions of tetrazolium salts, the formation of a precipitate was observed due to the nature of the formazan. In aqueous–alcoholic solutions, however, no precipitation was observed due to the solubility of the formazan in organic solvents. In such solutions (containing primary or secondary alcohols), the radiolytic reduction is found to be more effective, because the α -hydroxyalkyl radicals that form in the reaction of OH radicals and H atoms with the alcohol, also reduce the tetrazolium ion (Kriminskaya et al. 1987).

Different tetrazolium salts have been studied for dosimetry purposes both in solutions and in solid matrices. The 2,3,5-triphenyl-tetrazolium chloride (TTC) solutions and gels are found

■ Fig. 49.2

2,3,5- Triphenyltetrazolium chloride

to be useful for high-dose dosimetry (Krebs 1963; Kovács et al. 1996). The alcoholic solution of $0.045 \text{ mol dm}^{-3}$ TTC has a linear response of absorbance ($\lambda_{\text{max}} = 480 \text{ nm}$) with dose over the range of 1–16 kGy.

The aqueous solution of nitro blue tetrazolium chloride was investigated (Kovács et al. 1999) and it was observed that the NBT^{2+} ions were reduced radiolytically first to monoformazan (MF^+) and then to diformazan (DF) having high linear molar extinction coefficients at the absorption maxima of 522 nm and 570–610 nm. The formation of formazans was found more pronounced in the presence of alcohol and the aqueous-ethanol nitro blue tetrazolium solutions were found useful for high-dose dosimetry in the dose range of 0.1–30 kGy.

The response of the aqueous and aqueous–alcoholic solutions of tetrazolium violet (2,5-diphenyl-3-(1-naphthyl)-2H-tetrazolium chloride, TV) was found useful for dosimetry purposes in the 0.25–60 kGy dose range. The polyvinylalcohol-based TV-containing dosimeter films showed also suitable response in the 1–60 kGy dose range making it useful for radiation process control both in gamma and electron beam radiation processing (Emy-Reynolds et al. 2007a, b).

49.3.1.2 Organic Chemical Dosimeters

Ethanol-Monochlorobenzene Dosimeter

This dosimeter system, developed and introduced by Dvornik et al (1966), contains monochlorobenzene ($\text{C}_6\text{H}_5\text{Cl}$) in aerated ethanol–water solution. The original solution contained also small amounts (0.04 vol%) of acetone and benzene in order to inhibit the effect of impurities, but later it was shown (Coninckx et al. 1993) that the use of these minor additives is not essential. In order to match the radiation absorption characteristics of the product to be irradiated, tissue-equivalent dosimetry can be achieved by changing the concentration of monochlorobenzene between 4 and 40 vol% (Razem and Dvornik 1973a). In radiation processing practice, however, the solution containing 24 vol% of monochlorobenzene has achieved wide application and thus the dosimetry characteristics of this system have been thoroughly studied and established.

The dosimeter is based on the formation of hydrochloric acid (HCl) upon irradiation via dissociative electron attachment, since the monochlorobenzene, as a good electron scavenger, reacts both with the “dry” and the solvated electrons. The HCl is in dissociated form in the solution and its formation is shown in the following reaction scheme:

As shown, the chloride ions as well as the positive ions, formed due to ionizing radiation, are in solvated form in the solution, giving rise to formation of hydrochloric acid (Dvornik et al. 1969). The $G(\text{Cl}^-)$ was found to be independent of dose up to about 100 kGy (Razem et al. 1981) (which means that the dose response is linear) and of dose rate up to about 10 Gy s^{-1} (Razem and Dvornik 1973a, b), supporting the above described reaction mechanism. The $G(\text{Cl}^-)$ value is nearly independent of irradiation temperature between 20°C and 90°C (Dvornik 1970) and very little energy dependence was found for photons with energies greater than 50 keV in comparison with energy imparted to water or soft tissue (Miller 1985). The solution is not sensitive to impurities, can be stored both before and after irradiation in the dark for long periods.

The measurement of absorbed dose is carried out by measuring the concentration of HCl using alkalimetric or mercurimetric titration in the dose range of 0.4–400 kGy (Dvornik et al. 1966). The hydrogen ion concentration is determined with alkalimetric titration using bromphenol blue indicator. However, due to the reaction of the hydrogen ion with glass, this method should only be used at doses above 2 kGy. The mercurimetric method can be used in the entire dose range to determine the concentration of chloride ions using diphenyl carbazone indicator.

There are, however, other measurement methods developed mainly for routine process control in radiation processing, such as high-frequency conductivity (oscillometric) analysis, spectrophotometric evaluation, and conductivity measurement.

Dose Measurement Methods

1. *Conductivity methods.* In solutions, the electric current is carried by the ions, which start to migrate under the influence of the electric field strength between the electrodes. The conductivity of a solution is the sum of the conductivity of the electrolyte and that of the solvent. The measurement of conductivity is carried out by measuring the resistance in the solution by immersing a pair of inactive electrodes into the solution. In this way, the direct conductivity of the solution is measured in units of siemens (S).

The measurement of absorbed dose is possible by directly measuring the conductivity (in siemens, ohm^{-1}) of the irradiated dosimetry solutions by immersing a pair of inactive electrodes (e.g., bell electrode consisting of platinum rings) into the solution. The method can cover a wide dose range of 50 Gy to 1 MGy with an accuracy of $\pm 5\%$ and reproducibility of $\pm 3\%$ (Kovács et al. 1985). Due to the temperature dependence of the conductivity of the solutions, a temperature correction of the response with respect to that of the calibration can be carried out by using the Nernst equation (CRC Handbook 1978).

High-frequency conductivity (oscillometric) measurement. Oscillometry (Blaedel and Petitjean 1956), i.e., the high-frequency method of chemical analysis to measure or follow changes in the composition of chemical systems was introduced to measure absorbed dose

by evaluating the irradiated ethanol-monochlorobenzene (ECB) dosimeter solution (Földiák et al. 1973). Since the amount of ions present in the solutions is altered due to irradiation, the conductivity of the solution is changed. Thus, a relative measure of the conductivity of the dosimeter solution is obtained by a high-frequency oscillator circuit, which employs a capacitive cell. An oscillator circuit is characterized by the Q factor as well as by the frequency. Either the shift in the frequency or the change in the Q factor is utilized in the oscillometric measurements. In the case of the oscillometric measurements of the ECB solutions, the change of the Q factor is measured through following the change in conductance. Because there is no galvanic contact between the solution and the electrodes, the measurements can be carried out in sealed ampoules, which are placed in between the electrodes, so that the Q factor of the parallel oscillatory circuit is changed, thus producing a change in the amplitude of the oscillations giving a relative signal.

The oscillometric evaluation method is nondestructive thus making possible the reevaluation of the dosimeters later at any time due to the stability of the solutions. The effect of UV light during storage on the unirradiated and irradiated solutions, however, has to be avoided. In order to decrease the measurement uncertainty, the preselection of the glass ampoules according to their diameter may be needed. The oscillometric evaluation method is applicable in the dose range of 1–300 kGy for dose mapping in gamma processing, for routine process control in gamma, and in electron beam processing, as well as a transfer standard system (ISO/ASTM 2002b).

2. *Spectrophotometric analysis.* This method of analysis requires the addition of ferric nitrate and mercuric thiocyanate to the irradiated ethanol-monochlorobenzene solution (Razem et al. 1981). The radiolytically generated Cl^- ions react with the mercury(II) thiocyanate followed by the reaction of the liberated thiocyanate ions with ferric ions to produce the red colored ferric thiocyanate complex, which is measured at 485 nm. The method is applicable in the dose range of $10\text{--}10^4$ Gy.

Radiochromic Dye Solutions

The measurement of absorbed dose with radiochromic dye solutions is based on the color change induced by radiation. The most important systems are the leucocyanides or leucomethoxides of a number of triphenylmethane dyes, which were first used as dosimeters for UV radiation (Weyde and Frankenburger 1931) and then suggested for ionizing-radiation dosimetry by McLaughlin and Chalkley (1965). Depending on the substitutions on triphenylmethane both organic and aqueous solutions can be prepared. Four compounds have been studied extensively: pararosanine cyanide (McLaughlin and Kosanic 1974), hexa (hydroxyethyl) pararosanine cyanide (McLaughlin et al. 1971), new fuchsin cyanide (Farahani and McLaughlin 1988), and malachite green methoxide (Bobrowski et al. 1985).

In the presence of weak acid and polar organic solvents, the cyanide radical is detached due to ionizing radiation, leaving a deeply colored cation, the carbonium cation, which is stable in polar acidic solution. This phenomenon is utilized for dosimetry, since there is a nearly linear relationship between the increase of absorbance due to cation formation and the absorbed dose in the range of $10\text{--}3 \times 10^4$ Gy. These systems have the advantage of being tissue equivalent with respect to radiation absorption characteristics; their response is independent of impurities and of dose rate up to about 10^{12} Gy s^{-1} . The effect of UV light on the solutions, however, has to be avoided and the irradiation temperature effect ($\sim 0.2\text{--}0.3\%$ /°C) must be taken into account (ISO/ASTM 51540 2002c).

Concerning the practical use of these solutions, the introduction of light waveguides proved to be an important step by increasing significantly the optical pathlength for spectral analysis. These solutions are held in long plastic tubes of inner diameter of 1–2 mm, sealed at both ends with glass or plastic beads. The optical measurements are made with routine densitometers designed for the given application. Absorbed dose measurements can be made in a wide dose range with a reproducibility of about $\pm 3\%$ (Radak and McLaughlin 1984). One of the most important applications of these systems concerns food irradiation due to the applicable dose range and the ruggedness of the system.

The liquid dosimeter systems used most frequently in radiation processing are shown in [Table 49.1](#).

49.3.2 Solid Systems

Many of the solid dosimetry systems used in high-dose dosimetry consist of either ordered organic or inorganic crystalline materials or amorphous or quasi-crystalline materials (such as glasses or plastics). The advantage of using such materials in comparison with liquid systems is, among others, their small size, better spatial resolution for dose distribution measurements, ruggedness, and ease of handling. The evaluation methods of these systems include spectrophotometry, spectrofluorimetry, various types of luminescence measurements, and the analysis of radiation-induced signals via electron-spin resonance spectroscopy. The measurement of electric current or voltage changes in semiconductors and insulators or the variation of conductivity in doped polymer film systems is also utilized for dosimetry purposes.

49.3.2.1 Dosimetry Systems Based on the Measurement of Optical Absorption

The color of many solid-phase systems changes, when they are irradiated. Colorless systems get colored, while originally colored systems become darker or bleach and these changes can be

[Table 49.1](#)

Liquid chemical dosimeters for high doses

Dosimeter system	Method of analysis	Useful dose range (Gy)	Typical precision limits ($k = 2$)	Reference
Fricke solution	UV spectrophotometry	$2 \times 10^{-2} - 4 \times 10^2$	1%	ASTM E 1026-04
Ceric-cerous sulfate	UV spectrophotometry, potentiometry	$10^3 - 10^6$	3%	ISO/ASTM 51205
Potassium dichromate	UV–VIS spectrophotometry	$5 \times 10^3 - 4 \times 10^4$	1%	ISO/ASTM 51401
Ethanol-chlorobenzene	Titration or HF oscillometry	$4 \times 10^2 - 3 \times 10^5$	3%	ISO/ASTM 51538
Radiochromic dyes	Visible spectrophotometry	$10 - 3 \times 10^4$	5%	ISO/ASTM 51540

utilized for the measurement of absorbed dose. In certain transparent, clear solid materials, optical bands absorbing in the UV are produced. The appearance of these bands is due to the changes in the structure of these solid materials, such as the formation of unsaturated chemical bonds (Charlesby 1960; Dole 1972) or color centers occurring as electron-filled negative ion lattice vacancies.

One solid dosimetry system (silver halide emulsions in thin gelatin layer matrixes) undergoes radiation-induced darkening by chemical development of latent photographic images.

Other groups of these dosimeters contain certain dyes mixed into the basic material (in most cases a polymer), and the optical absorption of these dyes changes upon irradiation. These systems are simple to measure and apply, but their response is affected by environmental factors such as humidity, light, and temperature. Some of these systems are preferred in gamma processing, while the main application field of others is electron-beam dosimetry.

Color-Center Systems

Crystalline materials. Pure colorless optical quality LiF in various forms like natural LiF, ^6Li -enriched LiF, or ^7Li -enriched LiF can be used for dosimetry purpose by measuring the increase in their absorbances, ΔA , at the maxima of a number of color center absorption bands. The absorption of these radiation-induced characteristic LiF color centers absorbing in the UV, visible and near IR range allow dosimetry in the dose range of 10^2 – 10^7 Gy (McLaughlin et al. 1980; Baeyens et al. 1985). The dose ranges of these color centers – which are a progression of single (F-center), double (M-center), triple (N- or R-center), etc., electron-filled negative-ion vacancies – overlap, making it possible to measure a continuous wide range of doses provided calibration for each individual dosimeter is established. After 1 day, the radiation-induced absorption is stable for weeks when dosimeters are stored at room temperature (McLaughlin et al. 1979a). The characteristics of the M-center shows a small irradiation temperature coefficient ($+0.1\% (^{\circ}\text{C})^{-1}$), reasonable precision for routine applications ($\pm 5\%$), and negligible dose rate dependence. The radiation absorption properties of LiF differ only slightly from those of water over a wide range of energies (Miller and McLaughlin 1982; Hubbell 1982).

The optical-quality LiF dosimeter can be reused repeatedly if the darkened crystals are bleached to the colorless state by a high-temperature annealing treatment (550°C for 1 h).

Glasses. The potential dosimetric use of several various types of glasses has been studied (Kreidl and Blair 1956, 1959). These materials can be applied for the measurement of absorbed dose by spectrophotometric, densitometric, or fluorimetric analysis of color centers formed upon irradiation in the dose range of 10 – 10^4 Gy. High doses (10^3 – 10^7 Gy) can be measured utilizing the degradation of photostimulated luminescence intensity (Freytag 1971; Becker 1973). Although the routine use of a few systems is possible, the energy and dose rate dependence of their response as well as the fading after irradiation generally limits their application.

Undyed Solid Systems

In certain clear, transparent polymer materials new optical absorption bands – absorbing mainly in the ultraviolet or in the infrared region – form upon irradiation. These radiation-induced changes in the UV region involve (1) main-chain unsaturations of polyene groups (e.g., $-\text{C}=\text{C}-$ in polyolefins) or (2) side-chain unsaturations (e.g., $=\text{C}=\text{O}$ groups in polymethylmethacrylate) as described by Charlesby (1960) and Dole (1972). The increase of absorbance of these absorption bands can be used for dosimetry measurements.

The dosimetry utilization of polyethylene films in the 10^5 – 10^6 Gy dose range is based on ultraviolet at 240 nm (Chen et al. 1980) or infrared measurement of carbonyl or trans-vinylene groups formed upon irradiation and analyzed at 5,800 nm or 10,600 nm, respectively (Charlesby et al. 1964; McLaughlin et al. 1999).

Cellulose triacetate film dosimeter. The use of this dosimeter film is based on the radiation-induced absorbance change at 280 nm, which is linear in the dose range of 30–200 kGy (Puig et al. 1974; Tamura et al. 1981, ISO/ASTM 51650). The spectrophotometric measurement of the irradiated film is made on the steep high-wavelength edge of the absorption band; therefore, accurate setting of the wavelength is essential. The response of the film is lower for electron irradiation than for gamma by about 30% due to the O_2 diffusion during irradiation. The performance of the film is affected by relative humidity during irradiation (Tanaka et al. 1984). These effects were, however, not observed by Tanaka et al. when applying the films in high dose rate ($>1 \text{ MGy h}^{-1}$) electron radiation fields. The irradiation temperature coefficient of the film is about $+0.5\% \text{ } ^\circ\text{C}^{-1}$ (Tamura et al. 1981). The response of the dosimeter changes after irradiation due to the reaction of oxygen and the radicals present in the film (Gehring et al. 1985). The reproducibility of the radiation-induced change in absorbance was measured to be 5% ($k = 1$) by Tanaka et al. (1984).

Polymethylmethacrylate dosimeter. Several types of polymethylmethacrylate are known as potential dosimeters, and one system, clear (HX) Perspex, was developed for routine dose measurement (ISO/ASTM 51276). It is prepared using benzoyl peroxide as polymerization initiator. The irradiated clear Perspex dosimeters are measured by spectrophotometry usually at 314 nm or 315 nm, as the most stable wavelengths for evaluation (Chadwick 1969). The response of the HX Perspex was found to be independent of irradiation temperature in the range of 0–30°C, but at higher temperatures the response was decreasing (Miller and McLaughlin 1981). Miller et al. (1975) observed the effect of dose rate on the response too at values above 10^6 Gy s^{-1} .

Dyed Solid Systems

Polymer films or plates containing certain dyes that change color when irradiated are well known as dosimeters. The thickness of the dosimeters must be taken into account during evaluation, so that the response of each dosimeter is the absorption divided the thickness. In most cases, the radiation-induced response is nonlinear with absorbed dose and it is affected by temperature, humidity, light, and dose rate. Due to the combined effects of these factors and other environmental factors, careful calibration of these systems preferably using in-plant calibration is needed (Miller et al. 1975; McLaughlin 1978).

Some of these systems (like dyed cellulosic materials and indicator dyes in halogenated materials) are not accurate and reproducible enough for absorbed dose measurement, but these systems can be used as dose monitors or indicators to distinguish between irradiated and nonirradiated materials, e.g., in radiation sterilization (McLaughlin et al. 1988).

Dyed polymethylmethacrylate (PMMA) dosimeter. Polymethylmethacrylate dosimeters containing different types of dyes have been developed for routine dosimetry mainly in radiation sterilization and have been used extensively for many decades (Whitaker 1970; ISO/ASTM 2002e). Various types of the PMMA dosimeters are known, but the most popular are the red Perspex, the amber Perspex, and the Gammachrome YR.

When irradiating the red Perspex dosimeter, the appearance of an optical band absorbing between 600 nm and 700 nm can be observed resulting in the darkening of the original red color of the $1 \text{ cm} \times 3 \text{ cm}$ dosimeter (Whitaker et al. 1985). Spectrophotometric evaluation of

the irradiated dosimeter is performed at 640 nm (i.e., not at the absorption maximum), since the postirradiation effects (temperature and storage time) on the response of the dosimeter are the least pronounced at this wavelength. The useful dose range of the red Perspex dosimeter is 5–50 kGy. The amber Perspex is used for measurement of doses in the 3–15 kGy range at 603 nm or 651 nm (Barrett 1982). To measure low doses (0.1–3 kGy) mainly in food irradiation applications, the Gammachrome YR system was developed. It is evaluated after irradiation at 530 nm (Whitaker 1988). This dosimeter is applicable over a wide temperature range during irradiation, thus it is suitable for process control for foods irradiated at low temperatures provided that the dosimeters have been calibrated under these conditions (Biramonti et al. 1996).

The temperature and humidity during and after irradiation, as well as the diffusion of O₂ into the dosimeters, can affect the radiation-induced response of all types of Perspex dosimeters, but the packaging applied (i.e., airtight pouches) minimizes the effects of the latter two factors. The measurement of these dosimeters should be carried out at a specified time after irradiation due to short- and long-term instability. The effect of irradiation temperature becomes significant over 40°C being more pronounced at higher doses, e.g., the temperature coefficient of 1.5% (°C)⁻¹ was determined for a dose of 20 kGy (Miller et al. 1975). Postirradiation heat, on the other hand, changes the response significantly and should therefore be avoided during storage (Barrett et al. 1980).

The Perspex dosimeter “family” is frequently used in radiation processing for process control in a wide dose range mainly in gamma radiation processing. Due to the combined effects of environmental factors, however, they – like most dosimeters used in radiation processing – should be calibrated under conditions of use (Glover et al. 1985).

Film dosimeters. The radiation-induced change of optical absorption in various film systems has been utilized for dosimetry purposes for many decades. Although correct application of films requires controlled conditions because their response is affected by almost all environmental factors, these systems are widely used in both gamma and electron beam radiation processing. They are well suited for dosimetry of electron radiation because of their good spatial resolution characteristics, e.g., for dose distribution measurements as compared to other systems.

1. *Radiochromic film dosimeters.* Many polymer-based film dosimeters have been developed containing various types of dyes, whose color or depth of color changes during irradiation. Certain leucocyanides or leucomethoxides of triphenylmethane dyes are widely applied in the dose range of 10²–10⁶ Gy (McLaughlin 1974, 1977, 1985, ISO/ASTM 51275).

One of the established systems contains hexa(hydroxyethyl)pararosaniline cyanide in a nylon matrix and is available in large batches (McLaughlin 1966; Kantz and Humpherys 1977). This colorless thin film (~50 μm) changes to deep blue upon irradiation and is applicable in the dose range of about 3 kGy up to about 150 kGy. The response of the film is independent of the energy and type of the radiation (electron, gamma, and X-ray radiation) and of the dose rate up to about 10¹³ Gy s⁻¹ resulting in its use for process control for gamma as well as for low- and high-energy electron irradiation. The spectrophotometric evaluation of this film is carried out either at the maximum of the absorption band at 605 nm (dose range: 3–30 kGy) or at the edge of the spectrum at 510 nm (dose range: 30–150 kGy). Similarly to the Perspex dosimeters, the so-called specific absorbance (absorbance divided by thickness) of the irradiated films is used for the evaluation. The relative humidity during storage and irradiation significantly affect the response of the film. It was

found that at around 34% relative humidity the response is least affected by changes in the humidity and, therefore, the dosimeters are suggested to be conditioned and irradiated in such an environment (McLaughlin et al. 1983; Abdel-Fattah and Miller 1996). To ensure this condition and to avoid the effect of light, these dosimeters are sold in airtight pouches similar to the Perspex dosimeters. The response of these dosimeters depends in complex ways on dose, temperature, and humidity. It is therefore not recommended to calibrate them under fixed conditions, and to consider varying conditions by applying correction factors for the differences between calibration conditions and the conditions of use. The dosimeters should be calibrated in-plant at the conditions of use (Abdel-Fattah and Miller 1996). The radiation-induced color increases after irradiation, but this can be eliminated using a 5-min long postirradiation heat treatment at 60°C (Chappas 1980).

Polyhalo-styrene-based films containing similar dyes (e.g., malachite green methoxide) have similar characteristics as mentioned above, but these are free of humidity effects (Bishop et al. 1973).

Miller et al. (1988) have developed a thin (20 μm) polyvinyl butyral film containing the leucocyanide of pararosaniline, which changes from colorless to pink in its useful dose range of 2–100 kGy. The spectrophotometric measurement of the irradiated film is performed at 554 nm at the absorption maximum of the radiation-induced optical band. Another version of the same film contains the same dye and a radiation insensitive additive. Since the optical absorbance measured at 650 nm depends only on the thickness of the film, thus using the difference of the optical absorbance values measured at 554 nm and 650 nm respectively, as response, the measurement of thickness becomes unnecessary. A third version of this type of film is provided with adhesive backing and UV protective cover and it is to be used for reflected light measurement with potential for label dosimetry applications (Kovács et al. 2000b).

Polyvinyl alcohol (PVA) based films containing different tetrazolium salts have been found useful for routine dose measurement in gamma and electron radiation processing. 2,3,5-triphenyl tetrazolium chloride (TTC) dissolved in PVA films (changing from colorless to pink) have been found suitable for dose measurement in the dose range of 1–100 kGy by evaluating the 50 μm thick film at the absorption maximum of 493 nm (Kovács et al. 1996). Dosimeter films containing dissolved nitro blue tetrazolium chloride have a dose range of 5–50 kGy measuring the absorbance of the irradiated films either at the maximum of the absorption peak (540 nm) or at the shoulder of the spectrum (580 nm). To ensure suitable stability, conditioning of the films in the relative humidity range of 34–55% is recommended. Using reflectometric evaluation, this film can be applied as a label dosimeter system (Kovács et al. 2000).

A thin radiochromic film consisting of colorless transparent coatings of polycrystalline, substituted-diacetylene sensor layer on a clear polyester base, called *GafChromic*, was developed both for low- and high-dose determinations (Saylor et al. 1988). With various formulations, the useful dose range extends from 1 Gy up to about 40 kGy. The radiochromic reaction is a solid-state polymerization, whereby the films turn deep blue upon irradiation due to progressive 1,4-trans additions as polyconjugations along the ladder-like polymer chains (McLaughlin et al. 1994). The irradiated films can be evaluated by spectrophotometry at different wavelengths (670 nm, 633 nm, 600 nm, 500 nm, and 400 nm) depending on the absorbed dose. This film dosimeter has broad application in radiographic imaging, nuclear medicine, and dosimetry for blood irradiation, insect population control, food irradiation, and industrial radiation processing, although it has

been designed particularly for measuring radiation therapy absorbed doses (1–100 Gy) (McLaughlin et al. 1996; Niroomand-Rad et al. 1998).

2. *Other film dosimeters.* Colorless PVC foils are used at electron accelerators to monitor the irradiation process and the accelerator parameters (like scan width and beam spot). In these materials unsaturated chemical bonds form upon irradiation and the optical absorption of these new species can be measured by spectrophotometry at 395 nm in the dose range of 0.5–60 kGy (Artandi and Stonehill 1958). It is important to mention, however, that due to various factors (environmental effects on the response, dose rate effects, batch-to-batch variation, etc.) these films should not be considered and used as dosimeters, but only as dose indicators.

49.3.2.2 Dosimetry Systems Based on the Measurement of Luminescence

Thermoluminescent Dosimeters (TLDs)

In many inorganic crystalline materials, electrons are removed from the valence band (ground state) upon irradiation, leaving mobile, positively charged holes. These free charge carriers become localized by the impurities present in the crystal lattice (as defects), i.e., the filling of electron and hole traps between the valence band and the conduction band takes place during irradiation (Cameron 1970). The energy absorbed from ionizing radiation and stored in the crystal lattice can be released in the form of light by several methods, like heating (thermoluminescence), dissolution of the crystals (lioluminescence), excitation by ultraviolet or visible light (optically stimulated luminescence, OSL), and by friction (triboluminescence).

In the case of thermoluminescence during the carefully controlled heating of the irradiated crystalline material, the trapped electrons and holes leave the traps, recombine together with the emission of characteristic light, the amount of which is the measure of absorbed dose (Fowler and Attix 1966; Cameron et al. 1968; Horowitz 1984). The intensity of the emitted light as a function of temperature is known as the glow curve. Its shape, i.e., the position of the peaks, is characteristic of the crystalline material. These characteristic peaks of the glow curve – either the height of the peaks or the area below them – are used for the determination of dose. In the case of certain TL materials there is a linear relationship between the absorbed dose and the amount of emitted light in a given dose range. At higher doses, first supralinearity appears (i.e., the slope of the line gradually decreases) followed by saturation. The evaluation of the irradiated crystalline material (i.e., the heating process) destroys the radiation effect and the dosimeters, if fully annealed at high temperature, can be reused.

The most common materials used in thermoluminescent dosimetry are LiF, CaF₂, CaSO₄, Li₂B₄O₇, Al₂O₃, MgB₄O₇, BeO, and MgSiO₄, which are used either alone or with trace amounts of additives (e.g., rare earths or transition metals), since these additives can significantly influence the formation of imperfections in the crystal lattice, i.e., the formation of the structure of traps and luminescence centers. The TL dosimeters are used in various forms (such as powder, single crystal, and pellet) depending on the field of application.

The TL dosimeters are mainly used for the measurement of low doses, thus these systems are mostly used in radiation therapy, personal dosimetry (Christensen et al. 1982), and environmental monitoring (Deplanque and Gesell 1982). The use of thermoluminescent dosimetry in radiation processing (ISO/ASTM 2002g) where the doses are high is of limited importance due to supralinearity, saturation effects, and radiation damage. Calcium fluoride

(CaF₂) and calcium sulfate (CaSO₄) are used worldwide in different forms like natural and manganese-activated TL phosphors. The CaF₂:Mn system is characterized by a single glow curve (maximum intensity at ~260°C) and by a relatively large useful dose range (10 μGy–10 kGy). Both types of materials have high sensitivity, which allows the detection of very low doses even below 10⁻⁵ Gy (Björngard 1963). Due to their high effective atomic number, however, these materials also present an important over-response at low photon energies (~100 keV). As with silver halide films, this effect can be corrected by using suitable filters. For instance, to get an appropriate correction on energy dependence, a shielding (of about 1.4 mm Cu) is proposed during irradiation. Lithium fluoride (LiF) and lithium tetraborate (Li₂B₄O₇) with an effective atomic number similar to soft tissue are good for measurement of absorbed dose in tissue, water, or air. The useful dose range of LiF covers the range of 10⁻⁵–10³ Gy and its main advantage over CaF₂ is its much better energy response. The manganese- and titanium-activated LiF (LiF:Mg, Ti) is often used in environmental monitoring (Barquero et al. 2002). With respect to measuring mixed fields, it is important to note that due to the difference of the two Li isotopes (⁶Li and ⁷Li) toward neutron detection efficiency these systems can distinguish between radiations of different origin in environmental monitoring. During the past 15 years, various tissue-equivalent phosphors of high sensitivity (e.g., LiF:Mg, Cu, P; Al₂O₃:C) have been developed in different laboratories for environmental applications.

The Al₂O₃:Mg,Y system developed by Osvay and Bíró (1980) has favorable characteristics both for personal and environmental monitoring and for food irradiation control due to its very wide dose range (10⁻³ Gy–10 kGy).

Several investigations have been carried out to extend the dose range of the most common TL phosphors. The use of higher-temperature glow peaks results in saturation at higher doses thus extending the dose range. Applying this approach in the case of LiF at 470°C, the measurement of doses of 10⁶ Gy becomes possible and Li₂B₄O₇:Mn can be used up to about 10⁴ Gy by using the 200°C peak before reaching saturation. Lakshmanan and Bhatt (1979) studied several TL phosphors with respect to high-dose applications using high-temperature glow peaks. The highest dose (~5 × 10⁶ Gy) was reached with CaSO₄:Dy (Lakshmanan and Bhuwanchandra Bhatt 1978). Other systems like CaF₂:Mn, LiF, and Li₂B₄O₇:Mn were used for gamma and X-ray dose determinations up to about 10⁴ Gy.

UV treatment of TL materials irradiated with ionizing radiation releases the deeply trapped charge carriers into shallower traps when followed by the regular thermoluminescent evaluation procedure. Using this method, the Li₂B₄O₇:Mn system can measure doses of about 1 kGy, the LiF:Mg,Ti phosphor is suitable for dose determination of about 10 kGy, while the CaSO₄:Dy dosimeter can measure doses as high as 1 MGy (Christensen 1982). Even higher doses can be measured with the same systems by applying pre-irradiation of the phosphors with gamma rays to the region of saturation followed by the evaluation of loss of emission upon irradiation to higher doses of about 10⁶ Gy (Lakshmanan and Bhuwanchandra Bhatt 1978).

Taking into account all these observations, the use of TL materials for high-dose determination appears possible. The fact that there are very few examples of practical application for high-dose dosimetry can be explained with problems of supralinearity, energy dependence, limited accuracy (> ±5%), and the difficulties originating from the repeated use of the systems (Burgkhardt et al. 1977).

Lyoluminescent Dosimeters

Upon dissolution of certain irradiated crystalline materials in a suitable solvent, light is emitted. The phenomenon – called lyoluminescence (LL) and suggested for dosimetry by

Ettinger and Puite (1982) – is based on the reaction of the solvent (usually distilled water) and free radicals produced by irradiation in the crystal. The luminescence signal during dissolution is integrated over a certain time period (~ 20 – 30 s). The dosimeter material must be carefully weighed and the dissolution must be carried out under controlled conditions. Typical lyoluminescent materials are saccharides (mannose, glucose monohydrate, or trehalose dihydrate) and amino acids (glutamine, valine, phenylalanine, glutamic acid). The useful dose range of lyoluminescence depends on the crystalline material, e.g., it is about 1 – 10^3 Gy for saccharides, while for glutamine it is 10 – 10^5 Gy (Miller and Xie 1985). The lyoluminescent dose response depends on different parameters like temperature, purity of water, O_2 concentration of water, and batch-to-batch variation of the crystalline material. With respect to practical application of the method different lyoluminescent materials were investigated like mannose and alkali halides (NaCl, KCl, LiCl), but their usefulness has been prevented by many factors (Puite and Ettinger 1982).

Glutamine has been found suitable for LL dosimetry. The glutamine system has been developed for high-dose dosimetry as routine dosimeter in radiation processing (Puite and Ettinger 1982; Temperton et al. 1984). The irradiation temperature coefficient for this dosimeter is about $+0.35\%$ $(^\circ\text{C})^{-1}$ in the temperature range of 10 – 40°C . Miller and Xie (1985) found no dose-rate dependence up to about 10^7 Gy s^{-1} .

The widespread application of the method is limited by, e.g., the effect of environmental factors and the lack of commercial readers. It is, however, possible to adapt instruments designed for chemiluminescence investigations as suggested by Temperton et al. (1984).

Radiophotoluminescent Dosimeters

Fluorimetry is the measurement of the intensity and/or spectrum of fluorescent light, when, e.g., an optically excited molecule emits part of its excitation energy in the form of light. Fluorescence is a special type of luminescence characterized such that (usually only a part of) the absorbed energy is emitted micro- or nanoseconds after excitation.

Photoluminescence originating from certain organic or inorganic molecules is a versatile method of dosimetry that is useful in radiation therapy, radiation protection, and radiation processing and covers broad radiation spectra, radiation types, dose ranges, and dose rates. Such types of organic molecules are, e.g., bridged polyphenyl dyes, terphenyls, oligophenylenes, bipyridyls, which can be excited into triplet states and free radicals by ionizing radiation. Some of these compounds undergo efficient proton transfer reactions in phototautomeric triplet states when held in suitable liquid and polymeric solvents resulting in relatively broad separation of excitation and emission bands, which is a basic requirement for dosimetric applications. Inorganic molecules involve mainly alkali halide crystals, e.g., LiF, or metal oxides, e.g., Al_2O_3 . The irradiation of such systems results in the formation of lattice defects (color centers). If the defect being excited by light is itself the color center created by irradiation of the sample, a PL signal that is dependent on the absorbed dose may be obtained. This is termed radiophotoluminescence (RPL) and the RPL signal may be utilized in dosimetry. RPL is significantly different from the OSL method, as here the excitation with light does not result in ionization of the defect. (Botter-Jensen et al. 2003).

The basic advantage of applying fluorimetry for dosimetry purposes is the high sensitivity of the method as compared to, e.g., spectrophotometry. Other advantages are the wide dynamic range, use for both passive and real-time dosimetry and for both low- and high-dose rates, variable geometries of the dosimeters (pellets, films, optical fibers, etc.), and inexpensive multiuse radiation detectors.

Fluorimetry can be used for dosimetry in different ways. In fluorescent compounds such as fluorescein, the fluorescent light intensity decreases due to the radiation damage to the molecule. Anthracene that emits fluorescence at 440 nm was used in this way in pressed powder form or in gelatin (Attix 1959). The other way involves radiolysis products, formed upon irradiation of organic or inorganic molecules that yield optically stimulated luminescence. Collins et al. (1994) published results about the usefulness of the aqueous coumarin-3-carboxylic acid solution for dosimetry purposes in the therapy range. Upon irradiation, oxidation takes place resulting in the formation of a hydroxylated product of the original molecule, which gives fluorescence at 450 nm due to excitation at 388 nm. Other oxidation materials yielding fluorimetric products include calcium benzoate.

Besides oxidative processes, other radiation-initiated reactions like proton transfer, appearance of new absorption bands in the crystal lattice of, e.g., alkali halide molecules, can also lead to the formation of active materials giving optically stimulated luminescence. The use of inorganic microcrystalline solid-state fluorescent materials dispersed in a polymeric medium is a well-established technique for measuring and imaging relatively small radiation absorbed dose (10^{-4} – 10^1 Gy) (Miller et al. 1989a; Miller et al. 1991; Miller and Yoder 1996). Non-flexible photoluminescent glasses and alkali halides have also been used for dosimetry purposes (McLaughlin 1970; Regulla 1972).

The OSL-based *Sunna film* is a new dosimeter utilizing the measurement of fluorescence for high-dose dosimetry (ASTM E 2303-2004, McLaughlin et al. 1999). The film contains a microcrystalline dispersion of LiF in a polymer matrix. It is an opalescent flexible film of uniform thickness and dispersion concentration. Upon irradiation of the LiF crystals, the color centers induced are manifested by discrete optical absorption bands in the near UV and visible spectrum. The F-center in LiF is due to an excess electron trapped at an ionic vacancy, which has a narrow absorption band peaking at 247 nm. With increasing dose, more complex centers are formed absorbing in the visible spectrum, as represented by the M-center with an absorption peak at 443 nm (McLaughlin et al. 1979; McLaughlin 1996). The excitation of the irradiated crystal with light at the wavelength of the color center absorption can raise the electron from the ground state to an excited energy level followed by a temperature-dependent return to the ground state (Mott and Gurney 1948). This process in the ns timescale is accompanied by characteristic luminescence at a significantly higher wavelength. Out of the different color centers, the M-center has been shown to exhibit the strongest OSL with a broad emission band having peaks at 530 nm and 670 nm. This OSL behavior has been utilized at the Sunna film. The film has been found useful for dosimetry at 530 nm with a tabletop routine fluorimeter in the dose range of 50–200 kGy. By measuring the absorbance of the irradiated films at 240 nm, dose determination is also possible with spectrophotometry in the dose range of 5–100 kGy (Kovács et al. 2000, 2002). No humidity effect of the dosimeter was observed, but a significant irradiation temperature effect was found in the temperature range of 0–40°C. To stabilize the OSL signal after irradiation, a heat treatment method was introduced (70°C, 20 min). The film can be applied both for gamma and electron dose measurements.

49.3.2.3 Electron Paramagnetic Resonance (EPR) Dosimeters

In certain solid-phase materials, free radicals – paramagnetic species containing unpaired electrons – form upon irradiation. The concentration of these free radicals can be related to absorbed dose by electron paramagnetic resonance (EPR) analysis, sometimes referred to as

electron spin resonance (ESR). There have been various attempts to introduce, e.g., bone, teeth, saccharides, polymers for reference dose measurements, but due to stability and reproducibility problems the use of these systems are limited (Ostrowski 1974; Brady et al. 1968; Nakayima 1982; McLaughlin et al. 1993). When studying crystalline organic materials (e.g., amino acids), it was found that the concentration of free radicals formed is very stable for long periods. These radicals can be analyzed quantitatively using the EPR spectrum that has suitable resolution. The use of α -L-alanine has shown especially good characteristics for medium- and high-dose measurements as shown by Bradshaw et al. (1962) and by Regulla and Deffner (1982, 1985) (ISO/ASTM 2004).

During room temperature irradiation of α -L-alanine samples, free radicals form as shown in [Fig. 49.3](#).

The free radical most important in dosimetry is $\text{CH}_3\text{-CH-COOH}$ whose ESR spectrum is used for dosimetry after suitable calibration (► Fig. 49.4). The signal measured is the increase in the amplitude of the first derivative of the EPR spectrum, which is proportional to the mass of the sample.

The α -L-alanine dosimeter has been developed by Regulla and Deffner (1982). It can be used for dosimetry in the range of 10 – 10^5 Gy with precision of 1% (2σ). The dose response of the dosimeter is almost linear up to 10^4 Gy and reaches saturation at 10^6 Gy (► Fig. 49.4). The dosimeter consists typically of $\sim 90\%$ polycrystalline α -L-alanine powder and $\sim 10\%$ paraffin is added to form small rods of 4.9-mm diameter and 10-mm length. Other formulations are also known using binders such as cellulose, polyvinylpyrrolidone (Hansen 1984; Hansen et al. 1987), and polystyrene (Kojima et al. 1986). Thin polymer films were produced by Kojima et al. (1986), Janovsky et al. (1988), Garcia et al. (2004), Desrosiers and Puhl (2009). An important point when selecting the binder is that it should not show a competitive radiation-induced EPR signal.

The density of the alanine–paraffin dosimeter is 1.2 g cm^{-3} and radiation absorption characteristics are similar to those of biological tissue. The irradiation temperature coefficient varies with the dose level being $+0.015\% (\text{°C})^{-1}$ up to 10 kGy, while this value is $+0.3\% (\text{°C})^{-1}$ at 100 kGy (Desrosiers et al. 2004, 2009a, b; Sharpe et al. 2009a, 2009b). There is little fading when storing or irradiating the dosimeter below 50°C . The response of the dosimeter was found to be independent of dose rate up to 10^8 Gy s^{-1} and energy dependence was observed

Fig. 49.3

Radiation-induced decomposition of α -L-alanine

■ Fig. 49.4

Typical dose response of the α -L-alanine dosimeter with an insert showing the electron paramagnetic resonance (EPR) signal (Regulla and Deffner 1982)

only below 100 keV (Bartolotta et al. 1985). Humidity and UV light was shown to affect the dosimeter response, but by using hermetically sealed plastic pouches, this problem is avoided.

The high cost of the EPR spectrometer limits the routine application of the method. To overcome this problem there are continuous efforts to develop more compact and less expensive instruments for routine use.

There have been different approaches to use chemical methods to evaluate the irradiated alanine dosimeter. Gupta et al. (1985) introduced the dissolution of irradiated alanine powder in an aqueous sulfuric acid solution of ferrous-ammonium-sulfate and xylenol orange. The free radicals present in irradiated alanine oxidize the ferrous ions to ferric and these form a complex with xylenol orange, which absorbs at 525 nm. The measured absorbance increase is related to absorbed dose. The method can be used in the dose range of 10 Gy–4 kGy, which was later extended by Van Laere et al. (1989) to 12 kGy. Ebraheem et al. (1999) developed another method by dissolving the irradiated alanine powder in aqueous solution of 2,3,5-triphenyl tetrazolium chloride. The radicals produced by irradiation of alanine react during the dissolution with TTC forming pink-colored formazans with absorption maxima around 401 nm and 487 nm. This read-out method can be used in the 2–200 kGy dose range. Another version of the same principle is the use of aqueous solution of 1,4-phenyl diammonium dichloride to dissolve the irradiated alanine powder (Ebraheem et al. 2003). Upon dissolution, a complex of purple color forms showing an increasing absorbance (360 nm or 505 nm) with increasing dose in the range of 1–10 kGy. Beside spectrophotometry, fluorimetric evaluation can also be used by measuring the emission of the complex at 435 nm (1–20 kGy).

The solid dosimetry systems used most frequently for dosimetry in radiation processing are summarized in ▶ Table 49.2.

■ Table 2.2

Solid dosimeters for high doses

Dosimeter system	Method of analysis	Useful dose range (Gy)	Nominal precision limits ($k = 2$)	Reference
Perspex systems	VIS spectrophotometry	$10^3 - 5 \times 10^4$	3%	ISO/ASTM 51276
α -L-alanine	EPR	$1 - 10^5$	0.5%	ISO/ASTM 51607
Cellulose triacetate	UV spectrophotometry	$10^4 - 10^6$	3%	ISO/ASTM 51650
FWT-60 film	VIS spectrophotometry	$10^3 - 10^5$	3%	ISO/ASTM 51275
Risø B3 film	VIS spectrophotometry	$10^3 - 10^5$	3%	ISO/ASTM 51275
Sunna film	OSL	$10^{-3} \times 10^5$	3%	ASTM 2303
$\text{Al}_2\text{O}_3\text{:Mg,Y}$	TLD	$10^{-3} - 5 \times 10^3$	5%	ISO/ASTM 51956

49.4 Physical Methods of Dosimetry

The most common physical methods applied in the dosimetry practice of ionizing radiation are calorimetry and ionization methods. Calorimetry is a primary standard method in dosimetry used both to measure dose rate in various radiation fields and to calibrate standard and routine dosimeters. Ionization chambers are discussed in ► Chap. 48, Vol. 5, thus only calorimetric systems will be shortly described here, with particular respect to those applied mainly in radiation processing.

49.4.1 Calorimetry

Calorimetry is an absolute method of dosimetry, since almost all absorbed radiation energy is converted into heat that can be readily measured as a temperature rise of the calorimetric body. Calorimeters that are used as primary dosimeters do not require calibration and, ideally, their response is independent of dose rate, radiation characteristics, and environmental factors (Domen 1987). The calorimeters that are used in radiation processing for the measurement of absorbed dose are relatively simple and need calibration (ISO/ASTM 2003b). The use of calorimeters as primary standard dosimeters for electron beam irradiation is described by McEwen and Dusatuoy (2009) and for gamma irradiation by Seuntjens and Duane (2009).

49.4.1.1 Principles of Calorimetry

The use of calorimeters is based on the measurement of heat, since the energy deposited in the thermally insulated mass of the absorber is converted to heat. The measured energy per unit mass results directly in the absorbed dose, being the product of the measured temperature rise and the specific heat of the absorber (see ► Eq. 49.18). Thus a calorimeter consists of the absorber (also called calorimeter body or the core of the calorimeter), the instrumentation to

measure temperature, the heat insulation around the absorber (i.e., the surrounding medium), and in certain cases the outer core of the insulation (also called the jacket) (ISO/ASTM 51631). The calorimetric body must be thermally insulated from its surroundings – using, e.g., plastic foam or mounting the absorber with supports of low mass and low thermal conductivity – so that only a minimal heat is lost during and after irradiation.

The temperature rise is usually measured with calibrated thermistors or thermocouples. Thermistors are more sensitive than thermocouples, but the advantages of using thermocouples (consisting of a junction of two metals) are their small size and mass, and the known dependence of the output voltage on temperature.

For an ideal adiabatic case, the radiation-induced temperature rise of the absorber of the calorimeter is a linear function of time during irradiation at constant dose rate. The temperature rise of a semi-adiabatic calorimeter during irradiation as a function of time is shown in

► Fig. 49.5.

The temperature variation of the calorimeter absorber before and after irradiation is shown in region I and III, respectively, while region II illustrates the radiation-induced change. In order to get the correct dose value, the measured temperature difference ($T_c - T_0$) has to be corrected for heat losses by extrapolating the slopes of the temperature changes of regions I and III to the midpoint of irradiation resulting in ($T'_c - T'_0$).

The use of certain materials as absorbers in calorimeters can give rise to a problem, because not all absorbed energy might be converted into heat due to the appearance of endo- or exothermic chemical reactions resulting in erroneous dose determination. This phenomenon, called “heat defect,” has been observed especially in the case of water and polymer calorimeters. When using water calorimeters for measuring doses up to 10 Gy, Domen (1982) observed the production of 3.5% excess heat. Miller (1984) showed that in the case of pulsed electron irradiation doses above 5 kGy, the dose determination is affected by less than 1% by this phenomenon. Endothermic reactions were observed when working with tissue-equivalent plastic calorimeters leading to lower absorbed doses than expected (Bewley et al. 1972). Reaction with dissolved oxygen of radiation-generated free radicals in plastic calorimeters

■ Fig. 49.5

Temperature rise of a semi-adiabatic calorimeter before, during, and after irradiation

can result in exothermic reactions especially in the low-dose region (McDonald et al. 1976). The structure of many radiation-induced polymer changes can result in the change of the specific heat and this effect has to be taken into account too when constructing or using plastic calorimeters.

49.4.1.2 Calibration

Calorimeters can be calibrated in different ways depending on their construction and application. When used as a primary dosimeter, the temperature rise (ΔT) during irradiation is related to the absorbed dose D by

$$D = E/m = C_a \times \Delta T \quad (49.18)$$

where E is the absorbed energy, m is the mass of the absorber, C_a is the specific heat capacity of the absorber, which needs to be measured separately. The calorimeter may also be calibrated by irradiation in a known radiation field or by embedding an electrical heater in the calorimetric absorber (McLaughlin et al. 1989).

The calorimeters used in radiation processing are calibrated by comparison with reference standard dosimeters issued by a calibration laboratory. It is important to ensure that the calorimeter and the reference standard dosimeter receive the same dose during the calibration irradiation.

Calorimeters can be used as in-house standards for the calibration of other dosimeters. It is crucial to pay special attention to the irradiation geometry to ensure the same dose to the calorimeter and to the dosimeter being irradiated. The thickness of the calorimeter (i.e., the absorber) must be chosen so that, for unidirectional perpendicular electron beams, the absorbed dose measurement is the average dose on the ascending part of the depth-dose curve. Phantoms of, e.g., polystyrene have been built of similar size as the water, graphite, or polystyrene calorimeters allowing the secondary dosimeter to be placed at depths of interest to provide the same irradiation conditions both for the absorber and the reference or routine dosimeter.

49.4.1.3 Types of Calorimeters

Calorimetric methods can be classified also as isothermal, adiabatic, and heat-flow type calorimetry (Calvet and Prat 1956; Radak and Markovic 1970). In isothermal calorimetry, the temperature of the calorimeter body remains constant during irradiation, since a phase transformation induced by the absorbed energy of the radiation (e.g., melting or boiling of the absorber) is measured. Ideally, adiabatic calorimetry requires no heat exchange between the absorber and the surroundings. To ensure adiabatic conditions experimentally is always problematic, and thus so-called quasi-adiabatic conditions are achieved resulting in quasi-adiabatic calorimeters designed and used in various fields in radiation dosimetry (Genna et al. 1963). The principle of heat-flow calorimetry allows the heat exchange between the calorimetric body and the jacket by selecting a suitable heat insulation material that surrounds the absorber (Radak and Markovic 1962).

Various calorimetric dosimeters have been designed for use in radiation dosimetry in medical applications and in radiation processing. Calorimetry is often used to calibrate chemical and solid-state dosimeter systems, but, until recently, it was rarely applied for routine

dose monitoring. The increasing application of electron accelerators in radiation processing, however, gave importance to the use of so-called process calorimeters.

In medical applications, it is of basic significance that the radiation absorption characteristics of the medium to be irradiated and that of the calorimetric absorber should be similar. Thus, calorimeters to that purpose have been constructed of water (Domen 1982), graphite (Petree and Lamperti 1967), polystyrene, polyethylene–carbon mixture (Milwy et al. 1958), and A-150 tissue-equivalent plastic (McDonald et al. 1976; Smathers et al. 1977).

Two types of calorimeters are used in radiation dosimetry, i.e., the total energy absorption calorimeters (e.g., to determine the energy or power of a particle beam) and thin calorimeters that are partially absorbing and used to measure absorbed dose. The temperature of the calorimeter can be measured either during irradiation (online) or before and after irradiation (off-line).

Spherical calorimeters (Petree and Lamperti 1967; Murray and Attix 1973) and cylindrical ones (Domen and Ba 1987) have been constructed for use in isotropic fields as reference standards for gamma-ray fields at high dose rates (McLaughlin 1978, 1985, 1988).

A common design of semi-adiabatic calorimeters contains thin or thick disc-shape absorbers used mainly in monodirectional beams both for low-energy (McDonald et al. 1972) and for higher-energy electron beams (Bewley 1969). Water calorimeters of the same shape were designed by Brynjolfsson et al. (1963) and Fielden and Holm (1970).

Semi-adiabatic calorimeters have been designed for dosimetry at high-energy electron accelerators (1–10 MeV) both for calibration and for routine process control (Humphreys and McLaughlin 1989; Miller and Kovács 1985; Burns and Morris 1988) and also for low energies between 100 keV and 500 keV (Janovsky and Miller 1987). The disc-shape absorber is either water or graphite containing thermistors for temperature measurement placed in the center of the absorber. The absorber is placed in polystyrene foam insulation.

Calorimeters have been designed for use at industrial electron accelerators for dose measurement in the range of 1.5–50 kGy and 4–10 MeV electron energy. (ISO/ASTM 51631 2003b). These calorimeters are made with water, polystyrene (see Fig. 49.6), or graphite calorimetric body and are calibrated by comparison with transfer reference dosimeters

■ Fig. 49.6

The Risø-DTU polystyrene calorimeter

(Miller and Kovács 1985; Humphreys and McLaughlin 1989). The advantage of using graphite instead of water is the lack of thermal defects. Graphite calorimeters can measure lower doses (1.5–15 kGy) compared to the water calorimeter due to the smaller specific heat of graphite. Graphite calorimeters are mainly used for calibration purposes at standard national laboratories (National Institute of Standards and Technology, USA; Risø National Laboratory, Denmark; National Physical Laboratory, UK), and can also be used as routine dosimeters. Polystyrene calorimeters for lower electron energies (1.5–4 MeV) with 2-mm thick absorbers were designed by Miller et al. (2002). Polystyrene was chosen due to its radiation resistance, although its specific heat capacity changes with increasing dose ($\sim +1\%/MGy$) (Miller 1995).

Differential calorimeters consisting of two graphite discs (with separate thermocouples each) have been designed and used mainly for calibration of routine dosimeters (Janovsky 1985). During irradiation, only one of the two graphite discs is irradiated, while the other one is used as reference. The temperature difference measured between the two discs serves to calculate the dose. Radak et al. (1973) designed similar instrument for calibration at low electron energies (400 keV).

49.4.1.4 Dosimetry at Low-Energy Electron Irradiation

The dosimetry discussion in this chapter is generally intended for situations in which there is no significant dose variation within the measuring part of the dosimeter. This is normally the case for gamma and X-ray irradiation and for electron irradiation at energy above approximately 4 MeV, but at lower energies, dose gradients can become significant for thicker dosimeters. This situation might be acceptable if the dosimeter can be irradiated so that an average dose over the thickness of the dosimeter can conveniently be calculated. This is the case if the dosimeter is irradiated at the ascending part of the depth dose curve, but it is difficult if the dosimeter is thicker than approximately 1/3 of the electron range. Three-millimeter alanine pellets, e.g., can be used down to approximately 2.5 MeV. At lower energies, thinner dosimeters must be used, and 130-micrometer alanine films can be used down to approximately 300 keV.

It must be recognized that irradiation of many dosimeters with low-energy electrons (less than 300 keV) will lead to dose gradients through the thickness of the dosimeter. When the dosimeter is measured, this will lead to an apparent dose that is related to the dose distribution. For a given set of irradiation conditions, the apparent dose will depend on the thickness of the dosimeter, i.e., dosimeters of different thickness will measure different apparent doses.

One solution to overcome this problem is that all dose measurements are specified as dose to water in the first micrometer of the absorbing material. This is given the symbol D_w and is independent of dosimeter thickness (Sharpe et al. 2009b).

The relationship between D_w and the apparent dose strongly depends on dosimeter response function, dosimeter thickness, dose, radiation energy, accelerator window material and thickness, distance of the window from dosimeter, and temperature of air between window and dosimeter. The relationship must be calculated for each set of irradiation conditions.

49.4.2 Semiconductors for Dosimetry

Silicon diodes and other types of semiconductors have already been used for decades in radiation dosimetry for the measurement of dose and dose rate. There is a basic difference

between the two types of instruments, since the dose rate measurement is carried out “in situ,” while the diodes used for absorbed dose measurement are evaluated after irradiation.

When measuring dose rate, the basic principle is the generation of electric current upon irradiation through the p-n junction due to diffusion of the electron-hole pairs into the adjacent p and n layers (Muller 1970a, b; Parker 1970; Osvey et al. 1975). Current measurement for dose rate determination can be made in the so-called short-circuit mode. The p-n junction solar cells were found suitable for dose determination in the range of 10 Gy–1 MGy (Muller 1970b). Their use, however, requires individual calibration.

Semiconductor dosimeters cannot be used for dosimetry above 6 MeV photons and 10 MeV electrons due to radiation damage in the semiconductor material (Dixon and Eckstrand 1982) and because of the high-energy bremsstrahlung radiation, which – approaching the threshold energy required for a (γ , n) reaction in silicon – can induce radioactivity in the doped silicon material. Energy and temperature dependence were also observed when using these detectors. Preirradiation to higher doses (>0.1 MGy) was found useful to decrease the effect of radiation damage and to avoid temperature dependence (Dixon and Eckstrand 1982). The advantages of using such detectors for dosimetry involve good sensitivity, low cost, small size, and wide availability.

Semiconductor dosimeters are widely used for dose distribution measurements both in laboratory and at industrial-scale ^{60}Co gamma irradiation facilities (Rageh et al. 1985; Hartsom et al. 1995). Pesek (1985) used also p-n type detectors for the determination of the best irradiation position of objects to be irradiated. Special boron- and phosphorus-doped p-type silicon diodes were developed by Osvey et al. (1975). These systems, sealed against humidity and light effects, showed linear response with dose rate in the range of $1\text{--}10^5$ Gy s^{-1} . These detectors have been proven more resistant against radiation damage as compared to n-type diodes, but more pronounced temperature dependence was observed at higher dose rates (>10 Gy h^{-1}). Semiconductors were also applied to control the dose field of radiation-therapy irradiation facilities (Butson et al. 1996), as well as to follow the radiation-induced changes in electronic instruments (McLaughlin et al. 1989).

Fuochi et al. (1999, 2004, 2006, 2009a, b) have studied the dosimetry performance of bipolar power transistors in gamma and electron radiation fields for routine process control. These transistors have been investigated under laboratory conditions using electron beams of energies from 1.9 MeV to 8.6 MeV and gamma rays from ^{60}Co source and tested in industrial irradiation plants having high-activity ^{60}Co γ -source and high-energy, high-power electron beam. Their results indicated the usefulness of these detectors – after suitable calibration – for absorbed dose measurement in the dose range of 50 Gy to 50 kGy. Linear relationship was found in this dose range of 50 Gy to 5 kGy between the absorbed dose and a measured physical parameter (which is directly related to the charge carrier lifetime). Small semiconductors were suggested for dose control in flow systems like grain irradiation (Ehlermann 1988).

Abstract: This chapter is designed to serve as a review and reference for the wide and still-evolving field of particle sources and accelerators. The object of this chapter is to give a comprehensive and easily understandable survey of the field in greater detail to the users of accelerators, nuclear physicists and chemists, as well as students. The field of particle accelerators covers facilities from hand-size mass separators through room-scale cyclotrons to huge storage rings. In spite of their important differences, all of them own a key subsystem, the ion source. The parameters of the ion beam generated in and extracted from the ion source determine the features of the accelerated beam on the target. Therefore, in ➤ Sect. 50.1, the ion sources of particle accelerators are reviewed. ➤ Section 50.2 is devoted to the electrostatic accelerators. The cyclic and linear accelerators are summarized in ➤ Sect. 50.3 where a survey on beam parameters is also given.

50.1 Ion Sources

The field of *ion sources* has grown dramatically in the last decades. New areas of application have evolved, new kinds of ion sources have been developed, and existing types have been improved. This development was symbiotic with the growth of the fields of accelerators and applications. New requirements from the accelerators and applications forced ion source developers to elaborate new ideas and the appearance of a new or upgraded ion source made new experiments and applications possible. The stand-alone usage of ion sources (i.e., without any post-accelerator) is also becoming more and more popular. In many institutes, groups with small laboratories have been formed for ion source development and usage.

This short review cannot deal with all types of ion sources; it will focus on the most popular types used in *linear* and *cyclic accelerators*. The accelerators themselves are described in detail in ➤ Sects. 50.2 and ➤ 50.3 of this chapter. The most relevant ion source literature includes two excellent books (Wolf 1995; Brown 2004) and two of the many review articles (Angert 1994; Wolf 1996) devoted to the large family of ion sources. The proceedings of the biennially organized international ion source conferences contain the most detailed technical information (ICIS 1989–2009). One can also find reviews and useful links on the Internet (LINAC 1996; CASETECH 2005).

50.1.1 The Plasma Physics of Ion Sources

An ion source is a plasma generator from which beam of ions can be extracted. Most ion sources are “**plasma**” sources, that is, the ionization of atoms and ions occurs in a plasma formed in the chamber of the ion source. Thus, the physics of ion sources is mainly based on the physics of the plasma. First, a summary will follow on the most important plasma parameters and the main processes (from the point of view of operation of the ion sources) in the plasma.

50.1.1.1 Basic Plasma Parameters

Plasma density. The term “density” actually means number density here, that is, number of particles per volume. The plasma consists of *ions*, *electrons*, and *neutrals* (atoms, molecules), so one can define plasma neutral density (n_0), plasma electron density (n_e), and plasma ion

density (n_z). The subscript e means “electron” and the subscript z refers to a z-times ionized atom. In ion sources, the plasma is near neutral, that is

$$e \sum_z z n_z - e n_e \approx 0 \quad (50.1)$$

if all the ions are positive. The subscript z runs over the different charge states ($z = 1, 2, 3, \dots, Z$). This equation is not valid close to the plasma boundary. Some authors mean plasma density as simply the density of the plasma electrons. Typical values of the latter in ion sources are 10^{10} – 10^{16} cm^{-3} .

Plasma temperature. Generally, the concept of “temperature” is valid only for Maxwellian energy distributions, which cover most of plasmas but not all. In spite of this, quite often the “plasma temperature” is used also for plasmas of ion sources which are not in equilibrium. The ion temperatures T_z (of z-times ionized ions) and electron temperature T_e are not necessarily equal and in the presence of magnetic field the temperatures parallel and perpendicular to the field may be different, especially for the electrons. It is usual to express the plasma temperature in electron volts (eV) using the relationship $E = kT$, where 1 eV corresponds to 11,600 K. Typical plasma electron and ion temperatures are several tens of electron volts. In some plasmas (e.g., ECR, see in [Sect. 50.1.5.1](#)), however, the T_e electron temperature can be several keV or higher.

Ionization cross section, mean free path. In the plasma, several processes can take place in collisions: excitation, ionization, recombination, and charge exchange. For every process, a corresponding cross section (σ) and mean free path (λ) can be defined. If one of the plasma components has a number density of n , then

$$\sigma \lambda n = 1. \quad (50.2)$$

Confinement time. The average time between the creation and loss of an ion with a particular charge state $z = q/e$ (where q is the charge) is called confinement time or ion lifetime (τ_z). In this particular respect, the only types of losses considered are those caused by diffusion of ions out of the plasma (to the wall of the plasma chamber) or by their extraction using external electrostatic field. The (average) confinement times of every charge state must be large enough if further ionization is required (see in [Sect. 50.1.1.2](#)).

Cyclotron frequency. In a magnetic field, a charged particle moving with speed u in a plane perpendicular to the magnetic flux density B is forced to perform a circular motion (For a more general treatment, see [Sect. 50.3.3.1](#)). The angular frequency of this circulation is the “cyclotron frequency.” For electrons, the cyclotron frequency is

$$\omega_c = 2\pi\nu_c = \frac{e}{m} B, \quad (50.3)$$

where e is the elementary charge, B is the magnitude of the magnetic flux density, and m is the (relativistic) electron mass. A similar expression is valid for ions. Since the magnetic flux density applied in ion sources is usually $B = 0.1$ – 1 tesla, the frequency ν_c for electrons is 1–30 GHz, and for ions 100 kHz–10 MHz.

50.1.1.2 Fundamental Processes in the Plasma

Ionization. In most ion sources, the ionization of atoms and ions is caused by collisions with energetic electrons. An optimal value of the electron temperature T_e (or the electron energy $E_e = kT_e$, where k is the Boltzmann constant) is necessary for each ionization process. Generally,

E_e should be several times larger than the ionization potential of the subshell of the atom to be ionized. Multiple ionizations can take place in various ways:

1. *Step-by-step single ionization* on a z -times ionized atom A^{z+}

2. *Single ionization by excitation*

where the asterisk means an excited state. Note that many excited ions do not inject electrons but produce a photon when returning back to the ground state. These photons give the *visible light* of ion source plasmas. In [Fig. 50.1](#), typical cross sections of the step-by-step ionization can be seen. The cross section strongly depends on the electron energy. The cross sections of some other processes (double or multiple ionization in one step, Auger ionization, “shake-off,” etc.) are much smaller in most plasma ion sources.

All of the above processes have their effective cross sections. If the cross section of the ionization process $z_1 \rightarrow z_2$ is σ then, as a consequence of [Eq. 50.2](#), the mean time for a transition between the charge states z_1 and z_2 to take place is

$$\tau = \frac{1}{n_e \langle \sigma u_e \rangle}, \quad (50.6)$$

where n_e and u_e are the electron number density and speed, respectively, and $\langle \dots \rangle$ means averaging over temperature. Let τ_z be the confinement time of the z -charged ion (z can be any

Fig. 50.1

Ionization cross sections for argon (Brown 2004, p 211, reproduced with permission)

■ Fig. 50.2

Some ion sources and fusion facilities in the plasma plane. PIG: Penning Ion Gauge, ECRIS: Electron Cyclotron Resonance Ion Source, EBIS/EBIT: Electron Beam Ion Source or Trap, laser: plasma produced by laser ablation in solids, tokamak: fusion device of light ions, U^{92+} : fully stripped uranium ion

integer between 1 and Z and for simplicity sake, it will be assumed that τ_z does not depend on z). Then for $z_1 \rightarrow z_2$, the condition $\tau_z \geq \tau$ must hold. To produce multiply charged ions, the (average) confinement times must be larger than the (average) ionization times for every particular charge state. With a simple transformation, one obtains

$$n_e \tau_z \geq \frac{1}{\langle \sigma u_e \rangle}. \quad (50.7)$$

The conclusion is that the most important plasma parameters for the ionization are the T_e electron temperature (or the $E_e = kT_e$ electron energy) and the $n_e \tau_z$ factor. These two parameters determine the character of the plasma and the charge states in it. Moreover, the ion sources themselves can be characterized by their positions in the $(n_e \tau_z, E_e)$ plane (● Fig. 50.2). The figure also shows the typical values for $n_e \tau_z$ and E_e .

Ion charge loss processes. In the plasma, the opposite of the ionization process also takes place: ions can be recombined by “electron capture” or charge exchange. All these charge loss processes have their cross sections similarly to the ionization.

The equation of the plasma equilibrium state. The charge state distribution (CSD) in the plasma is a result of the dynamical processes mentioned above. Let n_z be the number density of the z -times charged ions with atomic number Z . Then the following simplified differential equation is valid ($z = 1, Z - 1$):

$$\frac{dn_z}{dt} = I(n_{z-1} \rightarrow n_z) + R(n_{z+1} \rightarrow n_z) - I(n_z \rightarrow n_{z+1}) - R(n_z \rightarrow n_{z-1}) - n_z/\tau_z \quad (50.8)$$

where I and R represent rates of ionization and recombination/charge exchange, respectively. For $z = 0$ and $z = Z$, the equations are simpler. In equilibrium state, the left side is equal to zero. On the right-hand side, the expressions are (from left to right):

(1) ionization (both charge and n_z increase), (2) recombination or charge exchange (charge decreases, n_z increases), (3) ionization (charge increases, n_z decreases), (4) recombination or charge exchange (both charge and n_z decreases), (5) loss due to the limited confinement time of the ions.

The quantities I and R usually depend on the number densities and the relative velocities of the interacting particles and on the cross section of the interaction itself.

The cross section of the charge transfer is usually considered only for the ion-neutral case (the electron transfer between two ions is negligible in most ion source plasmas). The charge state can change by one or (with much smaller cross sections) by two in one such step. The recombination with free plasma electrons is much less important in ion sources.

The challenge for ion source theorists is to formulate [Eq. 50.8](#) more precisely and solve it to get a charge state distribution that fits the experimental data. Several authors (Jongen 1980; Bliman and Chan-Tung 1981; West 1982; Brown 2004; Shirkov 1991, 2000; Wolf 1995; Melin and Girard 1997; Girard et al. 2002; ICIS 1989–2009) tried to write down and solve [Eq. 50.8](#) for a given ion source type. The results are quite satisfactory for some types (e.g., EBIS), but altogether there are still spaces to further explore the elementary processes in most of the ion sources.

50.1.2 Classification of Ion Sources

The parameters of the ion source must match the features of the accelerator, and these parameters strongly influence the final (beam) parameters of the accelerator. The most important ion source characteristics are:

1. Working range (the elements of the periodic table that can be ionized in the source)
2. Charge state distribution of the extracted beam
3. Size, energy spread, and emittance of the extracted beam
4. Electrical efficiency (ion intensity vs. electrical power consumption)
5. Gas efficiency (ion intensity vs. working gas consumption)
6. Maintenance period (replacement time of cathodes or other consumable parts, cleaning, etc.)

The requirements for these parameters are needed for choosing the appropriate type of ion source. There are many ion source types (a rough estimation: between 50 and 100) and they can be classified in several ways.

By working principle, they can be classified as hot filament sources, ion sources based on Penning discharge (PIG), radio frequency (RF) and microwave (MW) ion sources, electron cyclotron resonance (ECR) ion sources, electron beam ion sources (EBIS, EBIT), laser ion sources, cusp and multicusp ion sources, sputtering ion sources.

By application, they can be classified as internal (cyclotron) ion sources, external (cyclotron, synchrotron) sources, ion sources for noncyclic electrostatic accelerators, ion sources for linear accelerators, ion sources for implanters, mass separators, and stand-alone ion sources for atomic physics and applications.

By the ion and its charge state they can be classified as proton ion sources, light-ion sources (atomic number 1–10, charge 1–5), multiply charged heavy-ion sources (charge > 5), highly charged heavy-ion sources (charge > 10), and negative-ion sources.

By the physical condition of the material to be ionized, they can be classified as gas ion sources, solid materials ion sources, ion sources for beams of stable elements, and those of promptly produced radioactive elements.

By the operation mode, they can be classified as continuous working (CW) regime and pulsed mode (PM) regime ion sources.

The above classifications are not strict. In the next sections, the various ion source types will be reviewed.

50.1.3 Traditional and High-Current Ion Sources

This section gives a short overview of most traditional ion sources that deliver single or multiply charged ion beams with medium or high intensity.

50.1.3.1 The Plasmatron Family

The plasmatron is a family of ion sources that has been used for many years for the production of single- or low-charged beams. In all plasmatron types, the plasma is formed between the cathode and anode plates. Electrons emitted by the cathode gain energy by running the cathode–anode voltage difference and ionize the atoms injected into this volume. The produced ions are extracted through the circular slit of the anode.

The most popular member of the plasmatron family is the *duoplasmatron* (Fig. 50.3). Its idea is that the plasma density between the anode and cathode is greatly increased in a small volume by an intermediate electrode placed between the anode and cathode putting on

Fig. 50.3

Duoplasmatron. Courtesy and copyright of Evans Analytical Group (EAG 2010)

a suitable electrostatic potential. Furthermore, a magnetic field is applied in the volume in question, which partly traps electrons and thus increases the density. The result is a quasi two-stage ion source, where the function of the intermediate electrode is twofold: it is the extractor of the first stage (similarly to the anode it has a slit) and the emitter for the second stage. The ions are extracted through the anode into an expansion region, which can be considered as a third stage. Typical discharge voltages and currents are up to 250 V and 20 A, respectively. The duoplasmatron is able to strip a wide range of ions (from H to U, Keller and Müller 1976) with high intensity (current density: 100 A/cm^2) and medium charge. The gas efficiency is exceptionally good. Sometimes, a subsequent electrode is applied after the anode to form an anticathode (duopigatron).

50.1.3.2 Penning (PIG) Ion Source

The PIG (Penning Ion Gauge) has been the most popular cyclotron ion source for many years. The working principle is applied not only in ion sources, but in vacuum gauges and in ion-getter pumps as well. The principle of the PIG can be understood by [Fig. 50.4](#). The primary electrons emitted by the cathode are accelerated toward the anode wall. Because of the applied axial magnetic field, the electrons usually do not reach the anode. They fly toward the anticathode following a helical path. The circular motion of the electron (mentioned in connection with the cyclotron frequency in [Sect. 50.1.1.1](#)) only applies to the projection plane perpendicular to B . The velocity component parallel to B remains unaffected by the magnetic field, thus resulting in a helical path (see also [Sect. 50.3.3.1](#) for more detail). The electrical potential of the anticathode is close to the potential of the cathode, thus reflecting back most of the electrons. As a result, the electrons oscillate between the cathode and anticathode. The mean confinement time of the electrons will be large and they can perform many collisions with atoms and ions. The atoms injected through the gas inlet slit (or sputtered in the chamber from solids, see [Fig. 50.4](#)) are ionized and an arc discharge is formed in the chamber. The temperature of the mixture of the primary (emitted) and secondary (stripped) electrons is between ten and a few hundred eV. The ions can be extracted axially or radially.

Fig. 50.4

The Penning (PIG) ion source. 1 – cathode, 2 – indirect heating (optional), 3 – gas inlet, 4 – sputtering electrode (optional), 5 – anode, 6 – anticathode, 7 – ion beam (axial extraction), 8 – emission slit, 9 – extraction electrode, 10 – ion beam (radial extraction), 11 – plasma, B – magnetic flux density

Within the PIG family, several subtypes are known: PIG with direct heating (Livingston and Jones 1954; Jones and Zucker 1954), PIG with indirect heating (Morozov et al. 1956; Baumann and Bethge 1981), and PIG with cold cathode (Anderson and Ehlers 1956).

50.1.3.3 The Cusp Family

Placing two solenoids or permanent magnets, with their poles of the same polarity facing each other, a special magnetic field of “**cusp**” shape will be formed in a small volume. Applying many small “cusps” in rows around a rectangular or cylindrical plasma chamber, the arrangement is called “**multicusp**.” The (multi)cusp-shaped magnetic field can confine the electrons very effectively. Using a cathode (filament) and an anode (source chamber walls) in this volume, a discharge can be ignited and a simple, however, effective multicusp ion source is obtained.  Figure 50.5 shows a cusp and a multicusp arrangement.

The discharge in the multicusp source is sometimes maintained by external RF field coupled into the discharge volume by a small induction coil. Usually, but not always, a small starter filament is used to provide electrons to help plasma ignition. This type of ion source can also be called RF ion source (see in the next section).

The multicusp ion source (sometimes also called as “bucket” source, Wolf 1995) is nowadays widely used to produce single- or low-charged, high-current (up to some tens of mA) ion beams (Leung 1994). The main advantages of these sources are their stable plasma, the high output beam current, and that they can be made to have almost any size. Types for multicharged and negative-ion production were also developed (Wolf 1995; ICIS 1989–2009).

50.1.3.4 Radio Frequency and Microwave Ion Source

Dense plasmas can be generated by RF or MW discharge in magnetic field. For such discharges, a relatively high gas pressure (about 10^{-3} mbar) is necessary and this condition determines the

 Fig. 50.5

Mono-cusp (left) and multicusp (right) magnetic geometries

■ Fig. 50.6

Schematic pictures of two RF ion sources. *Left: the original Thonemann design (Thonemann 1953), right: RF multicusp source (Reijonen 2000)*

main features of such ion sources: low ionization degree, high extracted beam current, and stable operation (Angert 1994; Wolf 1995, 1996).

In the case of *RF ion sources*, the discharge is generated by an induction coil. This coil can be either inside or outside the plasma chamber. In the latter case, the wall material (like quartz) must be transparent for electromagnetic waves. An azimuthal RF electric field is generated in the plasma chamber by the alternating magnetic field. The electrons in the gas volume are excited into oscillation by the electric field and quickly gain enough energy to form plasma by ionizing the neutral atoms. The applied RF is usually a few (or a few times 10) MHz and the coupled power is a few hundreds of watts. In ► Fig. 50.6, schematics of two RF sources are shown.

MW ion sources differ from RF sources in frequency, size and magnetic field. Many MW sources work at **2.45 GHz** frequency due to the fact that cheap and reliable MW generators are commercially available (used also in microwave ovens). In MW ion sources (contrary to the RF sources), the size of the plasma chamber is in relation to the MW length in order to form a multimode cavity. In multimode cavities, the energy transfer from the electrical component of the electromagnetic wave to the electrons can be much more effective due to the increased power density in certain local places inside the plasma chamber. In MW sources, a magnetic field is superimposed to improve heating of the electrons. MWs entering the discharge chamber through a waveguide can propagate through the plasma and transfer their energy to free electrons that further ionize the gas atoms and ions. If the magnetic field strength fulfills the ECR condition (see ► Sect. 50.1.5.1 for more details), then the MW source can be considered and called a low-frequency ECR ion source (► Sect. 50.1.5.1).

50.1.4 Production of Ions from NonGaseous Materials

The normal and easiest way to produce plasma in any ion source is to use a gas dosing valve and inject the required element in gas form into the discharge chamber. Many elements of the periodic table, however, are not available in gaseous form. There have been various methods developed for *ion production from solids*. Some methods resulted in new types of ion sources

(e.g., sputtering ion source, laser ion source) many years ago. Nowadays, these methods are more and more applied in different kinds of ion sources. That is why these methods are described in a separate subsection. A very detailed description of these methods is presented by Wolf (1995, 1996). The most important methods for feeding solids into ion sources are summarized as follows.

1. **Evaporation from an external or internal oven.** Different kinds of ovens and mini-ovens have been developed to evaporate solids with melting points up to 2,000°C (Lang et al. 2000; Barué et al. 2002; Kidera et al. 2002; Závodszky et al. 2002). The ovens are usually very close to (or sometimes inside) the plasma chamber. An important requirement is the precise online monitoring of the oven temperature. Because evaporation is a continuous process, ovens are usually used in continuously operating ion sources.
2. **Use of volatile chemical compounds.** The use of chemical compounds that are volatile at room temperature is as easy as the use of a pure gas. The main disadvantage of this method is the amount of unwanted ions of the elements of the compound (usually H, C, N, O, F). The popular name of this method in ECR ion sources is MIVOC (Metal Ions from Volatile Compounds) developed in Finland (Arje et al. 1995; Koivisto 1998). Note that a combination of methods (1) and (2) also exists.
3. **Cathodic sputtering of the solid.** Sputtering is the most generally applicable universal method to feed atoms into an ion source discharge. The sputter electrode (or the end of the electrode) made of the required material is usually negatively biased. The sputter yield depends on the electrode potential, but this potential also affects the discharge and an optimum should be found. A support gas (like argon) is necessary for the stable operation. Sputtering is ideal for materials with high melting point like W, Ta, Mo, etc. The sputtering method is suitable for both continuous and pulsed operation (the bias voltage of the electrode can be switched simultaneously with the accelerator). Nowadays, the method is routinely used in PIG, ECR, RF, and negative-ion sources (Wolf 1996; Kitagawa et al. 2002).
4. **Evaporation by vacuum arc or laser.** Metal evaporation by vacuum arc (MEVVA) is also a method that resulted in a small family of independent ion source types (Brown 1992, 2004). A high voltage vacuum arc creates metal plasma that expands rapidly and can be further ionized. The physical basis of the laser method (or laser ion source) is very similar. If a powerful (power density $> 10^8$ W/cm²) laser beam hits a solid target, high energy can be transferred to a small volume of the solid material and very high charge states can be registered (Wolf 1995; Fournier 2000; Mironov et al. 2001). Both methods make operation in pulsed mode possible.

50.1.5 Sources of Highly Charged Ions

50.1.5.1 Electron Cyclotron Resonance (ECR) Ion Sources

Electron cyclotron resonance ion sources (ECRIS) are nowadays widely used for the production of high-charge-state heavy ions. Development of these sources began in the 1970s (Geller 1976). The conventional ion sources (mostly PIG-types) were inadequate for accelerators requiring highly charged ions. To improve their reliability and to lower their cost, better

sources had to be developed. The particle energy per nucleon (in MeV) delivered by cyclotrons is given by

$$E = K \left(\frac{z}{A} \right)^2, \quad (50.9)$$

where z and A are the charge state (charge number) and the mass number of the accelerated ion, respectively, and K is a factor depending on the size of the machine and its magnetic field. The value of K is generally between 10 and 1,000 MeV. Thus by increasing z by a factor of 2 or 3, one can increase the particle energy by 4 or 9 without changing anything else. The cost of such a change (i.e., replacing a PIG by an ECRIS) is several orders of magnitude lower than the cost of increasing K by a factor of 4 or 9.

Today, most of heavy-ion cyclotrons are equipped with an external ECRIS. Over the last 30 years, ECR ion sources have evolved from a single large, power-consuming, complex prototype (Geller 1976) into a variety of compact, simple, reliable, efficient, and high-performance sources of high-charge-state ions. They are stand-alone devices with their own power supplies, vacuum, and control systems. Altogether, about 100 high-charge-state ECRISs are working all around the world and 10–20 are being developed or upgraded. The “must-have” literature on ECR ion sources is the famous and excellent book by Richard Geller (Geller 1996) who was the inventor of the ECRIS. There are numerous review papers (e.g., Melin and Girard 1997; Hitz et al. 2000; Sortais 2000; Drentje 2003) devoted to the ECR sources. International ECRIS workshops are organized in every second or third year and in 2008 already the eighteenth such meeting was held in Chicago, USA. The proceedings of these workshops contain most detailed information on the ECR ion sources all over the world. The material of the last workshop can be found on the Internet (ECRIS 2008).

The layout of a typical 14 GHz ECRIS is shown in [Fig. 50.7](#). To get highly charged ions in ECR sources, two tasks have to be solved simultaneously: (1) The ions must be trapped in the chamber for a long time because their inner shells get ionized step by step. (2) A great number of energetic electrons are needed, while the energy of the ion component should be kept as low as possible.

The first condition is fulfilled using the so-called ***B*-minimum geometry** (B is the absolute value of the magnetic flux density in the plasma chamber). The superposition of two axial mirror coils and a radial hexapole magnet (see the magnetic system in [Fig. 50.7](#)) forms a magnetic structure in which the magnetic flux density is increasing in any direction starting from the center of the chamber, that is, it has a minimum there. This results in an effective *magnetic trap* for the electrons and the space charge of the electrons keeps the ions inside the trap (quasi-neutrality). The magnetic trap can be formed in several ways: it can consist of exclusively room-temperature permanent and electro-magnets (Biri et al. 2002), superconducting (SC) solenoids in combination with a room-temperature permanent magnet hexapole (Biri et al. 2000; Nakagawa et al. 2002; ECRIS 2008), SC mirror coils and an SC hexapole (Ludwig et al. 1998; ECRIS 2008), or solely permanent magnets (Muramatsu et al. 2002).

The electrons are heated by external high-power, high-frequency electromagnetic waves. The frequency is usually between 2.45 and 28 GHz (the most often used frequency is 14.5 GHz) and the applied MW power is several hundreds of watts, sometimes up to several kW. The cyclotron frequency of electrons is proportional to the magnetic flux density (see [Eq. 50.3](#)), that is, depends on the time-dependent position of the electron in the plasma. Because the

■ Fig. 50.7

Layout of a typical ECR ion source with room-temperature coils and with permanent magnet hexapole (ECR 2010)

magnetic flux density in B -minimum geometry increases from the center toward the chamber walls, the cyclotron frequency of electrons increases as well.

The geometrical points where the electron's cyclotron frequency equals the frequency of the external electromagnetic wave – in other words where the *ECR condition* is fulfilled – form a closed, “egg-shaped” surface. This surface is often called resonance surface or *resonance zone* and can be characterized by the strength of the magnetic field. For 14.5 GHz ECR ion sources, this value is 0.52 T. The electrons crossing many-many times the resonance surface following a strange, complicated serpentine path (► Fig. 50.8) gain energy by means of resonance (called cyclotron resonance for historical reasons) from the electromagnetic wave. (By a simplified model, resonance means that the electron and the electrical \mathbf{E} -vector of the electromagnetic wave rotate “together” with the same frequency on the resonance surface for a short time.) Some electrons get energies up to tens of keV, so they are able to tear off electrons even from inner shells. The ion component becomes cold because the resonance condition is not fulfilled for them. The gas to be ionized is fed into the plasma chamber by a needle valve.

The techniques of producing ions from solids have been mentioned in the previous section. The ions are extracted from the plasma chamber by the electrostatic extraction system (see ► Fig. 50.7) like in all other types of ion sources.

In ► Fig. 50.8, the path of one electron is shown in the cylindrical plasma chamber of an ECRIS. ► Figure 50.8 was made by the TrapCAD code (Vámosi and Biri 1996) which was recently upgraded (Biri et al., 2007). The demo version is available for downloading from the Internet (ECR 2010).

The ECRIS is the most popular ion source today. It is able to produce highly charged plasmas and ion beams from a wide variety of elements with high intensity both in continuous and pulsed modes. The most advanced ECR sources produce more than 1 mA of middle-charged heavy-ion

■ Fig. 50.8

Simulation of the path of a single electron in the ECRIS plasma chamber (Biri et al. 1997). Upper part (a, b, c) end views of the plasma chamber with different electron starting conditions, lower part (d) side view of the plasma chamber

beams (e.g., Ar^{8+}) and several μA of very highly charged beams, for example, Ar^{17+} , Xe^{36+} , U^{50+} (ICIS 1989–2009; Sortais 2000; ECRIS 2008 and references therein). The highest-charged extracted ion beams obtained in ECRIS are, for example, Xe^{44+} , Bi^{50+} , U^{55+} (Xie and Lyneis 1997; ECRIS 2008).

In most ECRIS devices, “tricks” are also applied to increase the intensity of highly charged ions. More information about gas-mixing, biased-disc, special-wall, etc. methods can be found in papers cited in this section.

50.1.5.2 Electron Beam Ion Source (EBIS) and Ion Trap (EBIT)

The working principle of the EBIS can be understood from ► Fig. 50.9. An intensive electron beam is collimated by a very strong axial magnetic field. Neutrals are hit and ionized by these electrons. The ions are radially trapped by means of the space charge of the electron beam. The axial trapping of the ions is caused by a special electrostatic profile generated by a number of drift tubes. The potential of the drift tubes can be independently varied, thus different potential shapes can be achieved (► Fig. 50.9A–C).

First, the profile A cleans the electron beam from the positive ions. Then neutrals are injected for a short time, meanwhile the profile B is set in, which traps the ions. The profile C pushes the ions toward the extraction region and prevents the diffusion of low-charged ions into the ionization volume. Finally, the profile A again opens the trap and highly ionized ions are extracted. It is obvious that the EBIS works in pulsed regime only. In this way, very high charges but low intensities can be achieved.

■ Fig. 50.9

Principle of the EBIS. B and U are the axial magnetic flux density and the electrostatic potential, respectively

The first EBIS (Donets et al. 1968) worked at room temperature. In later versions, the very high magnetic field (B is several teslas) is produced by SC coils (Wolf 1995). The EBIT, which is the same as EBIS but contains no extraction, finds its application in atomic and plasma physics studies. It is especially suitable for spectroscopic (X-ray) studies of highly charged ions. Traditionally, the EBIS is a successful injector of fully stripped light ions into synchrotrons, but is also useful for high charge states of heavy ions. Existing EBIS are capable of producing fully stripped Xe^{54+} ions (Donets 1993), while fully stripped uranium (U^{92+}) was detected in an EBIT with an electron energy of 198 keV (Marrs 1996). These high charges exceed those values produced by ECRIS, however the amount of such ultra-stripped ions is extremely low (10^4 Xe^{54+} ions/per pulse and ten U^{92+} ions were detected).

The working mechanism of EBIS is better understood than other ion sources. Because the electron component is a beam in EBIS, usually $j_e \tau_z$ is calculated (where j_e is the current density of electron) instead of the $n_e \tau_z$ factor (described in ▶ Sect. 50.1.1.2). ▶ Figure 50.10 shows the different charge states versus $j_e \tau_z$. In EBIS, the plasma parameters (e.g., electron number density and electron energy) are much better known than in other sources, so the calculations fit experiments better.

50.1.6 Other Ion Sources

50.1.6.1 Radioactive-Ion Sources

This subsection discusses ion sources in which the radioactive atoms to be ionized are produced online in nuclear reactions. For the ionization of atoms with radioactive nuclei, the key factor is the efficiency of the source, that is, the ratio of the number of ions in the beam with respect to the number of atoms injected into the source. This ratio for the nonradioactive-ion sources is usually between 10% and 90%. If only one required charge state is considered, this ratio is, of course, lower, depending on the nature of the charge-state distribution in the particular ion source.

■ Fig. 50.10

Calculated charge state distribution in EBIS (Arianer et al. 1982)

Two methods will be described briefly; they serve as examples of how to produce radioactive-ion beams. Both of them are connected with ECR ion sources, but other types of ion sources can also be applied to high-efficiency radioactive-ion beam production (Wolf 1995).

The radioactive elements are created by bombarding suitable targets with energetic (usually 30 MeV) cyclotron proton beams (Barué et al. 1998). Those released by the hot target in a neutral gaseous form are transferred by diffusion to an ordinary ECR ion source where they are ionized, extracted, and usually injected into a second accelerator. Production of both single and multicharged ions (of ${}^6\text{He}$, ${}^{13}\text{N}$, ${}^{19}\text{Ne}$, among others) is possible for post-acceleration.

The charge-breeding method is another powerful technology to produce multicharged radioactive beams (Sortais 2000). Two ECRIS units are coupled in such a way that the first one works in a high-pressure mode to produce single-charged ions from radioactive atoms (see the previous paragraph). Then the single-charged ions (called “1+” beam) are transported at a common 10–15 keV potential into another powerful ECRIS where they are decelerated upon entering into the plasma. This second (low-pressure) ECRIS operates as charge accumulator where the captured “1+” ions are multi-ionized into “ $n+$ ” ions (the method is sometimes called the “1+/ $n+$ ” method). The efficiency can reach 50% (Sortais 2000).

50.1.6.2 Ion Sources for Negative Ions

Heavy ions can be negative as well. A whole ion source family exists for the production of negative ions. Originally, these ion sources were able to generate negative H ions only. Nowadays, however,

they produce high-intensity negative (usually single-charged) heavy-ion beams. In such ion sources, electrons and negative ions have the same charge and thus both are extracted from the source together. Elimination of the high-intensity unwanted electron component is one of the major technological problems in designing negative-ion sources. The physical processes in negative-ion sources are still subject to investigations. Two main types of source are generally known: *surface* and *volume* ion sources (Brown 2004; Angert 1994; Wolf 1995).

In experiments with different types of ion sources (duoplasmatron, multicusp, etc.), it was recognized that negative ions were produced near an electrode surface, that is, at the edge of the plasma. Insertion of a floating electrode in the appropriate region of the plasma improved the yield of the negative ions. The addition of an alkaline surface layer (usually cesium) to the electrode, however, dramatically increased the negative ion (and electron) current (Kobayashi et al. 1976). The increase in ion source efficiency from the addition of Cs accelerated the development of negative-ion sources toward higher intensities. The structure of the up-to-date negative-ion sources is very similar to the multicusp ion sources in which the discharge is maintained by RF or MW power and a converter electrode with cesium surface layer generates the negative ions (Wolf 1996). This converter electrode can also act as a sputter electrode to produce (negative) metal ions. Sometimes, such sources are also called sputtering ion sources.

Volume-type negative-ion sources operate simply by virtue of the fact that every plasma contains not only positive ions and electrons, but some negative ions as well. With suitable modifications of the geometry of traditional positive-ion sources (PIG, duoplasmatron, cusp, etc.), these sources can work as negative-ion sources. A magnetic filter is often used inside the plasma chamber to deflect the unwanted electrons from the extraction area (Hahto et al. 2002). The region of the plasma near the extraction is poor in electrons and contains mostly single-charged positive and negative ions. In such plasma, even more H^- ions can be produced by volume processes with high efficiency.

The best negative-ion sources are able to deliver amperes of hydrogen beams and tens of mA of heavy negative-ion beams (Wolf 1995).

50.1.7 Beam Extraction

For further use, the ions must be extracted from the plasma of the ion source. In most cases, electrostatic extraction systems are applied. An electrostatic ion-optical system for a cylindrically symmetric beam consists of several coaxial electrodes with suitable shapes and apertures. The first one of these electrodes (called exit-hole or extraction-slit or plasma electrode) is usually on high positive potential, while the last one is on the ground and serves as an entrance slit to the beam transport channel. Between these electrodes further electrodes can be placed with various potential values. The most common arrangement is the triode system, which consists of three electrodes. Depending on the potential of the middle electrode, “accel-decel” or “accel-accel” potential configurations are obtained. In an “accel-decel” system, the middle electrode (which is often called a puller) has a small negative potential to prevent electrons from backstreaming to the plasma. This solution also has the possibility to change the extraction field strength without changing the beam energy. In [Fig. 50.11](#), a typical three-element extraction system is shown. The ECR ion source in [Fig. 50.7](#) has a four-element extraction system.

■ Fig. 50.11

Typical accel-decel extraction system with calculated equipotential lines and simulated beam trajectories (Spädtke 1998) (1, 2, 3 denote electrodes)

The maximum density j of the extracted current from a plasma is given by the Child–Langmuir law:

$$j = (1.72 \text{ A})(U/V)^{3/2} \frac{\sqrt{z/A}}{d^2}, \quad (50.10)$$

where U is the extraction voltage, A the mass number, z the ion charge state, and d the extraction gap width (distance between the plasma electrode and the puller).

Real extraction systems cannot reach this current density limit because of imperfect geometries. The trajectories of the extracted beam are influenced by the electrostatic field strength, the magnetic flux density (if any) and direction in the extraction region, the space charge density of the beam, and the shape of the plasma in the emission slit. The design of an ion-optical system involves the determination of the number, shapes, and potentials of these electrodes. There are elaborated theories and accepted methods to do that (Angert 1994; Wolf 1995, 1996; Brown 2004). Many efforts were carried out to find rules for the electrode shapes, distances, etc. Today powerful computer codes are available (e.g., Spädtke and Mühle 2000; Dahl et al. 1990; SIMION 2009). Using such codes, one can easily simulate the beam trajectories and find an optimal basic electrode arrangement.

The ion source with the extraction system is connected to the accelerator or directly to the target through a transport system. The transport system consists of several elements. After the extraction optics, an active beam-focusing tool is usually applied (electrostatic einzel lens or solenoid) followed by a charge separator. Diagnostics units are installed in the beam line to measure the beam quality. The most important beam parameters are the ion current, beam profile, and emittance. The beam current is measured by a special cup-shaped metal electrodes (Faraday cups) that convert the intensity of the stopped ion beam into electrical current. The beam profile and emittance can be diagnosed by several methods. The detailed description of different transport systems can be found in the ion source handbooks (Wolf 1995; Brown 2004).

50.2 Electrostatic Accelerators

50.2.1 Principles of Direct Voltage Accelerators

A straightforward method for producing energetic beams of accelerated particles for nuclear reaction experiments is offered by electrostatic accelerators. In these facilities, the ion beams of selected atomic number and atomic mass are either directly extracted from a gas discharge or are generated from a primary beam in subsequent sputtering and/or charge exchange processes. The beams are then accelerated to the energy needed through the equivalent total direct-current acceleration voltage connected to an acceleration tube inside the insulation column, which holds the voltage generator and the high voltage terminal. Since the beam energy is determined by the total acceleration voltage available in a direct current source, the intrinsic stability of the beam energy is guaranteed at high level and a smooth, stepless adjustment of the beam energy can be achieved within a broad energy interval.

Detailed introductions into the physics and technique of electrostatic accelerators can be found in monographs and review papers (Herb 1959; England 1974; Rolfs and Rodney 1988; Takács 1997), as well as in proceedings volumes of the series of Tandem Conferences (Migneco and Vinciguerra 1981; Aitken and Tait 1984; Heyder and Ziegler 1998) and International Conferences on Electrostatic Accelerators and Associated Boosters (Aitken and Tait 1973; Frick 1977; Jones and Martin 1981; Ventura and Thienberger 1986; Frick and Jaeschke 1990; Signorini and Spolaore 1993; Weisser 1996).

The development of electrostatic accelerators during the decades of their history has been motivated by the trends of ongoing and planned basic nuclear research and interdisciplinary applications based on accelerated ion beams.

The primary aim prescribed by former trends in nuclear structure physics was the broadening of the interval of particle energies and of the selection of atomic number and atomic mass of accelerated nuclei. The increase of the maximum voltage of the machines and the multiple use of the acceleration voltage achieved opened the new field of heavy-ion nuclear reactions and led to important results in nuclear structure physics around the middle of the twentieth century. Machines of rated accelerating voltages around 20–30 MV used in multiple acceleration mode offer beam energies in the hundred MeV region today. Due to increased technological difficulties related to the use of extreme high voltages on the one hand, and new technical requirements posed by the latest new trends in the physics of exotic nuclei on the other hand, more ambitious plans for increasing the rated terminal voltage seems to be absent nowadays. At the same time, however, parallel with the applications of large electrostatic accelerators in basic nuclear research, accelerated beams find broad scale interdisciplinary applications in many scientific fields. In most applied research projects, light ions of energies in the range of a few MeV are needed for such accelerator-based investigations. Consequently, along with further intense use of complex nuclear facilities built up around electrostatic accelerators of ~ 20 MV rated terminal voltage, a number of new electrostatic accelerator laboratories equipped with machines of a few MV voltage have been founded for interdisciplinary applications.

50.2.2 Accelerator Configurations

The basic factor influencing the construction and the feasibility limits of electrostatic accelerators is the need for insulating high voltages surpassing those normal for technical applications.

Atmospheric air typically used as insulator in high voltage facilities will break down around a field strength of 30 kV/cm, that is, insulating high voltage by atmospheric air can only be achieved, if field strengths on electrode surfaces are kept below this value through increasing the electrode dimensions accordingly. Due to spatial limitations, open-air accelerators (i.e., those not closed in vessels) are only practical up to a few hundred kV terminal voltages. Above this limit the accelerators should be closed in a steel vessel, in which air as insulator is replaced by pressurized dry electronegative gases with breakdown strength around 150 kV/cm. Even with such improved insulation strengths, voltages in the MV region can only be reached in large-size configurations.

As shown in [Fig. 50.12](#) for some machines, which were important steps in the history of electrostatic accelerators, the total length and diameter of the accelerator vessel are closely correlated with the rated nominal voltages of the machines. The high terminal voltage over the insulator surfaces in the column, used for holding the high voltage terminal and for screening the acceleration tubes and elements of the voltage generation, can be insulated with high-quality glass or ceramic insulators of multisectioned structure. Insulator elements are subjected to the total high-voltage difference in a linear voltage drop.

The limitation in ion energies set by the technical limitations of the terminal voltage in the classical single-ended electrostatic accelerators can be overcome by multiple use of the terminal voltage in the so-called tandem configurations. In [Fig. 50.13](#), a schematic figure of a classical single-ended electrostatic accelerator is compared with those of two typical tandem configurations.

In single-ended machines, positive ions extracted from an ion source in the positive terminal are accelerated through the terminal voltage in a single acceleration tube.

Fig. 50.12

The dependence of the dimensions of electrostatic accelerators on rated terminal voltage shown by vessel length (♦) and diameter (□) of some electrostatic accelerators

■ Fig. 50.13

Schematic pictures of single-ended and two-stage configurations of electrostatic accelerators

Tandem accelerators are equipped with two acceleration tubes called low-energy and high-energy tubes, for the subsequent acceleration of negative ions from earth potential toward the positive terminal and positive ions obtained from the negative ions via charge exchange toward ground potential. The whole acceleration process consists of two or three steps here. In the first step negative ions, extracted from an ion source at earth potential and injected after a charge stage selection by an injection magnet, are accelerated in charge state -1 toward the terminal in the low-energy tube. The charge exchange process in the terminal is generated by transmitting the negative ions through a gas cell or solid charge-stripper target. The charge state of the stripped ions will be distributed around a mean positive value, which depends on the kinetic energy and atomic number of the ion. The multiple-charged positive ions will pick up energy during the next acceleration steps in the high-energy tube according to their charge state and the potential difference passed. Since the equilibrium charge state obtained in the stripping process increases with ion energy, it is useful to apply a second stripper target down in the high-energy tube. In this way, the energy increase obtained in the rest of the tube will be further enhanced by the higher charge states reached in the second stripper.

As shown in [Fig. 50.13](#), the tandem principle can be realized both in the classical straight-line setup and in the more compact folded configuration. In the latter case, both the low-energy and high-energy tubes are contained in a single insulating column, and a 180° magnetic

charge-state analyzer and a beam-inflection sector are used within the terminal for coupling the low- and high-energy tubes.

Tandem accelerators can be used as flexible sources of highly charged heavy-ion beams as injectors of heavy-ion cyclic accelerators. In such applications, the charge state of the beam injected in the cyclic accelerator can further be increased by subjecting it to an additional charge exchange process behind the tandem accelerator. In the following, the charge states resulting from this post-accelerator stripper will be denoted by symbol z_{pa} .

The total energies E_t and post-accelerator charge states z_{pa} to be obtained on foil strippers as the function of the terminal voltage of the accelerator are summarized in [Fig. 50.14](#) for elements S, Fe, I, and U. Here, upper (a) and lower (b) parts relate to configurations with a single terminal stripper and an additional second stripper, respectively. (The latter is placed at one-third of the length of the high-energy tube.) Charge state values are calculated from an approximate model (Nikolaev and Dmitriev 1968), while the energies are given for case (a) and case (b) by the simple relations

$$E_0 = eV_0, \quad (50.11)$$

$$E_t = E_0 + ez_0 V_0, \quad (50.12)$$

and

$$E_0 = eV_0, \quad (50.13)$$

$$E_i = E_0 + ez_0 \frac{V_0}{3}, \quad (50.14)$$

$$E_t = E_i + ez_i \frac{2V_0}{3}, \quad (50.15)$$

respectively, where the subscript “i” refers to the intermediate (second) stripper.

50.2.3 Construction Units of the Accelerator

50.2.3.1 Ion Sources

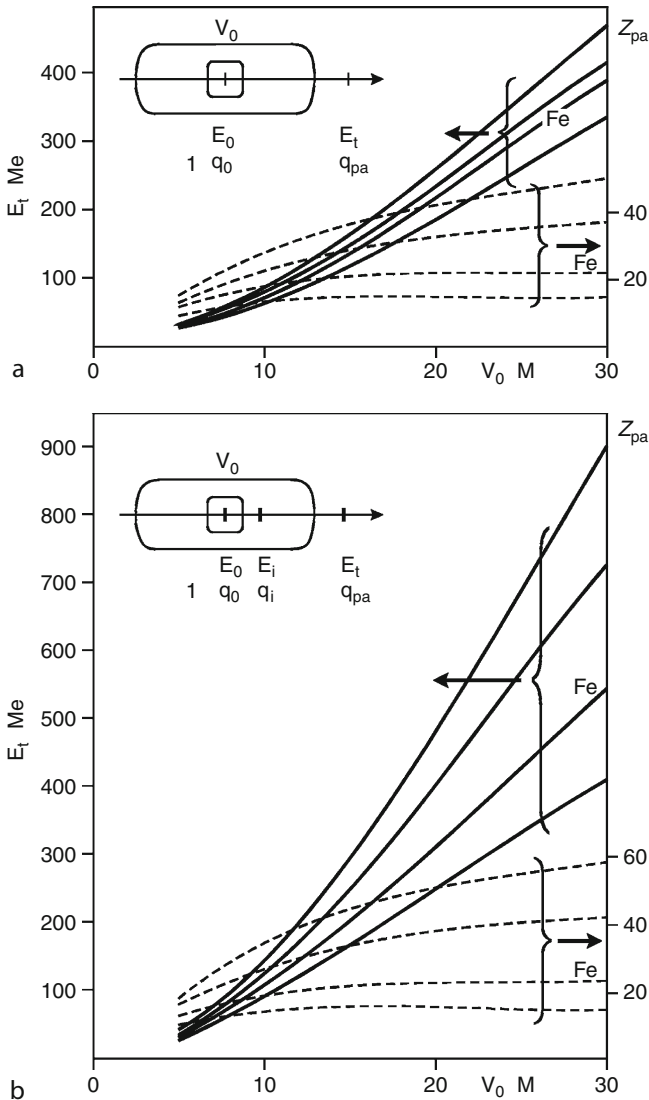

In single-ended electrostatic accelerators, RF ([Fig. 50.6](#)) and Penning sources ([Fig. 50.4](#)) are most often used. In the former case, extraction arrangements of Bayly and Ward and, alternatively, that of Thoneman and Harrison can be applied (Kiss et al. 1977). An improved version of the Penning source (Baumann and Bethge 1981) is especially well fitted to the production of multiple-charged light ions in single-ended machines. In tandem accelerators, duoplasmatron ([Fig. 50.3](#)) is regularly used for the production of light negative ions, while a broad selection of heavy ions can be delivered by sputtering sources (Middleton 1977, 1983).

50.2.3.2 Voltage Sources of the Accelerator

In the electrostatic accelerators, the high acceleration voltage is generated by charging up a capacitor made up by the high voltage terminal and the grounded vessel.

■ Fig. 50.14

Total energies E_t (full lines) and post-acceleration charge states z_{pa} (dashed lines) of sulfur, iron, iodine, and uranium beams obtained from a tandem accelerator as a function of the terminal voltage. Data are shown for the cases of a single terminal foil stripper and a combination of a terminal stripper with a second (intermediate) stripper placed at 1/3 of the length of the high-energy tube in the upper (a) and lower (b) part of the figure, respectively

In the classical arrangement called *Van de Graaff accelerator*, static charge is transferred to the terminal by an endless insulator belt running on pulleys from ground to terminal and back. The charge is deposited to and removed from the belt surface in electric discharges generated in special circuits at the base of the generator column and in the high voltage terminal,

respectively. In order to avoid mechanical and electric instabilities as well as to eliminate dust due to belt wear, the belt in more recent generations has been replaced with a flexible chain of small capacitors formed by metallic elements separated by insulator elements. Here, the metallic conductors are charged by electrostatic induction. In the *pellettron version*, the chain consists of metallic pellets spaced out along an insulating cord. The chain runs on conducting pulleys (Isoya and Nakashima 1970). The maximum transferred charge is limited here by the small surface of the individual pellets. This limitation can be overcome in the *laddertron* charging system, where the small pellets of the pellettron chain are replaced by pairs of small cylinders joined together by an elongated bar. The chain runs on pairs of pulley wheels (Allen and Joyce 1973; Aitken and Leese 1977).

While these arrangements have outstanding characteristics of terminal voltages up to around 20 MV and stabilities in beam energy 10^{-4} or better, the total charge transfer capacities of the moving transfer media limit the charging currents. Furthermore, mechanical wear appearing during service time may cause troubles and makes attendance and adjustments necessary.

Some alternative ways for generating direct voltages in the few MV range are offered by different realizations of the so-called *cascade generators*, in which mechanical charge transfer is replaced by electric or electronic multistage structures of high voltage rectifiers and capacitors. Here, the total accelerator voltage is given by summing up steps of direct voltages, which are obtained through the rectification of alternating voltages and stored in capacitors in individual stages of a power supply chain, respectively. The beam currents available from accelerators of such construction can be orders of magnitude higher than those delivered by machines with mechanical transport media.

The original construction named as *Cockcroft–Walton source* and shown schematically in panel (a) of Fig. 50.15 can be used in the region of a few hundred kV (Baldinger 1959). In this voltage source, N stages composed of a pair of rectifiers and capacitors of C capacitance are fed in series through the chain of capacitors. Due to AC feeding with frequency f of the system, and a load of current I , a ripple of

$$\delta V = \frac{N^2 I}{2fC}, \quad (50.16)$$

will appear on the total acceleration voltage.

At the same time, the total $2NV$ output voltage of the source will be lowered by a *voltage drop* of

$$\Delta V = -\frac{2N^3 I}{3fC}. \quad (50.17)$$

The cubic increase of the output voltage drop sets a limit on the increase of the total output voltage of the source. The number of stages is optimal at

$$N_{\text{opt}}^2 = \frac{VfC}{I}. \quad (50.18)$$

Beyond this limit, the output voltage drop starts decreasing with increasing N .

The limitations caused by serial charging of the DC condensers can be overcome by different arrangements, in which stages of the voltage sources are fed parallel, that is, each of them receive AC voltages to be rectified independently, and only the DC outputs of the stages are connected in series for their voltages to be summed up.

■ Fig. 50.15

Schematic pictures of high-voltage power supplies of cascade multiplier types. (a) Cockcroft–Walton generator, (b) Insulated core transformer (HVEC), (c) Dynamitron (Radiation Dynamics), (d) Tandetron (HVEC)

In *insulated core transformers*, developed by High Voltage Engineering Corporation and shown schematically in part (b) of [Fig. 50.15](#), independent feeding of the individual stages is given by separate secondary coils wound on successive separate segments of the core of a transformer driven by a single primary coil. The segments are insulated from each other to about 30 kV DC. The magnetic flux path penetrates the stack of insulated core elements; the return path from the insulated core is an iron cylinder enclosing the primary coil and is closed through an air gap which withstands the total output DC voltage difference generated by the voltage source. The source can be either directly integrated with the insulation column of the accelerator or housed in a separate pressurized vessel connected to the accelerator.

In *dynamitron* sources, developed by Radiation Dynamics Corporation and shown schematically in part (c) of [Fig. 50.15](#), the chain of high voltage rectifiers is fed by AC voltage at a frequency of around 100 kHz through semicircular capacitive plates that are situated inside a cylindrical liner near the wall of the vessel. The capacitive liner is fed by a powerful high-frequency oscillator. The source is integrated with the accelerator column of the machine, not shown here.

A *tandetron* machine, developed by High Voltage Engineering Corporation, is composed of a single stage or tandem accelerator configuration combined with a high voltage source essentially similar to that in the dynamitron machine. A tandetron accelerator of this type is shown schematically in part (d) of  Fig. 50.15.

50.2.3.3 Terminal and Insulator Stack

The construction elements of the electrostatic accelerators, which are elevated to the total accelerator voltage or to parts of it, should fulfill delicate mechanical and electrostatic requirements. On the one hand, heavy and voluminous elements should be positioned accurately in the pressure vessel over a total length of several tens of meters. A structure called insulating stack is built in the vessel for holding the high voltage terminal and elements of the charge transfer system. On the other hand, all elements should be screened by properly dimensioned smooth metallic electrodes with large enough radii of curvature to keep the local electric field strengths at the rated generator voltage under the breakdown value of the insulating media both in the electrode gaps and over the insulator surfaces. The most important screening elements are the high voltage terminal and the structure of equipotential hoops, which encloses the electrically graded elements of the solid insulators and acceleration tubes.

In an ideal construction, the same absolute field value would exist at every point of the high voltage electrode gaps in order to avoid voltage limitations set by strong local maxima in the field distribution. At the same time, axial field values appearing over insulating surfaces should be kept under surface sparking limits. The general rules to be followed in the optimum construction of the terminal and stack are summarized in the papers of Boag (1953), Kiss et al. (1967).

50.2.3.4 Acceleration Tubes

The ions directly extracted from the ion source in single-ended machines or obtained from charge exchange processes in tandem accelerators are subjected to the accelerating voltage inside the acceleration tubes located in the insulation stack of the accelerator. Tubes are built up of a series of insulating rings separated by metallic electrodes, and are kept under vacuum of the order of 10^{-4} Pa. The total terminal voltage is graded to the tube electrodes by a resistor chain. The tube has to meet serious mechanical, vacuum technical, and electrical requirements. The function of the tube electrodes is proper forming of ion beam trajectories, extracting secondary electrons released from tube construction elements by ion bombardment in the tube, limiting electrode sputtering, and screening the insulator surfaces from scattered ions and secondary electrons. Careful ion-optical design and tube-building technologies are equally important for good voltage holding and stable operation of the machine, limited bremsstrahlung load inside and around the accelerator, as well as for limiting wear. The historical development of electrostatic accelerators toward increased accelerator voltages was supported by new ideas in tube optics and technology (Joy 1990). The following milestones mark the road starting from classical tubes of homogeneous field toward improved ion-optical arrangements with better voltage-holding capabilities:

- Electron-suppressed tubes of *inclined field configuration* (Van de Graaff et al. 1962; Koltay 1963),
- *Spiraling tube configuration* (Allen 1966; Kiss et al. 1981),

- *Magnetically suppressed tube configurations* (Isoya et al. 1977), and
- *Tubes with axial gradient modulation* (Herb 1974; Kiss et al. 1988).

Tube-building technologies got developed through improved cementing methods and better-quality insulator and electrode materials.

50.2.3.5 Energy Analysis and Stabilization

The stabilization of the energy of the beam delivered by an electrostatic accelerator is achieved through the stabilization of the terminal voltage. In the classical electrostatic accelerators, energy adjustment and stabilization can be achieved through the proper control of the balance between charging current and loading currents toward and from the high voltage terminal, respectively. An overview of the systems developed for the energy stabilization of electrostatic accelerators is given in the reference (Takács 1997).

Driving error signals to a two-looped energy stabilization system are taken from a voltage sensing electrostatic device of limited accuracy called generating voltmeter and a high precision beam energy sensing system called magnetic beam analyzer. The *generating voltmeter* is an electromechanical device in which small stationary metallic plates are periodically exposed to and screened from the electric field, generated by the terminal near the wall of the pressure vessel, through sector-shaped windows cut on a rotary disc. The AC voltage to be sensed on a resistor connecting the stationary plates to the ground is proportional to the terminal voltage. The typical accuracy of the device amounts to 1%. With the *magnetic beam analyzer*, the high precision energy signal can be deduced through a comparison of beam current components to be measured on the exit slits of a magnetic deflection sector field used as a momentum analyzer behind the accelerator. The accuracy of the energy determination can be as good as 0.01%. A mixed signal deduced from a combination of the separate error signals is split into slow and fast components, driving a slow-charging current regulator system and a fast-loading current controller, respectively.

A typical actuating element for controlling a loading current component in the voltage stabilization is the *corona triode*. The unit, facing the terminal near the internal wall of the generator vessel, consists of a set of insulated needles centered in circular openings on a grounded screening cup. If the distance of the triode head from the terminal is set properly, a continuous corona discharge will appear on the needles, which represents a load to the terminal. The loading current can be electronically adjusted by the voltage stabilization system through controlling the voltage difference between the needles and the cup.

An alternative fast acting tool in energy stabilization is the so-called *capacitive liner*, which is a large-surface metallic cylinder surrounding the terminal near the vessel wall. High-voltage pulses delivered by the output of an energy stabilizing circuit will be transferred to the terminal through the high-voltage capacitor formed by the terminal and the liner. This stabilization principle can be advantageous in cases of very large accelerators, where multiple electrode configurations may cause complications in using the corona triode as actuating element.

In the case of scientific applications that require extreme beam energy stability, energy ripples originating from sources other than the acceleration voltage of the generator (e.g., ripples on the voltage of power supply feeding the ion source) can be removed by additional energy modulation through an electrode on the beam path. Modulation voltages can be connected to the terminal stripping tube or to the target insulated from the ground.

In parallel fed cascade voltage sources, characterized by high current and low inner resistance, a direct voltage adjustment and stabilization is used in place of voltage stabilization through additional regulated loading current components typical of Van de Graaff machines.

50.2.4 Beam Transport System

The particle beam generated in the accelerator and stabilized by the above-described electronic system may alternatively serve a variety of experiments. They need different types of collision and detection configurations to meet the requirements of the selected atomic and nuclear processes. Therefore, dedicated vacuum chambers are normally set up behind the exit port of the beam-defining and energy-sensing slits of the analyzing magnet. The beam can be directed with a switching magnet of several exit ports along the axes of vacuum transport tubes to any of the required chambers. The beam traveling several meters is confined and focused with magnetic lenses according to the needs of the experiments. Due to their high magnetic rigidity, the ions in the MeV energy range can only be focused by strong transversal magnetic fields. The appropriate elements are the magnetic quadrupole lenses (Hawkes 1970). A single quadrupole unit possesses focusing property in the x -direction, and defocusing property in the y -direction perpendicular to the longitudinal z -axis of the element. In order to achieve focusing in both directions, a second quadrupole lens should jointly be used, which is rotated by 90° with respect to the first lens. The two lenses make a quadrupole doublet.

50.2.5 Microbeam Channels

As treated in [Chap. 32 of Vol. 3](#), fine-focused particle beams find analytical applications in microscale lateral mapping of elemental concentrations in a sample through the detection of characteristic X-rays and/or nuclei released under particle bombardment. The focusing of a particle beam into microspots of sharply cut current density distribution can be achieved in an ion-optical system of high demagnification and minimized aberration effects (Watt and Grime 1995). This system can be composed of a magnetic condenser lens and a micro-focusing lens system. The condenser lens is a quadrupole doublet that forms a crossover of the order of millimeter size over a set of object slits. The short-focal-length second lens system consists of a doublet or triplet of elaborate quadrupole lenses and focuses the crossover as an object to a small-diameter image on the target surface. This can be achieved with a large object distance in the configuration. The average diameter of the beam spot can be as small as $1\text{ }\mu\text{m}$. A further optical element serves for periodic transversal beam deflections in two perpendicular directions for sweeping the beam over pixels covering a preselected area on the target that is placed in the image plane of the lens system. Elemental maps can be built up from the spectroscopic information since the beam deflection and data acquisition can be synchronized. In a similar way, morphological (optical-type) images can be built up from simultaneously acquired counts of secondary electrons released from the sample during ion bombardment. Furthermore, Scanning Transmission Ion Microscopic (STIM) images may be obtained through counting the number of ions transpassed the scanned pixels in the sample. STIM images give information on the lateral distribution of areal density of the bombarded layer without giving any analytical information.

Steps toward nanometer resolution are being taken by several groups (e.g., Watt et al. 2003; Glass et al. 2007; Andersson et al. 2008). In these nanobeam setups, the beam spot emerging from the above-mentioned microbeam system serves as an intermediate image for a second lens system. This is formed by electron-optically optimized groups of quadrupole-lens configurations (doublets and/or triplets) providing further demagnification. Several sets of precision-slit devices are arranged in proper positions to remove beam halos caused by ions scattered from construction elements of the long beam channel. In state-of-the-art nanobeam channels, a beam size of a couple of 10 nm has been achieved.

Detailed introduction to the physics and technique of microbeam channels can be found in the proceedings volumes of the series of International Conferences on Nuclear Microprobe Technology and Applications (Demortier 1982; Grime and Watt 1988; Legge and Jamieson 1991; Lindh 1993; Yang et al. 1995; Doyle et al. 1997; Przesky et al. 1999; Moretto and Bonin Mosbah 2001; Takai and Kamiya 2003; Jaksic and Bogdanovic Radovic 2005; Osipovicz et al. 2007; Rajta et al. 2009).

50.3 RF-Based and AC-Voltage Accelerators

RF-based particle accelerators are either linear, which accelerate particles in a single pass, or circular (i.e., cyclic) which recirculate the particles through an accelerating gap many times. This section is mainly devoted to the cyclic accelerators, and particularly to AVF (azimuthally varying field, see Sect. 50.3.2.3) cyclotrons, but other accelerators using RF or AC voltage for the acceleration will be briefly mentioned. Information about these accelerators can be found in the proceedings of dedicated international conferences (e.g., Strathdee 1985; Dutto and Craddock 1993; Suller and Petit-Jean-Genaz 1994; Duggan and Morgan 1995; Cornell 1996; Myers et al. 1998; Baron and Lieuvin 1999; Gudat and Zimmermann 2000; ACCELCONF 2009); operation principles, physicist's and engineering considerations are presented, for example, in Livingood (1961), Richardson (1965), Harvey (1974), Conte and Mackay (1991a), Weihrer (1996), Margaritondo (1998), Wangler (1998), Chao and Tigner (1999). An amusing review together with historical details about the cyclic accelerators can be found in Boslough (1985).

50.3.1 Basic Principles of Operation

In the *cyclic accelerators*, the acceleration of the charged particles is realized in a magnetic field, bending them to an approximately circular orbit, which is mostly chosen to be horizontal, and an RF electric field repeatedly increases its energy in each gap crossing. A schematic construction of such a system is shown in Fig. 50.16.

The orbit radius r for the particles moving with speed u in the homogenous magnetic field is

$$r = \frac{mu}{qB}, \quad (50.19)$$

where m and $q = ze$ are the mass and electric charge of the particle and B is the magnitude of magnetic flux density. The angular frequency ω of the circular motion

$$\omega = \frac{u}{r} = \frac{qB}{m}, \quad (50.20)$$

is independent of the radius of the particle orbit (see also Eq. 50.3 for electrons).

■ Fig. 50.16

Layout of cyclic acceleration. The magnetic flux density is perpendicular to the motion of particles

The electrodes are fed with an RF generator of angular frequency ω . A bunch of particles crossing the accelerating gap in the right phase (in which they gain the highest energy at the crossing) will feel accelerating field again when arriving at the next gap. The radius of the orbit is a function of the particle speed; it increases with time and therefore the particles follow a spiral path from the ion source to the edge of the magnet where they are extracted from the accelerator by a so called deflector system.

Equation 50.20 is the so-called *cyclotron equation*, and the accelerator that is based on this principle is the classical cyclotron. The accelerating electrodes are named dees after their D-shape and usually an electrostatic deflector compensating for the bending force of the magnetic field is used to extract the beam.

With this simple arrangement, only moderate energies can be achieved. As the speed of the particles increases, the angular frequency will slowly decrease, because the mass of the particles increases according to the relativistic equation

$$m = m_0 \left[1 - \left(\frac{u}{c} \right)^2 \right]^{-1/2}, \quad (50.21)$$

where m_0 is the rest mass and c is the speed of light in vacuum. Another disadvantage is that there is no vertical focusing in homogeneous magnetic field. Due to these facts, there is high loss of the beam intensity during the acceleration. The first cyclotrons accelerated protons and deuterons to the MeV range. To achieve higher and higher energies and to accelerate other particles, this simple machine was substantially modified later.

The *linear accelerator* (also called LINAC) is a series of cylindrical tubes, which are alternately connected to a high-frequency generator, as shown in Fig. 50.17. The charged particles are accelerated in the gaps between the tubes and then they drift inside the tube in a field-free region. While the particles are inside the tube, the direction of the electric field is reversed. If the length of tubes is increased in proportion to the particle speed, the particles will always arrive at the next gap at the correct phase of the RF voltage.

Both in cyclotrons and linear accelerators, particles can only leave the ion source when the voltage in the first gap has the correct sign to accelerate them, thus bunches of particles are accelerated, that is, their beam will have a pulsed structure. At the center of the cyclotrons, there

■ Fig. 50.17

Schematic structure of the linear accelerator. The arrows indicate the local direction of the electric field at a particular value of the RF phase

is room only for a small ion source, and PIG ion sources are mostly used (see Sect. 50.1.3.2). Any more powerful or sophisticated ion source (e.g., ECR or multicusp) can only be installed externally, with the ion beam injected through a beam line to the acceleration plane of the cyclotron.

50.3.2 Types of Cyclic and Linear Accelerators

50.3.2.1 Classical Cyclotron

In classical cyclotrons, the vertical focusing is achieved by decreasing the magnetic flux density at large radii (see Fig. 50.22 and discussion in Sect. 50.3.3.1). This is inconsistent with what is required by the relativistic mass increase. To compensate for the loss due to the phase delay of particles, high accelerating voltages were used. The classical cyclotron was a valuable instrument at one time and machines with pole diameter up to 3 m were built. The maximum energy of deuterons was in the 20–25 MeV region, the typical beam currents would be about 1 mA.

50.3.2.2 Synchrocyclotron

In synchrocyclotrons, (1) the magnetic field falls as a function of the radius giving the necessary vertical focusing of the beam and (2) the RF frequency is gradually reduced in the course of the acceleration so that a group of particles can cross the accelerating gap in the right phase. After each acceleration period, the frequency resumes its initial value and the acceleration of the next group begins. Thus, the beam comes from the synchrocyclotron in macropulses with the repetition rate of the RF system. The final energy of protons would be in the 600–700 MeV range, but the beam intensity is of the order of microamperes.

50.3.2.3 Isochronous Cyclotron

In isochronous cyclotrons, the magnetic field is increased along the radius at the rate of the relativistic increase of the mass of the accelerated particles. The time required for one revolution is constant during the acceleration, and a fixed-frequency RF system can be used. For vertical focusing, the magnetic field is appropriately shaped with radial or spiral sectors

(see ► Fig. 50.18). In recently built cyclotrons, this method is used to overcome the above-mentioned limitations in increasing the particle energy. To emphasize the shape of the magnetic field, this type of cyclotron is sometimes called *sector-focusing cyclotron* or *AVF cyclotron* (where AVF stands for “azimuthally varied field”).

There is a wide variety of AVF cyclotrons in operation regarding the types of the accelerated particles and the construction features. Detailed information can be found in the proceedings of the series of International Conferences on Cyclotrons (Dutto and Craddock 1993; Cornell 1996; Baron and Lieuvain 1999).

Negative-ion cyclotrons accelerate the negative ions of ordinary hydrogen (protium) and deuterium usually with high beam intensities (Jongen et al. 1996) and are used for radionuclide production. Commercial models are also available (Milton 1996; Bogdanov et al. 1999).

Heavy-ion cyclotrons accelerate ions of almost every element of the periodic table. Moreover, “secondary” radioactive ions can also be accelerated (e.g., Loiselet et al. 1996).

As for the construction of isochronous cyclotrons, the magnet of small- and medium-sized machines has the usual H-shape and the magnetic sectors are mounted onto the magnet pole. The large machines contain sector magnets (so-called separated-sector cyclotrons) and the accelerating system and other instrumentation are placed between the sectors. There are cyclotrons where the magnet is excited by SC coils (see, e.g., Goto et al. 1999). The number of the accelerating gaps can be more than two (as in the above simple model) and the so-called *higher-harmonic acceleration* (when the frequency of the RF system is a multiple of the revolution frequency of the beam) can also be used.

Separated-sector cyclotrons accelerate protons up to 600 MeV with beam intensities of the order of 1 mA (Stammbach and Adams 1999). In heavy-ion cyclotrons the particle energy can reach 25–200 MeV/nucleon (Gelbke 1999), and the intensity of the beam depends very strongly on the effectiveness of the production of the ions. The parameters of some well-known machines are summarized in ► Table 50.1. The value K is used at heavy-ion cyclotrons to calculate the maximum energy of the accelerated particle (see ► Eqs. 50.9 and ► 50.41 later).

■ Fig. 50.18

Pole faces of the isochronous cyclotrons: the “hills” are the sectors. Between the hills, the magnetic field is made stronger by reducing the pole gap

50.3.2.4 Synchrotron

It can be seen from [Table 50.1](#) that to increase the energy beyond 1 GeV is technically not sensible by increasing further the pole diameter of a magnet. In the relativistic region at a given magnetic flux density, the mass of the magnet is proportional to the square of the proton energy while its bending radius is linearly proportional to the energy. To build a magnetic ring is more economical (its mass is proportional to the radius) but, in consequence, the acceleration should be completed on a constant or nearly constant radius.

The ring of the synchrotron contains “bending” magnets; between them are the focusing and accelerating RF sections. At the beginning of the acceleration, the particle should have a minimum kinetic energy which is determined by the initial magnetic field and radius of the accelerator. Then the magnetic field is varied during the acceleration. A cycle begins with low magnetic field and finishes with the highest one. The repetition rate and the beam intensity are usually low. The frequency of the accelerating RF field also increases during the cycle. The particle is pre-accelerated by another accelerator up to the injection energy.

Synchrotrons are used to accelerate not only protons and heavier ions, but electrons and positrons as well. The electron is fully relativistic in the GeV region; its speed is close to that of light and is practically unchanged during the acceleration. The main difference between light-charged particles (such as electrons) and much heavier ones (like protons and still heavier ions) is that the circulating (i.e., accelerating)¹ electrons suffer considerable energy loss by producing a substantial amount of electromagnetic radiation, the so-called synchrotron radiation. Some characteristic parameters of synchrotrons are listed in [Table 50.2](#).

^a Also other ions, electrons, and positrons for LEP-II collider.

The synchrotron radiation consists of individual photons with random directions and momenta. The total energy W irradiated during one revolution by one electron is about

$$W/\text{keV} \approx 90 \frac{(E/\text{GeV})^4}{R/\text{m}}, \quad (50.22)$$

where E is the total energy of the electron and R is the radius of the circular path. The energy spectrum of the radiation is characterized by a “critical frequency”

$$\omega_c = \frac{2c}{3R} \left(\frac{E}{E_0} \right)^3, \quad (50.23)$$

where c is the speed of light in vacuum and E_0 is the rest mass energy ($m_e c^2$) of the electron. The energy of the photon is $\hbar\omega$. Half of the energy is emitted by photons carrying less than the critical energy $E_c = \hbar\omega_c$, and the other half by more energetic photons.² Most of the energy is irradiated in the direction of the electron velocity, that is, tangentially. Without energy fed in constantly, the circulating electrons would slow down.

The intensity distribution of the synchrotron radiation is schematically shown in ► Fig. 50.19. The energy of the radiation increases rapidly with the energy of the particles. One can see that the synchrotron is a good transformer of the RF power supplied to the acceleration system into shortwave radiation (visible light and X-rays). A review of synchrotron light sources is given by Eriksson (1994).

■ Fig. 50.19

Spectral distributions (intensity versus wavelength) of the synchrotron radiation for different electron energies

50.3.2.5 Storage Ring

When a particle hits a target, a substantial part of its energy is spent on accelerating the center of mass of the colliding partners. To concentrate all energy on the excitation of the colliding system, two particle beams are driven at each other. In a head-on collision of two 100 GeV protons, the same amount of energy is spent on excitation as if a 20 TeV proton hit another one in a fixed target. (Note the relativistic kinematics.)

The encounter of two particles belonging to two colliding beams has a very low probability, because the number density of the colliding particles is very low. Two beams “see” each other almost transparent, and for one collision event to occur, the beams should be driven at each other many times, that is, the beams should be stored and they should have a suitably long life.

The construction and operating principles of storage rings are the same as those of synchrotrons. The special requirements are:

1. Suitable beam lines and arrangement for the collision experiments.
2. Very good vacuum (order of 10^{-10} Pa), because a major loss of the beam comes from its interaction with the residual gas.
3. The ring is filled via so-called “multi-turn” injection in order to increase the particle number density.
4. The collective motion of the particles should be controlled by beam cooling.

Some parameters of storage rings and colliders are collected in [Table 50.3](#).

50.3.2.6 Linear Accelerators

The structure of the linear accelerator shown in [Fig. 50.17](#) is named *Wideröe* structure or π -mode structure. The reason for the second name is that the configuration of the electric field is repeated in every two gaps. Bunches of particles are not accelerated in every gap, but must be spaced with a free gap between every pair of bunches. In another version, the drift tubes are

■ **Table 50.3**

mounted into a resonating tank powered by the RF system. In this structure, the charges oscillate between the ends of the drift tubes. This is the *Alvarez* or 2π -mode structure, where the particles are accelerated simultaneously in each gap.

As the speed of particles increases, the drift tubes get longer. The final energy of the particles is limited by the available RF driver frequencies, the lengths of the drift tubes and that of the whole accelerating system. These types of linear accelerators are used to accelerate protons and heavier particles. To produce higher energy ion beams, such structures are coupled in a synchronized accelerating system.

The relativistic particles, electrons, and positrons require a source of higher frequency. In the MW region, there are high-power sources for feeding linear accelerators of the *cylindrical waveguide* type. A wave traveling in a waveguide can be used to accelerate light particles if its phase velocity is slowed down to a value where the particles can keep in phase with the traveling wave. Then the particles may “surf” along the wave with the phase yielding an accelerating force. Some parameters of a few huge linear accelerators are summarized in [Table 50.4](#).

50.3.2.7 Radio Frequency Quadrupoles

The radio frequency quadrupole (RFQ) is used to accelerate protons and heavier ions. It uses four parallel electrodes around the beam axis as shown in [Fig. 50.20](#). The RFQs operate at high frequencies, typically from tens to hundreds of MHz. The electrodes, which are called “vanes,” are placed in a cavity forming a resonant structure. The adjacent electrodes have opposite charges. From the end, the RFQ looks like an electric quadrupole. This arrangement of electric field focuses the beam in one plane and defocuses it in the other one. Since the electric field oscillates, a net focusing effect can be obtained along the length of the vanes.

A longitudinal field can be created by perturbing the electrodes in a periodic way, that is, a part of the originally transverse field is distorted into the longitudinal direction. A convenient

The RFQ structure

perturbation is the sinusoidal modulation. The sinusoids of the horizontal and vertical electrodes have to be displaced by half a period. The period of the perturbation is adjusted to create synchronism between the “wave” and the particle to be accelerated and, in addition, the transverse RF field provides an alternating gradient focusing. Details of an operating RFQ accelerator is presented, for example, in RFQ (2003).

50.3.2.8 Coupled Accelerators

To produce beams of extreme specifications, for example, very high-energy particles or heavy-ion beams, a chain of accelerators have to be used (see ▶ Tables 50.2–50.4 and the Internet sources referred to there). Generally, the ions coming from the ion source are accelerated in the first step by an electrostatic accelerator and after a bunching system, preparing the DC beam for the acceleration in an RF-based structure, they are accelerated further by cyclic or linear accelerators.

50.3.2.9 Microtrons

For electrons, the relativistic effects are already dominant at relatively low energies, so when increasing their energy, their revolution frequency lags behind. Assume that electrons are

moving cyclically in a plane perpendicular to a magnetic field, and they receive a push in every revolution from an electric field when passing a gap. If the energy of electrons at the gap crossing is changed so that the accelerating frequency is a multiple of the new revolution frequency, then the electrons can resonate with the RF field and can be accelerated (in harmonic mode). For such a system, the RF wavelength must be in the centimeter region and the magnetic field has to be uniform in a relatively wide range. The schematic layout is shown by the left panel in ▶ Fig. 50.21. The circles represent the bunches of electrons accelerated. In this arrangement, electrons can be accelerated to energies of a few MeV. A high-energy portable microtron is discussed by Sobenin et al. (1994).

50.3.2.10 Betatrons

The betatron, like the microtron, is used to accelerate only electrons, but the operation principle differs from that of RF-based accelerators. It is also a circular accelerator. Its schematic layout is shown in ▶ Fig. 50.21. The electromagnet is supplied by an AC current and the changing magnetic flux density in the gap generates an “electromotive” force (e.m.f.), which can accelerate (or decelerate) the electrons along the circular orbit. This e.m.f. is relatively low, so the electrons complete millions of revolutions to get an energy of the order of 10 MeV. The intensity of the electron beam is pulsed according to the frequency of the supplying AC voltage, which is usually 50 Hz (sometimes higher up to 400 Hz). The accelerated electrons are mostly used to hit an internal target and the produced bremsstrahlung is used. Applications and technical information are available on the Internet (BETATRON 2009).

50.3.3 Focusing the Particle Beam

In cyclic accelerators, the beam takes many turns and the particles should keep together in a bunch both longitudinally and transversally. By the action of focusing forces, the particles perform “synchrotron” and “betatron” oscillations around an imaginary “synchronous” particle moving on a stable/smooth “equilibrium orbit.”

■ Fig. 50.21

Layout of the microtron (*left*) and betatron (*right*). Note that the viewpoints of the sketches are different: the beam lies in the plane of the diagram of the microtron, whereas the plane of the beam is perpendicular (horizontal) to that of the cross section of the betatron

50.3.3.1 Magnetic Field

The force \mathbf{F} upon a charged particle moving in a magnetic field is

$$\mathbf{F} = q(\mathbf{u} \times \mathbf{B}), \quad (50.24)$$

where q is the charge of the particle and \mathbf{u} is its velocity, and B is the magnetic flux density. The axial component of \mathbf{B} takes care of the radial focusing of the beam. In a uniform field, \mathbf{B} has no radial component and \mathbf{F} has no axial component. In a field that falls as a function of radius (see [Fig. 50.22](#)) the radial component of \mathbf{B} produces an axial component of \mathbf{F} , which directs particles leaving the median plane of the magnet back to this plane (this is the focusing force in the classical cyclotron). In the median plane, there is no focusing force.

The radial variation of the magnetic field may be described by means of the “**field index**” n defined by

$$n = -\frac{dB/B}{dr/r}. \quad (50.25)$$

A positive value of n implies a focusing effect. The value of n varies with the radius r (it is zero at the center of the magnet) and it can be used to calculate the motion of particles in the radial and axial directions at a particular radius. Ignoring the detailed discussion, particles displaced axially or radially from their equilibrium orbit will sense a force which is proportional to the displacement (like a simple harmonic oscillator) and will perform stable axial and radial oscillations, which are known as “**betatron**” oscillations. These oscillations are stable when n lies between 0 and 1. Any ion leaving the ion source in a direction not in the median plane and not on the equilibrium orbit will make axial and radial betatron oscillation.

A field increasing with the radius (i.e., when n is negative) will make an axial defocusing effect: if a particle is moving off the median plane, a force pushes it even further off. In isochronous cyclotrons, however, where the magnetic flux density increases with the radius in accordance with the mass of the accelerated particles, the forces arising at the edges of the sectors will cause axial focusing.

By adding sectors to the pole tips as shown in [Fig. 50.18](#), an azimuthal variation is induced in the magnetic field. Since the magnetic field varies with the azimuthal angle, so must

Fig. 50.22

Representation of the axial (vertical arrow) and radial (horizontal arrow) components of \mathbf{B} in a nonuniform magnetic field. The slanted arrow shows the direction of the resultant force \mathbf{F} acting on the charged particle

the radius of the orbit. The particles zigzag inward and outward with respect to a circle, called the “equivalent” orbit, which would be the orbit given by the azimuthally averaged field, enter and leave a sector non-normally. The curvature of the magnetic field lines at the boundaries of the sector, combined with the non-normal motion, is responsible for the axial focusing.

To describe the magnetic field variation, the “**field flutter**” f is defined by

$$B_h = B(1 + f), \quad (50.26)$$

$$B_v = B(1 - f) \quad (50.27)$$

where B_h and B_v are called the hill and valley field, respectively, and B is the magnitude of the magnetic flux density averaged over a complete revolution.

The velocity of a particle moving in the AVF cyclotron has a radial component u_r , which reaches maximum when the orbit crosses the circular orbit (see [Fig. 50.18](#)). Since the field varies as a function of θ , there is an azimuthal component B_θ and therefore there is a force F acting upon the particle. This force can be expressed as

$$F = qu_r B_\theta. \quad (50.28)$$

Again, suppressing the details, this force acts such that a particle always returns toward the median plane and the axial motion is a harmonic oscillation again.

This force alone is able to compensate for the defocusing effect of the radially increasing field up to a limited energy. Additional focusing forces can be obtained by the use of spiral ridges instead of the straight radial ones as shown in [Fig. 50.18](#). The angle α between a tangent to the spiral and the radius vector at the point of tangency is called the “spiral angle.”

The motion in such a composite field shows that the resultant force causes axial oscillations of angular frequency ω_z

$$\omega_z \approx \frac{\omega f}{\sqrt{2}} (1 + 2\tan^2 \alpha)^{1/2}. \quad (50.29)$$

The radial increase of the average magnetic field comes partly from the effect of the hills and partly from the concentric current-carrying coils mounted on the upper and lower poles. The isochronous field B_r is defined as an average of the magnetic flux density over an orbit of radius r . It can be shown that

$$B_r = \frac{m_r}{m_0} B_0 = \left(1 + \frac{T}{E_0}\right) B_0, \quad (50.30)$$

where m_r is the particle mass on the orbit of radius r , B_0 , and m_0 are the values of those at radius zero, and T and E_0 are the kinetic energy and rest mass energy of the particle. The effect of the spiral ridges should counteract the axial instability due to this rising field.

The radial betatron oscillation frequency can be determined by numerical calculations and it is usually close to the revolution frequency of the particle:

$$\omega_r \approx \frac{m_r}{m_0} \omega. \quad (50.31)$$

50.3.3.2 Coupled Resonances

There is a coupling between the axial and radial oscillations, which can cause coupled resonances. Detailed examinations show that they are present when the axial and radial

frequencies are related to each other in certain simple ways. Define the quantities v_z and v_r as the number of axial and radial oscillations per revolution:

$$v_z = \frac{\omega_z}{\omega}, \quad (50.32)$$

$$v_r = \frac{\omega_r}{\omega}. \quad (50.33)$$

Resonance occurs when $v_r = v_z$, $v_r = 2v_z$, etc. If a particle makes many turns at radii close to the resonant value in the course of the acceleration, a disastrous increase in the betatron amplitude may develop.

Imperfections in the magnetic field can induce additional radial and axial oscillations. When v_r and v_z are integers or ratios of integers, the disturbance caused by a field imperfection occurs with same phase in each revolution so that a disastrous increase may result in the amplitude.

50.3.3.3 Electric Field

The particles crossing the gap between the dees are accelerated by a time-dependent force

$$\mathbf{F}_e = q\mathbf{E} = ze\mathbf{E}, \quad (50.34)$$

where \mathbf{E} is the electric component of the RF field.

As might be expected, the particles subjected to an accelerating force begin to oscillate around their equilibrium orbit, thus the amplitude of the radial oscillation will be increased. However, in addition to the acceleration, this electric field produces a weak axial focusing force. [Figure 50.23](#) shows two trajectories in the electric field of a gap. The particle beam is at first focused and then defocused. Since the particle is accelerating during the gap crossing, the focusing force acts for a longer time than the defocusing force, so the net result is that the particles tend to return toward the median plane. The force depends also on the time of the crossing with respect to the phase of RF field. If the dee-to-dee potential decreases in time, the defocusing effect will be further weakened.

The electric axial focusing effect is only important in the first few rounds, because it is proportional to the ratio of the energy gain to the kinetic energy of the particle. The almost uniform magnetic field in the center of the magnet (field index n is close to zero) produces at the same time an especially weak axial focusing.

■ Fig. 50.23

Focusing effect of the electric field (*dashed lines*) at gap crossing

50.3.3.4 Phase Stability

The acceleration is continued while the particles gain energy at the gap crossing, that is, they arrive at the dee gap when the RF electric field produces an energy gain rather than an energy loss.

In a perfectly isochronous magnetic field, the particles move fully in phase with the RF field. If a particle loses the “right phase” for any reason, there will be a “phase slip” in one direction or the other. In classical and isochronous cyclotrons, it is not possible to stabilize the phase of the gap crossing and the acceleration continues until the phase error becomes so great that deceleration occurs.

In synchrocyclotrons and synchrotrons, there is a mechanism that guarantees that a particle arriving too early at the dee gap will arrive later in its next revolution. All particles will cross the gap with different phases relative to the RF oscillation, arriving either too early or too late with respect to the synchronous particle. The synchrocyclotron is operated such that the ions pass the gap in the phase of decreasing field strength. In this way, the ions that arrive there too early get a larger-than-average push. That will steer them onto a path of slightly larger radius, which implies a lower revolution frequency. They will thus arrive at the next gap more in phase with the others, that is, its phase will be closer to φ_s as shown in [Fig. 50.24](#). Therefore, the phase of the accelerated particles will perform stable oscillations, known as “**synchrotron**” oscillations, around the stable value φ_s .

50.3.4 Beam Parameters

50.3.4.1 Energy

Accelerators can accelerate particles up to *relativistic speeds* where the total energy, momentum, and kinetic energy are the following:

$$E = \gamma m_0 c^2, \quad (50.35)$$

Fig. 50.24

Phase-stability principle in synchrocyclotrons. The symbols t and t_{RF} stand for the periodic time of the particle and the RF field, respectively

$$p = \beta\gamma m_0 c, \quad (50.36)$$

$$T = (\gamma - 1)m_0 c^2, \quad (50.37)$$

where $\beta = u/c$ is the particle speed relative to the speed of light, and $\gamma = (1 - \beta^2)^{-1/2}$ is the Lorentz factor. For a particle moving in a plane perpendicular to the magnetic field, the momentum in terms of the orbital radius r , the magnetic flux density, and charge is

$$p = qBr. \quad (50.38)$$

In the ultra-relativistic case

$$E \approx T \approx pc. \quad (50.39)$$

In the *nonrelativistic region*

$$T = \frac{1}{2} m_0 u^2. \quad (50.40)$$

Note, however, that at nonrelativistic speeds it is much more common to denote the kinetic energy simply by E , which convention will be followed from this point on.

The isochronous cyclotrons can accelerate different particles from protons to the ions of the heaviest elements. The energy of the particles is determined by the setting of the cyclotron, and that can be changed in a wide range. The relativistic behavior of the particles can be neglected for the sake of these considerations. The heavy-ion cyclotron can be specified by the so-called K factor determining the maximum kinetic energy of the ions by the relation

$$E_{\max} = K \frac{z^2}{A} \quad (50.41)$$

where $z = q/e$ and A are the charge state and mass number of the ion, respectively, and E_{\max} is measured in MeV.

50.3.4.2 Intensity

The average intensity of a beam is usually given as an electric current, generated by the charge of moving particles through a cross section of the beam tube. Other usual units are particle electric current (electric current divided by the charge state of the ions of the beam) and the number of particles in unit time (pps meaning particle per second) or in one pulse.

The beams coming from cyclic and linear accelerators consist of short pulses of particles, that is, their beam has a time structure as shown in [Fig. 50.25](#). The repetition frequency of the bunches (“microstructure”) is determined by the RF system, while the “macrostructure” can be varied by switching on and off the acceleration process. Taking into account the *duty factor*, which is the fraction of time when there is current, the peak current is much higher than the measured average current of the beam.

The distribution of the beam intensity in the plane normal to the beam direction (i.e., its cross section) defines the size of the beam. The shape of the beam is usually an ellipse. The horizontal and vertical dimensions have special importance; these values are calculated by ion-optical calculations and, as a rule, they are measured by beam diagnostic devices. The size and shape of the beam vary along the beam line; where the size is small, its angular divergence is large. The distribution of the particles inside the beam is not uniform. To a first approximation,

■ Fig. 50.25

Time structure of the beam

it can be taken to be Gaussian around an axis. In some cases, the particle distribution may show a high peak, which is named a “hot spot” of the beam.

50.3.4.3 Emittance and Acceptance

The beam consists of a large number of particles. Most of them move along orbits that differ from the equilibrium orbit (e.g., the axis of a beam line). This behavior is characterized by the property called the emittance of the beam. This parameter is derived from considerations of the particle motion in the phase space, which is a six-dimensional hyperspace composed of the particle coordinates (x, y, z) and the three momentum components (p_x, p_y, p_z) (Banford 1966).

The volume of the hyperspace populated by the particles remains constant (Liouville’s theorem), while the shape and the magnitude of its various cross sections may vary along the beam line. At beam transportation (which is done by steering, bending, and focusing), the motions in the propagation direction (z -axis) and in transverse directions (x - and y -axes) are mutually independent, so the motion in the planes (x, p_x) , (y, p_y) , and (z, p_z) can be treated separately. The axial momentum of the particles can be taken to be constant, and, instead of p_x and p_y , the angular divergence x' and y' can be used to represent the beam in the two-dimensional phase space of (x, x') and (y, y') . The displacement from the axis and the divergence are directly observable quantities. The particles composing the beam cover regions with their (x, x') and (y, y') coordinates in this phase space, which can be circumscribed by ellipses or parallelograms.

The emittance of the beam is the area of this region, which will not change during the transportation. In other words, one of the parameters can be decreased only at the expense of an increase of the other one. If the axes of the ellipse coincide with the coordinate axes x – x' or y – y' , the position of the phase ellipse is normal (“waist” in the beam envelope). The emittance in the horizontal (x, x') and vertical (y, y') planes are used to represent the beam.

The *transportation of a beam* requires manipulation on the phase space regions to arrive at a desired shape. The shape and the orientation of the phase space ellipse can be changed by positioning and setting the optical elements. To decrease the beam loss on the collimating system of an experimental chamber, the emittance of the beam should match the acceptance of the experimental setup (see ► Fig. 50.26). The *acceptance* of a device is the phase space area containing all the points whose input displacement and divergence coordinates are such that the particles having those values will be transmitted. If the acceptance required by the

■ Fig. 50.26

The acceptance of a hypothetical device is represented by the rectangles and the emittance of the input beam by the ellipses. In diagram (a), the beam emittance is too big for complete transmission whatever its shape is. In diagrams (b) and (c), the emittances are equal or less than the acceptance. The beam is correctly shaped and therefore transmitted completely only in diagram (c)

experiment is smaller than the emittance of the beam, then the unused part of the phase space ellipse should be cut (i.e., the particles having the required parameters are selected from the beam, and physical obstacles are used to prevent the passage of the unwanted particles). Therefore, the transportation can be carried out only with some loss. The optimal places of the diaphragms of the collimating system are to be set by considering various points of view (sources of the background radiation, optics, accessibility, etc.).

50.3.4.4 Luminosity

The term luminosity is used in connection with colliding beam experiments to determine the production rate of a collision. The *instantaneous luminosity* is proportional to the overlap integral to the densities of the two beams. The total number of individual collisions in an experiment is given by the cross section of the collision process times the *integrated luminosity*, which is defined as the instantaneous luminosity integrated over the total time of the experiment. More details can be found in the work of Conte and Mackay (1991b).

50.3.4.5 Brightness and Brilliance

These terms are used to characterize the intensities of the synchrotron light sources. The *brightness* is proportional to the number of photons hitting the target per second. It is inversely proportional to the bandwidth of the photon beam. The *brilliance* is defined as the brightness per area of the source. For more details, see the work of Eriksson (1994).

50.4 Editors' Notes

1. There is an apparent contradiction between the constant speed of electrons and their acceleration. Note that a circulating mass constantly changes its velocity even if the angular

frequency is constant. The rate of this velocity change (called centripetal acceleration) is one of the reasons for the production of synchrotron radiation. The energy loss caused by radiation would, of course, decrease the speed of electrons unless they are constantly accelerated, which they indeed are (p. 2352).

2. In other words, ω_c is the median of the frequency/energy distribution (just like the half-life $T_{1/2}$ is that of the lifetime distribution of radionuclides). See ► Chap. 9 in Vol. 1 on “Stochastics and Nuclear Measurements” (p. 2353).

51.9 *Editors' Notes* 2401

Abstract: Methods of isotope enrichment and isotope separation are reviewed. Several examples of commercially important or historically important separative processes are discussed.

51.1 Introduction

The small differences in chemical and physical properties of the isotopes of all but the lightest elements make their separation from each other unusually difficult. That difficulty is often compounded by the fact that the desired *isotopic molecules* (isotopologues) are often present at low or very low concentration in the starting material.¹ These factors, taken together, imply the processing of very large amounts of feedstock, at high reflux, through numerous separative stages. This, in barest outline, accounts for the high cost of samples of most separated isotopes.

Over the past 50 or more years, the nuclides of greatest industrial and/or military importance have been ^{235}U , the heavy isotopes of hydrogen, $^2\text{H}(\text{D})$ and $^3\text{H}(\text{T})$, and in greatly reduced amount, ^6Li and ^7Li , ^{10}B , ^{13}C , ^{15}N , and ^{18}O . Samples of many other enriched isotopes, chiefly for medical or research use, have been or are available. Very often, these have been obtained by electromagnetic separation, a process which is too expensive for large-scale separations.

During peak production, on the order of \$1 billion of ^{235}U was enriched per year from the natural abundance level (0.7%) to 1.5–4% for use in graphite- or water-moderated power reactors, or at higher enrichment for military purposes. Again, at its peak, worldwide production of deuterium (>99%) from water or other natural abundance feeds (0.015%) was on the order of several thousand metric tons per year. These rates of production demanded large-scale expensive industrial efforts.

A variety of processes have been used to separate isotopes on industrial or large pilot plant scales. These include (for U) gaseous diffusion, gas centrifugation, thermal diffusion, electromagnetic separation, laser-based methods, and various nonequilibrium vapor expansion processes. Because the properties of ^{235}U and ^{238}U are so very similar, the enrichment per separative unit (stage) is very small (except for laser-based methods), and it is necessary to multiply the effect by repeating it many times in a cascade. For enrichment of lighter isotopes (D from H, or ^{13}C from ^{12}C) separation factors are larger and the list of practical processes broadens to include chemical exchange, distillation, electrolysis, and similar methods. Even then, however, enrichment factors are close enough to unity that production of highly enriched samples requires partial separations carried out many times over in a multistage cascade. So far as the basic theory of cascade design is concerned, the particular process or type of separating unit is irrelevant. Once a given separative process has been selected, the design of the individual separative unit completed, and the separation factor per separative stage established, the problem of isotope separation reduces to an understanding of the principles of cascade design. In [Sect. 51.2](#), those principles are reviewed. The theory, originally due to Cohen (1951), was developed for uranium separation during the Manhattan Project (1942–1945). The highly abbreviated version below follows Benedict et al. (1981). Other reviews include those of London (1961), Spindel and Ishida (1990), Villani (1976), and Vértés and Kiss (1987).

51.2 Theory of Cascades: Terminology

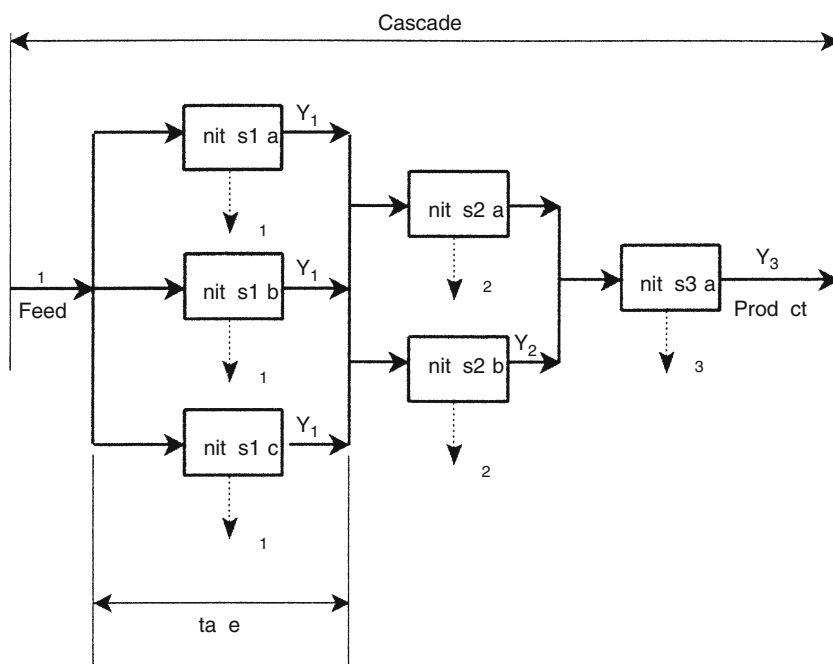

The relation between a separation unit, a stage, and a cascade is outlined in [Fig. 51.1](#).² The smallest element in a separation plant is a unit that might be a single plate in a distillation or chemical-exchange column, a gas centrifuge, a single laser separator, one membrane separative unit, etc. A group of such units, connected in parallel, all taking feedstock of the same chemical and isotopic composition, and producing a partially enriched product stream of different composition is called a stage. Sometimes a single unit serves as a stage, but more often single units have low capacity and many units in parallel are required. Because the separation per stage is generally less than the total required enrichment, stages are usually connected in series; the resulting assembly is called a cascade. A cascade with the same number of units in each stage is “*squared-off*,” while one in which the number of units per stage decrease as the product (or waste) end is approached is a “*tapered cascade*.”

In further discussion, it will be useful to employ the idea of an “ideal” stage, one where the feed stream is acted on to produce two exit streams (one product, one waste) that are in equilibrium with one another. Because actual stages always involve various inefficiencies, the number of stages in a real plant is always larger than the ideal number.

Examination of [Fig. 51.1](#) shows that each separating unit gains feedstock at a rate Z (mol/s) of material of isotopic composition z , and produces an enriched product stream at rate

Fig. 51.1

Relationships between separative units, stages (s), and cascades. The cascade shown is tapered; see text for other definitions

Y and isotopic composition y , and a waste stream at rate X and composition x . Material balance demands $Z = X + Y$ and $Zz = Xx + Yy$.

It follows that $Y/Z = \theta = (z - x)/(y - x)$ and $X/Z = (y - z)/(y - x)$. Y/Z , the ratio of heads to feed flow rates, is known as the “cut,” θ . The fraction of desired component in the heads stream is the “recovery,” $r = (yY)/(zZ) = y\theta/z$. The overall “separation factor,” α , is the ratio of head to tail isotopic ratios.

$$\alpha = \frac{y/(1 - y)}{x/(1 - x)}. \quad (51.1)$$

It is also convenient to define head-to-feed or tail-to-feed separation factors, β and γ .

51.3 Types of Separations: Cascades

51.3.1 Rayleigh Separation

Consider a separating unit where the heads, enriched in one component, are slowly removed (at zero feed) so the material remaining in the stage is progressively depleted in that component. A one-plate batch distillation from an unreplenished pot is a good example; the problem is equivalent to a differential separator fed with a continuously varying feed of tails composition. Equations governing such a separation were first deduced by Lord Rayleigh (1902), who found

$$\ln\left(\frac{X}{Z}\right) = \int \frac{1}{\alpha' - 1} \left[\frac{\alpha'}{1 - x} + 1 - x \right] dx, \quad (51.2)$$

where α' is the instantaneous or “local” separation factor.

For the case $|\alpha' - 1| \ll 1$, remembering that $X/Z = (1 - \theta)$, one obtains:

$$\alpha_{\text{overall}} - 1 = (\alpha' - 1) \left(1 + \frac{\theta}{2} + \dots \right). \quad (51.3)$$

► Equation (51.3) demonstrates that the overall separation factor (i.e., the ratio of isotopic compositions of the material remaining in the pot to that stripped away, and which is the parameter of practical usefulness) is greater than the instantaneous (single stage) α' and becomes much greater as the cut, θ , approaches unity. None of this is particularly surprising. The equations simply state that if one starts with a mixture and slowly strip away the more volatile component, at the end one will be left with a pot containing a sample highly enriched in the less volatile component. This multiplicative feature of Rayleigh distillation has tempted many workers into using it to determine single-stage separation factors, α' , but this is dangerous because experimental errors are multiplied as the stripping ratio increases. The assumption of an unvarying long-term state of equilibrium throughout is hard to meet, and the method is not recommended as a method for determining single-stage separation factors.

51.3.2 Simple and Countercurrent Cascades

A simple cascade is one where the feedstock for each stage, say the i th, is the heads cut from the $(i - 1)$ th stage. The $(i - 1)$ th tails are sent directly to waste as they have insufficient value to

warrant reprocessing. Thus, successive stages process progressively smaller amounts in the ratio of the cuts, θ_i . In a simple cascade, it is impossible to obtain a high recovery of the desired component because of the losses in the tails stream. The method can only be employed when the feedstock is abundant and cheap.

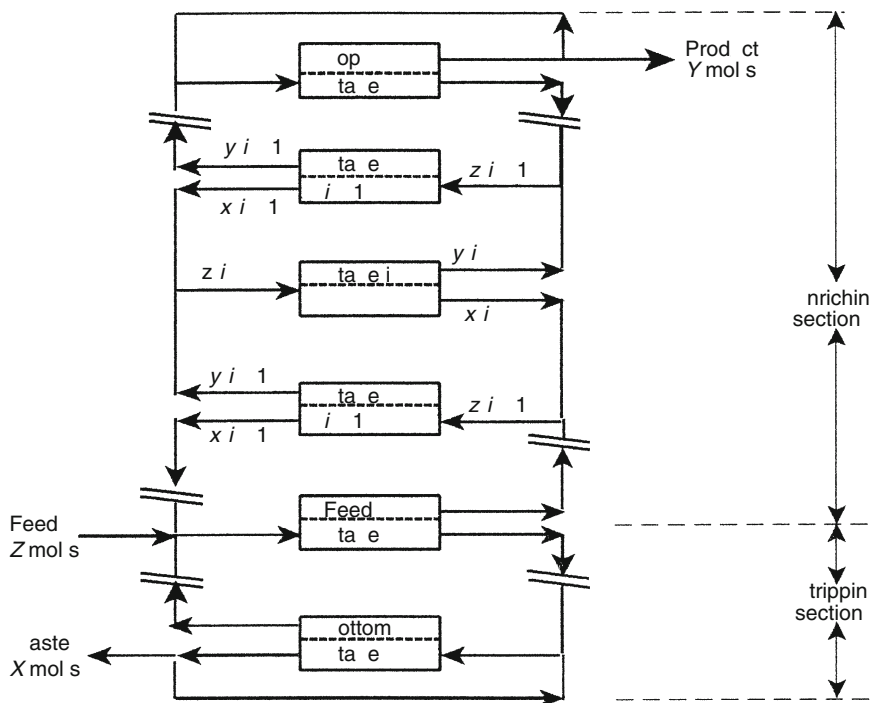

The countercurrent recycle cascade,  Fig. 51.2, is more commonly encountered because costs are usually such that tails warrant reprocessing. Here each stage, say the i th, is fed by a mixture of the heads stream from the $(i - 1)$ th, and tails stream from the $(i + 1)$ th, stages. A distillation column is a good example. Feed is introduced around the midpoint of the cascade. The portion between feed and product end is designated the “enriching” section, and the portion between feed and waste withdrawal, the “stripping” section. The enriching section is essential to give the desired product, the stripping section only serves to reduce the amount of feed required per unit amount of product.

If feed is cheap, e.g., natural water fed to a deuterium separation plant, the stripping section might be dispensed with. The countercurrent streams moving from product or waste ends back to the feed point are known as “reflux” streams. Materials balance requires the sum of product and waste withdrawal rates to equal the feed rate.

The processing rate, however, is much larger because countercurrent reflux material is being continually processed and reprocessed.

 Fig. 51.2

Separative stages arranged in a countercurrent recycle cascade

In short, one finds

$$y_i - x_{i+1} = \frac{(y_p - y_i)}{X_{i+1}/P}. \quad (51.4)$$

Here y_p is the isotopic composition at the top stage, P is the product withdrawal rate, and, as before, X_{i+1} is the tails withdrawal rate at the $(i + 1)$ th stage. The ratio (X_{i+1}/P) is the reflux, which for a simple countercurrent cascade is independent of stage number (i.e., such a cascade is squared off). Note that y_i and x_{i+1} approach each other as X_{i+1}/P approaches infinity, which happens at total reflux. In that case, the number of stages required to carry out a given overall separation is a minimum and is given by the *Fenske equation* (Fenske 1932):

$$n_{\min} = \frac{\ln \left[\frac{y_p/(1 - y_p)}{x_w/(1 - x_w)} \right]}{\ln \alpha}, \quad (51.5)$$

where x_w is the isotopic composition of the waste.

Equation (51.5) shows n_{\min} increases as the overall separation is increased and as the separation factor α gets closer and closer to unity. For the latter reason, the minimum number of stages required for isotope separation can be very large. To cite a practical example, in a ^{235}U diffusion plant with $\alpha = 1.0043$, producing 90% enriched product, and rejecting 0.3% tails, from natural uranium (0.7%) feedstock, $n_{\min} \approx 1,870$. Of course, under the conditions of total reflux no product is withdrawn, it is all held in the cascade as inventory. For finite product withdrawal, even more stages will be required.

With infinite (total) reflux, the concentration ratios on successive stages reach their maxima. Conversely as the reflux ratio decreases the concentration ratios follow. They reach unity (no enrichment) at minimum reflux. Material balance considerations yield an expression for the minimum reflux ratio (Eq. (51.6)).

$$\left[\frac{X_{i+1}}{P} \right]_{\min} = \frac{x_p(\alpha x_{i+1} + 1 - x_{i+1}) - \alpha x_{i+1}}{(\alpha - 1)x_{i+1}(1 - x_{i+1})} \quad (51.6)$$

When α is close to 1 the minimum reflux ratio is large. At the feed point in the uranium plant enriching to 90% ^{235}U , the minimum reflux ratio is 29,100, but at the product end of the cascade, it approaches zero.

Clearly a practical separation plant can operate at neither minimum reflux (where the separation is zero, but the rate of production is high), nor at minimum number of stages (where the rate of production is zero, but the separation is high). A compromise is required. Because for given separation the optimum reflux varies with stage number, it is usual to design “tapered” cascades for isotope separation. This results in marked savings in material hold-up in the cascade, and in plant size and investment, but at the cost of a more complicated design and increased operating complexity.

51.3.3 The Ideal Cascade

An ideal cascade is one which is tapered to yield minimum interstage flow and thus minimum operating cost. In an ideal cascade, the heads stream from the $(i - 1)$ th and the tails stream from the $(i + 1)$ th stages are mixed to form the feed to the i th stage. Obviously for best efficiency the two streams should be of identical isotopic composition, otherwise some separative work is

being used to no good purpose. Materials and isotope balance considerations lead to the result that the number of stages in an ideal cascade is just twice the minimum number of stages at total reflux, less one. Expressions for the ratio of the numbers of stages in the stripping to enriching sections are available (Benedict et al. 1981). The function that describes the tapering depends sensitively on the single-stage separation factor and the overall separation required. For the presented illustration (^{235}U separation with $y_p = 0.9$, $x_w = 0.003$, $z_f = 0.007$, and $\alpha = 1.0043$, where z_f is the feed composition), one finds that 213.6 moles of feed results in 212.6 moles of depleted tails (waste). The number of stages is twice the minimum less one, or 3,738, with 410 stages in the stripping section and the rest in the enriching section. The figures are characteristic of uranium enrichment using gaseous diffusion and natural abundance feedstock. The interstage flow at the feed point, $i = 410$, is enormous, $M_{410}/P = 58,229$, but decreases rapidly as one moves away from the feed point. ▶ Figure 51.3 represents this schematically.

Figure height is proportional to stage number, and width to interstage flow. A proportionality between interstage flow and capital investment and energy demand is expected. Once feed product and waste isotopic abundances are set, the plant size diverges to infinity with α approaching 1 according to $1/(1 - \alpha)^2$. It is therefore of the utmost importance to select a practical process with the largest possible α in order to minimize plant size and capital investment. Still, α is small for many isotope separations and this accounts for the

■ Fig. 51.3

Ideal cascade for uranium isotope separation

enormous size (cost) of industrially important isotope separation plants. For the presented example of gaseous diffusion enriching uranium, about 42×10^6 moles of UF_6 must be processed for every mole of 90% $^{235}\text{UF}_6$ product.

51.3.4 Equilibrium Time

This section is concluded with brief remarks on the time required to bring the cascade from start to first withdrawal of product. Due to their large size, many isotope separation plants have inventories that correspond to many days of normal production. [Equation \(51.7\)](#) is an approximate relation between the time to first production, t_p , feed and product isotopic compositions at equilibrium, single-stage separation factor, α , and the residence time per stage, h , for a cascade like that in [Fig. 51.3](#). The behavior of t_p is similar to that for plant size, i.e., t_p diverges to infinity proportionally to $1/(1 - \alpha)^2$.

$$t_p = \frac{8h}{(1 - \alpha^2)} \left[\frac{y_p - 2y_p z_f + z_f}{y_p - z_f} \ln \frac{y_p - z_f}{z_f(1 - y_p)} - 2 \right]. \quad (51.7)$$

For the 90% ^{235}U example, and taking $h = 1$ s, $t_p \approx 30$ days. In cascades that are not tapered, t_p will be even longer because of the increased inventory of enriched material in upper stages.

Long time to production implies the necessity for safeguards against stage-to-stage remixing in the event of power failure or other problems. In a distillation plant a power failure causes the column to drain and results in isotope remixing in the boiler. It is then necessary to start over at considerable economic and emotional cost.

51.4 Isotope Separation Processes

The selection of a particular separative process including the design of individual units and their incorporation into a cascade depends principally on engineering and economic considerations. These must take account of the desired output, available starting material, energy demands, etc. It comes as no surprise, then, that a wide variety of methods have been used for isotope separation. The more important of these are listed in [Table 51.1](#), and, in the balance of this chapter some will be briefly discussed.

Table 51.1

Commonly used methods for isotope separation

Electromagnetic	Electrolysis
Thermal diffusion	Electromigration
Gaseous diffusion	Chromatography
Gas centrifuge	Ion exchange
Chemical exchange	Supersonic nozzle expansion
Distillation	Mass or sweep diffusion
Exchange distillation	Membrane pervaporation
Photochemical and laser	

The aim is to illustrate the principles above, and not to give an exhaustive review of methods of isotope separation, nor a detailed treatment of any one method. Useful reviews of isotope separation have been given by Kistemaker et al. (1958), London (1961), Bigeleisen (1969), Spindel (1975), Rae (1978), Benedict et al. (1981), and Spindel and Ishida (1990), among others.

While the single-stage factor α is the best single measure of separative ease, a process cannot be optimized on that basis alone. Engineering considerations, and convenience, are also important. Even for a given isotope there is no single best method, but experience over the past half century or more demonstrates that *electromagnetic separation* is the most versatile means for the production of small quantities of isotopes of moderate to heavy mass. Alternatively, the simplest and most inexpensive method for small-scale separation of isotopes of light to moderate mass is the *thermal diffusion column* (Clusius and Dickel 1938). However, for large-scale separation of light elements, distillation and/or chemical exchange or exchange distillation are the best. For heavy elements (read uranium), gaseous diffusion and gas centrifugation have been employed on large scale, together (more recently) with various separative processes based on laser technology.

51.4.1 Electromagnetic Separation

Electromagnetic separators (large-scale mass spectrometers, also known as “*Calutrons*” because they were originally developed at the California cyclotron laboratory), were constructed at Oak Ridge in the early 1940s to separate ^{235}U from natural abundance feed in kilogram quantities. This method of uranium isotope separation was discontinued in 1945 because of high cost. Under high vacuum conditions, it is possible to obtain genuinely large separation factors in an electromagnetic separator (high resolution in the language of the mass spectroscopist), but this important advantage is offset with a number of difficulties. To begin, the source must be chemically treated to provide compounds of appropriate volatility and chemical purity. More importantly, the electromagnetic process has inherent high losses. First, only a small fraction of feed is ionized and then extracted through the electrical accelerating slits. There are scattering losses in the beam, and space charge effects result in high loss and degradation of separation factors as ion current increases. These factors work against electromagnetic separation for large-scale isotope production, although the method is well suited for preparing small quantities (milligram to gram) of separated isotopes for research and specialized medical purposes. As an example, consider the medical products company “*Theragenics*,” which produces a “rice-sized” implantation seed of ^{103}Pd used for the treatment of prostate cancer. The separated isotope is currently produced using cyclotrons, but the company plans to employ a new production facility using refurbished plasma separation equipment purchased from the Department of Energy, Oak Ridge. Also, it will soon expand operations and produce isotopes for other medical therapies. Another, and apparently more versatile facility designed for the electromagnetic preparation of small amounts of separated (usually high mass) isotopes is the ISOLDE online isotope separator at the European accelerator facility CERN. This facility has been recently described in detail by Kugler (2000) and Habs et al. (2000).

Many of the problems in electromagnetic separation are rooted in the technology of handling plasmas at high charge density. They are analogous to the ones experienced in the controlled thermonuclear fusion program. Developments there might result in a new look at large-scale electromagnetic isotope separation.

51.4.2 Thermal Diffusion

When a gas mixture is subjected to a temperature gradient, diffusion occurs and a concentration gradient is established. Enskog (1911) and Chapman (1916) deduced the transport equation, which relates separation factor, θ , to the temperature gradient.

$$\ln \theta = g \ln \frac{T_2}{T_1}. \quad (51.8)$$

The thermal diffusion factor, g , can be obtained from the kinetic theory of gases if the intermolecular potential is known. In first order, it is proportional to $(m_2 - m_1)/(m_2 + m_1)$. Momentum transport vanishes for particles following an inverse sixth power potential. If the potential falls off with a power greater than six, the lighter molecule concentrates in the high-temperature region, and if less than six it concentrates in the cold region. Calculation shows that g is small for mixtures of isotopes (order 10^{-2}), but Clusius and Dickel (1938) successfully developed an elegant countercurrent apparatus that multiplies the elementary effect.

A schematic diagram of a Clusius–Dickel column is shown in Fig. 51.4a. An electrically heated wire or tube runs down the axis of a cylinder with a refrigerated wall.

The resulting temperature gradient establishes thermal diffusion in the radial direction and the consequent mass gradient causes convection. Molecules near the center move up the tube with respect to gas near the cold wall. The countercurrent flow thus established leads to multiplication of the elementary separation factor. The theory of such columns has been developed in detail, but will not be reviewed here (Jones and Furry 1946; London 1961).

In practical application a number of individual thermal diffusion columns, each about 3 m long, are connected in a cascade. Fig. 51.4b shows a cascade of 11 columns used to

Fig. 51.4

(a) Hot Wire Thermal Diffusion Column (Clusius–Dickel column). (b) Four-stage thermal diffusion cascade for argon isotope separation

separate argon isotopes at Mound Laboratories USDOE (or its commercial heir, Isotec Corp.). Separations and production rates are indicated (notice that ³⁸Ar concentrates in the middle of the cascade, which in this case is operated without a stripping section). Thermal diffusion dissipates large amounts of power, and for that reason, it is primarily of interest for laboratory-scale separations. Results illustrating the versatility of the method are given in ▶ [Table 51.2](#).

51.4.3 Large-Scale Separations, Energy Demands, and Comparisons

Sections 0 and 0 demonstrate that almost any desired isotope can be separated by thermal diffusion or electromagnetic methods on a small scale. For large-scale separation, enormous amounts of material must be processed and energy consumption, cascade design, and other such factors become important. ▶ [Tables 51.3](#) and ▶ [51.4](#) list theoretical upper limits of single-stage separation factors for H/D, ¹²C/¹³C, and ²³⁵U/²³⁸U for several different separative methods.

■ [Table 51.2](#)

Isotopes separated by K. Clusius and coworkers by thermal diffusion (Clusius and Dickel [1938](#); Clusius and Starke [1949](#))

Year	Isotope	Abundance (%)	Separation factor	Final purity
1939	³⁵ Cl	75.7	53	99.4
1939	³⁷ Cl	24.3	775	99.6
1942	⁸⁴ Kr	57.1	45	98.3
1942	⁸⁶ Kr	17.5	940	99.5
1950	²⁰ Ne	90.5	210	99.95

Comparison of separation factors for some isotopes using different methods

Method	H/D	¹² C/ ¹³ C	²³⁵ U/ ²³⁸ U
Chemical exchange	3	1.02	1.001
Distillation	1.05–1.7	1.01	1.0000
Gaseous diffusion	1.2	1.03	1.004
Centrifuge, 250 m/s	1.01	1.01	1.026

■ Table 51.4

Some H/D separation factors for distillation

Compound	T/K	P/kPa	Separation factor
Hydrogen	24	250	1.5
Methane	112	100	1.0036
Ammonia	239	100	1.036
Water	378	120	1.024

It has been shown that α values of a few tenths percent or so, lead to reflux ratios at the feed point of 10^4 or greater. In gaseous diffusion, UF_6 diffuses from high to low pressure through a porous membrane. The upper limit of the separation factor is given by Knudsen theory of molecular flow. In an ideal cascade with $(\alpha - 1) \ll 1$, theory optimizes the cut at each stage, $\theta = 0.5$. The minimum reflux energy is therefore the work of ideal recompression, $RT \ln 2 = 1.9 \text{ kJ/mol}$ at 333 K. The real compression is not isothermal and warms the gas by about 5%. That heat must be removed at each stage, which increases the compressor bill from ~ 1.9 to $\sim 2.0 \text{ kJ/mol}$ of gas processed. If, roughly, one assumes the equipment operates at one half the ideal efficiency, the energy cost increases to $\sim 4 \text{ kJ/mol}$. For the example of the uranium plant that was discussed approximately 42×10^6 moles are processed for each mole of 90% ^{235}U product (Benedict et al. 1981). Thus the energy demand, just for reflux, is estimated at an enormous $17 \times 10^{10} \text{ J/mol}$ product. A more realistic calculation based on a 1972 DOE estimate for its then most efficient plant gives almost 2.5 times that $45 \times 10^{10} \text{ J/mol}$ total energy demand. In 1975, at or near the peak of production, installed gaseous diffusion capacity for ^{235}U was $\sim 3.2 \times 10^5$ moles/year (Spindel 1975), which if completely used would have required a power input of $\sim 4,500 \text{ MW}$.

Of course, at any given time, a large fraction of the separative capacity was not being used, or was only being used for partial enrichment (from 0.7 to 3.5% or 4% as required for fueling nuclear power plants). However, even the scaled down demand was enormous. It was almost certainly responsible for the decision to phase out gaseous diffusion enrichment replacing it with gas centrifugation or laser separation processes (*vide infra*).

Now compare the energy demand for reflux in gaseous diffusion with that required for distillation. In an ideal distillation, heat must be added only at the boiler, and extracted only at the condenser. In between there are many separating units (plates or stages) where vapor is continually condensing and liquid continually evaporating. However, the heat of vaporization is exactly the negative of the heat of condensation, so if the column is perfectly adiabatic, the plates in the column do not contribute to the energy demand. A well-designed laboratory distillation column has on the order of 100 plates in a 1 or 2 m length, so the energy cost per stage is around a percent or so of the heat of vaporization, and the reflux cost is several tens rather than several thousands of joules per mole processed. When chemical exchange is compared with distillation, the reflux energy increases by about a factor of ten, i.e., it is now proportional to the heat of chemical reaction rather than to the heat of vaporization. The height equivalent per theoretical plate (HETP) also increases, and energy demand per stage rises from several tens to several hundreds of joules per mole processed.

One can now appreciate the reasons for the high cost of enriched uranium. The single-stage separation factors are low, as is the natural abundance. This leads inexorably to a high reflux

demand and a large number of stages. Additionally, the historically practical processes have a large reflux cost, and the result is an extremely expensive product. The world is now blessed (?) or cursed (?) with a large oversupply of enriched uranium. Consider how much sooner this might have occurred were there a practical uranium distillation process with cheap reflux.

51.4.4 Gaseous Diffusion

The examples discussed in earlier sections were chosen to illustrate principles of cascade design for gaseous diffusion in a UF_6 separation plant because of historical and engineering interest in that process. Design details are classified or confidential, but in essence the gas is fed at the higher pressure into a set of parallel tubes with porous walls. The process is simplified by virtue of the fact that there is only one natural isotope of fluorine, so all enrichment is due to uranium isotope effects. The diffusion through the pore structure can be described in the limit by the laws of Knudsen flow. UF_6 is extremely reactive, and much of the technology focuses on the handling of this dangerous material in quantity. Design details of the diffusion tubes are not available but presumably the walls are constructed from a spongy alloy of high nickel content. To appreciate the genuinely large scale of the operation, one should note that the Portsmouth, Ohio facility (now closed) involved a production facility that covers 93 acres ($\sim 0.38 \text{ km}^2$), but has a floor area nearly three times larger than that ($\sim 1 \text{ km}^2$), since much of the plant has several stories.

51.4.5 Centrifugation

The use of centrifuges for isotope enrichment was suggested as early as 1919 by Lindemann and Aston (1919), but successful experiments awaited the development of vacuum centrifuges by Beams and coworkers in the late 1930s (Beams 1938). The devices rotate in vacuum chambers suspended on metal capillaries through which gas is introduced and withdrawn. Thorough discussions have been given by London (1961) and Benedict et al. (1981).

In a centrifugal field, the energy per mole at distance r from the axis is $M(\omega r^2)/2$, where M is molar mass and ω angular velocity. The ratio of partial pressures (p) for two isotopologues (primed and unprimed) at the wall, r_w , and on the axis, r_0 , yields the elementary separation factor.

$$\alpha = \frac{p'(r_w)/p(r_w)}{p'(r_0)/p(r_0)} = e^{\frac{(M'-M)(\omega r_w)^2}{2RT}}. \quad (51.9)$$

► Equation (51.9) shows α to be a simple function of the absolute (molar) mass difference, $(M' - M)$. This is in contrast to most methods of isotope separation where α depends on the ratio of masses, or the ratio raised to some power. Centrifuge α' values for $^{235}\text{UF}_6/^{238}\text{UF}_6$ at several peripheral speeds are shown in ► Tables 51.5 and ► 51.6. The values are far above those for gaseous diffusion.

► Figure 51.5 is a schematic diagram of a countercurrent gas centrifuge separation unit with externally pumped streams. Important problems of shaft and bearing design, frictional loss, vibrational damping, materials of construction, and strength of materials are relevant. Already in 1961, London (1961) compared maximum peripheral velocities of thin wall steel,

■ Table 51.5

Separation factors α for $^{235}\text{U}/^{238}\text{U}$ in a centrifugal field as a function of the peripheral speed (ωa) and relative radial position (r/a), where $a = r_w$ is the rotor radius

r/a	400 m/s	500 m/s	700 m/s
0	1.101	1.162	1.343
0.5	1.075	1.119	1.247
0.8	1.035	1.056	1.112
0.9	1.018	1.029	1.058
1.0	1.0	1.0	1.0

1.0	1.0	1.0	1.0

titanium, and glass fiber rotors (318, 427, and 527 m/s, respectively). More recent materials have moved this level beyond 700 m/s where the UF_6 separation factor is in excess of 1.3.

It is interesting to compare the economics of gas centrifugation to gaseous diffusion, albeit crudely. London (1961) divides enrichment cost into two principal categories: (1) specific investment, i.e., capital cost per separative work unit (SWU) amortized over the plant life, and (2) power cost per SWU. (SWU, which is a function of quantities and concentrations of feed, product, and waste provides a quantitative measure of the isotope separation task for any conceivable process.) The latter comprises the bulk of operating costs. The estimates, which are crude, clearly demonstrate an advantage for gas centrifugation.

These considerations led the European community to elect gas centrifuge production for enriched uranium to be used in its power production facilities. The United States also turned away from gaseous diffusion because of its high cost. Its diffusion plants have been retired. After extensive development a large gas centrifuge facility was constructed, but that in turn was abandoned in favor of even more economical laser separation processes (see below). In around 2002, the laser separation plants have also been closed, presumably due to present day oversupply of enriched uranium.

51.4.6 Aerodynamic Isotope Separation

The basic idea of aerodynamic isotope separation is illustrated in ▶ Fig. 51.6a. Feed, such as UF_6 , diluted with light gas, H_2 or He , to a total pressure ~ 2.5 kPa, is fed through a slit-shaped

■ Fig. 51.5

Gas centrifuge isotope separation unit

nozzle into a region of much lower pressure. The flow is such that the velocity in the forward direction is supersonic. Because of kinetic-molecular effects a certain fraction, θ , diverges from the feed jet (~ 0.05 mm) enriched in the lighter isotope, while the rest of the jet passes through a second and somewhat wider “skimming” slit (~ 0.2 mm). An alternate radial design, [Fig. 51.6b](#), yields significantly larger separations.

51.5 Distillation and Exchange Distillation: Large-Scale Production of Deuterium

It is instructive to use the case of enriched deuterium production to describe distillation and exchange distillation isotope separation. To begin, the historical background of the need for

■ Fig. 51.6

(a) Schematic of a crude nozzle aerodynamic separator. (b) An improved nozzle separator

deuterium, the magnitude of world demand, and related questions will be commented on. Historically, the principal demand for deuterium was in the form of heavy water, D_2O , for use as a moderator in certain types of nuclear reactors. Deuterium is an excellent neutron moderator, and more importantly, has a low-absorption cross section for slow neutrons. Therefore, a reactor moderated and cooled with D_2O can be fueled with natural uranium and thus avoid the problems of uranium isotope enrichment. This was the route chosen by Atomic Energy of Canada for its nuclear electric power program. Their CANDU reactors (CANada Deuterium Uranium) require approximately 0.8 t D_2O per megawatt (McAlpine and Evans 1985), and cumulative Canadian production exceeds 11,000 t. American production ended in 1981 after cumulative production of $\sim 7,000$ t. That material had been mostly used as a moderator in reactors breeding plutonium from uranium fuel. The United States, and most worldwide nuclear power programs, use pressurized normal water reactors. There are no large-scale commercial uses of deuterium except as a moderator in power production or breeder reactors. One can assume that deuterium and tritium were used in weapons programs, but that activity is tapering off, and hopefully will soon end. In spite of the large number of bombs in military stockpiles, 1945 to present, this should not have amounted to any significant fraction of world deuterium production. Also, although deuterium is widely employed in scientific research, this does not consume any large fraction of the available stockpile.

The very low D/H natural abundance ratio (0.015%, 150 ppm) is the factor responsible for the high cost of heavy water. Materials balance shows it to be necessary to process a minimum of 8,000 mol feed per mol of product, and even more for reasonable values of tails analysis (for more recent GS plants the feed/product ratio reached nearly 40,000 to 1).³ At peak, Canadian production is ~ 800 t/year, which means feed quantities approaching 2.4×10^6 t/year. Such amounts demand cheap and easily accessible feed (i.e., water), or alternatively, require D production to be parasitic on some other large industrial process, e.g., NH_3 used for fertilizer production or petrochemical processing. However, very often even large-scale industrial facilities are not large enough to be a practical source of deuterium on the scale described above.

► Table 51.7 contains a partial list of possible processes for heavy water production. Distillation, while the simplest, is prohibitively expensive (except for low-temperature

■ Table 51.7

Possible processes for heavy water production (Rae 1978)

Process	Remarks
Distillation	Size excessive, except for H ₂
Chemical exchange	Most promising
Diffusion	Barrier or membrane cost excessive
	High energy demand
Electrolysis	Excessive energy cost
Gravitational	Excessive energy cost
Adsorption	High absorbent volume
Biological	Excessive volume
Crystallization	Impractical on large scale
Selective photochemical	Promising if selectivity approaches 10 ⁴

distillation of H₂/HD) because the α values are too close to 1. This implies high reflux, and large capital investment. A small-scale Indian plant used water electrolysis followed by hydrogen distillation (~ 14 t/year D₂O), and several somewhat larger plants (~ 65 t/year), parasitic to fertilizer production, and based on ammonia distillation or ammonia–hydrogen exchange have been described (Galley 1983).

In view of the enormous quantities of methane processed in the petroleum and natural gas industries, it is unfortunate that the separation factor for CH₃D/CH₄ is unattractively small. Of the other processes in ■ Table 51.7, most have high energy or large capital cost per SWU. Laser and photochemical methods continue to be investigated but have not proven economical for H/D separation, even on small scale (McAlpine and Evans 1985). Historically, and still at present, the most promising methods are those based on chemical exchange (H₂S/H₂O, H₂/H₂O, H₂/NH₃). These equilibria have large separation factors that are pronounced functions of temperature. This allows the design of dual temperature processes, which provide efficient thermal refluxing and yield decided economic advantage. Other exchange processes employ chemical refluxing, normally much more expensive.

Because of the very large enrichments required in heavy water production, cascades must taper markedly. In the upper stages the relative advantage of chemical exchange over water distillation vanishes. Most heavy water plants carry out the last portion of the enrichment by distillation (from 20 to 30 atom percent D to 99.85%). Accordingly both exchange and distillation will be briefly treated in this section.

51.5.1 Monothermal Isotope Exchange, the ¹⁵N Example

Taylor and Spindel (1958) described the preparation of 99.8% ¹⁵N using the reaction,

The reaction occurs at acceptable rate for $[\text{HNO}_3(\text{aq})] = 10$ M, $T = 298$ K, with $\alpha = (^{15}\text{N}/^{14}\text{N})_{\text{aq}}/(^{15}\text{N}/^{14}\text{N})_{\text{gas}} = 1.055$. The value calculated from the theory of isotope effects⁴ and

spectroscopic data is 1.096, so there appears to be an exchange between species other than NO(g) and HNO₃(aq). In the actual process, aqueous acid flows downward through a packed column countercurrent to an uprising gas stream containing the NO. A two-column cascade was employed in which 4% of the acid flow was shunted to the upper stages, and the remaining 96% decomposed to NO for recycle by treatment with SO₂. The depleted NO from the lower section is mixed with air and water to generate a waste HNO₃(aq) flow. Thus, the Spindel–Taylor process based on ▶ Eq. (51.10) separates a nitric acid feed stream into a highly enriched nitric acid product and a slightly depleted nitric acid waste, while converting SO₂(g) and air to H₂SO₄(aq). The minimum ratio of H₂SO₄ to ¹⁵N is 1.5 times the minimum reflux, so for product at 0.998 ¹⁵N generated from feed at 0.00365, with $\alpha = 1.055$, $n(\text{SO}_2) = (3/2)[(\gamma_p - z_f)/z_f][\alpha/(\alpha-1)] = 7,930$. This is a high-reflux requirement. The cost of the consumption of $\sim 8 \times 10^3$ moles SO₂ per mole product is partly offset by the fact that H₂SO₄ is a more valuable commodity than SO₂. It is important to note that even though the cascade is tapered, the amount of reflux chemical required is unchanged from the “squared-off” cascade because reflux demand is proportional to interstage flow at the feed point. The principal advantage of tapering is that it results in much lower holdup of valuable enriched ¹⁵N, and a corresponding reduction in time to production from startup.

51.5.2 Dual Temperature Exchange: The GS Process

To avoid the high cost of chemical reflux, Geib (1946) and Spevack (1957) independently suggested a dual temperature process. Consider application to the H₂S/H₂O exchange known as the GS (Geib–Spevack, Girdler–Sulfide) process. The method exploits the fact that the isotope-exchange equilibrium constant is temperature-dependent. The scheme which results is illustrated in ▶ Fig. 51.7. Here the isotope of interest, D, concentrates in the liquid.

The feed (H₂O) is introduced at the top of a *cold tower* where it equilibrates in a countercurrent multiplate column against a gas stream (mostly H₂S). The D concentration builds toward its maximum at the bottom of the cold tower. The essential distinction between the GS process and standard chemical reflux is that in the GS process, the reflux is carried out thermally. The hot tower serves as refluxer for the cold tower. At the top of the cold tower, an intermediate point in the plant, the D content of the gas stream, u_g , is set by equilibration against the cold feed, the separation factor is α_c , $\alpha_c = [z_f/(1 - z_f)]/[u_g/(1 - u_g)]$. Next, that gas is introduced to the bottom of the hot tower where it equilibrates with the waste flow, $\alpha_h = [x_w/(1 - x_w)]/[u_g/(1 - u_g)]$. (The symbols have been defined in earlier sections.) The overall separation, S , in a stage containing both a hot and a cold tower is $S = \alpha_c/\alpha_h$. Notice that S is an effective separation factor.

Both the hot and cold towers contain a number of plates, so S is much larger than it would be for single equilibrations at the hot and cold temperatures. If the feed abundance is small, the fraction of isotope extracted can be approximated as $(1 - \alpha_h/\alpha_c)$. For the GS process (hot tower temperature = 138°C, $\alpha_h = 1.80$; cold tower temperature = 32°C, $\alpha_c = 2.32$) the recovery of deuterium is 0.224 fraction.

A very large industrial scale GS plant (100 kg/h 99.8% D₂O) operated by Ontario Hydro has been described in some detail by Rae (1978). The GS part of the plant consisted of three stages of hot/cold towers with a total enrichment from natural abundance to 20% D₂O. Each tower

■ Fig. 51.7

Schematic of dual temperature GS plant. First stage steel towers are ~7 m diameter, and 60 m high

contained a hot and cold section. Deuterium is carried forward to the second and third stages only in the gas phase. Any deuterium not extracted is returned to waste (Lake Huron) after removal of H_2S (i.e., there is an H_2S stripper to satisfy environmental regulations, but there is no deuterium stripping).

The plant tapers markedly between towers 1 and 2, and 2 and 3. Because deuterium recovery increases with increasing α_c/α_h , it might be supposed the hot tower should run at as high a temperature as possible, and the cold tower at as low a temperature as possible, and this would be so in the absence of complications. The selection of 30°C – 32°C for t_c is necessary in order to avoid precipitation of solid hydrate H_2S – H_2O . In GS pilot plant operations, freeze-ups regularly occurred until t_c was raised above 30°C . The optimum t_h , 130°C – 140°C , is determined by balancing the improvement in overall separation (S) as t_h increases against higher heating costs.

The discussion of the GS process will be closed with the comment that it is dangerous. A GS plant requires a large inventory of highly toxic H_2S , which is employed at elevated temperature and pressure in a corrosive environment. Safety of operating personnel and of the population in the area surrounding the plant is a major concern.

Bigeleisen (1958, 1969) has discussed the separation factors for a number of exchange reactions that involve hydrogen. The ones with the highest separation factors also have the largest temperature coefficients; see ► Fig. 51.8.

It is interesting to note that the GS process, which has one of the smallest separation factors of those shown, appears to be the most practical large-scale industrial process. That is because the kinetics of the exchange are favorable, even in the absence of a catalyst. That factor, combined with the further advantage that an abundant and cheap feedstock (water) is employed, and that the process is nonparasitic (i.e., not coupled to a large-scale production plant for some chemical commodity), accounts for the dominance of the GS method.

Even so, a good deal of effort has been applied to other systems that show larger separation factors. Could they be efficiently implemented, plant size and capital investment per product unit would drop significantly. To that end, Butler et al. (1978) described nonwetting catalysts that allow efficient H_2O –HD exchange. Delmas et al. (1969) reported work on amide catalyzed NH_3 /HD exchange at low temperature. Note that separation factor is ~ 8 at liquid ammonia temperatures. Galley (1983) has reviewed work on catalyzed exchanges between hydrogen and methyl amines. This process is designed to be parasitic on Haber–Bosch ammonia synthesis plants.

51.5.3 Distillation

Distillation is a countercurrent process in which equilibrium is maintained between liquid and vapor, normally in a vertical column containing packing, thin wetted walls, or bubble cap plates. The single-stage separation factor for distillation is given by the vapor pressure isotope effect.⁵ Because mixtures of isotopic molecules show little or no nonideality in either liquid or vapor phase (Jancsó et al. 1993), liquid vapor separation factors should be virtually independent of isotope enrichment (plate number), and the analysis of the distillation process is

■ Fig. 51.8

Semilog-plot of deuterium fractionation factor (α_{gas}) vs. the reciprocal of temperature for some compounds of hydrogen (Bigeleisen 1969)

simplified. In large-scale plants, however, there is usually an appreciable pressure drop along the column and thus a change in boiling temperature. In that case, α can no longer be assumed to be independent of plate number.

For most separations of interest the required enrichment usually cannot be managed using a single column and it is necessary to place several columns in series. This can be rather a convenience instead of an annoyance, since in that case the plant can be tapered at column interconnections.

The properties of a fractionating column that are important for isotope separation are (1) the throughput that determines production rate, (2) height equivalent per theoretical plate (HETP) that determines column length, (3) the hold-up per plate that determines plant inventory and time to production, and (4) the pressure drop per plate that should be as small as possible. The choice of a particular column is invariably a compromise between these factors. A voluminous literature concerning the design of columns, packings, and staging is available.

The energy consumption of a distillation plant is an important consideration. In the limit, as for any separative process, it is only necessary to introduce an amount of energy equivalent to the entropy of mixing, $E = T\Delta S_{\text{mix}} = RT[z_f \ln(z_f) + (1 - z_f) \ln(1 - z_f)]$. In practice, however, many irreversibilities arise. To approach the ideal value the column would have to be lengthened to infinity (for complete separation), the boil-up rate varied according to plate number, and the pressure drop made infinitesimally low. This is impossible. If, instead, one elects the common simplification of boiling all liquid in the pot, and condensing all vapor in the head, it follows that to separate one mole of component having abundance z_f from a mixture, at least $1/[z_f(\alpha - 1)]$ moles of the mixture must be boiled and recondensed, even if the column perfectly adiabatic (London 1961). Since the heat of vaporization of a liquid at its normal boiling point is typically $\sim 10RT$ (*Trouton's rule*) the quantity of heat put into the boiler and extracted from the condenser is $q \approx 10RT/[z_f(\alpha - 1)]$ per mole. To take a specific example, consider $^{14}\text{N}_2/^{14}\text{N}^{15}\text{N}$ separation by distillation with $\alpha = 1.0038$, $T = 78\text{ K}$, and $z_f = 0.0074$, in which case $q \approx 2.3 \times 10^8\text{ J/mol}$ of $^{14}\text{N}^{15}\text{N}$. This contrasts with the value of 28 J/mol for the perfectly reversible process. The difference is striking.

Even though the energy demand for distillation is many times the minimum reversible energy for separation, it is still small compared to the energy demand of most irreversible processes. On a laboratory scale the power costs of distillation are almost always low compared to the cost of building and operating the equipment. As the scale of operations increase, however, power costs become proportionally more important; this is because they rise approximately in direct proportion to production rate, but other costs increase more slowly. As a consequence at some point it becomes economic to consider staged columns employing vapor recompression and heat exchangers. In the best case, London suggests energy demand can be reduced significantly, perhaps by as much as a factor of ten. This is well worth a significant increase in capital cost and vapor recompression, or other energy-saving schemes should be (are) an essential feature of industrial-scale isotope separation distillation plants.

51.5.4 Specific Examples, Isotope Separation by Distillation

Distillation plants have been or are being operated for the separation of the following isotopes: (1) D by distillation of hydrogen, water, or ammonia; (2) ^{10}B by distillation of BF_3 or exchange distillation of BF_3 : ether complexes; (3) ^{13}C by distillation of carbon monoxide; (4) ^{15}N by

distillation of NO; (5) ^{17}O and ^{18}O by distillation of water or NO; (6) ^{22}Ne by distillation of neon; (7) ^{36}Ar by distillation of argon. There may be others not listed.

Single-stage factors, $\alpha = P'/P$, the prime referring to the lighter isotopologue, are given to good approximation by the vapor pressure ratios of the separated isotopologues, although there may be corrections for excess free energies of mixing in both liquid and vapor phases. Also, to good approximation, $\ln \alpha = A/T^2 - B/T$. The positive constant A is characteristic of each particular isotopologue pair, and B can be either positive or negative depending on the details of molecular interaction in the condensed phase (Jancsó and Van Hook 1974; see also [► Eq. \(15.22\) in Chap. 15, Vol. 2](#)). In certain cases, A and B may be available from theory or spectroscopic measurements. Most often it is advantageous to distill at as low a temperature as possible (except when B is positive and large, as it is for hydrocarbons). Of course, as temperature drops, so does vapor pressure, and at low enough temperature throughput falls to unacceptable values. It is impractical to design isotope production plants, even on a laboratory scale, for vapor pressures less than about 0.05–0.1 bar.

51.5.4.1 Hydrogen

Distillation of hydrogen for deuterium production is attractive because of the large vapor pressure isotope effect ($P(\text{H}_2)/P(\text{HD}) = 1.7$ at 21 K), although this is somewhat offset by corrections for liquid and vapor nonideality (Bigeleisen 1963). The production of D by distillation of hydrogen (parasitic to industrial-scale ammonia production) has been employed in moderate-sized plants (Galley 1983), but high concentrations of nitrogen and other impurities in ammonia synthesis gas introduce complications. A design of a hydrogen distillation unit was described by Clusius and Starke (1949). Natural hydrogen cooled to its dew point is fed to a primary tower where it is split into a bottom fraction of 5–10% HD and a top fraction of essentially pure H_2 . The bottoms are fed to a second tower where separation to nearly pure HD is completed. This intermediate product is warmed, and then fed to a catalytic exchanger where it disproportionates to the room temperature equilibrium mixture (in which the ratio of concentrations of H_2 , HD, and D_2 is 1:2:1), which is fed to the bottom of yet another distillation tower. Here the mixture fractionates to a top mixture of HD and H_2 , and a bottom product fraction that is essentially pure D_2 . The light fraction is fed to the top of tower 2 for recovery of HD. A 1983 report (Galley 1983) mentioned the Nangal, India, plant with an estimated capacity of 14 t/year of D_2O using this process.

A special problem that occurs in the distillation of hydrogen is the need to minimize the conversion of ortho to para hydrogen. At room temperature the equilibrium ortho/para ratio is close to 3, but that ratio drops rapidly with temperature, and at the boiling point (20 K) it is essentially zero. The reaction of ortho to para releases about 1.5 times the heat of vaporization. This would significantly increase power consumption if allowed to occur. The ortho–para reaction is catalyzed by paramagnetic and ferromagnetic materials, including oxygen and certain steels, and accordingly, these materials must be carefully excluded from the low-temperature portions of the equipment.

51.5.4.2 Carbon Monoxide

A plant for the production of ^{13}C via CO distillation was described by London (1961). CO is easy to distill. Its vapor pressure curve follows N_2 closely and liquid nitrogen can be used as

a convenient refrigerant. At the boiling point of nitrogen, 77.4 K, $(\alpha - 1)$ for $^{12}\text{C}^{16}\text{O}/^{13}\text{C}^{16}\text{O}$ is 0.0078 and for $^{12}\text{C}^{16}\text{O}/^{12}\text{C}^{18}\text{O}$ is 0.0057. At 72 K the vapor pressure is ~ 0.25 bar and the α values are 0.0096 and 0.0070, respectively (Jancsó and Van Hook 1974). This increase in α makes it well worthwhile to operate the plant at reduced pressure. The triple point of CO (68 K, 0.15 bar) establishes a lower limit for the operating temperature. Natural abundances of ^{13}C and ^{18}O are 1.1% and 0.2%, respectively.

The CO distillation plant used a two-section vacuum-insulated column packed with wire gauze rings. The upper section was 5.2 m long with a diameter of 3.2 cm, the lower 4.6 m \times 1.9 cm. The column contained about 600 plates. An intermediate boiler re-evaporated part of the downward flowing liquid at the junction. Note that this plant accumulates product in the liquid and enriches toward the bottom. Enriched CO (0.4 g/day with $\sim 65\%$ ^{13}C content and 0.05 g/day with $\sim 5\%$ ^{18}O content) is withdrawn from the bottom of the column and converted to CH_4 and H_2O by catalytic reaction with hydrogen. Arrangements were made to automatically collect the contents of the different sections of the column in the event of power failure; the isotope inventory corresponded to about 2 months of production.

51.5.4.3 Nitrous Oxide

Macinteer et al. (1965, 1979, 1989) described production of ^{18}O , ^{17}O , and ^{15}N by low-temperature distillation of NO. The isotope effects are some three to five times larger than those for other diatomic molecules with similar boiling points. The large α values imply marked efficiencies. They reduce the number of plates required for a given separation and markedly decrease time to production. Even so, these advantages are offset in part by the relatively high cost of the feed material, and its chemical instability and toxicity. A theoretical analysis of NO separation factors established the fact that the abnormally large α values are due to the formation of dimers that are negligibly dissociated in the boiling liquid, but completely dissociated in the vapor (Bigeleisen 1960).

51.5.5 Exchange Distillation

Exchange distillation takes advantage of the fact that condensed phase–vapor phase separation factors can be enhanced (as compared to liquid–vapor factors) by association–dissociation equilibria in one or the other phase. A good example is found in $^{10}\text{B}/^{11}\text{B}$ separations. At the normal boiling point of 173 K, the vapor pressure isotope effect for BF_3 , $\ln \alpha \approx \ln [P(^{10}\text{BF}_3)/P(^{11}\text{BF}_3)] = -0.0075$, is sufficiently large for useful separation by distillation (Neetley et al., 1958). Compare this effect, however, with association–dissociation constants (K_{eq}) for reactions of the type

At the convenient operating temperature 298 K values for $\ln K_{\text{eq}}$ lie between 0.02 and 0.03 (Palko and Drury 1969). Obviously a distillation plant based on the larger separation factor, and operating at a more convenient temperature, promises superior performance.

51.6 Chromatography

Chromatography is a widely used separative process employing exchange between a stationary phase and a mobile fluid phase. It thus differs from distillation or liquid–liquid extraction that employs two mobile phases. There are a number of distinctly different chromatographic processes. If the moving phase is a vapor carried along in a stream of permanent gas and the stationary phase is a suitably supported liquid film, one speaks of *gas–liquid chromatography*. If, alternatively, the stationary phase is a solid of high absorptive capacity, one has *gas–solid chromatography*. If the moving phase is a solution at low concentration in a liquid solvent or a high-temperature–high-pressure fluid solvent of liquid or near-liquid density, one speaks of liquid chromatography, or super-critical fluid chromatography, as appropriate. In yet another mode, the stationary phase might be an ion-exchange resin and the moving phase an aqueous (or nonaqueous) solution. A general discussion of chromatography as applied to isotope separation has been given by Glueckauf (1961). Some years ago Van Hook (1969) reviewed the field of gas chromatographic isotope separation and more recently he commented on other chromatographic separations of isotopes (Van Hook 1985).

The essential feature of any chromatographic process is that it offers opportunity for multiple equilibrations between the mobile and stationary phases. By straightforward analogy with distillation where the single-stage separation factor is given by the vapor pressure isotope effect, one defines the single-stage chromatographic factor in terms of the equilibrium distribution coefficient between mobile and stationary phases. This accounts for one of the great advantages of chromatography, i.e., the possibility of tailoring the separation factor to fit the problem (within limits) by varying the chemical nature of the stationary phase, the solvent for the mobile phase, the temperature, etc.

Another advantage of chromatography is the fact that it offers columns containing large numbers of theoretical plates (in excess of 10^6 for gas chromatography, 10^5 or more for liquid elution chromatography). Therefore, it can achieve complete or substantially complete enrichments even for cases where separation factors are small enough to limit the applicability of other methods. Still, this advantage is offset by serious difficulties. In chromatographic experiments, a small amount of adsorbate (isotopic mixture in the present case) is placed on the first plate, or the first few plates, and subsequently washed through the chromatographic column using an eluent mobile phase. The more strongly adsorbed isotope lags the less strongly adsorbed one(s). As elution proceeds, separation increases, but so do band widths. The technical problem is to adjust conditions to optimize separation for given band broadening.

Throughout any chromatographic process it is easy to see that not all plates are carrying out separative work. In fact separation only takes place at the front and rear of the moving band. At any given instant, most of the column is empty of adsorbate. A direct comparison between the number of plates in chromatography, where there are a very large number indeed, but only a few of them are working at a given time, and the number in reflux distillation, where there are far fewer plates, but all are working, is inappropriate. It can even be misleading. Another important difficulty in chromatography is that band broadening and other diffusive inefficiencies increase dramatically (and nonlinearly) with column loading. The result, except in special cases, is that it is difficult to scale-up chromatographic separations to produce useful amounts of separated isotopes. Most often, chromatography is better suited to the analysis of isotopic mixtures than it is to the production of separated isotopes.

51.6.1 Gas Chromatography

To illustrate gas chromatography is chosen first. ▶ [Figure 51.9](#) shows an idealized chromatogram plotting detector response versus time. Here t_0 is time from injection to elution of inert nonadsorbed material, and t_1 and t_2 are retention times for components of interest. For difficult separations $t_0 \ll t_1 \approx t_2$. The resolution, R , between component bands is related to the band width (w), $R = (t_2 - t_1)/(2w)$, and the number of plates (assumed to be the same for both isotopes) is $n = 4(t/w)^2$.

The separation factor is $\alpha = t_2/t_1$, and the *Henry's Law* constant characterizing the equilibrium is $K_H = (V_c/V_g)(t/t_0 - 1)$. V_c and V_g are the volumes of condensed and vapor phases in the column (i.e., for gas-liquid chromatography, V_c is the volume of the liquid film on the supported packing or open tubular wall, and V_g the volume of void space, respectively. If the column is in the linear range (small loading), the resolution is given

$$\frac{R^2}{t} = \frac{1}{16} \frac{V_g}{V_c} \frac{C}{K_H} \left(\frac{\alpha - 1}{\alpha} \right)^2 \quad (51.13)$$

where C is a constant characterizing the apparatus. ▶ [Equation \(51.13\)](#) can be employed to optimize the separation (see, e.g., Bruner et al. 1966; Matucha 1989). Usually, C , α , and K_H are temperature dependent, but α and K_H much more than C . Also, α most often increases as temperature falls according to $1/T$ or $1/T^2$ (Jancsó and Van Hook 1974), and K_H , $K_H \approx K_H^0 \exp(b/T)$, normally increases exponentially as temperature falls. These two criteria conflict for the best choice of temperature and it is necessary to determine the optimum compromise. With α and K_H set by the selection of operating system and temperature, resolution is proportional to V_g/V_c . For maximum resolution, the vapor volume is increased by electing open tubular columns, i.e., wetted wall columns with minimal liquid loading, and therefore minimal capacity. The result is the expected one.

Examples of gas chromatographic isotope separation are shown in ▶ [Figs. 51.10](#) and ▶ [51.11](#). The gas chromatographic trace of a separation of a mixture of protio and deuterio-acetylenes is shown in ▶ [Fig. 51.10](#) (Phillips and Van Hook 1967). The separation is interesting, all known preparations of these acetylenes lead to a disproportionated mixture of C_2H_2 , C_2HD ,

■ [Fig. 51.9](#)

An idealized chromatogram. The ordinate shows detector response, the abscissa is time

■ Fig. 51.10

Gas-liquid chromatographic separation of deuterated acetylenes at -78°C using triethyl-amine liquid phase supported on Chromosorb-P. Elution (min, left to right) is in the order C_2H_2 – C_2HD – C_2D_2 . The broadening is a consequence of strong amine-acetylene interaction (Phillips and Van Hook 1967)

■ Fig. 51.11

High-resolution gas-liquid chromatographic separation of perdeutero-perprotio *n*-alkanes on an open tubular fused silica column coated with cross-linked phenylmethyl-silicone (140°C , $0.5\ \mu\text{m}$ film, $\sim 1.5 \times 10^5$ theoretical plates); see Matucha (1989)

and C_2D_2 . Consequently, pure C_2HD can only be obtained by separation of the ternary mixture.

Distillation is inappropriate because the triple point lies above 1 atm, and not only is the compressed gas dangerous but it also tends to polymerize except when dilute. The authors attempted to scale-up chromatographic separation, but resolution deteriorated with column loading and the method was found to be impractical except for preparation of very small amounts of C_2HD .

■ **Table 51.8**

Gas chromatographic separation factors for C_2H_6/C_2D_6 for several different liquid phases on firebrick at two temperatures (Phillips and Van Hook 1966)

Column	Gas liquid separation factor, $\ln[(t(H)/t(D))]$	
	150 K	200 K
15% w/w acetaldehyde	0.03	0.01
33% w/w ethanol	0.06	0.07
15% w/w methylcyclopentane	0.08	0.10
Vapor pressure ratio, $\ln[P(C_2D_6)/P(C_2H_6)]$	0.065	0.075

► **Table 51.8** shows the dependence of gas–liquid chromatographic separation factors for C_2H_6/C_2D_6 on temperature and liquid phase. Significant differences are obtained by varying the polarity of the liquid loading of column substrate, and the temperature. The results clearly demonstrate that careful attention must be paid to both factors when optimizing chromatographic separations. ► **Figure 51.11** is an example of a more recent high-resolution separation using an open tubular liquid film capillary column. Again, it nicely demonstrates the power of gas chromatography for small-scale (analytical) separations.

51.6.2 Isotope Separation by Redox Ion-Exchange Chromatography

Fujii and coworkers (Fujii et al. 1989; Nomura et al. 1996; Nakanishi et al. 1996) have reported on the use of anion redox chromatography applied to the U(IV)–U(VI) couple and utilizing Ti (III) as reducing agent and Fe(III) as oxidizing reagent to separate uranium isotopes. In an intensive development process, Asahi Chemical Industries in collaboration with Tokyo Institute of Technology refined the process enabling recovery of the reducing and oxidizing reagents (Sego 1992). This is an obvious requirement for practical implementation of this separation method. In a typical set of experiments (Nomura et al. 1996), a 0.1 M U(VI) solution in 3.6 M HCl was fed to a column packed with a highly porous strongly basic anion exchanger supported on 50 μ m porous silica beads to form a uranium adsorption band. The band was then eluted with a solution containing 3.5 M HCl, 0.6 M V(IV), a reducing reagent, and 1 M Fe (II), a catalyst for the U(VI)–U(IV) exchange. A cyclic process utilizing two 1 m columns was employed with intermittent addition of the redox reagents after each band pass. After a total migration of ~ 192 m, the uranium band, now 1.4 m long was extracted from the column and fractions collected for elemental and isotope ratio analysis. Results from one such experiment are shown in ► **Fig. 51.12**.

It is interesting to note that these data (amply confirmed with many additional experiments on uranium and other systems) show that the temperature dependence and the odd–even mass ratios of isotope-exchange fractionation factors of uranium and other metals differ significantly from the predictions of the well-established theory of isotope effects based on vibrational properties (Bigeisen and Mayer 1947). That observation, one of theoretical importance, has been shown to be a consequence of the large nuclear isotope field shifts found in the heavy elements. The field shifts introduce new mechanisms for understanding the

■ Fig. 51.12

Uranium concentration profile and isotope separation factors for a U(VI)–U(IV) sample eluted from an ion-exchange column; see text (Nomura et al. 1996)

physical basis of the unusual temperature dependences and large mass-independent isotope effects now well established in exchange equilibria of the heavy elements (Bigeleisen 1996).⁶

51.7 Photochemical and Laser Isotope Separation

The idea of using selectively absorbed radiation to effect isotope separation is an old one. Hartley et al. (1922) proposed synthesis of HCl from a mixture of H_2 and Cl_2 , where only one Cl_2 isotopologue would be photoexcited, then go on to react preferentially. The actual experiment, using white light filtered through natural chlorine, failed, but for the incidental reason that the reaction involves a lengthy chain mechanism, a fact not appreciated in 1922. A later photochemical experiment succeeded in separating mercury isotopes by exciting gas phase Hg atoms with light from a mercury arc made from a pre-separated mercury isotope. The method succeeded, first because mercury has a relatively simple spectrum with widely separated lines, and second because a monoisotopic light source was available.

The essential conditions for photochemical isotope separation are (1) the existence of a significant isotope shift in the absorption spectrum of the element or compound being irradiated (i.e., larger than the band width of the incident radiation), (2) a rapid reaction of the excited state that leads to production of some atom or molecule readily separable from the mixture, and (3) a light source with spectral band narrow enough to excite only one isotopic species, and intensity large enough to carry out that excitation efficiently. It was the invention of the laser that provided a convenient source of intense radiation of narrow band width and made photochemical isotope separation practical. The first laser isotope separation (on bromine) was reported in 1967 (Tiffany et al. 1967), and since that time, a large amount of development work has been carried out, and small-scale separations have been reported for

many elements. An enormous literature dealing with the theoretical and experimental aspects of laser pumped processes has developed. There will be made no effort to review this material but, below, the conceptual basis of laser isotope separation will be simply indicated in broadest outline.

51.7.1 Outline of a Laser Isotope Separation (LIS) Scheme

McAlpine and Evans (1985) divide any LIS scheme into five parts:

1. Exchange with bulk feed. Usually, it will not be possible to apply LIS directly to cheap bulk feed (e.g., water or methane for H/D separation), and the desired isotope must be chemically exchanged into a “working” molecule. If the isotope of interest is rare, it will be important that the working material be recyclable. Although step (1) involves conventional chemistry, its cost may dominate the overall LIS.
2. Selective excitation. The working molecule is irradiated with a laser tuned to a frequency that excites only the desired species.
3. Excited state molecules are converted to some new and isotopically enriched chemical species (molecules, free radicals, ions, etc.).
4. Capture of the secondary species before it converts to a form where enrichment will be lost by decay or exchange.
5. Final conversion of the secondary species to useful chemical or physical form.

Note that it is only in step (2), above, that technology based on laser physics is involved. Nonetheless in the overall LIS process each and every step is important, and may be critical. In the actual lasing step, it may be advantageous to employ long wavelength lasers because they have relatively good efficiency and low-energy cost per photon. An important parameter in step (2) is the photon efficiency, ε , which gives the fraction of absorbed photons that yield excited species containing the desired isotope. This is approximately

$$\varepsilon = \frac{1}{1 + \frac{1}{\delta S}} \quad (51.14)$$

S is the selectivity ratio for photon absorption under the experimental conditions, and δ is the relative abundance of the desired isotope. ▶ Equation (51.14) demonstrates, for example, that S values on the order of 10^3 are required before more than about 10% of photons are used to excite D in natural abundance H/D mixtures ($\delta \approx 1.5 \times 10^{-4}$). The selectivity required for uranium separation is less because $\delta(\text{D}) < \delta(^{235}\text{U})$, but in a real sense that is misleading because the density of spectroscopic states for molecules containing heavy atoms (or for the isolated atoms themselves) is orders of magnitude larger than for light species. Hence the spectroscopic requirements are much more difficult to implement.

Practical LIS schemes usually involve the absorption of more than one photon. It is convenient to refer to a schematic energy level diagram like the ones sketched in ▶ Fig. 51.13. Provided laser fluence is sufficiently high, a species will absorb enough photons to decompose if the pulse is sufficiently short so that collisions (which lead to deactivation) do not occur during the pulse. As the molecule absorbs photons, it is said to be “pumped” up the excitational ladder. In the low-energy region, the density of states is small and radiationless processes leading to deexcitation are slower than pumping. In this region, the states are isotopically well separated, and with proper laser tuning, the desired isotope is preferentially

■ Fig. 51.13

Two-photon photoionization using lasers of the same (*right*) or different frequency (*left*)

excited. As pumping continues, the level spacing decreases (in vibrational spectroscopy because of anharmonic effects, for example), and the laser becomes increasingly “off-resonance.”

This results in a drop or “bottle-necking” in pumping efficiency, but once this intermediate region is passed, the level density increases dramatically as dissociation is approached, and pumping efficiency once again increases. However, near dissociation, the level density for undesired species is also high, and in this region, pumping does not lead to isotope discrimination, but only to dissociation. Also, the high density of states near dissociation leads to an increase in the efficiency of radiationless decay and exchange, which may cause isotopic scrambling or recycling to the ground state. One finds that short pulse lasers of high fluence are necessary for efficient separations.

51.7.2 LIS of Deuterium

The ideas in the last section are nicely illustrated with one of the many LIS schemes proposed for H/D enrichment. The multiphoton dissociation of fluoroform, CHF_3 , will be considered first. Certain vibration/rotation bands of CHF_3 , CDF_3 , and CTF_3 are spectroscopically well separated, and selective excitation of the heavier isotopologue is practical. For $\text{CDF}_3/\text{CHF}_3$ the selectivity is greater than 2×10^3 when a CO_2 laser is tuned to the ν_5 *R* branch in the vicinity of 980 cm^{-1} . Dissociation occurs primarily via the reaction, $\text{CDF}_3 \rightarrow \text{CF}_2 + \text{DF}$. Heads enrichment as high as 2×10^4 have been reported (Herman and Mailing, 1980) and there is little or no anharmonicity bottle-necking. Because of the high cost of CHF_3 , recycling would have to be incorporated into any practical process. A possibility is the exchange, $\text{CHF}_3 + \text{HDO} \rightarrow \text{CDF}_3 + \text{H}_2\text{O}$, but without a catalyst this reaction is too slow to be practical. The overall economics of LIS H/D enrichment will be determined by the details of the feedstock and exchange reaction selected (Bigeisen et al. 1983).

An alternative LIS scheme is one in which a vibrationally excited molecule reacts preferentially with another species. An example is the hydrogen halide–olefin addition reaction, $\text{HX}^* + \text{R}_1\text{R}_2\text{C} \rightarrow \text{CH}_2=\text{R}_1\text{R}_2\text{CXCH}_2\text{D}$ (Mailing et al. 1978). The reaction involves sequential

absorption of several quanta from a CO₂ laser near 5 μm which selectively excites DX to a vibrational quantum number of 3 or more. Successful implementation of this scheme would be expensive because of the highly corrosive nature of the halogen acids.

51.7.3 LIS for Uranium

Uranium isotope enrichment by LIS has been exhaustively studied and the conceptual outlines of two separate programs have made their way into the open literature. These methods are multiphoton dissociation of UF₆ and LIS of monatomic uranium vapor (atomic vapor laser isotope separation, or AVLIS). AVLIS was selected by the United States DOE as the process to be used in its separation plants during the 1980s and 1990s, but, once again due to the present oversupply of separated uranium, the plant has recently been closed.

51.7.3.1 AVLIS

The spectrum of uranium metal vapor is complex with over 3×10^5 lines in the visible region. Still, many of these are very sharp and show sufficient isotope separation to permit selective excitation. The basic idea of AVLIS is to irradiate uranium metal vapor at a concentration around 10^{13} atoms cm^{-3} (higher concentrations destroy the separation due to collisional broadening). Uranium is a refractory metal, and vaporization is difficult. Electron bombardment under high vacuum yields an atomic beam that passes through the laser radiation field where ^{235}U is selectively excited.

The isotope shift $^{235}\text{U}/^{238}\text{U}$ is only $\sim(1/5) \times 10^4$ and it is necessary to select a very narrow ^{235}U line, and to carry the ionization process out in two steps (because line widths in the ionization region are broad and hence not selective). In the first step ^{235}U is excited from its ground state to some state well below the 6.18 eV ionization potential. That is followed by a less-selective absorption into the ionization continuum (using another laser). The ionized uranium atoms are then swept to a charged plate and collected. Even though selectivity is high, Benedict, Pigford, and Levi writing in 1981 state that the charge exchange that occurs during atomic collisions deflects enough ^{238}U to the collector to lower the heads enrichment factor to about 10. At that time, the single-stage product of $\sim 6\%$ ^{235}U was the highest yet obtained from natural abundance uranium. Presumably enrichment factors have now improved. Even for the earlier figure, however, nearly complete stripping of ^{235}U was claimed. This is a valuable feature because the feed is expensive. In summary, AVLIS has a sufficient single-stage enrichment factor to produce uranium of high enough ^{235}U content to power light water reactors. Furthermore, because AVLIS is an excellent stripper, it can be used to produce 2–3% ^{235}U from the large stockpile of tails now available from earlier gaseous diffusion or gas centrifuge separations. This confers an additional economic advantage.

51.7.3.2 LIS of UF₆

Although UF₆ has a conveniently high vapor pressure at room temperature, its absorption spectrum is much more complex than that of the metal because of the large number of vibrational and rotational states superposed on each electronic state. Moreover, at room temperature these bands are broadened sufficiently to preclude selective absorption.

However, if the molecules are cooled, the population of thermally excited vib-rot states falls drastically and the spectrum simplifies. Thus, at 77 K, 69% of UF_6 is in its lowest vibrational state, and this increases to 85% at 55 K. However, the vapor pressure is untenably low at such temperatures (7×10^{-3} Pa at 77 K), and equilibrium cooling is out of the question. Still by cooling in a nonequilibrium expansion nozzle, uranium vapor concentration can be kept at a useful level and LIS is possible. None of this changes the fact that molecular LIS was abandoned in favor of AVLIS.

51.8 Other Isotope Separation Processes

A number of other processes for separating isotopes are documented. A partial list includes membrane pervaporation, thermal diffusion of liquids, mass diffusion, electrolysis and electro migration, differential precipitation, solvent extraction, biological microbial enrichment, and more. Although not discussed in this chapter, some are suitable for small-scale laboratory separations, and others have been applied on reasonably large scale to D/T, H/T, and $^6\text{Li}/^7\text{Li}$ and presumably to other pairs of isotopes.

51.9 Editors' Notes

1. Isotopic molecules – or isotopologues – mean molecules of the same compound that only differ in isotopic composition. Related terms such as isotopomers are explained in [▶ Sect. 15.1 of Chap. 15, Vol. 2](#), on “Isotope Effects,” a topic closely associated with isotope separation (p. 2371).
2. The Author uses the terms “separation unit,” “separative unit,” and “separating unit” interchangeably (p. 2372).
3. The GS process is described in [▶ Sect. 51.5.2](#). See also [▶ Fig. 51.7](#) (p. 2385).
4. See [▶ Sect. 15.4 in Chap. 15 of Vol. 2](#) on “Isotope Effects” (p. 2386).
5. See the theory of vapor pressure isotope effect in [▶ Sect. 15.5.1, Chap. 15, Vol. 2](#) (p. 2389).
6. See more about mass-independent isotope effects in [▶ Sect. 15.8 of Chap. 15, Vol. 2](#) (p. 2397).

Abstract: In 1805, Bucholz extracted uranium from a nitric acid solution into ether and back-extracted it into pure water. This is probably the first reported solvent-extraction investigation. During the following decades, the distribution of neutral compounds between aqueous phases and pure solvents was studied, e.g., by Peligot, Berthelot and Jungfleisch, and Nernst. Selective extractants for analytical purposes became available during the first decades of the twentieth century. From about 1940, extractants such as organophosphorous esters and amines were developed for use in the nuclear fuel cycle. This connection between radiochemistry and solvent-extraction chemistry made radiochemists heavily involved in the development of new solvent extraction processes, and eventually solvent extraction became a major separation technique in radiochemistry. About 160 years ago, Thompson and Way observed that soil can remove potassium and ammonium ions from an aqueous solution and release calcium ions. This is probably the first scientific report on an ion-exchange separation. The first synthesis of the type of organic ion exchangers that are used today was performed by Adams and Holmes in 1935. Since then, ion-exchange techniques have been used extensively for separations of various radionuclides in trace as well as macro amounts. During the last 4 decades, inorganic ion exchangers have also found a variety of applications. Today, solvent extraction as well as ion exchange are used extensively in the nuclear industry and for nuclear, chemical, and medical research. Some of these applications are discussed in the chapter.

52.1 Introduction

The origin of solvent extraction is shrouded in mystery, but the method might have been used already by the Persian alchemist al-Razi who is believed to have used extraction to separate metals (Al-Razi ~900, Heym 1938).

In 1805, almost a century before radioactivity was discovered, Bucholz extracted uranium from a nitric acid solution into ether and back-extracted it into pure water (Bucholz 1805). In his pioneering work, Bucholz performed extraction as well as strip and he concluded that the degree of extraction depends on the phase volume ratio as well as the salt concentration in the aqueous phase. His work was not only the first well-documented solvent extraction experiment but also, in fact, the first application to radiochemistry. During the following decades, the distribution of several neutral compounds between aqueous phases and pure solvents was studied experimentally as well as from a theoretical point of view (Peligot 1842; Berthelot and Jungfleisch 1872; Nernst 1891). Selective extractants for analytical separation of several elements became available during the first decades of the twentieth century. Between 1940 and the early 1950s, extractants like organophosphorous esters and amines were developed for use in the nuclear fuel cycle. This connection between radiochemistry and solvent extraction chemistry made radiochemists heavily involved in the development of new solvent extraction processes, and eventually solvent extraction became a major separation technique in radiochemistry.

The first description of an ion-exchange separation may be the passage in Exodus, where Moses purified the brackish water of Marah with a piece of wood (Exodus). Another ancient reference to the use of ion exchangers is given by Aristotle, who described that seawater loses its salt contents if it is passed through certain types of sand (Aristotle ~330 BC).

About 150 years ago it was observed that soil can remove potassium and ammonium ions from an aqueous solution and release calcium ions (Thompson 1850; Way 1850). This is probably the first scientific reference to an ion-exchange separation. Surprisingly, the discovery

of Thompson and Way antedates the ionic dissociation theory (Arrhenius 1887) that explains the chemistry behind the ion-exchange process. The first synthesis of the type of organic ion exchangers that are used today was reported by Adams and Holmes (1935). Since then, ion-exchange techniques have been used extensively for separations of various radionuclides in trace as well as macro amounts. During the last 4 decades, inorganic ion exchangers like manganese dioxide and hydrated antimony pentoxide have also found a variety of applications.

Extensive information about solvent extraction and ion exchange can be found, e.g., in refs. Rydberg et al. (1992), Walton and Rocklin (1990), Harland (1994), and Moyer (2009).

52.1.1 Solvent Extraction Theory

The simplicity, speed, and versatility of solvent extraction make it an excellent radiochemical separation method. Even simple equipment like a test tube or a separation funnel allows radiochemists to perform elaborate studies within a few minutes. The method works for a wide concentration range, from the rather concentrated solutions in uranium production or nuclear fuel reprocessing to one-atom-at-a-time separations of the heaviest elements.

According to International Union of Pure and Applied Chemistry (IUPAC; Rice et al. 1993), the definition of *solvent extraction* is “the process of transferring a substance from any matrix to an appropriate liquid phase.” If the substance is initially present as a solute in an immiscible liquid phase, the process is synonymous with *liquid–liquid extraction*. In the following, IUPAC nomenclature (Rice et al. 1993) will be used if not otherwise stated. The solutes discussed in this chapter are usually metal ions or, in some cases, acids. As liquid phases only aqueous and organic phases will be considered, although other types of liquid–liquid systems exist as well, e.g., molten salts or liquid metals.

Most inorganic species are only slightly soluble in inert organic solvents. Consequently, the extraction can occur only through interaction with an organic molecule, the *extractant*. The organic phase sometimes consists of a pure extractant, but more commonly, the extractant is dissolved in an inert organic *diluent*. In industrial extraction, the diluent is often a hydrocarbon-like kerosene or toluene. In small-scale extraction a variety of diluents is used, e.g., chloroform, carbon tetrachloride, and many others. The extractant is defined as “the active component(s) primarily responsible for transfer of a solute from one phase to the other” (Rice et al. 1993), but usually the word denotes all components of the solvent that are involved in the extraction. Usually the term “extraction” is reserved for the transfer from an aqueous to an organic phase, while the opposite transfer direction is called *strip* or *back-extraction*.

As mentioned above, solvent extraction is based on the distribution of a solute between two immiscible phases. Gibbs’ phase rule (Gibbs 1876) can be applied, namely:

$$P + F = C + 2 \quad (52.1)$$

where P is the number of phases, F the number of degrees of freedom, and C the number of components. Thus, a system consisting of two immiscible solvents and one solute distributed between them has one degree of freedom at constant temperature and pressure. Consequently, if the solute concentration in one phase is constant, the concentration in the other phase is also constant. The relationship between these concentrations led to Nernst’s distribution law (Nernst 1891). This law can be expressed as

$$k_d = \frac{c_{\text{org}}}{c_{\text{aq}}} \quad (52.2)$$

where c_{org} is the concentration of an extractable species in the organic phase and c_{aq} the concentration in the aqueous phase. Thus, k_d , referred to as the distribution factor, is dimensionless. From ▶ Eq. (52.2) it follows that the distribution factor does not depend on the total solute concentration or the phase volumes. Nernst proved that his equation was valid for a number of organic acids, if taking dimerization and dissociation into account. A decade later, Morse extended the validity of Nernst's equation to metal salts (Morse 1902).

It is also possible to derive the Nernst distribution law from thermodynamic considerations using the concept of free energy (Lewis and Randall 1923). At equilibrium, the chemical potential of a solute X has to be the same in the aqueous and the organic phase, i.e.,

$$\mu_X(\text{aq}) = \mu_X(\text{org}) \quad (52.3)$$

For each phase $\mu_X = \mu_X^0 + RT \ln a_X$, which gives

$$\mu_X^0(\text{aq}) + RT \ln a_X(\text{aq}) = \mu_X^0(\text{org}) + RT \ln a_X(\text{org}) \quad (52.4)$$

In this equation μ_X^0 is the standard chemical potential in the (given) phase and a_X is the chemical activity of X. It is defined as

$$a_X = f_X[X] \quad (52.5)$$

where f is the activity coefficient.

If ▶ Eq. (52.5) is combined with ▶ Eq. (52.4) the result can be written

$$\frac{a_X(\text{org})}{a_X(\text{aq})} = e^{[\mu_X^0(\text{aq}) - \mu_X^0(\text{org})]/RT} = K_d \quad (52.6)$$

K_d is sometimes called the thermodynamic partition ratio. It is related to the concentration partition ratio via the ratio between the activity coefficients, i.e.,

$$k_d = K_d \cdot \frac{f_X(\text{aq})}{f_X(\text{org})} \quad (52.7)$$

The expressions given for k_d and K_d are valid if there is only one species that distributes between the phases. Usually the situation is more complicated; e.g., in metal ion extraction, the metal can be present in the aqueous phase as free metal ion as well as positive, neutral, or negative complexes. In the organic phase, it is present as an uncharged complex. For such cases, the *distribution ratio* is used. It is abbreviated D and it is defined as:

$$D = \frac{c_{\text{org}}}{c_{\text{aq}}} \quad (52.8)$$

where c_{org} is the total analytical concentration of, e.g., a metal in the organic phase and c_{aq} the corresponding total analytical concentration in the aqueous phase. D is easy to determine by radiometric methods since it is equal to the ratio between the specific activities of the phases. This is one reason why liquid–liquid extraction is a common method in radiochemistry.

The extracted fraction of an element can be calculated using the expression

$$\%E = \frac{D\Theta}{(1 + D\Theta)} \cdot 100 \quad (52.9)$$

where $\Theta = V_{\text{org}}/V_{\text{aq}}$

Another useful definition is that of the *separation factor*, SF_{AB} , between the elements A and B in a liquid–liquid system. It is simply defined as

$$SF_{AB} = \frac{D_A}{D_B} \quad (52.10)$$

52.1.2 Extraction Systems

There are four major types of extraction systems that can be used for separation procedures:

Extraction of simple inorganic compounds can be exemplified by the classical distribution of iodine between water and carbon tetrachloride or by the extraction of, e.g., RuO_4 , OsO_4 , or AsI_3 into an organic solvent. Such extraction procedures are usually rapid, selective, and well suited for radiochemical separations.

A metal ion, M^{v+} , may also form a complex with an organic anion A^- to form a neutral, hydrophobic complex MA_v . The organic reagent often is an acid, HA, and the anion A^- a bidentate chelating agent. The mechanism is therefore often referred to as *chelate extraction*. An example is the extraction of thorium with acetylacetone, HAa:

In this case, the bidentate ligand saturates the eight coordination sites of thorium, i.e., the complex contains no water at all. This makes it hydrophobic and gives high D values.

Chelate extraction was used more than a century ago (Cazaneuve 1900). Many of the important chelating agents were developed during the first half of the twentieth century, e.g., cupferron (Bandish and Fürst 1917), dithizone (Fischer 1933, 1934), and thenoyltrifluoroacetone (Reid and Calvin 1950). Many of these extractants are important in analytical chemistry since they provide a possibility to perform extremely selective separations and preconcentrations.

Another possibility to extract a metal ion is to replace its hydrate water by a *solvating* reagent. This makes the metal species less hydrophilic and it can be transferred to an organic phase. The solvating reagent can be the organic phase or it can be dissolved in a diluent. A well-known example is the extraction of uranium by tri-*n*-butyl phosphate from nitric acid:

Solvate extraction, which is also known as adduct extraction, became really important during the Manhattan Project when there was a need to produce uranium, plutonium, and other elements. Thus, tri-*n*-butyl phosphate was introduced for uranium and plutonium extraction (Flanary 1956). Trioctylphosphine oxide and bis-2-ethylhexyl phosphoric acid were also developed at this time (Mason and Peppard 1963; Siddall 1959; McKay 1956). These reagents are used not only in the nuclear fuel cycle but also for production of lanthanides and many other metals.

As discussed in [Sect. 52.3.5](#), the extractants now developed for actinide partitioning in partitioning and transmutation processes employ the solvate-extraction mechanism.

In *ion pair extraction* the concentration of the inorganic anion L^- is high enough to form the complex $\text{ML}_n^{(v-n)-}$. This complex usually is an inner sphere complex that is more weakly hydrolyzed than the uncomplexed metal ion. It can therefore be extracted as an ion pair with the organic cation Q^+ . Metal anions like TcO_4^- and ReO_4^- can, of course, be extracted without any extra inorganic anions. Q often is a primary, secondary, or tertiary amine or a quaternary

ammonium salt. These types of extractants are often referred to as liquid ion exchangers because of the similarity between the ion-pair formation process and an ion-exchange process. Negatively charged ion-pair extractants (e.g., sulfonic acids) that directly extract metal ions also exist. They are not, however, of great importance because of their poor selectivity.

Cationic alkylamine extractants were introduced in 1948 (Smith and Page 1948) for uranium production on an industrial scale. A few years later similar reagents based on phosphorous or arsenic, e.g., tetraphenylphosphonium and tetraphenylarsonium cations were introduced (Tribalat 1949). Today tertiary amines like trioctylamine extractants play a very important role in uranium production. Amines and quaternary ammonium salts are also used for production of many other metals, e.g., rare earth metals.

Ionic liquids are somewhat related to ion-pair extractants but they might nevertheless be regarded as a separate class of extractants. An ionic liquid is a salt that forms a stable liquid. In recent years, ionic liquids with melting point below 100°C, also called room temperature ionic liquids or RTIL, have been of great interest for separations. In the nuclear industry, RTIL are of interest as potential extractants of, e.g., uranium and lanthanides as well as useful fission products such as palladium, rhodium, and ruthenium. An example of such a reagent is protonated betaine bis(trifluoromethanesulfonyl) imide that has been used to separate the uranium oxides UO_3 , UO_2 , and U_3O_8 from each other (Jagadeeswara Rao et al. 2008)

There are also other types of extractants such as *crown ethers* that have a ring structure that fits an atom with a certain ionic radius, thus forming a hydrophobic and extractable species. These reagents have been used, e.g., for isolation of cesium and strontium. Many extractants also combine several of the mechanisms mentioned above.

Sometimes a mixture of two extractants gives a higher distribution ratio than the extractants separately. This is referred to as *synergy*. The reason for synergy is that one extractant neutralizes the charge of the metal ion while the other replaces remaining hydrate water molecules, e.g.,

52.1.3 Equipment

Small-scale solvent extraction is often done batchwise in separation funnels or test tubes. However, for more elaborate extraction studies and industrial processes continuous extraction is usually preferred. All continuous solvent extraction equipment consists of a *mixer* for phase contact and mass transfer and a *separation part* for phase disengagement. The main types of continuously working apparatus are:

- *Mixer-settlers*: stepwise phase contactors with conditions close to equilibrium in each step and pure outgoing phases.
- *Columns*: differential phase contactors without equilibrium in each step (“bottom”) and continuous phase contact without total phase disengagement.
- *Centrifuges and centrifugal extractors*: usually no equilibrium and phase disengagement in a centrifugal field.

Mixer-settlers consist of a mixing chamber, usually with an impeller that also pumps the liquid through the system, and a separation chamber in which the phases are separated by gravity. The size ranges from laboratory equipment with a volume of a few milliliters per step to

industrial settlers with a volume of several thousand cubic meters. The main advantages of mixer-settlers are that they are easy to construct, cheap, easy to run, need very little service, have well-defined steps, and also that it is easy to add more steps to an existing facility. The disadvantages are that they contain a large organic phase volume (= high capital costs) and also that it takes a rather long time to reach steady-state after start-up of the plant. On the other hand steady-state is not destroyed if halting the system, i.e., restart is very simple. In the nuclear industry, the large volumes make mixer-settlers less suitable for elements that may cause criticality problems.

Columns are either dynamic (e.g., pulse columns) or static, i.e., without mechanical mixing of the phases. The size and capacity cover a wide range, from a few centimeters diameter and about 50 cm length to 4 m diameter and 60 m height. The main advantage of columns is that a large number of steps can be contained in one column. The disadvantages are that they are more difficult to design and scale-up than mixer-settlers and also that they are sensitive to load variations and crud (e.g., solid particles in the solutions). They cannot be halted without losing steady-state and it is also impossible to add more steps once the column has been constructed. An advantage in the nuclear industry is that it is easy to construct columns that are safe against criticality (the maximum volume is well defined) provided that the concentration of fissile material is kept within the design limits.

Centrifuges or centrifugal contactors are used when rapid phase disengagement is necessary to prevent chemical or radiolytical degradation of an extractant or an extracted compound. They are also an attractive alternative if the requirements on the phase purity are high. The liquid holdup volumes are often small, and therefore this type of equipment is also suitable if expensive reagents are used. The difference between a centrifuge and a centrifugal contactor is mainly that the centrifuge has an external mixer and each centrifuge is one well-defined step, while a centrifugal extractor has internal mixing and several steps integrated within one unit. The advantages of centrifuges and centrifugal extractors are that they have high capacity despite their rather small volumes and that they give a good and rapid phase separation. The disadvantages are that they are mechanically complicated, difficult to scale up or down and sensitive to solid entrainment. Centrifuges are used for nuclear science but not very much in the nuclear industry. This may change in the future, when partitioning and transmutation processes may require extraction with short contact times to avoid problems with radiolysis.

Practically all of the industrial extraction processes are run in the counter-current mode, i.e., the fresh solvent meets an aqueous solution that has already been through all extraction steps except the last one. In such a counter current battery the fraction of the element of interest that remains in the aqueous phase is

$$\varphi_n = \frac{P - 1}{P^{n+1} - 1} \quad (52.14)$$

where P is the *extraction factor* ($P = D \cdot \Theta$; Θ is the phase volume ratio) and n = the number of steps. The extracted fraction is

$$\psi_n = 1 - \varphi_n \quad (52.15)$$

52.1.4 Ion-Exchange Theory

Ion-exchange resins are either cation or anion exchangers. The former group may be classified as strong, moderate, or weak acid cation exchangers, while the anion exchangers are classified

into weak and strong base exchangers. There are also other types of ion exchangers, e.g., chelating resins and bifunctional resins. A typical ion exchanger consists of functional groups attached to a polymer matrix. As an example, a strong acid type cation exchanger typically consists of sulfonic acid groups bound to a cross-linked polystyrene matrix. The exchange reaction can be written as:

where M^+ is a metal ion and X^- an anionic ligand.

Moderately strong cation exchangers contain $-\text{PO}(\text{OH})_2$ as a functional group, while weak acid cation exchangers contain the functional group $-\text{COOH}$. Strong base anion exchangers contain the group $-(\text{CH}_2\text{NR}_3)\text{Cl}$, while weak base anion exchangers contain $-(\text{CH}_2\text{NHR}_2)\text{Cl}$ or $-(\text{CH}_2\text{NH}_2\text{R})\text{Cl}$. In these formulas, R represents an alkyl chain.

For the exchange reaction given in [Eq. \(52.16\)](#) a *selectivity coefficient* can be defined as

$$K_s = \frac{[\text{R-SO}_3\text{M}] \cdot [\text{HX}]}{[\text{R-SO}_3\text{H}] \cdot [\text{MX}]} \quad (52.17)$$

The selectivity coefficient depends on several parameters, e.g., on the type of ion exchanger, the charge of the exchanged ion, and the conditions of the solution.

It is also possible to define a *distribution ratio* for the ion exchanger. This ratio is expressed as

$$K_D = c_{\text{res}} / c_{\text{aq}} \quad (52.18)$$

where c_{res} is the equilibrium concentration of the exchanged ion in the resin (mol/kg) and c_{aq} the concentration in the aqueous solution (mol/m³). Thus, the SI unit of K_D is m³/kg.

In radiochemistry, the distribution ratio is more useful than the selectivity coefficient. It can be determined easily by using radioactive tracers.

52.1.5 Equipment

Ion exchangers are always solid and operated as columns, membranes, or surfaces covered with ion exchanger (liquid ion exchangers are solvent extraction reagents, e.g., ion-pair reagents). The size of such columns ranges from a few millimeters up to several cubic meters, and the flow capacities from a few milliliters per minute to several cubic meters per hour (the latter range covered by a scaling factor of about 17,000).

52.2 Solvent Extraction and Ion Exchange in Small-Scale Nuclear Chemistry

52.2.1 Nuclide Production

Solvent extraction and ion exchange are widely used to produce various radionuclides from irradiated targets. The common routine is that the target is dissolved in an aqueous phase, often a mineral acid, and then treated with a suitable extractant or ion exchanger to isolate the nuclide of interest. Several steps are often applied to obtain the desired radiochemical purity.

A well-known example is actinide or lanthanide separation when the individual trivalent metal ion can be isolated from a bombarded target by multistage solvent extraction or ion-exchange chromatography.

52.2.2 Isolation of Exotic Radionuclides

The distribution of a species between two immiscible phases may be extremely specific and the process itself very fast. This makes solvent extraction well suited for isolation of exotic nuclides from complex nuclear reaction product mixtures (in this context “exotic” refers to nuclides with a half-life shorter than ~ 60 s and nuclides that can be produced only at a one-atom-at-a-time scale). Under ideal conditions, the transport through a liquid interface can be completed within fractions of a second; a measured value for transfer of nitric acid from water to tributylphosphate is 12 ms (Lunes and Wishow 1985). Phase separation can also be obtained within a few milliseconds if applying a centrifugal field on the mixture of the two solvents. Another possibility to get an efficient phase separation is to sorb the extractant onto a solid material and thus using one liquid and one solid phase; this technique is utilized in liquid–liquid partition chromatography (LLPC) and high-performance liquid chromatography (HPLC).

More thorough descriptions of the techniques outlined below can be found, e.g., in refs. Trautmann (1995), Kratz (1999), and Skarnemark (2000) together with several references to applications of the methods and the results obtained.

Solvent extraction techniques employed for fast separations are either continuous (when chemical separation and nuclear measurements are performed online during irradiation) or batchwise. There are also combinations of the techniques, e.g., collection of a continuously produced nuclide followed by batchwise separation and measurement. The batch and online approaches both have advantages and disadvantages when studying short-lived nuclides. Generally, batchwise techniques are the best when performing measurements that do not require constant source strength, e.g., half-life determinations, while continuous techniques (or batch techniques with a high repetition frequency) are more convenient when performing long-term measurements that require a comparatively constant source strength. Such measurements include $\beta\gamma$ - and $\gamma\gamma$ -coincidences, as well as $\gamma\gamma$ -angular correlations.

The original technique for batchwise solvent extraction separations consisted of dissolving the irradiated sample in an aqueous phase, mixing the aqueous phase with an organic solution in a funnel, shaking for some time, and waiting until the phases had settled. If necessary, consecutive back-extractions and re-extractions were performed until the radiochemical purity of the product was acceptable. The method was time-consuming and required a lot of manpower, and it was difficult to obtain separation times shorter than ~ 30 s. Nevertheless, the method has been used with good results for studies of several rather short-lived fission products as well as for studies of chemical properties of the transactinide elements rutherfordium and dubnium, using $78\text{ s }^{261}\text{Rf}$ and $34\text{ s }^{262}\text{Db}$ as tracers.

Batch experiments are hampered by the time needed for phase separation and the need to repeat the experiments a large number of times to get sufficient counting statistics. To overcome these limitations the group at the Institut für Kernchemie, University of Mainz (Germany) has developed an apparatus (Trautmann 1995), where the extraction agent is sorbed onto a plastic powder. Thus, the phase separation problem is taken care of by using a solid organic phase. The apparatus was operated by an electronic programmer, which decreased the need for manual work and made it possible for a single person to perform

hundreds of experiments in a comparatively short time. The technique also took advantage of the possibility to pulse the Mainz TRIGA reactor, i.e., each pulse irradiation was followed by an automatic batch separation.

This type of solvent extraction procedure was developed for several elements and used very successfully in nuclear spectroscopy investigations of nuclei in the area around $A = 100$. The technique has also been used for fission yield determinations.

Automated Rapid Chemistry Apparatus (ARCA) is another successful technique using solid organic phases and computer control. It was developed at the Gesellschaft für Schwerionenforschung (GSI), Darmstadt (Germany). ARCA is an HPLC system based on fast repetitive chromatographic separations in micro columns. Depending on the separation procedure to be performed, the columns can be filled either with an organic extractant adsorbed on an inert supporting material, or with ion exchanger.

The ARCA II system (Schädel et al. 1989) consists of

1. A section for collecting activity from the gas-jet and for carrying out the chemical separations
2. An HPLC section of pumps, valves, and solvent reservoirs
3. An electropneumatic valve system
4. A control unit

All parts in contact with solutions are made of inert materials. The chemical separation section is symmetrical and operated in an alternating mode between left and right. Simultaneously three operations are performed: activity from the gas-jet (Stender et al. 1980) is collected on a polyethylene frit, previously collected activity is dissolved and transported to a column for chemical separation on one side, and the next column is washed and conditioned on the other side. The products of interest are eluted from the columns onto preheated tantalum or titanium disks and the eluent is evaporated. After flaming and cooling, the disk is placed in the measuring position. Typical times from the end of irradiation to the start of measurements are 50 s, which makes it possible to study nuclides with a half-life down to 10–15 s.

ARCA was constructed mainly to study chemical and nuclear properties of the transactinide elements. It has been used successfully to obtain data on the chemical behavior of rutherfordium, dubnium, and seaborgium.

At the Department of Nuclear Chemistry, Chalmers University of Technology, a new type of liquid–liquid separation centrifuge, the H-centrifuge, (Rydberg 1969) was developed in the late 1960s. The centrifuge was designed for studies of solvent extraction equilibria, but the holdup time was so short that it could be used also for investigations of short-lived nuclides. Therefore multistage solvent extraction equipment based on the centrifuge was developed. The equipment is called Short-lived Isotopes Studied by the AKUFVE technique (SISAK); AKUFVE is a Swedish acronym for Apparatus for Continuous Investigation of Distribution Coefficients in Solvent Extraction. SISAK is the only fully continuous solvent extraction technique that is used for studies of exotic nuclides.

The SISAK version presently in operation, SISAK 3 (Persson et al. 1989) uses centrifuges with a holdup volume of ~ 0.3 ml/phase and maximum flow rates of 3 ml/s per phase.

In a typical SISAK experiment, see ► Fig. 52.1, radionuclides are continuously transported from the production site in an accelerator or a research reactor to the SISAK equipment via a gas-jet transport system (Trautmann 1995; Skarnemark 2000). The nuclides carried by the gas-jet are dissolved in an aqueous phase in a static mixer, and then a specially designed degassing centrifuge (Skarnemark 2000) is used to separate the carrier gas and volatile products

■ Fig. 52.1

A SISAK set-up used for liquid-liquid extraction of rutherfordium from heavy-ion reaction products

from the liquid. The temperature of the solution is usually $\sim 70^{\circ}\text{C}$ to enhance the dissolution of the aerosol particles (clusters) delivered by the gas-jet, to increase the efficiency of the degassing centrifuge and to speed up the solvent extraction kinetics in the subsequent separation steps. The solution leaving the degasser is fed into a centrifuge battery that consists of 1–4 H-centrifuges. The transport time from the target site to the detection system depends on the number of centrifuge steps and the flow rate. For a one-step chemistry, i.e., a degassing centrifuge and a single centrifuge for extraction, and maximum flow rates, the overall transport time is around 2.5 s, including ~ 1 s for the gas-jet. This fast transport has allowed detailed γ -spectroscopic studies of nuclides with half-lives down to ~ 1 s. The shortest-lived nuclide so far observed with SISAK is 0.57 s ^{114}Ru .

From the last centrifuge, the solution containing the element to be studied is pumped to a flow-through measuring cell installed at the nuclear detection system. The volume of the cell is chosen to enhance the count-rate of the isotope(s) under investigation. γ measurements are performed directly on the measuring cell that could be filled with ion-exchange resin or extraction chromatography material to increase the holdup time in front of the detectors. $\beta\gamma$ coincidence measurements are performed on a small, thin-walled cell using plastic scintillators for β detection. α measurements are performed using a specially developed liquid scintillation system (Wierczinski et al. 1996).

Rapid SISAK solvent extraction procedures have so far been developed for 20 elements. The SISAK technique has mainly been used for nuclear spectroscopic studies of short-lived fission products in the regions with deformed nuclei around $A \approx 110$ and $A \approx 150$ and to characterize previously unknown nuclei, e.g., ^{116}Pd and $^{243,244}\text{Np}$. Attempts have also been made to use SISAK for fission yield measurements. Recently the technique was successfully applied to one-atom-at-a-time studies of rutherfordium (Omtvedt et al. 2002, 2007).

52.2.3 Studies in Complex Chemistry

Solvent extraction is an excellent method to study complex equilibria and to determine complex formation constants. Suppose that an organic acid distributes between an organic and an aqueous phase with the distribution ratio k_D and also that the fraction of A^- present in the aqueous phase dissociates with the dissociation constant k_a . The anion A^- present in the aqueous phase can form complexes with the metal ion M^{v+} . The uncharged complex MA_v will distribute with the distribution ratio λ . The stability constants of the complexes are β_{1ij} where 1 is the number of metal ions in the complex (only mononuclear complexes are considered), i is the number of A^- ions in the complex, and j is the number of hydroxyl ions. Usually the β_{1i0} constants are determined under conditions where hydrolysis, and thus the concentration of OH^- , is negligible. Knowing these constants, the β_{10j} constants can be determined under less acidic conditions where all HA is dissociated into A^- , i.e., $[A^-]$ is constant if $[OH^-]$ is varied.

It can be shown that in such a system, the distribution ratio of the metal ion (D_M) can be written as

$$D_M = \frac{\lambda_v \beta_{1v0} [A^-]^v}{1 + \sum_{i=1}^v \beta_{1i0} [A^-]^i + \sum_{j=1}^{\omega} \beta_{10j} [OH^-]^j} \quad (52.19)$$

where v is the maximum number of A^- and ω the maximum number of OH^- in the complex.

Equation (52.19) requires (1) that no mixed complexes containing A^- and OH^- are formed and (2) that the metal is present in trace amounts, i.e., the metal ion concentration does not affect the concentration of the complexing agent. If D_M is measured as a function of $[A^-]$, the stability constants β_{1i0} and β_{10j} can be determined. To minimize the uncertainty of the constants at least 10–20 points are required. The distribution ratio value determinations can be done in funnels or test tubes, but to speed up the work and make the chemical conditions well defined, the AKUFVE apparatus was developed (Rydberg 1969). The AKUFVE (see Fig. 52.2) consists of a mixing chamber connected to a centrifuge for continuous, absolute phase separation, i.e., under ideal conditions no phase contains more of the other phase than the amount that corresponds to the solubility. The outgoing phases are pumped to a sampling device where samples are taken for subsequent radiometric or ICP-MS analysis. Online radiometric measurements are also possible. The phases are then pumped back to the mixing chamber. The aqueous phase contains cells for online measurements of the hydrogen ion concentration as well as a reducer to keep redox sensitive elements in the desired charge state. Chemicals to change, e.g., pH are added into the mixing cell. Temperature is measured at several points in the system. The centrifuge is made of palladium-passivated titanium or polyetheretherketone (PEEK).

The AKUFVE can be used to determine D values in the range $10^{-5} < D < 10^5$. The time needed for determination of a complete extraction curve is about 1 day. A typical AKUFVE extraction curve is shown in Fig. 52.3. This curve shows how to determine complex stability constants if the formed complex is not extractable. In such a case, it is possible to start with the metal tracer extracted into a suitable organic solvent. With the increasing concentration of the complexing agent in the aqueous phase, the extraction will decrease. By plotting the ratio between D_0 (without complexing agent) and D versus the concentration of the complexing agent it is possible to calculate the complex stability constants.

52.2.4 Studies of Plutonium Speciation

Plutonium is a difficult element to investigate since its redox potentials make possible four oxidation states – Pu(III), Pu(IV), Pu(V), and Pu(VI) – to coexist in solution at the same time. Thus, it is important to have experimental methods to determine the speciation. At high

concentrations, e.g., spectrophotometry can be used. However, since most experiments are performed at tracer-level concentrations, there is also a need for radiochemical methods. One such method is solvent extraction with HTTA (thenoyltrifluoroacetone) as reported by Choppin et al. (1997).

In this method Pu(IV) is extracted below pH 1, Pu(VI) in the pH range 1–2, Pu(III) above pH 3, while Pu(V) is poorly extracted even at pH 5. The method has limitations, e.g., because pH adjustments may perturb the redox equilibria. Other extractants used for plutonium speciation include tri-*n*-butyl phosphate (TBP), bis-2-ethylhexyl phosphoric acid (HDEHP).

52.2.5 On-Line Determination of Iodine Speciation in Reactor Water

Another application of solvent extraction to redox speciation studies is the method developed for iodine (Malmbeck and Skarnemark 1995). It was used for online speciation of iodine in the Forsmark BWR power plant in Sweden. Iodine can enter the reactor water in two ways, either by fission of “tramp” uranium (uranium that is adsorbed on the outer surface of the fuel pins) or via leaking fuel pins. In this method, a tiny stream of water was withdrawn from the reactor system and used as feed for a 20 stage mixer–settler battery. The mixer–settlers were arranged in four batteries with 4, 4, 6, and 6 mixer–settler units. Part of such a mixer–settler battery is shown in ► Fig. 52.4.

In the first four-stage mixer–settler battery, elementary iodine and organic iodides like CH_3I are extracted into an aliphatic kerosene. In a second four-stage mixer–settler battery, the

► Fig. 52.4

Small mixer-settler battery of the type used for iodine speciation experiments

organic phase is contacted with an aqueous phase containing NaI carrier, Na_2SO_3 as reductant and H_2SO_4 . The organic iodides remain in the organic phase, while iodine is reduced to iodide and stripped to the aqueous phase. The aqueous phase from the first extraction step is mixed with NaI carrier, HNO_3 and NaNO_2 to oxidize iodide to iodine. This iodine is then extracted into kerosene in a six-stage mixer-settler battery together with iodine that has been present in the reactor water as HIO. After these steps, the aqueous phase only contains iodine as iodate and periodate. The aqueous phase from this extraction battery is first mixed with KIO_3 carrier and H_2SO_4 , and then with Na_2SO_3 to reduce IO_3^- and IO_4^- to I^- . Then NaNO_2 is added and the formed iodine is extracted in a further six-stage mixer-settler battery. The aqueous phase from this step only contains a residual fraction with a few percent of the incoming iodine, probably as colloids.

Thus, in total, the method continuously produces fractions that represent the reactor-water contents of elementary iodine, organic iodides, iodide + hypiodous acid, and iodate + periodate. By comparing the specific activity of different iodine isotopes, it is also possible to determine the relative age of the iodine species in the different fractions.

52.2.6 Radioanalytical Chemistry

During the last decades methods such as Inductively Coupled Plasma Optical Emission Spectroscopy (ICP-OES), Inductively Coupled Plasma Mass Spectroscopy (ICP-MS), and Resonance Ionization Mass spectrometry (RIMS) have decreased the need for selective radiochemical procedures. Many long-lived radionuclides today have lower detection limits if using, e.g., ICP-MS than if performing radiometric measurements with reasonable measuring times. At present, the half-life limit is a few hundred years, i.e., nuclides with longer half-life (e.g., ^{99}Tc , ^{235}U , ^{238}U , ^{237}Np , or ^{239}Pu) should preferably be measured by ICP-MS and more short-lived nuclides (e.g., ^{90}Sr , ^{137}Cs , ^{238}Pu or ^{244}Cm) should be measured by radiometric methods. Thus, the main applications for modern radioanalytical methods are:

1. Determination of nuclides with half-life less than a few hundred years
2. Preconcentration of samples where the analyte is below the detection limit, e.g., the determination of ^{99}Tc in seawater.
3. Pretreatment of samples to be determined by ICP-MS to reduce the influence of interfering masses. An instructive example is the measurement of ^{99}Tc , where a separation from ^{99}Ru is imperative. Other examples are $^{238}\text{U}/^{238}\text{Pu}$ and $^{241}\text{Pu}/^{241}\text{Am}$. This pretreatment is not necessary if using a high-resolution ICP-MS, as such an instrument is capable of resolving the small mass differences within an isobar.

There is an enormous number of radioanalytical procedures based on solvent extraction and here it is only possible to give a few examples. The examples chosen have been taken from the analysis of samples from the European PHEBUS project performed at the Nuclear Chemistry, Chalmers University of Technology. Very briefly, the Phebus reactor was used to study the products formed in severe reactor accidents. The released gases and aerosols were collected in filters and in water at different positions in the experimental setup.

The unseparated samples were characterized by a high concentration of $^{134,137}\text{Cs}$ that made direct γ -spectroscopic determination of other nuclides impossible as well as by presence of fission product elements with a nonnatural isotopic composition. Thus, radiochemical separations were a prerequisite for successful radiometric and ICP-MS measurements.

The quantitative analyses were performed on acid solutions resulting from the leaching of filter cartridges. One set of samples contained 1 M HNO_3 + $\sim 2 \times 10^{-5}$ M HF and another, with a higher nuclide concentration 1 M HNO_3 and 0.002 M HF. The samples also included iodine trap samples in 4 M NaOH.

Cobalt: The separation procedure for Co was based on the extraction of Co(II) by Cyanex 272 (bis(2,4,4-trimethylpentyl) phosphinic acid) in toluene. First, the pH of the solution was adjusted to ~ 5 by addition of NH_3 . Then cobalt was extracted into Cyanex 272 in toluene. In separate experiments, the yield of the extraction step was determined to be $40 \pm 3\%$. After phase separation, the extract was contacted with 1 M HNO_3 to strip the cobalt. The yield of the strip step was measured to be $>99\%$ in separate experiments.

After phase separation, the HNO_3 solution was used for γ -spectrometry and ICP-MS measurements. No interfering elements could be seen.

Nickel: An equal amount of 10% sodium citrate solution was added to the sample. The acidity of the samples was then adjusted to $\text{pH} > 7.5$ by addition of NH_3 . Thereafter, 2 ml 1% dimethyl-glyoxime (DMG) was added to the solution. The nickel-DMG complex was extracted into pure chloroform. The extraction was repeated with fresh chloroform to improve the yield. The combined organic phases were then washed with 0.5 M NH_3 to remove impurities. Nickel was then back-extracted into 0.5 ml HNO_3 . The back-extraction was repeated once to improve the yield. The HNO_3 solution was then used for ICP-MS and liquid scintillation measurements. γ -spectrometry showed no contamination that could disturb the LSC measurements. The overall yield of this standard procedure is $>99\%$.

Zinc: First NH_3 was added to the sample until the pH was ~ 2.5 . Then zinc was extracted into 0.3 M Cyanex 302 (bis(2,4,4-trimethylpentyl)-monothiophosphinic acid) in toluene. The extract was then contacted with 5 M HNO_3 to strip the zinc. 1.5 ml of the HNO_3 solution was used for γ -spectrometry and ICP-MS measurements. It contained no other radionuclides and no elements that could interfere with the ICP-MS measurement. The chemical yield of the extraction and strip steps has been determined to be $>99\%$ in separate experiments.

Rubidium: The stable isotopes ^{85}Rb and ^{87}Rb were determined by direct ICP-MS measurements. It should be pointed out that the original intention was to isolate the individual alkali and alkaline earth metals by using cation and ion-exchange columns. The radioactive rubidium and barium isotopes had, however, decayed before dissolution of the samples and therefore only stable isotopes of these elements were determined (by ICP-MS), with the exception of ^{90}Sr , ^{134}Cs , and ^{137}Cs .

Strontium: The stable isotopes ^{84}Sr , ^{86}Sr , and ^{88}Sr were determined by direct ICP-MS measurements on the sample solutions. ^{87}Sr was not determined because it is shielded by its β -decay precursor ^{87}Rb , i.e., there should be no ^{87}Sr from fission present in the samples. ^{90}Sr has been determined indirectly via growth-and-decay of its daughter ^{90}Y , using the following standard procedure:

Sample solutions measuring 50 μl were mixed with 350 μl 5 M HNO_3 and 2.4 ml 0.1 M $\text{Al}(\text{NO}_3)_3$. The aluminum nitrate was used to complex fluoride ions. ^{90}Y and disturbing nuclides (mainly lanthanides) were extracted into 1.0 M HDEHP (bis-2-ethylhexyl orthophosphoric acid) in Solvent 70 (an aliphatic kerosene); 2.0 ml of the aqueous phase was taken out, and ^{90}Y was allowed to grow for 115 h, which gave about 72% of the equilibrium activity of ^{90}Y . The grown-in ^{90}Y was then extracted into 1.0 M HDEHP in toluene. The organic phase was washed twice with 1 M HNO_3 to remove any traces of the rather radioactive aqueous phase. ^{90}Y was then measured by Cerenkov counting directly on the organic phase. The decay of ^{90}Y was followed for approximately nine half-lives, and then the sample activity at the time of

separation was determined by a simple extrapolation of the decay curve. The decay curve gave the correct half-life of 64.1 h, which implies that the ^{90}Y sample did not contain any interfering β -emitters. The chemical yield of this procedure is known from earlier work to be $95 \pm 1\%$.

Zirconium: The sample solution was mixed with 1 M HNO_3 and 0.1 M $\text{Al}(\text{NO}_3)_3$ to complex fluoride ions and to keep the acidity high. Zr was then extracted into 0.5 M HTTA (thenoyltrifluoroacetone) in xylene. It is essential that the contact time is at least 15 min to assure complete extraction. At 1 M HNO_3 HTTA is very selective and only tetravalent elements like Zr are extracted. The organic phase was then washed with 1 M HNO_3 to remove impurities. γ -spectrometry was performed directly on the organic phase. For ICP-MS measurements zirconium can be back-extracted using 10 M HNO_3 .

Technetium and rhenium: 100 μl of the sample solution was diluted to 5 ml by addition of 0.1 M KBrO_3 . The bromate assured that technetium was present as TcO_4^- . Then TcO_4^- and ReO_4^- were extracted into 5 ml 0.05 M TOA (tri-*n*-octylamine) in toluene. The organic phase also contained 2.5% (by volume) *n*-dodecanol to prevent third phase formation. For further analysis 4 ml of the organic phase was taken out. Finally, TcO_4^- and ReO_4^- were back-extracted into 1 ml of 10 M HNO_3 . This solution was diluted and fed into the ICP-MS system.

The final fraction was also measured γ -spectrometrically. As expected, no γ -emitters could be observed, except a slight contamination of $^{134,137}\text{Cs}$. This contamination did not interfere with the ICP-MS measurements.

In separate experiments the yield of the extraction step has been determined to be $>99\%$ for Tc and $>98.6\%$ for Re. The back-extraction yield is $>99\%$ for both elements.

Molybdenum and tungsten: 1 ml of the sample solution was diluted to 20 ml with 1 M lactic acid. The acid was not treated to break up the esters that are known to form. In a separate experiment, the degree of esterification was determined to be about 10%. This does not affect the yield of the separations. In order to complex the fluoride ions ($\sim 10^{-6}$ M) in the solution, $\text{Al}(\text{NO}_3)_3$ was added to a final concentration of ~ 0.01 M. Mo and W were then extracted into 20 ml of 0.05 M TOA in toluene. The organic phase also contained 2.5% 1-dodecanol to prevent third phase formation. Finally, Mo and W were back-extracted into 10 ml of 1 M HNO_3 . This solution was diluted and measured by ICP-MS.

The final fraction was also measured γ -spectrometrically. As expected no γ -emitters could be observed.

In separate experiments, the yield of the extraction step was determined to be $>99.5\%$ for Mo and W. The back-extraction yield was $>99\%$ for both elements.

Ruthenium: 5.0 ml of the samples were made ~ 5 M with respect to HNO_3 and 0.1 M with respect to H_5IO_6 . The aqueous solutions were heated to $\sim 75^\circ\text{C}$ for 1 h to oxidize Ru to RuO_4 . The heating was performed in a closed vessel to prevent gaseous RuO_4 from escaping. RuO_4 was then extracted into 2 ml of toluene. The organic phase was measured by γ -spectrometry.

Antimony: In the direct γ -measurement of the samples, the four strongest peaks of ^{125}Sb could be observed and used for determination of the concentration. Chemical separation was also successfully performed as follows. 2 ml of the sample solution was converted from nitrate to chloride medium by repeated evaporations with concentrated hydrochloric acid. After dissolution in 3 M HCl , antimony can be extracted into pure chloroform (or another organic solvent). It can then be back-extracted into 0.1 M HCl . The extraction step is not quantitative, and three to four extractions with fresh solvent are required to obtain an acceptable yield. The back-extraction step is quantitative. The γ -spectrometric investigation showed that neither the organic nor the final aqueous phase contained anything but antimony isotopes.

Iodine: The samples contained no radioactive iodine isotopes other than ^{129}I and they were therefore analyzed only by ICP-MS and without chemical separation. However, the following radiochemical method was also developed for the samples. Some Na_2SO_3 was added to the solution to reduce iodine to iodide. Then iodide carrier was added in a concentration of $\sim 10^{-3}$ M. An equal amount of 0.1 M NaNO_2 was added to oxidize iodide to I_2 . The elementary iodine was then extracted quantitatively into pure kerosene. It could then be back-extracted into an aqueous phase containing 0.2 M H_2SO_4 and 0.05 M Na_2SO_3 . The back-extraction is not quantitative and thus it has to be repeated at least twice with a fresh aqueous phase.

Cesium: ^{133}Cs and ^{135}Cs were determined by direct ICP-MS measurements of the sample solutions. ^{134}Cs was determined by γ -spectrometry and ^{137}Cs by γ -spectrometry and ICP-MS, which gave an opportunity for intercalibration of the methods. The results agreed within the error limits.

Lanthanides: 0.2 ml of the nitric acid solutions were diluted to 20 ml with a 0.1 M $\text{Al}(\text{NO}_3)_3$ solution. The $\text{Al}(\text{III})$ ions were present to complex fluoride ions. Then the $\text{Ln}(\text{III})$ ions were extracted into 20 ml 1 M HDEHP (bis-2-ethylhexyl orthophosphoric acid) in Solvent 70. The organic phase was washed with 2 ml 0.01 M HNO_3 . Thereafter the lanthanides were back-extracted with 2.2 ml 5 M HNO_3 . The strip solutions were combined and used for ICP-MS measurements. A contact time of 60 s was used for extraction as well as for back-extraction.

In separate experiments the yield of the extraction step has been determined to be $>99\%$ for all lanthanides. In the washing step $>99.9\%$ of the lanthanides stay in the organic phase. The total yield of the two-step back-extraction is $>99\%$.

Neptunium, plutonium, americium, and curium: To improve the sensitivity, neptunium, plutonium, americium, and curium were measured after chemical separation. For americium and curium, chemical separation and radiometric measurement were the only alternative; due to the short half-lives, α -spectrometry is more sensitive than ICP-MS.

200 μl of the sample solutions were mixed with 0.4 ml 0.4 M $\text{Al}(\text{NO}_3)_3$ and 3.6 ml 1 M HNO_3 . The resulting $\text{Al}(\text{III})$ concentration was ~ 0.01 M. This measure was taken to complex the fluoride ions present in the solution ($\sim 10^{-5}$ M). 0.3 ml 10 M HNO_3 and 0.3 ml 3.1 M $\text{NH}_2\text{O}\cdot\text{HCl}$ was added to the samples to reduce Pu to Pu(III). Thereafter the samples were heated to $80\text{--}85^\circ\text{C}$ for 15 min and 8 ml 2.1 M NaNO_2 was added to oxidize Pu(III) to Pu(IV). After cooling to room temperature, Pu and Np were extracted into an equal amount of 0.5 M HTTA in xylene. The contact time was 20 min to get close to equilibrium. The resulting organic phase was used for the Pu and Np determination and the aqueous for Am and Cm. The organic phase was washed with 10 ml 1 M HNO_3 . Then Pu and Np were back-extracted into 0.5 ml 10 M HNO_3 , using 5 min contact time. The acid concentration was adjusted to 1 M, and Pu and Np re-extracted into 0.5 M HTTA in xylene. The contact time was 20 min. Pu and Np were back-extracted with 1 ml 10 M HNO_3 . The aqueous phase was diluted to 1 M HNO_3 and measured with ICP-MS and α -spectrometry.

The pH of the aqueous phase from the first HTTA extraction was then adjusted to 1. When adjusting it is important not to exceed $\text{pH} \sim 2$, because a too high pH will cause an irreversible sorption of trivalent actinides on the walls of the extraction vessel. Am and Cm were then extracted into 2.5 ml 1 M HDEHP in kerosene. The extraction was repeated with 2.5 ml of fresh HDEHP solution to increase the yield. The contact time was 60 s. Then Am and Cm were back-extracted into 1 ml 7 M HNO_3 . The acid was diluted to 1 M HNO_3 , and used for α -spectrometry.

The total yield of Np, Pu, Am, and Cm is known to be $>99\%$ in these separations.

52.2.7 Production of ^{234}Th Tracer

In chemical investigations, thorium is often used as an analog for tetravalent actinides. The reasons are that it has only one, stable valence state and also that it is more easy to handle than, e.g., Pu(IV). ^{232}Th is, however, not always suitable because of its low specific activity. In, e.g., solvent extraction experiments ^{234}Th ($T_{1/2} = 24.1$ days) is more convenient because the chemical concentration can be kept at a tracer level. ^{234}Th is formed in the decay of ^{238}U and, thus it can be isolated from uranium. Here one procedure will be described in more detail.

The procedure (Albinsson et al. 2002) involves one cation-exchange column with Dowex 50 W X-8 (C1) and one column with Dowex 50 W X-4 (C2). The ^{234}Th is formed by growth from natural or depleted uranium in an ether solution. This ether solution is contacted with a few milliliters of water. In this step, thorium will be stripped while uranium stays in the ether solution. The aqueous phase is then transferred to column C1. Since the solution has an almost neutral pH, thorium will be strongly sorbed onto the column. The column is then washed with water to remove traces of uranium.

In the next step, oxalic acid is added to the column to elute thorium as an oxalate complex. The solution is then evaporated to dryness. After cooling ~ 15 ml concentration HNO_3 and ~ 4 ml concentration HClO_4 are added to the evaporation residue. The solution is evaporated again to remove the oxalic acid by wet combustion.

The evaporation residue is dissolved in 6 M HCl and transferred to column C2 where thorium is sorbed. Remaining traces of uranium and other decay products pass through the column. The column is washed with 6 M HCl and then thorium is eluted with 0.5 M oxalic acid. The wet combustion procedure is repeated to remove all oxalic acid and then the residue is dissolved in water while heated. The dissolution step is repeated and then the ^{234}Th tracer solution is ready for use.

Theoretically, ~ 12 MBq of ^{234}Th can be produced from 1 kg of aged ^{238}U . The chemical yield of the procedure is $>90\%$ and the specific activity of the ^{234}Th tracer is 1–3 PBq/mol Th.

52.2.8 Production of ^{239}Np Tracer

^{239}Np is often a good alternative to ^{237}Np in experiments that can be performed in a few days, e.g., investigation of solvent extraction properties. It is a β -emitter with short half-life (2.3 days), i.e., it does not create any significant amount of long-lived radioactive waste. One way to produce ^{239}Np is via the α -decay of ^{243}Am ($T_{1/2} = 7,370$ a). ^{243}Am can easily be sorbed on a cation-exchange column. In the production procedure used at Nuclear Chemistry, Chalmers University of Technology, ^{239}Np is first eluted from the column with 0.6 M HCl and 0.1 M H_5IO_6 . The periodic acid oxidizes neptunium to NpO_2^+ that does not stick to the column at this HCl concentration. Americium remains in its trivalent state and is strongly sorbed on the column.

When the neptunium has been eluted, the eluate is evaporated to dryness. Iodine disappears as I_2 gas, i.e., there is no solid evaporation residue. Neptunium is then dissolved in a suitable acid.

The amount of ^{243}Am sorbed on the column is 370 MBq, and thus it is possible to obtain 370 MBq of ^{239}Np at each elution if allowing maximum growth. Since almost no longer-lived isotopes of neptunium are present (only 0.05% of the americium is ^{241}Am that decays to ^{237}Np) the specific molar activity of ^{239}Np is ~ 2 EBq/mol if the column is eluted more often than a few times per year.

52.3 Solvent Extraction and Ion Exchange in the Nuclear Industry

52.3.1 Uranium Production

Solvent extraction is used extensively for production of uranium with every uranium atom passing at least one solvent extraction process on its way from the uranium mine to the fuel element factory. In the most common process, uranium ore is leached with sulfuric acid containing an oxidizing agent, e.g., chlorate, to oxidize uranium to U(VI). In this environment, uranium forms the complex $\text{UO}_2(\text{SO}_4)_2^{2-}$, while the unwanted daughter product radium remains in the sludge as insoluble RaSO_4 . The aqueous phase is then contacted with a tertiary amine (R_3N) and the anionic uranium complex is extracted, probably as $(\text{R}_3\text{NH})_4\text{UO}_2(\text{SO}_4)_3$. Uranium is then back-extracted to an aqueous phase that contains either chloride or carbonate ions. If the leachate contains molybdenum, it is advantageous to back-extract with chloride since this procedure is selective and retains molybdenum in the organic phase. In this case, the organic phase has to be regenerated from time to time by treatment with ammonium carbonate to back-extract the accumulated molybdenum. The aqueous phase containing uranium is treated with NH_3 to precipitate uranium as ammonium diuranate, also referred to as yellowcake. Finally, the yellowcake is purified to the product U_3O_8 .

52.3.2 Thorium Production

In nature thorium is commonly present as monazite, a lanthanide phosphate mineral that contains 1–15% ThO_2 and usually 0.1–1% U_3O_8 . Thus, thorium is often produced as a by-product together with rare earth metals and uranium. There are several production methods (see, e.g., Ritcey 2006). The choice of method depends not only on the composition of the ore but also on whether thorium is the main product or a by-product.

A common procedure begins with a treatment of monazite sand with 50–70% sodium hydroxide at $\sim 1,400^\circ\text{C}$ to convert thorium oxide to hydroxide. The filtered hydroxide is then dissolved in hydrochloric acid and the pH adjusted to 5–6 to precipitate thorium but not the main fraction of the rare earth elements. After dissolution of the hydroxide in nitric acid, thorium is extracted with methyl isobutyl ketone (MIBK) or TBP in kerosene. Thorium is then stripped from the solvent using an alkali solution.

There are also thorium recovery processes based on extraction from sulfuric acid solutions, e.g., with primary, secondary, or tertiary amines or alkyl phosphorous acids such as bis-2-ethylhexyl phosphoric acid (HDEHP) or dibutylbutyl phosphonate (DBBP). Thorium is then stripped into a nitric acid solution. The alkyl phosphorous acid processes are often employed when recovering thorium as a by-product in uranium production.

Finally, thorium is precipitated as oxalate and calcined to ThO_2 .

52.3.3 Uranium Isotope Enrichment

Neither solvent extraction nor ion exchange has become common methods for enrichment of ^{235}U but processes based on both techniques have been developed and successfully tested. They are based on chemical separations involving redox couples like U(IV)/U(VI) or U(III)/U(IV). The isotope ^{235}U shows a very slight preference for the higher valence and by combining a large number of steps a separation can be obtained.

The solvent extraction process was developed in France and is commonly referred to as the CHEMEX process (Pesme 1982). It uses the exchange reaction that takes place between tetravalent and trivalent uranium ions in an aqueous solution, in this case concentrated hydrochloric acid. The heavier isotope ^{238}U has a tendency to concentrate in the trivalent species, while the tetravalent one becomes enriched in ^{235}U . A catalyst is used to speed up the rate of exchange. If using a solvent that extracts U(IV) it is possible to obtain a fraction that is slightly enriched in ^{235}U . As extractant, TBP in an aromatic diluent was chosen. The extraction is performed in a pulse column. In a plant for high-enriched uranium (HEU) centrifugal contactors might be used especially for the higher assay sections. By doing so, the stage times and corresponding specific uranium inventory could be reduced significantly. After passing through the column, the enriched and depleted uranium streams must be chemically treated so that they can be recirculated through the column again (refluxed) or sent to another column for additional enrichment.

The ion-exchange process, also referred to as the Asahi process, was developed in Japan. It is based on the chemical isotope effect between tetravalent and hexavalent uranium. The aqueous phase flows through an ion-exchange column, and the net effect of all the chemical reactions is a “band” of uranium that moves through the ion-exchange column. In this continuous separation system, ^{235}U and ^{238}U tend to accumulate at the entrance and exit ends of the adsorption band, respectively. The adsorbent is an anion-exchange resin with high separation efficiency and an exchange rate over 1,000 times faster than the rates obtained in most commercially available resins.

The two exchange processes discussed here are representative of alternative enrichment processes that have been under study in several countries. At present, however, no country has built or operated a full-scale uranium enrichment plant based on an exchange process. The CHEMEX process has, however, been tested in pilot scale. The primary proliferation concern is that these processes are based on standard chemical engineering technology.

52.3.4 Reprocessing of Nuclear Fuel

Some countries, e.g., France, Japan, Russia, and the United Kingdom have chosen to reprocess their spent nuclear fuel to recycle uranium and plutonium as nuclear fuel and to obtain a high active waste (HAW) fraction that is less radiotoxic than the spent fuel itself. In this process, very high separation factors are necessary. The fission product activity has to be reduced by a factor of $>10^7$ and the separation factor between uranium and plutonium must be at least 2×10^4 . All full-scale reprocessing processes are based on solvent extraction, and today the plutonium uranium redox extraction (PUREX) process dominates the market completely.

In a modern PUREX plant, the fuel pins are first cut into pieces that are 3–5 cm long. The fuel is then dissolved in 6–11 M nitric acid, while the cladding hulls do not dissolve. Sometimes $<0.05\text{ M AlF}_3$ is added to the nitric acid to improve dissolution of, e.g., zirconium by complex formation. The solution is then diluted to 3–4 M and nitrite is added to assure that plutonium is present as Pu(IV) and uranium as U(VI). Plutonium and uranium are then selectively extracted into TBP in aliphatic kerosene. Fission products and trivalent actinides remain in the aqueous phase. The extract is scrubbed with nitric acid to remove all contaminants except traces of ruthenium, neptunium, and zirconium.

Plutonium is then back-extracted into an aqueous phase by reduction to Pu(III) by U(IV) or Fe(II) sulfamate. Uranium is not reduced and remains in the organic phase. Later on, it is back-extracted to an aqueous phase containing very dilute (0.01 M) nitric acid.

The plutonium fraction is then purified by several cycles comprising oxidation to Pu(IV), extraction, scrub, and back-extraction by reduction to Pu(III). This purification removes neptunium and the last traces of fission products. Finally, Pu(IV) is back-extracted into ~ 0.2 M nitric acid. The plutonium nitrate is then converted to PuO₂ or Pu metal.

The uranium fraction is concentrated by evaporation and nitric acid is added to ~ 3 M. Uranium is then extracted into a TBP solution that is scrubbed with a reducing solution to remove traces of plutonium and neptunium. This process is repeated twice. Then uranium is back-extracted into 0.01 M nitric acid and converted to uranium oxide.

The fission product solution is vitrified and stored in a final repository. More information about reprocessing can be found, e.g., in ref. Choppin et al. 2002.

The aim of the present improvement work on the PUREX process is to make the separations more selective and to create effluent streams of high purity. Thus, modifications are performed to make neptunium end up in a fraction for later transmutation in a reactor or accelerator-driven system. This can be achieved by a better control of redox conditions in the process. Today neptunium is partially co-extracted with plutonium and uranium. There are also suggestions to withdraw product streams with ⁹⁹Tc and ¹²⁹I, respectively, i.e., long-lived nuclides that might be of interest for transmutation.

52.3.5 Partitioning and Transmutation

Spent nuclear fuel can either be reprocessed (see ► Sect. 52.3.4) or put directly into a deep underground repository like in, e.g., Sweden or Finland. In both cases, the material stored in the repository contains long-lived radionuclides like ²³⁷Np and ²⁴³Am as well as varying amounts of plutonium. Therefore, the storage facility has to fulfill strict safety requirements for a very long time, typically several hundred thousand years for unprocessed fuel.

In partitioning and transmutation (P/T) the most radiotoxic elements will be removed from the waste fraction and “burned” in specially designed reactors or accelerator-driven systems. The advantages of P/T are the removal of long-lived, radiotoxic elements from the waste, which decreases the time necessary for a safe storage from several hundred thousand to ~ 700 years, and the possibility to utilize almost 100% of the energy contents of the fuel, to be compared to $\sim 3\%$ in an once-through fuel cycle with direct disposal. In a long time perspective, accelerator-driven P/T would also make it possible to produce energy from natural uranium or thorium instead of using thermal reactors.

The P/T process will be coupled after an improved PUREX process that puts all technetium, iodine, and neptunium into the waste fraction or into special fractions. Thus, the waste will contain fission products and minor actinides (americium and curium). The process will probably be a solvent extraction process although molten salt systems are also studied as an alternative. The main issue will be to obtain pure Am and Cm fractions for subsequent destruction, i.e., fractions that do not contain any lanthanides. Some of the lanthanides, which are chemically very similar to trivalent actinides, have very high neutron cross sections. Therefore, they must be removed to make actinide burning possible. In some cases, it may also be desirable to transmute some long-lived fission products, e.g., ⁹⁹Tc and ¹²⁹I, to more short-lived nuclides.

The development of P/T processes in the European Union, Japan, and the United States has created a new interest in solvent extraction chemistry. The process has to be extremely efficient and it should preferably be based on extractants and diluents containing nothing but carbon,

hydrogen, oxygen, and nitrogen (the CHON principle). By doing so, the organic phase will be completely incinerable after use, without creating additional waste. The CHON principle also means that many traditional extractants cannot be used for P/T since they contain phosphorous, sulfur, or other non-CHON elements.

During the last 15 years, several EU framework programs have been dedicated to the partitioning of nuclear waste for nuclear transmutation. The liquid–liquid extraction projects have been NEWPART between 1996 and 1999 (Madic et al. 2000), PARTNEW between 2000 and 2003 (Madic et al. 2004), EUROPART between 2004 and 2007 (Hill et al. 2007), and at present ACSEPT. The running project started in 2008 and was planned to continue till 2011. In the United States, much effort is put into the UREX (Law et al. 2001) and TRUEX (Alexandratos et al. 1993) processes, and in Japan into ARTIST (Tachimori et al. 2002).

It is impossible to give a summary of all work that is performed in this field. The European projects, however, started with the, at that time, almost impossible task of separating trivalent actinides from trivalent lanthanides with high separation factors. A few years later the separation factors had increased from 5–6 to $\sim 1,000$. This was far too high since it made stripping difficult. Today the work has arrived at new molecules that have an appropriate separation factor, i.e., around 100, and appropriate distribution ratios. Too high separation factors are not useful since the phase separation in the equipment used in industrial liquid–liquid extraction processes does not allow higher separation factor than 10–20. This development, which has been achieved by using nitrogen donor ligands that have a higher affinity for trivalent actinides than for trivalent lanthanides, is described in Ekberg et al. (2008).

No P/T exists today, apart from reprocessing and production of mixed oxide (MOX) fuel (an embryo of P/T), but it is likely that demonstration facilities will be built within the next decades.

52.3.6 Water Clean-Up in Nuclear Power Stations

In a nuclear power station, there are several ion-exchange systems for water clean-up. In a typical BWR there are purification circuits after the steam condenser, in a small stream from the reactor vessel and for the water in the fuel storage pool. In a pressurized water reactor (PWR), part of the coolant in the primary circuit is withdrawn, cooled, and pumped through an ion-exchange filter. As indicated by the word “filter,” these ion exchangers are also used to remove particles from the liquids. They often consist of mixed cation and anion exchangers that are very finely ground; bead sizes of ~ 400 mesh are common.

The ion exchangers become very radioactive, and for organic ion exchangers a limit is set at an absorbed dose of $\sim 10^6$ Gy. Remotely controlled systems are used to backwash the filters and change the resin when too much activity leaks through or the pressure drop becomes too large.

52.3.7 Final Storage of Radioactive Waste

Ion-exchange processes are also of utmost importance in the Swedish concept for final storage of nuclear fuel. According to this method, the spent nuclear fuel will be placed in copper canisters that are disposed into bentonite-filled shafts at about 500 m depth in the granite bedrock close to the Forsmark nuclear power plant. In this concept there are four barriers that will prevent radionuclides from leaking into the groundwater: (1) the fuel itself is very insoluble in water, (2) the copper canister is chemically stable, (3) bentonite clay (sodium montmorillonite) is

a good ion exchanger, and (4) the bedrock itself is an excellent ion exchanger that makes most cations sorb strongly. The Swedish groundwater is strongly reducing, i.e., long-lived elements like plutonium and technetium will be reduced to Pu(IV) and Tc(IV) that are strongly retained on the “ion-exchange column” formed by the rock surfaces.

A similar repository is under construction in Finland, close to the Olkiluoto nuclear power plant.

52.4 Acronyms

ACSEPT	European P/T project
AKUFVE	Apparatus for continuous determination of distribution ratios in solvent extraction
ARCA	Automated Rapid Chemistry Apparatus
ARTIST	Japanese P/T project
BWR	Boiling Water Reactor
CHEMEX	French uranium enrichment process based on solvent extraction
CHON	Contains only carbon, hydrogen, oxygen or nitrogen
EUROPART	European P/T project
HAW	High Active Waste
HEU	High-Enriched Uranium
HPLC	High-Performance Liquid Chromatography
ICP-MS	Inductively Coupled Plasma Mass Spectrometry
ICP-OES	Inductively Coupled Plasma Optical Emission Spectrometry
IUPAC	International Union of Pure and Applied Chemistry
LLPC	Liquid-Liquid Partition Chromatography
MOX	Mixed OXide fuel
NEWPART	European P/T project
PARTNEW	European P/T project
PHEBUS	European reactor safety project
P/T	Partitioning and Transmutation
PUREX	Plutonium Uranium Redox EXtraction
RTIL	Room Temperature Ionic Liquid

Abstract: The history, theoretical fundamentals, and practical application of thermochemistry are briefly reviewed. The main advantages of the method – the speed and selectivity of chemical separation of complex mixtures of short-lived radionuclides, including transactinide ones – are analyzed. Prospects of thermochemistry in production of radionuclides widely used in science and technology are considered on the basis of the performed systematic investigations of the thermochemical behavior of volatile compounds of the elements of the periodic table.

53.1 Introduction

The increasing interest in studying short-lived radionuclides, including transactinide ones, in the early 1960s created a demand for improved or newly created methods allowing fast and highly selective separation of various radioelements.

The analysis of the trends in development of analytical and radiochemical methods showed that the simplest and most effective way to satisfy this demand was through high-temperature gas chemistry. The already gained experience in using a variety of gas chromatography versions logically led to the choice of thermochemistry (TC), i.e., stationary non-isothermal gas–solid chromatography based on thermal variation of the interaction between the volatile radioactive species (atoms or molecules) and the adsorbent. In this method, a negative temperature gradient is produced in the direction of the carrier gas flow or, alternatively, in vacuum. It is, consequently, this temperature gradient that retards the transport of species in the column. If the slowing-down is different for different species, they are separated. Thus, it becomes possible to concentrate components of complex mixtures supplied to the thermochemical column even continuously (in contrast to ordinary gas chromatography).

Historically, the term “thermochemistry” was first applied to the method for separation of mainly volatile organic compounds in which the temperature field with a negative gradient moves along the column, so that the outlet temperature gradually increases ousting the separated substances from the column. In this case the thermochemical diagram is a curve expressing the time (t) or temperature (T) dependence of the outlet concentration, i.e., $c = f(t)$ or $c = f(T)$.

In radiochemistry, the most popular version is TC with a stationary temperature gradient, in which the concentration of a substance and its local distribution depend on the distance or temperature, i.e., $c = f(x)$ or $c = f(T)$. This means that the volatile compounds remain in the thermochemical column. In the literature this method was previously referred to by various jargon terms, e.g., “horizontal distillation,” “separation on the gradient tube,” “separation on the temperature gradient,” etc.

It is particularly noteworthy that Marie and Pierre Curie used the method in question as far back as the end of the nineteenth century when they discovered Ra and Po (Curie and Curie 1898). Polonium sulfide was distilled in a carbon dioxide flow into a tube with a negative temperature gradient, where it was precipitated in a narrow zone. Unfortunately, this experience and method has long been forgotten. What may also be considered the first publication on the use of TC in radiochemistry is the paper by Merinis and Bouissieres (1961) on separation of noncarrier-added spallogenic products: radioactive Hg, Pt, Ir, Os, and Re isotopes have been separated from macroscopic gold targets bombarded with medium-energy protons. Another important work of those, which stimulated the further development of TC, was an attempt to

separate and identify the artificial element 104 (now named rutherfordium), an analog of Hf, which clearly showed advantages of the method in the study of short-lived radionuclides (Zvara et al. 1971).

The simple equipment required and the high efficiency of the method stimulated its rapid theoretical and practical development in the 1960s, marked with some outstanding results, as for example, the characterization of previously unknown isotopes of many elements from the periodical system and even more – the discovery of new transactinide elements. Much has been contributed for the increasingly wide use of TC by a group of radiochemists (I. Zvara, B. Eichler, Yu. T. Chuburkov, V. P. Domanov, S. Hübener, A. B. Yakushev, et al.) from the Flerov Laboratory of Nuclear Reactions (JINR Dubna, Russian Federation). This and another group (H.W. Gäggeler, A. Türlér, R. Eichler, et al.) from the Paul Scherrer Institut, Villigen, Switzerland, still successfully continue the development of thermochemistry.

53.2 Equipment and Techniques

Thermochemical set-up: Figure 53.1 displays a typical thermochemical apparatus (Hickmann et al. 1993), the main part representing a gradient oven providing the required temperature field along the column. The oven may be made of a large number of short sections or by winding a heat-releasing wire (nichrome, superkanthal, platinum, etc.) on an insulating tube (quartz, porcelain, alundum, etc.) in a varying mode. To smooth the temperature field of the oven, it has a heat-conducting tube inside and a thermal-insulating

Fig. 53.1

Thermochemical setup and typical profile of temperature along the column (Reproduced with permission from Radiochimica Acta, Hickmann et al. 1993)

coating outside. The simplest design is an oven heating at one end of a long heat-conducting tube surrounded with a vacuum enclosure. This design ensures almost linear temperature distribution along the apparatus. The “cold” end of the tube is usually cooled with water or even liquid nitrogen.

The thermochromatographic apparatus also comprises

- A system for carrier gas (and/or reactant gas) supply, purification, and flow rate control; or, alternatively, an appropriate vacuum system.
- A system for injection of substances to be separated (periodic or continuous).
- A system for trapping outgoing reactant gases and possible radioactive gases or aerosols.

Thermochromatographic columns (TCC) are usually made of glass, quartz, porcelain, or metallic tubes, chemically resistant to reactant gases. They may be open (hollow) or filled with various substances (metals, oxides, halides, etc.). Probes, containing the radionuclides of interest, are inserted into the TCC at places of maximum temperature (T_S) in a batch mode before the experiments (off-line) or continuously (online) using gas jets with the radionuclides of interest adsorbed on microdisperse aerosol particles (KCl, MoO₃, etc.).

Temperature profiles: A method for determining the profile of the distribution of separated substances in the column is of major importance in thermochromatographic experiments. Most of them are carried out with radionuclides emitting radiation that penetrates through the columns walls (relatively “hard” β and γ rays), which allows the radioactivity within the column sections to be measured off-line either by cutting the column into small parts or by collimating the detector used and screening the column. Mixtures of radionuclides usually require the use of HPGe detectors because of the high-energy resolution. If sufficient activities of radionuclides decaying with emission of high-energy γ -quanta are used, it is in principle possible to monitor the substance distribution in the column online during the thermochromatographic experiment by using one or several well-collimated movable detectors.

The situation becomes much more complicated when the radionuclides used undergo α decay or spontaneous fission, i.e., if non-penetrating radiation needs to be detected. If these radionuclides are long-lived, the column is cut into small sections, the substances adsorbed on its inner surface are washed off with appropriate solutions, and the resulting solutions are analyzed. In the case of short-lived radionuclides, e.g., transactinide elements, semiconductor or track detectors (mica, quartz) placed inside the column are used. They allow single decays to be determined at each point of the column. In principle, other methods may be used to determine the distribution of substances in the column, e.g., photospectrometry and X-ray fluorescence.

The experiment result is a thermochromatogram. An example is given in [Fig. 53.2](#) (Hickmann et al. 1993), which displays the distribution of bromides of uranium fission products continuously supplied to the column for 15 min. The thermochromatogram for each chemical species allows the determination of the basic parameter T_a , the adsorption temperature (center of gravity of distribution of the substance in the column).

Numerous experiments have shown that this quantity depends first of all on the chemical composition of the volatile substance and on the column material (adsorbate–adsorbent interaction). In addition, it depends on the starting temperature of the column, the period of the thermochromatography procedure, the temperature gradient, the diameter of the column, type and flow-rate of carrier gas (or gas-reagent), and some other parameters. Thus, the adsorption temperature T_a is not a constant and, for example, varies inversely with the duration of the thermochromatography procedure of a particular experiment. Therefore, it is

■ Fig. 53.2

Element distribution in a thermochematographic column with 9 vol% hydrogen bromide as reactive additive to the carrier gas nitrogen, together with the temperature profile along the column. Quartz-powder column, 15 min exposure time (Reproduced with permission from *Radiochimica Acta*, Hickmann et al. 1993)

essential for researchers to try to find ways of transferring the variable T_a to standard constants $\Delta \overline{H}_a^0$ and $\Delta \overline{S}_a^0$, enthalpy and entropy, respectively, used in ordinary gas chromatography.

53.3 Theory

53.3.1 Transport of Volatile Species Along the Column

All theoretical treatments of the thermochematographic process (Merinis and Bouissieres 1969; B. Eichler and Zvara 1975; Steffen and Bächmann 1978b; Novgorodov and Kolatchkowski 1979), beginning with papers by Merinis and Bouissieres (1969), are based on the fact that the species' (atom, molecule) transfer time within the TCC breaks into two components – the residence time in the gaseous phase and the residence time on the surface of the column. The latter is governed by the average lifetime of the species in the adsorbed state τ_a (s) related to the temperature by the Frenkel equation (Frenkel 1924):

$$\tau_a = \tau_0 \cdot \exp\left(\frac{Q}{RT}\right), \quad (53.1)$$

where τ_0 is the period of oscillation of the species in the adsorbed state perpendicularly to the surface (s); Q is the adsorption heat ($\text{J} \cdot \text{mol}^{-1}$); R is the gas constant ($\text{J} \cdot \text{mol}^{-1} \cdot \text{K}^{-1}$); T is the absolute temperature (K).

The total time of the species transfer (transport) in the column from the starting temperature T_s to the adsorption temperature T_a is most comprehensively described by B. Eichler and Zvara (1975):

$$t = \frac{T_0}{gu_0} \ln \frac{T_a}{T_s} + \frac{sT_0 \frac{V}{A} \exp\left(\frac{\Delta \overline{S}_a^0}{R}\right)}{vgu_0} \int_{T_s}^{T_a} \frac{1}{T} \exp\left(-\frac{\Delta \overline{H}_a^0}{RT}\right) dT \quad (53.2)$$

where T_0 is the standard temperature, 298.15 K; g is the gradient of the temperature for its linear distribution along the column ($\text{K} \cdot \text{cm}^{-1}$); u_0 is the linear velocity of the carrier (reagent) gas in the column under standard conditions ($\text{cm} \cdot \text{s}^{-1}$); s and v are the open surface and the open volume of the column per its unit length, (cm) and (cm^2) respectively; V/A is the ratio of the standard molar volume to the standard molar surface (cm); $\Delta\overline{H}_a^0$ is the adsorption enthalpy ($\text{J} \cdot \text{mol}^{-1}$); $\Delta\overline{S}_a^0$ is the adsorption entropy ($\text{J} \cdot \text{mol}^{-1} \cdot \text{K}^{-1}$).

This equation is derived on the assumption that the main characteristic parameters of the adsorption interaction ($\Delta\overline{H}_a^0$ and $\Delta\overline{S}_a^0$) are independent of the temperature, that there is no surface diffusion, and that the carrier (reagent) gas adsorption is negligibly small. Solution of this equation, i.e., finding $\Delta\overline{H}_a^0$ is virtually reduced to solution of the integral in expression (53.2). This may be done either numerically or by replacing the integral by the difference of the so-called integral exponential function represented in the tabulated form:

$$\int_{T_s}^{T_a} \frac{1}{T} \exp\left(-\frac{\Delta\overline{H}_a^0}{RT}\right) dT = \left[E_i^*\left(-\frac{\Delta\overline{H}_a^0}{RT_a}\right) - E_i^*\left(-\frac{\Delta\overline{H}_a^0}{RT_s}\right) \right] \quad (53.3)$$

Analyzing (53.2) B. Eichler and Zvara (1982) considered the effect of various standard state models (V/A) and values of $\Delta\overline{S}_a^0$, calculated on the basis of the molecular-kinetic concepts as the loss of degrees of freedom of the particle (atom) on its transition from the gas phase to the adsorbed state, on $\Delta\overline{H}_a^0$. With given mobile and localized adsorption and five standard states, the theoretically calculated values of $\Delta\overline{S}_a^0$ for absorption of Po on the Cu surface vary in a very wide range from -31.10 to $-512.27 \text{ J} \cdot \text{mol}^{-1} \cdot \text{K}^{-1}$ (B. Eichler and Zvara 1982). Naturally, this strongly affects the values of $\Delta\overline{H}_a^0$ calculated by expression (53.2). In the case of polyatomic molecules, when one has to take into account the entropy variation due to variation of internal degrees of freedom, rotation of the molecule, and probably chemical bond of molecules with the surface, a theoretical calculation of $\Delta\overline{S}_a^0$ becomes much more complicated. Thus, the uncertainty in evaluation of $\Delta\overline{S}_a^0$ results in approximate values of $\Delta\overline{H}_a^0$ only. Several attempts have been made to calculate empirically $\Delta\overline{S}_a^0$ and $\Delta\overline{H}_a^0$ for various compounds, e.g., chlorides and oxides (B. Eichler 1976), and to determine experimentally these two main parameters of the adsorption interaction, but their values obtained for a majority of adsorbate–adsorbent pairs are still estimates. Therefore, it is desirable to cite these values together, no matter how they were obtained.

The generally accepted theoretical value of $\Delta\overline{S}_a^0$ is the one obtained for the mobile adsorption model and the standard state $V/A = 1 \text{ cm}$ (B. Eichler and Zvara 1982)

$$\Delta\overline{S}_a^0 = R \cdot \ln\left(\frac{1}{(1 \text{ cm}) \cdot v_B} \sqrt{\frac{kT_a}{2\pi m}}\right) + \frac{1}{2}R, \quad (53.4)$$

where R is the gas constant; v_B is the characteristic adsorbent frequency equal to $5 \times 10^{12} \text{ s}^{-1}$ for quartz; k is the Boltzmann constant; T_a is the adsorption temperature (K) (B. Eichler et al. 2002); m is the mass of the molecule (g).

The key question about the values of $\Delta\overline{S}_a^0$ and $\Delta\overline{H}_a^0$ and, if possible, about their dependence on the temperature may be eventually solved by carrying out quite systematic series of experiments with several experimental conditions, e.g., experiment period, starting temperature, gas composition and velocity, column diameter, etc., varied over a wide range for one and the same adsorbate–adsorbent pair (Steffen and Bächmann 1978b; Chuburkov et al. 1993). Provided that $\Delta\overline{S}_a^0$ and $\Delta\overline{H}_a^0$ are temperature-independent, dependence of $\ln \frac{-\lg v_0}{sT_a \cdot (1 \text{ cm})}$ on $\frac{1}{T_a}$

Table 53.1

Values of ΔS_a^0 ($\text{J} \cdot \text{mol}^{-1} \cdot \text{K}^{-1}$) obtained by various methods

Compound	Experiment (Steffen and Bächmann 1978b)		Empirical dependence (Chuburkov et al. 1993)	Equation 10.4
	Isothermal chromatography	Thermo-chromatography		
ReO_3	-187.0 ± 5.0	-147.3 ± 17.0	-150 ± 5	-166.3
HReO_4	-206.4 ± 3.4	-114.8 ± 11.0	-133 ± 3	-168.9
IrO_3	-191.0 ± 6.2	-137.0 ± 15.3	-150 ± 5	-168.1

(v_0 is the volume gas flow under standard conditions) yields a straight line with a slope $-\Delta H_a^0/R$ and an intercept on the x -axis at $\ln \frac{RT_0}{-\Delta H_a^0} + \frac{\Delta S_a^0}{R}$.

► Table 53.1 illustrates the different approaches of determination of ΔS_a^0 in the case of adsorption of volatile Re and Ir compounds with oxygen-containing carrier gas systems on TCC quartz surfaces. Undoubtedly, experiments are of primary importance in determining the entropy values.

53.3.2 The Potential of Thermochemistry for Radiochemical Separations

In analytical chemistry the quality of separation is characterized by the criterion for separation of two substances ($R_{1,2}$), expressed in TC as:

$$R_{1,2} = \frac{T_{a1} - T_{a2}}{2(\sigma_1 + \sigma_2)} \quad (53.5)$$

where T_{a1} and T_{a2} are the temperatures of the centers of gravity of the distribution of substances 1 and 2 (K); σ_1 and σ_2 are the standard deviations of their distribution (K).

Two theoretical contributions have focused on the distribution of the substance in the course of its motion along the TCC (Novgorodov and Kolatchkowski 1979; Zvara 1985). In one of them the general relations of gas chromatography are adopted. The height equivalency to the theoretical plate (HETP), H (cm), for the laminar flow in an open straight tube column, is (Giddings and Seager 1960)

$$H = \frac{2D_{\text{gas}}}{u_x} + \frac{d^2 u_x}{96D_{\text{gas}}} \quad (53.6)$$

where D_{gas} is the diffusion coefficient of the substance under study in the carrier gas ($\text{cm}^2 \cdot \text{s}^{-1}$); u_x is the linear velocity of the carrier gas defined as

$$u_x = u_0 \cdot \frac{T}{T_0} = \frac{4v_0 T}{\pi d^2 T_0} \quad (53.7)$$

where u_0 is linear velocity of the carrier gas under standard conditions ($\text{cm} \cdot \text{s}^{-1}$); d is the diameter of the column (cm); T is the temperature of the column (K). The diffusion coefficients correlate according to the molecular-kinetic concepts:

$$D_{\text{gas}} = D_{\text{gas}}^0 \left(\frac{T}{T_0} \right)^{3/2} \quad (53.8)$$

where D_{gas}^0 is the diffusion coefficient under standard conditions. Considering (53.7) and (53.8), expression (53.6) takes the following form

$$H = \frac{aT + b}{\sqrt{T}} \quad (53.9)$$

where $a = \frac{\pi D_{\text{gas}} d^2}{2v_0 \sqrt{T_0}}$ and $b = \frac{v_0 \sqrt{T_0}}{24\pi D_{\text{gas}}}$.

For isothermal gas chromatography the dispersion (σ^2) of the substance distribution in the column increases with the coordinate x (i.e., the zone is expanded) as

$$\sigma_{\text{exp}}^2 = xH \quad (53.10)$$

As described above, an advantage of TC over ordinary gas chromatography is that the decrease in the temperature of the column slows down the motion of the zone of the substance to be separated. In addition, the delayed part of the zone meets a higher temperature and is speeded up while the leading part, on the contrary, is slowed down. Thus, the distribution of the substance formed at each moment of the process, i.e., at each individual adsorption temperature, is determined by the fact that the expanding of the zone is equal to its compression

$$d\sigma/dt = (d\sigma/dt)_{\text{exp}} + (d\sigma/dt)_{\text{comp}} = 0 \quad (53.11)$$

As follows from (53.9) and (53.10) and in view of $T = T_s + gx$, the dispersion causing the expanding of the zone is

$$\sigma_{\text{exp}}^2 = \frac{a(T_s + gx) + b}{\sqrt{T_s + gx}} \cdot x \quad (53.12)$$

Differentiation of this expression results in the expression

$$\left(\frac{d\sigma}{dt}\right)_{\text{exp}} = \frac{1}{4\sigma\sqrt{T}} [a(3T^2 - TT_s) + b(T + T_s)] \cdot w_{\text{zone}} \quad (53.13)$$

where w_{zone} is the velocity of the moving center of gravity of the zone ($\text{cm} \cdot \text{s}^{-1}$). The compression component can be expressed, according to Ohline and Deford (1963), as

$$\left(\frac{d\sigma}{dt}\right)_{\text{comp}} = -g\sigma\Delta\overline{H}_a^0 \frac{w_{\text{zone}}}{RT^2} \quad (53.14)$$

Substituting (53.13) and (53.14) into (53.11) yields

$$\sigma^2 = \frac{R\sqrt{T_a}[aT_a(3T_a - T_s) + b(T_a + T_s)]}{4g\Delta\overline{H}_a^0} \quad (53.15)$$

By using the derived basic equations of TC (Novgorodov and Kolatchkowski 1979), the distribution of a substance along the column was calculated for the simplest case, i.e., when the substance is injected in the column in the form of a δ -function [$c = f(s, t) = \infty$].

Figure 53.3 displays the computed thermochematogram of three hypothetical substances with $\Delta\overline{H}_a^0 = -84, -126, \text{ and } -168 \text{ kJ} \cdot \text{mol}^{-1}$ for three process periods of 10, 100 and 1,000 s. The calculation was carried out with the parameters $d = 0.3 \text{ cm}$; $v_0 = 0.5 \text{ cm}^3 \cdot \text{s}^{-1}$; $D_{\text{gas}}^0 = 0.1 \text{ cm}^2 \cdot \text{s}^{-1}$; $T_s = 1,100 \text{ K}$, and $g = -16 \text{ K} \cdot \text{cm}^{-1}$. Not only retarding but also compression of the zone of the hypothetical substances is obvious. Note that the calculations

Fig. 53.3

Distribution of three hypothetical substances in the TCC for three exposure times (see explanation in the text)

were carried out for the carrier gas velocity close to the optimum velocity, the expression for which was derived from (53.6)

$$v_{0(\text{opt})} = \pi D_{\text{gas}}^0 d \sqrt{\frac{6(T_s + T_a)}{T_0}} \quad (53.16)$$

The standard deviation σ for the substance with $\Delta \overline{H}_a^0 = -126 \text{ kJ} \cdot \text{mol}^{-1}$ and $T_a = 500 \text{ K}$ is 3.6 K under the conditions considered.

A slightly different approach to determine the distribution of a substance in no carrier amounts (n.c.a.) was introduced by Zvara (1985). Using the Monte Carlo method and assuming that species leaving the surface of the column with an adopted probability immediately start moving at the carrier gas velocity, the author calculated the extent of the “jump” ($\overline{\eta}$) of the species to the next adsorption event, which is on the average equal to

$$\overline{\eta} = \frac{11 v_0}{48 \pi D_{\text{gas}}} \quad (53.17)$$

The calculations for the case like the one considered above yielded $\sigma = 21 \text{ K}$ for $T_a = 476 \text{ K}$ (Zvara 1985).

The calculations of the standard deviation σ were experimentally checked (Nguyen et al. 1984a) with chlorides of n.c.a. radiolanthanides. The reactant gas was an $\text{H}_2 + \text{HCl}$ (1:1) mixture thoroughly purified of O_2 and H_2O . The starting temperature was $1,373 \text{ K}$. The thermochematographic quartz column with the inner diameter of 1.25 mm was thoroughly cleaned and treated with the reactant gas at the starting temperature of $1,373 \text{ K}$. The experiments lasted for 1 h and volatilization of the chlorides was 95% in 2 min , i.e., their injection in the column was close to the “instant” (near to δ -function) mode. The optimum gas flow rate of $0.33 \text{ cm}^3 \cdot \text{s}^{-1}$ was provided. The average value of T_a for the lanthanide (La, Ce, Nd, Sm, Eu, Gd,

Yb, Lu) chlorides was 840 K and $\sigma = 5\text{--}6.5$ K. Calculation by (53.16) for $D_0 = 0.795 \text{ cm}^2 \cdot \text{s}^{-1}$ (Bretshneider 1966) and $\Delta \overline{H}_a^0 = -200 \text{ kJ/mol}$ (B. Eichler 1976) yielded $\sigma = 8.7$ K. A slight discrepancy between experiment and theory is probably due to stronger temperature dependence of D_{gas} : the real exponent in Eq. (53.8) is not 1.5 but 1.8 (Bretshneider 1966).

Gas-thermochromatographic separation techniques found wide application in radiochemistry because here, as pointed out above, the quality of separation is much less dependent on the duration and mode of sample injection in the column than in isothermal gas chromatography. The problems arising from the effect of the size of samples as well as time and mode of their injection in ordinary isothermal gas-chromatographic columns on the separation efficiency are discussed in textbooks and monographs. This issue, however, requires particular consideration in the case of gas TC. On the basis of Eqs. (53.2) and (53.15), substance distributions along the TCC were calculated for a prolonged injection mode, in particular for cork injection (Nogare and Juvert 1962), i.e., in the most often occurring case in radiochemistry, when substances are supplied into column continuously (online operation in conjunction with a reactor or an accelerator). In these computer-aided calculations the injection profile was divided into 100 pseudo- δ -functions. The response, i.e., the distribution of the substance in the thermochromatographic column, was determined for each of the input models first, and all the responses were summed subsequently. The computing parameters were the same as in the calculation shown in Fig. 53.3.

Figure 53.4 displays the distribution of a substance with $\Delta \overline{H}_a^0 = -84 \text{ kJ/mol}$ via cork injection. The ordinate shows the relative concentration, namely per cent of the injected substance, over the column length corresponding to $\Delta T = 1 \text{ K}$. Curves 1, 2, and 3 are for the sample injection times t_{in} equal to 0.1, 0.5, and 1.0 of the experiment time t_{exp} . The peaks, which result from the infinite number of divisions (100) of the injection profile, clearly show the motion of the substance in the TCC and the gradual compression (concentration) of the adsorption zone. For example, at the experiment period $t_{\text{exp}} = t_{\text{in}} = 100 \text{ s}$ the extreme right peak corresponds to the transfer time 0.5 s, the next one to 1.5 s, then to 2.5 s, 3.5 s, etc. Accordingly, at $t_{\text{exp}} = t_{\text{in}} = 10 \text{ s}$ the peaks (right to left) correspond to the transfer times 0.05, 0.15, 0.25 s, etc.

It is also illustrated, that at $t_{\text{exp}} = 10 \text{ s}$ and $t_{\text{in}} = 5 \text{ s}$ the adsorption peak is already formed 5 s after the initiation of the thermochromatographic process. The calculations were carried out for the optimum carrier gas flow rate (53.16). This flow rate might be appreciably larger, e.g., in the study of very short-lived radionuclides (with $T_{1/2} \approx 1\text{--}3 \text{ s}$) (Zvara et al. 1998), but this will result in an increased σ , i.e., in worse separation.

The separation criteria in the case of continuous sample injection in the TCC ($t_{\text{in}} = t_{\text{exp}}$) over a period of 10, 100, and 1,000 s for two pairs of substances with $\Delta \overline{H}_a^0 = -84$ and -126 kJ/mol and $\Delta \overline{H}_a^0 = -126$ and -168 kJ/mol are 0.43, 1.05, and 2.26 and 0.84, 1.27, and 1.66, respectively. Hence, satisfactory separation of the hypothetical substances under consideration is attained as soon as after 100 s.

These theoretical considerations of the thermochromatographic process presume that the adsorption entropy and enthalpy do not depend on the temperature. It was also postulated that the adsorbent was homogeneous, its surface was not saturated with the adsorbate (monolayer or less), and the carrier (reagent) gas was “unsorbable.” Diffusion in the solid phase (adsorbent) and surface diffusion were ignored. Furthermore, in the theoretical considerations the effect of the carrier (reagent) gas pressure on the substance transport was not taken into account, which, however, should be considered in the case of TC at reduced reactant gas pressures and vacuum TC or with densely filled columns.

■ Fig. 53.4

Distribution of a substance in TCC for cork injection: (1) – $t_{in} = 0.1 t_{exp}$, (2) – $t_{in} = 0.5 t_{exp}$, (3) – $t_{in} = t_{exp}$ (see explanation in the text)

53.4 Systematic Experiments

Thermochematographic investigations in radiochemistry deal with volatile (as a rule, at temperatures up to 1,500 K) radioactive elements or their compounds. At the above-mentioned temperatures most elements form one or more volatile compounds: hydrides, halides, oxides, sulfides, oxyhalides, hydroxides, organic derivatives, etc. Radionuclides used in TC are produced in various nuclear reactions. They are mainly fission products of uranium and transuranium elements, spallogenic products of reactions involving medium-energy particles, and radionuclides produced at accelerators of low-energy charged particles (p, d, ^3He , α) or of heavy ions (^{18}O , ^{22}Ne , ^{48}Ca , etc.). The latter occupy a prominent place in

thermochromatographic experiments as they are used for synthesizing atoms of new elements. The rapid development of TC was significantly due to the study and realization of the potency of this method for discovering new elements, the isotopes of which are characterized by half-lives from a few seconds to tens of seconds, too small for “usual” chemical investigations. To attain these objectives and to plan efficient work on synthesis, purification, and detection of new elements, a lot of experiments have been carried out to study the behavior of not only analogues of new elements of the periodic table but also impurity elements.

Hydrogen, air, oxygen, water vapor, halogens, hydrohalogens, CCl_4 , BBr_3 , SOCl_2 , sulfur vapor, and mixtures of some of them were used as reagent gases. The choice of the reagent gas is dictated by the conditions to be created. They must allow domination of only one volatile compound of the element under study for correct interpretation of its behavior. Most experiments were carried out with relatively long-lived radionuclides, whose volatile compounds were injected in the thermochromatographic column either directly from the pre-irradiated target or from a specially prepared sample. In this case the speed at which the volatile compound is supplied into the column depends on the diffusion speed in the sample and the rate of interaction with the reagent gas, and the injection profile usually has a decreasing exponential form. In some experiments volatile compounds were supplied into the TCC in a continuous mode immediately after production of the desired radionuclide in the reactor or at the accelerator.

Below, a brief review of the volatile compounds of most chemical elements at n.c.a. amounts, which were used in thermochromatographic experiments, will follow. The adsorption temperature was taken as the volatility criterion, which allows planning of thermochromatographic separations in preparative radiochemistry. As this quantity is not constant, its variation within traditional duration times of the thermochromatographic process (15–60 min) shall be taken into account. In addition, this variation applies to the adsorption temperatures of each component of the mixtures under separation. A particular contribution to systematic thermochromatographic investigations has been made by B. Eichler, who published a remarkable review of mainly his own works more than 30 years ago (B. Eichler 1976).

Group 1: The main compounds of alkali elements relevant for thermochromatography are the chlorides. B. Eichler and Malzeva (1976) separated Cs and Fr chlorides in a column filled with quartz sand as is described. The adsorption temperatures T_a at a chlorine flow of $t_{\text{exp}} = 1,800$ s were 670 and 590 K, respectively. According to other authors (Rudstam and Grapengiesser 1973), T_a for NaCl and RbCl are 720 and 680 K, respectively, while Merinis and Bouissieres (1969) give a T_a for CsCl of 620 K. Alkali bromides and iodides show similar behavior. The alkali elements may also be studied in the form of metals, e.g., in vacuum thermochromatographic columns of high-melting metals (Hübener and Zvara 1979).

Group 2: Ca, Sr, and Ba chlorides were investigated, and their adsorption temperatures turned out to be equal to approximately 1,200 K (B. Eichler and Domanov 1974). For Ra dichloride, T_a is slightly lower (1,130 K) (Merinis et al. 1970). The thermochromatographic investigations of these metals are described systematically (Hübener and Zvara 1982).

Group 3: The most completely studied compounds in thermochromatography are the lanthanide and actinide chlorides. Their temperatures of adsorption on quartz are presented in [Table 53.2](#). The behavior of bromides is similar to that of the chlorides (Hickmann et al. 1993). The adsorption temperatures of La and Tb trichlorides (Kim et al. 1987b) are 30 K higher than for their tribromides. High-temperature thermochromatographic investigations of volatile hydroxides of hexavalent U and Pu (probably W analogues) started recently (Hübener et al. 2001). Interesting results were obtained in thermochromatographic studies

		UCl ₆	390 (Gärtner et al. 1997)

of plutonium in moist oxygen (Domanov et al. 2002). Observed adsorption zones with $T_a \approx 720, 520, 400,$ and 170 K were attributed to plutonium compounds PuO_2 , PuO_3 , $\text{PuO}_x(\text{OH})_y$, and PuO_4 , respectively.

The study of metals or lanthanide and actinide suboxides using thermochemical columns of high-melting metals (Ti, Zr, Ta, Mo, W) is particularly promising. The experiments were carried out in vacuum (Beyer and Novgorodov 1976) or in inert helium atmosphere with Na and Ca vapor added as a reducing agent (Hübener and Zvara 1979). Adsorption of metals on metal surfaces was heretically treated (Roßbach and Eichler 1984), with both the adsorption enthalpy and entropy calculated for 63 adsorbates on 22 adsorbents. Lanthanide (B. Eichler et al. 1985b) and actinide (B. Eichler et al. 1985a) adsorbates were considered analogously. The

potential of vacuum thermochemistry for the separation of lanthanides was demonstrated (Beyer and Novgorodov 1976), where Lu, Yb, and Tm as well as Gd, Eu, and Sm were satisfactorily separated in a tantalum column with no more than 50 theoretical plates. Particularly noteworthy are the experiments with the excellent separation of Cf–Md achieved in a molybdenum TCC (Hübener and Zvara 1982), and Cm–Bk in a niobium TCC (Taut et al. 2000). The behavior of heavy actinides in TCC made of Ti, V, Nb, and Ta has been studied by Taut et al. (1998, 2001).

Group 4: The thermochemical behavior of the elements of this group received special consideration because they are assumed to be lighter analogues of the first transactinide element 104 (Rf). Zr and Hf chlorides and bromides have been studied carefully, but the results were extremely discrepant. While in early investigations the adsorption temperature of the Ti, Zr, and Hf tetrachlorides was found to be 438, 463, and 453 K, respectively (B. Eichler 1976), parallel investigation of T_a for the Zr and Hf tetrachlorides yielded 393 and 373 K, respectively (Kim et al. 1987b). Evidently, the uncontrolled oxygen content of the reactant gas led to very high T_a for ZrCl₄, e.g., 550 K (Bayar et al. 1978a) and even 840 K (Hickmann et al. 1993). This effect was carefully studied (Domanov and Kim 1988; Domanov et al. 1988), who assumed existence of volatile oxychlorides ZrOCl₂ and HfOCl₂, thermally stable in the gas up to the temperature of approximately 700 K. Their T_a values are slightly higher than the T_a of the analogue tetrachlorides (383 and 373 K) and are equal to 423 K (for ZrOCl₂ and HfOCl₂). The behavior of hafnium and zirconium bromides is similar to chlorides. Thermochemistry of Hf and Zr chlorides and bromides have also been performed in columns filled with NaCl, KCl, CsCl, and KBr. The T_a increase considerably (to about 850 K) because of chemical interaction resulting in formation of compounds like (Na,K,Cs)₂(Zr,Hf)(Cl,Br)₆ (Tsalas and Bächmann 1978; Kim et al. 1987a). Stability of these compounds increases in the series Na→Cs.

Group 5: Elements of this group form two well-known types of volatile compounds: halides and oxyhalides. Noteworthy vanadium compounds are VCl₄ (or VOCl₃) with T_a = 298 K (B. Eichler and Domanov 1974) and VCl₃ (or VCl₂) with T_a = 684 K (Novgorodov et al. 1986a). The adsorption temperatures of Nb and Ta pentachlorides on quartz were found to be 410 and 770 K, respectively (B. Eichler and Domanov 1974). The value of T_a for tantalum is unexplainably overestimated. This is confirmed by the fact that the adsorption temperatures for pentabromides of the two elements are similar and are equal to approximately 330 K (Belov et al. 1974; Zvara et al. 1975). Carefully performed experiments (Domanov and Kim 1988) yielded close T_a values for Nb pentachloride and oxychloride on quartz, 333 and 373 K, respectively. The adsorption temperatures of Nb and Ta pentachlorides in the columns filled with KCl and CsCl increase to approximately 530 and 660 K for the respective adsorbents, which is due to formation of compounds like (K,Cs)(Nb,Ta)Cl₆ (Tsalas and Bächmann 1978).

Group 6: High-melting elements of this group form a variety of volatile compounds whose adsorption temperatures on quartz are listed in ▶ Table 53.3. It is, however, difficult to interpret the composition and properties of oxychlorides because of their close T_a values. In TCC filled with KCl or CsCl, molybdenum chloride forms two approximately equal peaks at T_a = 533 and 453 K or 653 and 573 K, respectively (Tsalas and Bächmann 1978).

Group 7: The main volatile compounds formed by the elements of this group are halides, oxides, oxyhalides, and hydroxides. ▶ Table 53.4 shows that many experiments have been carried out, there is a large difference between the adsorption temperatures of the compounds as, for example, ReO₃ and HReO₄.

■ Table 53.3

Volatile compounds of elements of group 6 of the periodic table

WO_2Cl_2	448 (Helas et al. 1978), 570 (Belov et al. 1972), 423 (Chuburkov et al. 1996), 423 (Yakushev et al. 1993)
WO_3	>1,300 (Bayar et al. 1975)
H_2WO_4	830 (Bayar et al. 1975), 650 (Vahle et al. 1999)

The adsorption temperatures of Tc and Re chlorides in the columns filled with KCl or CsCl increase to 813 or 873 K and to 613 or 643 K, respectively (Tsalsas and Bächmann 1978). When Mg and Ca oxides were used as adsorbents (Zhuikov 1982a), this leads to a considerable increase in the adsorption temperatures. These solid phases very likely might be considered as effective filters in preparative radiochemistry.

Group 8: Interest in this group of elements arises first of all from the existence of very volatile osmium tetroxide, with osmium being an analogue of element 108 (Hs). ▶ Table 53.5 presents absorption temperatures for various volatile compounds of group 8 elements. The T_a value of Ru and Os chlorides on KCl or CsCl surfaces is 873 K (Tsalas and Bächmann 1978). Osmium tetroxide adsorbs on a CaO surface at 733 K (Zhuikov 1982a).

RuO _x Cl _y	438 (Bayar et al. 1978e)

Group 9: The behavior of chlorides, oxides, and hydroxides of the elements from this group has been studied in thermochemical experiments (► Table 53.6). It is, however, very difficult to interpret the composition of these compounds, as is evident, for example, from T_a values for IrO₃ and H₂IrO₄.

Group 10: Elements of this group form relatively volatile dichlorides, the adsorption temperatures of which on quartz are 763, 863, and 803 K for NiCl₂, PdCl₂, and PtCl₂, respectively (B. Eichler and Domanov 1974). For the latter compound values of 543 and 663 K are (Merinis and Bouissieres 1969; Merinis and Bouissieres 1961), which is probably due to the presence of macro amounts of more volatile gold chloride. Compounds with oxygen are known only for platinum (Domanov et al. 1982; Domanov and Zvara 1983). The adsorption temperatures on quartz for PtO₂, PtO₃, and “platinum acid” PtO_x(OH)_y are estimated to be 573, 373, and 293 K, respectively. According to a later work (Zude et al. 1993), the adsorption temperatures of Pt on quartz in a flow of dry and humid air are 535 and 550 K, respectively.

■ Table 53.6

Volatile compounds of elements of group 9 of the periodic table

Probable compound	Adsorption temperature on quartz, K
CoCl ₂	771 (Novgorodov et al. 1986a), 658 (B. Eichler et al. 1976), 653 (Rudstam and Grapengiessser 1973)
RhCl ₃	883 (B. Eichler et al. 1976)
IrCl ₄	848 (Merinis and Bouissieres 1961), 823 (Merinis and Bouissieres 1969), 1,008 (B. Eichler and Domanov 1974)
IrO ₂	673 (Steffen and Bächmann 1978b)
RhO ₃	373 (Domanov and Zvara 1983)
IrO ₃	530 (B. Eichler and Domanov 1975), 523 (Domanov et al. 1982), 353 (Domanov and Zvara 1983), 493 (Steffen and Bächmann 1978b), 520 (B. Eichler et al. 1993)
H ₂ IrO ₄	433 (Domanov et al. 1982), 288 (Domanov and Zvara 1983), 580 (B. Eichler et al. 1993)

The high volatility of “platinum acid” arouses special interest and calls for further investigations. In addition, Pt forms thermochromatographically promising volatile carbonyl halogenides (Herrmann and Denschlag 1969).

Group 11: In this group of elements it is difficult to identify a single type of compound, which could be used in systematic investigations. The most stable valence states for Cu, Ag, and Au are +2, +1, and +3. The most volatile compound is gold trichloride with the adsorption temperature on quartz of approximately 463 K (Merinis and Bouissieres 1961). Silver chloride is reported with $T_a = 893$ K (B. Eichler and Domanov 1974) or 823 K (Rudstam and Grapengiessser 1973). Behavior of elemental Ag and Au was investigated and their adsorption temperatures were found to be very high, 1,133 and 1,403 K (B. Eichler 1976), respectively. Volatile sulfides show more promise in this group – the adsorption temperatures of ¹⁹⁵Au and ¹¹¹Ag sulfides in a sulfur vapor flow were found to be 770 and 650 K, respectively (Korotkin et al. 1988).

Group 12: Elements of this group are among the most intensively ones studied. T_a of quartz for Zn, Cd, and Hg are approximately 660, 600, and 300 K, respectively (B. Eichler 1976). The adsorption temperatures for their chlorides are also relatively low: 580, 630, and 350 K, respectively (B. Eichler 1976). Sulfide adsorption temperatures are slightly higher, namely 830 and 880 K for ZnS and CdS (Korotkin et al. 1988). Mercury sulfide, like mercury oxide, is unstable at high temperature and shows the behavior of the element. With copper or nickel used as adsorbents, T_a sharply increases (approximately 1,000 K) only for zinc (B. Eichler 1976). The adsorption temperatures of Zn, Cd, and Hg on quartz surface in vacuum are about 1.5 lower than in a hydrogen atmosphere: 460, 350, and 200 K, respectively (B. Eichler 1976). Adsorption of Hg on different surfaces (Cu, Ag, Au, Ni, Pd, Pt) has been studied by Niklaus et al. (2003).

Group 13: Adsorption temperatures for elements of this group on quartz surface in a hydrogen atmosphere are quite low: 830, 580, and 610 K for Ga, In, and Tl, respectively (B. Eichler 1976). Strong absorption on copper and nickel surfaces is observed only for Ga (B. Eichler 1976), as in the case of Zn (see above). In vacuum, T_a on quartz is slightly lower: 455 K for In and 420 K for Tl. For chlorides of HCl and H_2O gas mixtures, absorption peaks are found which correspond to InOCl, InCl, and InCl₃ with T_a = 655, 475, and 385 K, respectively (Novgorodov et al. 1986b). For InCl₃, a value of T_a = 313 K was found (Rudstam and Grapengiesser 1973). Thallium reveals increased volatility in the oxygen atmosphere; the adsorption temperature is approximately 500 K (Bayar et al. 1978c). An interesting observation is the volatility of thallium micro amounts in sulfur vapor; the adsorption temperature is 450 K (Kim et al. 1988). An even more unexpected result was obtained in thermochromatographic experiments at a reduced HF vapor pressure. The adsorption temperatures of Ga, In, and Tl monofluorides or oxyfluorides were 460, 350, and 340 K, respectively (Novgorodov et al. 1987a, b, 1988).

Group 14: The best-studied compounds among the group 14 elements are Ge, Sn, and Pb dichlorides. Their absorption temperatures on quartz are 840, 590 (Rudstam and Grapengiesser 1973), and 588 K (B. Eichler and Domanov 1974). For the highly volatile GeCl₄ and SnCl₄, T_a is estimated to be approximately 300 K (B. Eichler and Domanov 1974). The metals show low volatility, their adsorption temperatures on quartz in a hydrogen flow are 1,050, 1,060, and 780 K for Ge, Sn, and Pb, respectively (B. Eichler 1978). The effect of the carrier gas on Pb adsorption is shown: its adsorption temperature is 950 K in an argon gas flow compared to 730 K in a hydrogen gas flow (Fan and Gäggeler 1982). Adsorption of these elements in metallic TCC (Ni, Mo, Au) is also strong, and T_a varies from 900 to 1,200 K (B. Eichler 1978). Tetravalent lead may form highly volatile tetraalkyl (methyl-, ethyl-) compounds, which might be considered in thermochromatography.

Group 15: As, Sb, and Bi trichlorides are adsorbed on quartz at 300, 330, and 420 K, respectively (B. Eichler and Domanov 1974). A similar adsorption temperature (300 K) was found for SbCl₃ (Hickmann et al. 1993). The adsorption temperature of antimony pentachloride was only mentioned (Rudstam and Grapengiesser 1973), and T_a for SbCl₃ and SbCl₅ were found to be 840 and 590 K, respectively. The T_a for BiOCl was found to be 580 K (R. Eichler et al. 2000). TC of the elements in the form of metals yields similar values of T_a ≈ 830 K on quartz surfaces for all three elements (B. Eichler 1976). If copper or nickel is used as an adsorbent instead of quartz, the As- and Bi-adsorption temperatures increase to approximately 1,100 K (B. Eichler 1976). Ultramicro amounts of Bi show interesting behavior in sulfur vapor: T_a on quartz is 590 K (Korotkin et al. 1988). For BiO(OH) hydroxide a T_a ≈ 770 K was observed (R. Eichler et al. 1999).

Group 16: The data on the thermochromatographic behavior of the elements from this group are difficult to systematize. Tellurium and polonium in the elemental state are adsorbed on quartz in hydrogen flow at T_a ≈ 730 and 520 K, respectively; and in vacuum at 575 and 370 (B. Eichler 1976). With copper and nickel used as adsorbents, T_a significantly increases, reaching 1,088 K for Se(Ni), 823 K for Po(Cu), and 943 K for Po(Ni) (B. Eichler 1976). Polonium adsorption on various surfaces under isothermal conditions is considered (Gäggeler et al. 1985), where it was found to be very strongly adsorbed on the palladium surface (T_a > 1,300 K). Volatile Te and Po tetrachlorides are adsorbed on quartz at T_a = 448 and 563 K (B. Eichler and Domanov 1974); a value of T_a for PoCl₄ was reported to be 450 K (Gärtner et al. 1999). A similar value for TeCl₄ (T_a = 450 K) was obtained (Hickmann et al. 1993),

where T_a for tellurium tetrabromide and tetraiodide are also given, which are 560 and 480 K. With KCl and CsCl used as adsorbents, tellurium tetrachloride adsorbs at $T_a = 473$ and 713 K, respectively (Tsalsas and Bächmann 1978). For PoOCl_2 , the T_a value was determined to be 320 K (R. Eichler et al. 2000) or 530 K (Gärtner et al. 1999). Adsorption of TeO_2 on quartz at approximately 900 K was also mentioned (B. Eichler 1976).

Group 17: All halogens and interhalogens are highly volatile. Their temperatures of adsorption on quartz lie within the range from 241 to 473 K (Merinis et al. 1972). Interestingly, monatomic iodine is adsorbed at 473 K, while molecular iodine is adsorbed at 268 K. Compounds of Br, I, and At with oxygen in air flow have $T_a = 273$, 263, and 280 K (B. Eichler and Domanov 1975). For compounds of iodine with oxygen (IO_x) a value of $T_a = 573$ K is given (Rudstam and Grapengiesser 1973). The adsorption temperatures of iodine and astatine on quartz in vacuum (B. Eichler 1977) are 275 and 230 K. With various metals used as adsorbents, T_a substantially increases because of formation of more stable chemical compounds. For example, the adsorption temperatures of iodine and astatine on silver are very different, 1,200 and 663 K, respectively. Bromine and iodine adsorb on the platinum adsorbent at 873 and 798 K (Rudstam and Grapengiesser 1973). The adsorption temperature of astatine on the Pd surface is 515 K (B. Eichler and Chun 1985).

Group 18: There is no study on the adsorption of noble gases in open thermochemical quartz columns available because of the difficult set-up for adequate experiments. It is safe to suggest that the Xe adsorption temperature should be below 100 K (B. Eichler et al. 1995). With palladium as an adsorbent, Rn was adsorbed at 168 K (B. Eichler and Chun 1985). This indicates that elements of this group must be purified of all other elements to a very high degree.

The brief review of volatile compounds of the elements of the periodic table used in thermochemical experiments in some cases reveals discordance of adsorption temperatures. This inconsistency, sometimes quite substantial, is probably due to incorrect experimental condition and interpretation which results first of all from the following:

- Insufficient purification of the carrier (reactant) gas
- Inadequate purification of the adsorbent
- Variation in the chemical form of substances injected in the starting zone of thermochemical columns for formation of volatile compounds
- Limited information on the kinetics of formation and dissociation of volatile compounds
- Variation in the sample injection profile (“online” or “off-line” experiments)
- Some above-mentioned variation in the period of experiments

Naturally, most investigators studied or took into account the effect of these factors on the adsorption temperature, though not fully and accurately, perhaps. Most important for the accurate characterization of volatile compounds and their T_a are, in the authors' opinion, experiments with various pure reactant gases or their mixtures (Domanov and Kim 1988; Domanov et al. 1988; Nguyen et al. 1984a), with significantly different periods of duration of the TC experiments (Fan and Gäggeler 1982), and with different initial starting compounds (Chuburkov et al. 1996; Steffen and Bächmann 1978b). These approaches will be adequate, when compounds, transferred through the TCC, are chemically stable both in the gas phase and on the surface of the adsorbent. The picture considerably complicates if the transfer of the substance under study is accompanied by chemical reactions resulting in decomposition and formation of the initial and secondary volatile compounds on the surface of the adsorbent. This is most conspicuous in the case of polyvalent elements of groups 6–9. For example, the

Fig. 53.5

Dissociative character of ruthenium oxide adsorption on the SiO₂ surface

scheme on [Fig. 53.5](#) is accepted for transfer of ruthenium compounds with oxygen (Steffen and Bächmann 1978a).

Developing this assumption, B. Eichler et al. (1992) determined the enthalpy and entropy of the dissociative adsorption for the reactions

Thorough investigation of noncarrier-added amounts of ^{183,184}Re in dry and humid oxygen allowed (R. Eichler et al. 1999) to conclude that there was no volatile ReO₂ in the temperature range considered (up to 1,400 K) and that the peaks previously ascribed by other authors to ReO₂, ReO₃, and HReO₄ actually corresponded only to the latter two compounds formed in different ways.

Far more complications arise when volatile Mo and W oxychlorides are dealt with. Even in pure chlorinating reactant gases, tetra-, penta-, and hexavalent states of Mo and W may exist in the form of not only chlorides but also oxychlorides due to chemical reactions involving the adsorbent (SiO₂). In these complicated cases useful information can be probably gained in thermochemical experiments at reduced reactant gas pressures (about 0.1 Pa) (Adilbish et al. 1977), i.e., when the stepped nature of formation of volatile oxidation products is particularly conspicuous. It should be mentioned that the volatility of monomeric molecules, such as MoO₃, PdCl₂, FeCl₃, RhCl₃, is very small. Experimental values of *T_a* for these compounds most probably correspond to their polymer species such as (MoO₃)₃, (PdCl₂)₅, (FeCl₃)₂, etc.

53.5 Preparative Radiochemistry

The rapid development of thermochemistry in the 1960–1970s was stimulated first of all by the desire of researchers to discover new short-lived radionuclides and to investigate their nuclear-physical and chemical properties. Various methods for fast chemical separation in both liquid and gaseous phases were described in a review (Herrmann and Denschlag 1969), allowing investigation of radionuclides with half-lives of about 1 s. New radionuclides produced at reactors (neutron-rich radionuclides) and at medium-energy particle accelerators (neutron-deficient radionuclides) have been discovered and investigated. For gas chemistry, chemically stable substances were utilized as targets, from which the produced radionuclides were transferred under controllable conditions into known volatile compounds for their subsequent thermochemical separation. The most comprehensively studied targets were UF₄ (Weber et al. 1971), U₃O₈ (Röder and Herrmann 1966; Wolf 1973), AgCl (Novgorodov 1982), Au (Adilbish et al. 1977; Bayar et al. 1974), and others. The most widely used source of neutron-rich radionuclides was ²⁵²Cf (Bögl and Bächmann 1975).

TC remained advantageous for these investigations until the advent of ISOL (isotope separator online) facilities operating online with reactors or medium-energy accelerators (Talbert 1970). Radioisotopes of known elements with half-lives well below 1 s (^{11}Li , ^{35}Na , ^{74}Rb , ^{150}Lu , Hg isotopes, and others) were discovered and investigated at these facilities with targets composed of metal melts or finely dispersed powder (Beyer et al. 1989). The tubular connection of the target to the ion source may in principle be regarded as a TCC.

Consideration was also given to potentialities of TC for separation and concentration of relatively large amounts of radionuclides used in science and technology (Khalkin et al. 1979). The data given in ▶ Sect. 53.4 of this review described conditions of thermochemical separations to be selected for virtually any target-product pair. This may be distillation of macro amounts of the target elements, e.g., Zn (Novgorodov et al. 1990), Cd, and Hg (B. Eichler and Domanov 1974) in vacuum or Au via chlorination (Merinis and Bouissieres 1961). Of interest is scenario in which the irradiated target is burnt in the reactant gas (O_2 , Cl_2 , and others) with the formation of a nonvolatile residue, while the nuclear reaction product is transferred by the gas flow further to the TCC (Bayar et al. 1978b; Vakhtel et al. 1976). These separations were usually carried out in a horizontal apparatus similar to that displayed in ▶ Fig. 53.1, but recently the vertical arrangement of the TCC is believed to be more rational (Rösch et al. 1994) (▶ Fig. 53.6).

This arrangement greatly decreases the carry-away of gaseous products against the direction of incoming reactant gas flow and allows the process to be easily automated. The target is

■ Fig. 53.6

Apparatus for routine separation of $^{94\text{m}}\text{Tc}$ from irradiated ^{94}Mo targets: (1) – TCC-inner quartz tube for adsorption of $^{94\text{m}}\text{Tc}$; (2) – middle quartz tube for condensation of $^{94}\text{MoO}_3$; (3) – outer quartz tube; (4) – electric resistance oven (Rösch et al. 1994)

loaded in bottom of the open apparatus, the apparatus is closed using inserted smaller quartz tubes, the reactant gas is passed through it, and then the assembly is placed in the vertical oven with the required temperature distribution. After the termination of the separation process the assembly is taken out of the oven, cooled, and from it the inner TCC is removed with the adsorbed product, which can be washed off with a minimum volume of an appropriate solution. This apparatus, first developed to separate the positron emitter ^{94m}Tc from the irradiated molybdenum oxide in 25 min (Rösch et al. 1994), was subsequently used more universally for separations of the systems $^{110}\text{Sn}/^{111}\text{In}$ (Rösch et al. 1997), $^{186}\text{W}/^{186}\text{Re}$, $^{188}\text{W}/^{188}\text{Re}$ (Novgorodov et al. 2000), and $^{72}\text{Se}/^{72}\text{As}$ (Novgorodov et al. 2001).

Multiple use of the target material, when separation of nuclear reaction products does not entail changes in its chemical composition, holds the greatest promise for production of some radionuclides. ▶ Table 53.7 presents examples of using such targets for producing radionuclides relevant for nuclear medicine. The ^{67}Ga , ^{111}In , and ^{201}Tl separation procedure consists in merely heating massive targets at controllable pressure of the reactant gas. The target material loss does not exceed 0.1% in one cycle of radiochemical separation, but it is easily restored after 20–30 target irradiation-radionuclide separation cycles. In addition, multiple use of the target material gradually leads to a high specific activity of the produced radioactive samples due to periodic separation of impurities. Moreover, the use of gaseous reactants at lowered pressure (1–10 Pa) allowed the application of the thermochemical columns for ISOL setups (*Isotope Online Separations*) as a chemical transport between target and mass separators, cf. ▶ Table 53.7 and Adilbish et al. (1977, 1979).

It should be noted that thermochemistry might be used for construction of generator systems (B. Eichler 1976). By now the parent–daughter radionuclide pairs $^{188}\text{W}/^{188}\text{Re}$ (Novgorodov et al. 2000) and $^{72}\text{Se}/^{72}\text{As}$ (Novgorodov et al. 2001) have been comprehensively studied.

53.6 Investigation of New Transactinide Elements

Thermochemistry entered into wide use for the identification of new elements due to the assumption that transactinide elements ($Z = 104\text{--}118$) belong to groups 4–18 of the periodic table, where lighter homologues are known to form volatile compounds. The crucial

■ Table 53.7

Separation of medical radionuclides from massive targets

Radionuclide	Target	Reaction	Separation conditions	References
^{67}Ga	^{70}Ge	(p,xpyn)	1,375 K, (HF+H ₂ O 1:1), 1.5 Pa	(Novgorodov et al. 1988)
^{111}In	Ag	(α ,2n)	1,150 K, (HCl+H ₂ O 10:1), 7 Pa	(Schomächer et al. 1988) (Novgorodov et al. 1986b)
^{111}In	^{112}Sn	(γ ,n)EC	1,225 K, (HF+H ₂ O 1:1), 0.4 Pa	(Novgorodov et al. 1987a)
^{201}Tl	$^{204,206,208}\text{Pb}$	(p,xn)EC, EC	825 K, (HF+H ₂ O 1:1), 0.4 Pa	(Novgorodov et al. 1987b)

feature of the method was its “high speed,” i.e., the time needed to transfer accelerator-produced atoms of the elements under study from the target to the detectors, which was a few tenths of a second, according to various estimates (Belov et al. 1974). Chemical studies of new elements is an extreme challenge, because the lifetime – even of comparatively long-lived ones of their isotopes – is of the order of a few seconds or tens of seconds only and the rate of their production at modern accelerators is very low (an atom per a few hours or even days). Other problems are laborious measurements of decay events and incomplete knowledge of the decay properties (half-lives, ratios of spontaneous fission, alpha decay, and electron capture), though chemical identification is normally preceded by elaborate physics experiments on determining the yield of the desired isotope of the new element, its decay mode, and half-life. The experiments are carried out with varying combinations of target nuclei and accelerated ions, the energies of which also vary. To achieve a high yield of the desired isotope of the new element, neutron-rich isotopes of both the target and the accelerated ion are used, e.g., ^{238}U , ^{244}Pu , ^{248}Cm and ^{18}O , ^{22}Ne , ^{26}Mg , ^{48}Ca , respectively. Using accelerated ions of neutron-rich radionuclides like ^{90}Kr , ^{132}Sn , or ^{140}Xe has been suggested, but not reported for the production of the heaviest elements so far.

During the experimental studies of chemical properties of transactinides early approaches exploited the possibility to detect spontaneous fission in thermochromatographic columns by mica or quartz track detectors at temperatures below 400°C , while more modern setups employ Si detectors to register α decay or spontaneous fission at room temperature and below (liquid nitrogen). Then, the technique, however, is limited to the study of highly volatile atoms or compounds.

The history of discovery of the first transactinide elements is closely associated with the rivalry for priority of their discovery and identification and with mutual criticism of the researchers (Flerov and Zvara 1971; Hyde et al. 1987; Flerov and Ter-Akopian 1987). Now these matters are no longer acute owing to establishment and joint work of international collaborations.

On the assumption of analogy between transactinide elements and group 4–18 elements halides, oxyhalides, and oxides of the first transactinide elements were expected to have increased volatility, which might allow good selectivity of their separation and concentration by gas chemistry methods (IC and TC). The first identifications of Rf (element 104) were carried out by isothermal chromatography of its most volatile compound, the chloride (Zvara et al. 1969a, b; Chuburkov et al. 1969). It was shown that the behavior of Rf chloride was analogous to the behavior of Hf tetrachloride. Thermochemistry was first used in investigations of transactinide elements in 1971 (Zvara et al. 1971). ▶ Figure 53.7 shows a schematic diagram of the apparatus used and the results obtained, i.e., the distribution of spontaneous fission events.

The measured distribution of decay events over the thermochromatographic column is a basis for evaluating the adsorption enthalpy ΔH_a^0 . Evaluation of ΔH_a^0 for a single decay event is performed by the method proposed by Zvara (1985), who developed a microscopic model of TC. On its basis the migratory process of individual atoms in the column is simulated by the Monte Carlo method with allowance made for their radioactive decay.

Similar setups were used to study chemical properties of volatile compounds of elements 105–108 (Db, Sg, Bh, Hs) at different laboratories. Recently, a monograph (Zvara 2008) in detail covered theoretical considerations related to the thermochromatographic behavior of single atoms of transactinide elements. A remarkable contribution (Türler 1999) most

■ Fig. 53.7

(a) Schematic of the experimental apparatus to investigate the volatility of ^{259}Rf and $^{170,171}\text{Hf}$ chlorides; (b) temperature profile in the column; (c) distribution of spontaneous fission tracks (circles) and distribution of γ -activity $^{44\text{m}}\text{Sc}$, $^{170,171}\text{Hf}$ (lines) (reproduced with permission from Dissertation B., Türlér 1999)

comprehensively describes gas chemistry of halides of the first two transactinides, Rf and Db, and oxychlorides of the third one, Sg. Sg was shown to form volatile oxychlorides (Schädel et al. 1998; Türlér et al. 1999) as well as oxyhydroxides (Hübener et al. 2001). Considering the high volatility of rhenium hydroxide HReO_4 , many researchers (Belov et al. 1972; B. Eichler 1976) planned to use and used (Zvara et al. 1984) an analogous compound for the identification of element 107 (Bh). However, HReO_4 turned out to partially decompose in the TCC at a temperature of about 600 K (R. Eichler et al. 1999) with formation of ReO_3 . Evidently, this is why Bh was chemical identified with its oxychloride BhO_3Cl (R. Eichler et al. 2000b), though under isothermal conditions. High volatility of HsO_4 , expected in analogy to OsO_4 , has motivated the development of thermochemistry setups where the TCC consists of detectors suitable for the registration of α -particles and fission fragments emitted by species adsorbed within the TCC (Kirbach et al. 2002). This technique has first been used to compare adsorption of OsO_4 and HsO_4 (Düllmann et al. 2002). It appears that the volatility of HsO_4 , though high, is somewhat lower than that of OsO_4 . This highly efficient radiochemical separation technique has since found application in studies of nuclear aspects related to the production of Hs isotopes (Dvorak et al. 2006, 2008).

The lack of isotopes with half-lives long enough for their chemical investigation of elements 109–111 (Mt, Ds, Rg) prevented chemistry experiments with these elements to date. However,

the closed-shell element 112 – for which the name *copernicium* (Cn) has recently been approved – has been the focus of a series of experiments. Following initial experiments (Yakushev et al. 2001, 2002), recent studies suggest (R. Eichler et al. 2007) that the trend in sublimation enthalpies established in group 12 by the lighter homologues is fully preserved (R. Eichler et al. 2008).

It should be noted that all experiments on the study of properties of transactinide elements aim at finding first of all the distinctions between the properties of the analogue elements under study. As for elements with high Z electrons close to the nucleus have relativistic velocities, “relativistic effects,” which are proportional to Z^2 , strongly affect their chemical properties. These effects are expected to be most pronounced in transactinide elements and their compounds. Theoretical investigations in this area (Pershina 1996) showed, for example, that elements with larger Z are more noble and more volatile (B. Eichler et al. 1995). Analogy of Rf (as a p-element) and Pb was predicted (Glebov et al. 1988), but experiments disproved the prediction (Zhuikov et al. 1989). At present the series of relative volatilities of some analogue elements or compounds have been established in ascending order:

$\text{HfCl}_4 < \text{RfCl}_4 \approx \text{ZrCl}_4$
$\text{HfBr}_4 < \text{RfBr}_4 \approx \text{ZrBr}_4$
$\text{DbOCl}_3 < \text{NbOCl}_3$
$\text{DbBr}_5 < \text{TaBr}_5 \approx \text{NbBr}_5$
$\text{SgO}_2\text{Cl}_2 \approx \text{WO}_2\text{Cl}_2 < \text{MoO}_2\text{Cl}_2$
$\text{BhO}_3\text{Cl} < \text{ReO}_3\text{Cl} < \text{TcO}_3\text{Cl}$
$\text{HsO}_4 < \text{OsO}_4$
$\text{Hg} < \text{element 112 (Cn)}$

Scarce experimental data on chemical behavior of transactinides gained for many years emphasize enormous difficulties of the investigations, on the one hand, and their scientific importance for further study of the periodical table and structure of matter, on the other hand.

53.7 Conclusion

The relatively short time of development of thermochemistry and the value of the results obtained with it allow the lines of its further development to be outlined as follows:

- Theory and experimental investigations of the gas–solid interaction of a variety of adsorbent–adsorbate systems.
- Study of physicochemical properties of transactinides to find distinctions between their behavior and the behavior of the analogue lighter elements. Obviously, thermochemistry compares favorably with isothermal gas chromatography in the study of extremely rare events of formation and decay of isotopes of new elements.
- Use of thermochemistry in production of radionuclides for science and technology (first of all for nuclear medicine). It should be noted that this method holds promise too for development of generator systems.

Acknowledgments

The authors are grateful to Dr. A. B. Yakushev and Dr. S. N. Timokhin for providing information and important comments that helped to complete this review. The authors acknowledge contribution by Dr. Ch. Düllmann concerning the recent developments related to the transactinide elements.

Abstract: Some radionuclides, like ^{10}Be ($T_{1/2} = 1.5$ Ma), ^{14}C ($T_{1/2} = 5,730$ years), ^{26}Al ($T_{1/2} = 0.716$ Ma), ^{53}Mn ($T_{1/2} = 3.7$ Ma), and ^{60}Fe ($T_{1/2} = 1.5$ Ma), ^{146}Sm ($T_{1/2} = 103$ Ma), ^{182}Hf ($T_{1/2} = 9$ Ma), ^{244}Pu ($T_{1/2} = 80$ Ma) are either being produced continuously by the interaction of cosmic rays (CR) or might have been produced in supernovae millions of years ago. Analysis of these radionuclides in ultratrace scale has strong influence in almost all branches of sciences, starting from archaeology to biology, nuclear physics to astrophysics. However, measurement of these radionuclides appeared as a borderline problem exploiting their decay properties because of scarcity in natural archives and long half-life. The one and only way seemed to be that of mass measurement. Accelerator mass spectrometry (AMS) is the best suited for this purpose. Apart from AMS, other mass measurement techniques like inductively coupled plasma-mass spectrometry (ICP-MS), thermal ionization mass spectrometry (TIMS), resonant laser ionization mass spectrometry (RIMS), secondary ionization mass spectrometry (SIMS) have also been used with limited sensitivity and approach.

This chapter gives an essence of measurement of cosmogenic or supernova-produced radionuclides with various mass spectrometric techniques with special emphasis on AMS. The challenges of AMS measurement like isobaric interference, and development of chemical methods for separation of isobars have also been discussed. An abridged discussion has been made on the other techniques like ICP-MS, TIMS, RIMS, and SIMS.

54.1 Introduction

A survey of the Table of Nuclides reveals the presence of few radionuclides with half-lives in the range of thousand to million years. In general sense or in terms of nuclear sciences these radionuclides are named as long-lived radionuclides. Interestingly, cosmologists or astrophysicists designate them as “short-lived” radionuclides comparing their half-lives with the time span of creation of the solar system (Gounelle 2006; Fitoussi et al. 2008b). These radionuclides have important bearings in the astrophysical context as well, answering many hitherto unraveled questions. How the Earth was formed billions of years ago? What is the erosion rate of rocks and soils in the Earth or in the Moon and so on?

These radionuclides are either being produced continuously in the upper atmosphere by the interaction of solar cosmic rays (SCR) or galactic cosmic rays (GCR) or had been produced in supernova (SN) long back and deposited on the Earth millions of years ago. The production cross section of cosmogenic radionuclides (extraterrestrial or terrestrial) is extremely low. The signatures of SN radionuclides are almost faded out. In both cases, these radionuclides are present only in minuscule amounts in the Earth's crust and therefore their detection requires *state-of-art* instrumentation. Even with the availability of very powerful instruments, detection of these radionuclides requires rigorous chemical treatment, from sample collection to ion source preparation. Sometimes chemical separation is mandatory to overcome the problem of isobaric interferences.

Analysis of cosmogenic radionuclides present in ultra trace scale cannot be based on their nuclear decay properties as in the experimental time period only a small fragment of the sample is decayed; therefore, statistically significant result cannot be obtained. The mass measurement is much more precise and sensitive compared to decay counting because in mass measurement, every individual atom is counted and one has not to wait for the decay of the radionuclide.

In Vol. 2 of this handbook, the origin of elements has been discussed in detail. Therefore, the present authors will exclude that part, except for some comments on the importance of particular radionuclides. In this chapter, the principles and instrumentation of accelerator mass spectrometry (AMS), the key player for detection of cosmological radionuclides in ultra trace scale, will be discussed in detail. Detailed discussion of all the research works carried out to date with cosmogenic radionuclides is out of scope. Only the detection of million-year half-life radionuclides in ultra trace concentration will be touched, followed by concise description of the required chemistry. Rather than giving a general description, a few of them have been chosen and described in separate sections. Inductively coupled plasma-mass spectrometry (ICP-MS), thermal ionization mass spectrometry (TIMS), secondary ion mass spectrometry (SIMS), or resonant laser ionization mass spectrometer (RIMS), etc. have also been used for detection of cosmogenic radionuclides. However, these techniques have much lower sensitivity compared to AMS. Brief discussions on these instruments have been appended at the end of this chapter. This chapter ends with a conclusion.

54.2 Accelerator Mass Spectrometry (AMS)

54.2.1 Principle and Components of AMS

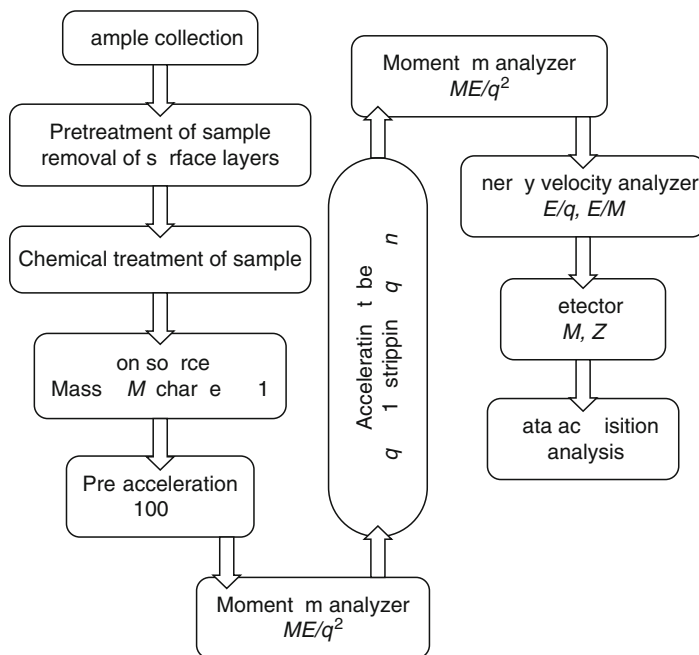

Among various mass measurement techniques, AMS is the best suited and widely used for the analysis of cosmological radionuclides. In AMS, the ratio of the desired nuclide and its more abundant stable isotope is measured. For example, ^{14}C ($T_{1/2} = 5,730$ years) is measured as the ratio of $^{14}\text{C}/^{12}\text{C}$. In AMS measurement, the most common problems are the following: (1) molecular ion interference (e.g., $^{12}\text{CH}_2$ or ^{13}CH have nearly the same mass as ^{14}C). The interfering molecular ion species are much more abundant than the radionuclide of interest. The acceleration of ions in AMS dissociates the molecular ion species and finally only the nuclides of interest enter the detector. (2) isobaric interference (e.g., ^{14}N is trillion times more abundant than ^{14}C in the atmosphere). Even in the presence of a minute amount of ^{14}N , it is impossible to detect ^{14}C . Measurement of the long-lived radionuclides is a big challenge as it suffers from the interference of stable isobars. AMS is capable of measuring the isotopic ratio of certain elements up to the order of 1 in 10^{15} cleverly removing the isobaric interference in different steps (discussed in following sections). This sensitivity is achieved approximately in a 1-h measurement using a sample weighing less than 1 mg. Various factors, for example, efficiency of ion beam production, the control of the background, and minimum level sample contamination, are responsible to achieve the detection limit in AMS. In some favorable cases, it is possible to measure the isotopic abundance ratio even in the order of 10^{-16} .

The various steps of AMS measurement include (1) collection of samples from the possible sources, (2) cleaning and chemical treatment, (3) injection of the sample into the ion source, (4) acceleration of the desired isotopes, and finally (5) measurement of the isotope ratio. Block diagram of various AMS steps has been presented in [Fig. 54.1](#).

The tandem accelerator (in which the ion beam experiences two acceleration stages: one before stripping and one after stripping) is the most often used accelerator in the AMS facilities. Negative ions are injected in the tandem accelerator. Stripping of electrons at the center of tandem converts the negative ion to a positive ion, which is then accelerated and transmitted as positive ion from the accelerator.

■ Fig. 54.1

A pictorial diagram of various accelerator mass spectrometry (AMS) steps

In general an AMS facility consists of the following components that are discussed in the following sections.

1. Ion injector system
2. Tandem accelerator
3. High energy beam selector
4. Faraday cups
5. Ion detector

54.2.1.1 Ion Injector System

The ion injector system consists of three major components: (1) negative ion source, (2) pre-acceleration system, and (3) beam analysis equipment. Commonly, Cs sputter ion source is used to generate negative ions. Sputter-source produced negative ions traverse through the efficient energy and mass analysis equipment before being injected to the accelerator. Molecular interference is significantly reduced in this analyzer, which in turn reduces the background of the unwanted ions.

Ion Source

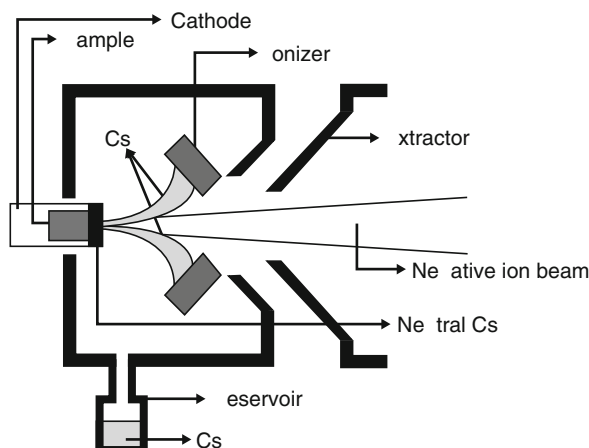

The injection of negative ion beam to the tandem for the first-stage acceleration reduces huge isobaric background of some nuclides at the beginning because their competing isobars do not

form negative ions. Moreover, negative ions of noble gas and some other elements are quite unstable and they often fail to reach the terminal of the tandem accelerator. For example, ^{14}C and its competing isobar ^{14}N have electronic configurations $[\text{He}] 2s^2 2p^2$, and $[\text{He}] 2s^2 2p^3$ respectively. Therefore, $^{14}\text{C}^-$ is highly stable and $^{14}\text{N}^-$ is totally unstable. The unstable $^{14}\text{N}^-$ is suppressed at the very beginning, that is, in the ion source itself. Similarly, for the radionuclides ^{26}Al and ^{129}I , the interfering isobars ^{26}Mg and ^{129}Xe do not form stable negative ions and hence are suppressed. If this is not the case, it is often possible to use appropriate molecules such as oxides, fluorides, or hydrides to reduce the background interference as well as to increase the negative ion current as elemental ion currents found to be low for many elements. For example, ^{41}Ca suffers isobaric interference from ^{41}K . Selection of a molecule like CaH_3^- or CaF_3^- helps to reduce isobaric background because potassium does not form potassium trihydride or trifluoride negative ions. Therefore, the negative ion source helps to get rid of the million times more abundant naturally occurring stable isobars of the long-lived radionuclides. High charge state of ions is also preferred in the tandem accelerator to remove the molecular interference from the desired one because molecular ions become highly unstable for charge $+q \geq 3$ and fragment immediately. This feature of tandem accelerators eliminates the need for high mass resolution to resolve the molecular interference.

The cesium sputtered ion source is an ideal device to generate negatively charged atomic or molecular ions from the solid sample material. Ion sources of this type are operational in AMS facilities across the world because of their low cross contamination probability and reasonable negative ion yields for almost all the radionuclides measured by AMS. Moreover, reliability of this device can be improved by simple modifications. A schematic diagram of a Cs sputtered ion source is shown in [Fig. 54.2](#). The cathode is a metallic cylindrical body made of silver, copper, or aluminum, having a small cavity inside along the cylindrical axis. Chemically treated sample containing the desired nuclides, mainly in the form of powder, is loaded into the cavity. The cathode then acts as target for the ion source. The sample is sputtered by Cs beam to generate the desired negative ions. The latter are extracted as a negative ion beam for injection

■ Fig. 54.2

A schematic diagram of Cs sputter ion source

into the accelerator. The probable factors determining the negative ion yield are (1) electron affinity of the element, (2) physical condition of the sample, (3) ion–atom collision, and (4) atomic ion current.

Negative ion yield is proportional to the electron affinity of the element. Sputter yield depends on the difference between electron affinity of the desired atom and the effective work function. Work function varies upon the environment of the surface of the sample. Physical conditions of the sample affect the properties of atoms on the surface. The probability of negative ion formation is enhanced by the presence of Cs layer at the surface of the sample and electron cloud near the sample surface. Samples are mixed with metallic powder (e.g., Ag or Nb) to improve the thermal and electrical conductivity. Ion–atom collision kinematics reduces the sputter yield for heavy elements. Production of negative ions is at the maximum for normal incidence of the sputtering beam, but the total sputter rate, which means positive, negative, and neutral emission, increases when the angle of incidence is away from the normal. Atomic ion current is very low or zero for some elements. In that case, selection of one molecular ion out of many possible molecular ions (like oxides, hydrides, or carbides) becomes important (Tuniz et al. 1998).

Apart from the sputter source, gas sources are also used to convert CO₂ directly to negative ion beam, minimizing the effort of sample preparation. However, gas sources are not common in AMS because of two reasons: (1) low negative ion yield in comparison with sputter sources and (2) the cathode needs to be changed frequently. Recent developments are going on gas sources at AMS laboratory in Woods Hole, USA, where the source produces positive ions, which are converted to negative ions by passing through alkali vapor (Tuniz et al. 1998).

Pre-acceleration System

The pre-acceleration system provides definite acceleration to the negative ions extracted from the ion source so that they can be injected to the accelerator. The ions extracted from the ion source carry 10–30 keV energy, which is enough for direct injection in small tandem accelerators (~3 MV). The minimum ion energy required for injection of ions is known as injection energy. In large tandem accelerators (4–15 MV), injection energy of 50–150 keV is required, which is obtained from the pre-acceleration system. Pre-acceleration also reduces the energy spread of the negative ion beam before injection.

Injection Magnet

The negative ion beam extracted from the sample passes through a beam-analyzing magnet and is injected to the accelerator. When the ions pass through the injection magnet of uniform magnetic field B directed perpendicular to the ion path, ions are deflected along different radii depending on their mass (M), energy (E), and charge (q). Radius of curvature, ρ of the ion path is related to M , E , and q as

$$\frac{ME}{q^2} \propto (B\rho)^2 \quad (54.1)$$

Ions having specific mass and well-defined energy are allowed to the accelerator. In case of a big AMS facility, a large magnet is required to deflect ions up to mass 200 or even higher with good resolution. Specific design of the injector magnet may help in achieving good focusing of beam. An insulated vacuum chamber placed between the pole-pieces allows fast switching of nuclides.

54.2.1.2 Tandem Accelerator

Tandem is a class of accelerator that accelerate ions by applying an electrostatic field with a feature of supplying high voltage. A tandem accelerator consists of two accelerating tubes, for low- and high-energy acceleration, along with a metal electrode, known as terminal, kept at the center and in between the two accelerating tubes of the tandem. The terminal is kept at a large positive potential ($V_T \approx 0.2\text{--}15\text{ MV}$) and therefore known as voltage dome. Tandem accelerators achieve two-stage acceleration with a single voltage by converting the electric charge of negative ions at the high-voltage terminal. The accelerator is housed inside a large steel tank that contains insulating gas with significant high pressure (usually a 4:1 mixture of N_2 and CO_2 at $\sim 300\text{ kPa}$ or pure SF_6 at $\sim 100\text{ kPa}$) to prevent electrical discharging of the high-voltage surfaces within the accelerator. Voltage holding capacity may also be improved by the addition of SF_6 to the mixture of N_2 and CO_2 . The steel tank isolates the high-voltage surfaces of the accelerator electrodes from the outside.

The structures within the tank, which support the terminal electrode, are referred to as *columns*. The low-energy column starts from the tank base nearest to the ion source and ends at the center of the terminal. The high-energy column connects the terminal region to the tank base opposite to the ion source. The columns are composed of a series of metal planes, with each plane electrically isolated from the next by glass blocks, which are glued to each plane. There are approximately 200 such planes in each of the low- and high-energy columns. A large spring inside the high-energy tank base compresses both columns with tremendous force, holding the columns and the terminal region suspended within the tank. A controlled charging system is used to hold the terminal voltage constant. The charging system is composed of a rotating rubber belt or metal-plastic chains. Normally, belts are dusty and cause spark affecting the insulating properties. Therefore, chains with alternate metal and plastic cylinders called pelletron are used for most stable charging current, which is a very important parameter for AMS. In tandem accelerators, high voltage is generated by a radio frequency (RF) power supply connected to the accelerator tank that provides high current capacity as well as high stability.

Selection of terminal voltage is crucial and solely depends on the radionuclides under analysis. High energies are more effective in identifying nuclides of interest in some cases (e.g., ^{36}Cl , ^{41}Ca , and ^{59}Ni) where the stable isobar needs to be highly separated. Successful operation of the accelerator for AMS experiments requires constant and stable terminal voltage over a long period of time. This is because change in terminal voltage causes change in beam trajectory through the analyzing magnet. Equilibrium must be established between the charge brought to the terminal by the pelletron chains and that which flows from the terminal to the ground through the column resistors.

Negatively charged ion beam, having energy $E_i = eV_i$, where V_i is the injection voltage, is transported from the injector toward the terminal in vacuum. Negative ions are therefore accelerated to high energy as they approach the terminal kept at positive high voltage. While the beam enters the region that houses the terminal, it passes through an electron stripper, either gas or thin carbon foil, which strips electrons from the ions in the beam, leaving the beam positively charged (charge = $+q$). The function of the stripper is to convert the ions from negative to positive for further acceleration when they leave the terminal. Thin carbon foils of $2\text{--}5\text{ }\mu\text{g}/\text{cm}^2$ thickness or gas or the combination of both serve satisfactorily as stripper. The positively charged beam accelerates away from the high positive potential at the terminal and exits the accelerator at very high energy, E . The energy of ions is

given as follows: $E = E_i + (q + 1)eV_T$, where V_T is the terminal voltage. Molecular ions are dissociated at high energy and filtrated afterward, which in turn reduces the background of the desired ion beam.

54.2.1.3 High Energy Beam Selector

It is an efficient beam-analyzing equipment that analyzes the beam and simultaneously rejects the unwanted ions, at the maximum possible extent before the beam reaches the detector. The use of two different kinds of high-energy analyzers are required to select ions of specific E/q and M/q in the detector. The most popular approach is to use a magnetic analyzer, which selects a beam of required ME/q^2 followed by an electrostatic analyzer to select E/q . Use of velocity analyzer is necessary to remove ambiguities in selecting desired ions in heavy ion AMS measurements. In a nutshell, when high-energy ions are passed through the electric and magnetic field of mass analyzers, they are separated spatially according to their momentum, charge, and energy. Specific window is set to select the ions of interest from the rest of the beam. Individual ions are counted after their proper identification with correct mass and atomic number.

Wien Velocity Filter

The Wien filter uses an electrostatic field E perpendicular to a magnetic field B to disperse ions of different energies. When electrically charged particle of charge q passes through an electric field, it feels an electric force on it. If electric force is expressed as F_e , then $F_e = qE$. In a similar way, when the particle crosses a magnetic field it feels magnetic force, which is given by $F_m = q(\mathbf{v} \times \mathbf{B})$. The net force on the ions will be zero and hence they will be unperturbed as they travel through the crossed fields. This leads to the balance of electric and magnetic force field, that is, $F_e = F_m$; $qE = q(\mathbf{v} \times \mathbf{B})$ and hence the magnitude of ion velocity is $v_{ion} = E/B$. Ions with velocity, $\mathbf{v} = v_{ion}$, pass perpendicularly through the crossed fields along the optical axis without any change in their trajectories because the net force acting on them is zero. All other ions will feel a nonzero force and hence will be deflected from their straight path. By placing a proper slit, only those ions that feel zero force are allowed to pass through the crossed electric and magnetic fields. If a monoenergetic ion beam is passed through a Wien filter, the beam will be separated according to the ion velocities and hence their masses, since $E = Mv^2/2$. The reason is that the electric and magnetic forces cancel each other. Ions with different velocities will be deflected from the optic axis as $\mathbf{v} = v_{ion}(1 + \delta)$, where δ is the deviation in velocity. The radius of the trajectory of the ions with velocity v_{ion} upon action of the magnetic field is given by

$$\rho = \frac{Mv_{ion}}{qB}. \quad (54.2)$$

The trajectory of ions passing through the Wien velocity filter is shown in  Fig. 54.3.

Magnetic Analyzer

The analyzer magnet is used to select the desired ion species. As the ions travel through the magnetic field whose B is perpendicular to the direction of motion, the magnetic force (Lorentz force) makes the particles to move in a circular path. Kinetic energy of the ions is not affected by the influence of the magnetic field, only the direction of motion changes. Radius of curvature of the path of ions is proportional to the velocity of the ions. Double focusing magnetic analyzer with narrow object and image slits are used to achieve high

■ Fig. 54.3

Wien velocity filter

resolution for ions of known mass and charge. In general, 90° deflecting magnet is used for the good separation of beams of different mass and charge state. If the ions of charge q and energy E from the accelerator pass through a magnetic analyzer, then they are separated according to the atomic mass M in a uniform magnetic field \mathbf{B} directed perpendicularly to the plane of motion. The radius of curvature ρ of the path of each ion depends on M , E , and q following

► Eq. (54.1).

Electrostatic Analyzer

An electrostatic analyzer behaves like a filter. It only allows particles within a certain range of energies and charges to pass through. It consists of two parallel cylindrical or spherical conducting plates that have different voltages. This voltage difference sets up an electric field, which acts on charged particles.

The upper plate of the electrostatic analyzer remains at a positive voltage, and the lower one at a negative voltage. Any positively charged particle coming toward the top plate will be pushed to the bottom plate, because like charges repel each other. When the charged particle enters through the entrance slit of an electrostatic analyzer, it starts to feel the electric force field and moves down toward the bottom plate as it travels. This movement depends on its energy-to-charge ratio, E/q . If the ratio is low, that means either the particle is having low energy E , or the field pushes the particle too hard that is, high q , then it will fall short of the exit. On the other hand, if the ratio is high, that means the particle is with high E , or low q , then it will cross the slit. Therefore, the lucky particles that have just the right ratio of energy and charge pass through the exit slit. These outgoing particles from the slit are the desired particles because they must have a certain energy-to-charge ratio.

The analyzer only measures positively charged particles. In case of measurement of the negatively charged particle instead of positive, one needs just to reverse the voltages of the plates, so that the top plate gets negative voltage and the bottom gets positive voltage.

Gas-Filled Magnet

In a common magnetic analyzer, the path of the ion beam is kept in vacuum. The magnetic rigidity, which is defined by the ratio of the momentum of the ion and its electrical charge, governs the trajectory of the ion in a magnetic field region and is normally a constant throughout the path of the ion in vacuum. When the ion beam passes through the magnetic analyzer, ions having different magnetic rigidities are spatially separated in the focal plane of the apparatus according to their charge state. Ions carrying higher charge are deflected more

than those with lower charge. Therefore, magnetic rigidity can be used in identifying ions along with energy or velocity. The situation becomes more and more complicated for heavy ions. While passing through the matter (like absorber and window foil) heavy ions emerge with a distribution of ionic charge states and follow different trajectories in the magnetic field. The trajectories of the isobaric nuclei will be essentially identical if the ions have the same energy and the same charge state and cannot be separated. Gas-filled magnet is a unique technique used for good isobaric separation.

A gas-filled magnet is a special kind of magnetic analyzer, which contains gas instead of vacuum in the region of the beam path. Gas pressure inside the magnet is controlled from outside. Entrance and exit end of the gas-filled magnet is separated by two thin foils from the high vacuum component of the accelerator. While the ion beam passes through a gas-filled magnet, each ion undergoes several interactions with the gas atoms as well as the atoms of the foils. Due to the ion-atom interaction, charge exchange takes place between them. The trajectories of ions in vacuum and in gas-filled magnetic field region are illustrated in [Fig. 54.4](#). If the mean free path of the ions between the charge-changing collisions is short enough, depending on the gas pressure and the atomic collision cross sections, the ions will closely follow the trajectory determined by the mean magnetic rigidity, corresponding to the mean charge state q_m of the ion. The behavior of ions moving in a magnetic field changes largely with the gas pressure, which is of the order of 1–10 torr. For the ions with the same mass number but with different atomic number (isobars), the mean charge state in the gas is different and the corresponding trajectories in the magnetic field are therefore spatially separated. The average charge (q_m) of the ion depends on the atomic number Z and is roughly proportional to its velocity. Therefore, the average magnetic rigidity, $\langle B\rho \rangle \propto Mv/q_m$ is almost independent of the velocity distribution of the ions. The trajectories of the ions will be determined by the mass number A and the atomic number Z of the ion. A gas-filled magnet can therefore direct the isobaric ions along separate paths, and hence separate them. Gas-filled magnets are very useful for ions having high energies so that energy loss within the gas becomes small and that does not affect detector performance (Knie et al. 1999, 2004).

54.2.1.4 Faraday Cups

A Faraday cup is a specially designed metallic cup used to measure current directly from the ion beam in vacuum. The measured current in turn provides the number of ions reaching the

Fig. 54.4

Schematic diagram of the heavy ion trajectories in the magnetic field area (a) in vacuum (b) in gas

conducting cup. If the measured current in the Faraday cup is 1 nA, then 6 billion singly charged ions ($= 10^{-9}/1.6 \times 10^{-19}$) are impinging the cup in each second. When an ion beam strikes the metallic surface, it emits electrons. As a result, an electric current is induced in it. An electrical circuit is attached to the cup to amplify and conduct the current to a measuring device. The design of the cup may be sufficiently complicated to measure small current and high-energy beam, which does not stop in the cup.

54.2.1.5 Ion Detector

The detection of ions coming to the detector is the final step of AMS measurement. Mass, M and atomic number, Z of the ion is inferred measuring the parameters discussed below. (1) Total energy of ion coming into the detector. (2) Rate of energy loss of ions: The rate at which the ion loses energy per unit path length is called the stopping power of the medium. Energy loss is calculated from the Bethe–Bloch formula excluding relativistic effect ($v \ll c$, speed of light) as

$$-\frac{dE}{dx} = \left(\frac{e^2}{4\pi\epsilon_0} \right)^2 \frac{4\pi n Z^2}{m_e v^2} \ln \left(\frac{2m_e v^2}{I} \right) \quad (54.3)$$

where Ze , E , v , and x are the charge, energy, velocity, and the distance traveled by the ion respectively; e and m_e are charge and rest mass of electron; n is the electron density in the medium; and I is the mean excitation potential of the medium. Electron number density n in the medium is calculated as

$$n = \frac{z\rho N_A}{A_s}. \quad (54.4)$$

N_A is Avogadro's number, and A_s , z , and ρ are the mass number, atomic number and density of the stopping material, respectively. The rate of energy loss of the ion increases to a maximum and then abruptly falls to zero beyond the peak, which is known as Bragg peak. (3) Energy loss of the ion at the Bragg peak, which increases linearly with atomic number of ion, z . (4) Range of ion is an important parameter to measure which is calculated as

$$R = \int_E^0 dx = \int_E^0 \frac{dE}{(dE/dx)}. \quad (54.5)$$

Energy loss is obtained from [Eq. \(54.3\)](#) as

$$\frac{dE}{dx} \propto Z^2 f(v), \quad (54.6)$$

where, $f(v)$ is a function that depends on the speed of ion. Combining [Eqs. \(54.5\)](#) and [\(54.6\)](#), range of ion R is calculated as

$$R = \int_E^0 \frac{dE}{(dE/dx)} \propto \frac{m}{Z^2} F(v). \quad (54.7)$$

Since, $dE = d(Mv^2/2) = Mvdv$; M is the mass of the ion and $F(v)$ is a function of the speed of ion. Therefore, the range of ions with same velocity varies inversely proportional to Z^2 .

(5) When an ion passes through a specific thickness of the absorber, residual energy after the absorber is measured to determine atomic number Z of the ion. (6) Flight time of the ions between two detectors determines the speed of the ions and hence mass of the ions are also determined.

Different kinds of detectors are designed to measure these parameters accurately. Sometimes isobar identification appears to be difficult in AMS measurement. Therefore, the best possible combination of ion beam-analysis equipment and a sophisticated detector is required for proper identification of ions. Interfering isobars may come from the sources like (a) angular scattering and energy straggling, (b) variation in electron multiplication and recombination in the detector, and (c) effects of noise and pileup in the electronics. In order to measure the isotope ratios below 10^{-15} or even lower it is necessary to measure background levels to the order of magnitude lower than the isotopic ratio. Ion identification detector also provides a mechanism for rejecting ions with incorrect E , M , or Z only when count rate total is much less. The principles of three types of detectors will be discussed below in brief.

Solid-State Detectors

Solid-state or, more strictly, surface barrier detectors are semiconductor detectors, built usually from a single crystal of either silicon or germanium, which are used to detect charged particles. An electric field gradient is introduced between the front and rear surfaces of the semiconductor crystal. When an energetic ion strikes on a surface barrier detector, it immediately produces one or more energetic electrons. These energetic electrons rapidly achieve thermal equilibrium with other electrons in the medium losing their energy mostly by ionizing atoms. Ionization process leads to the creation of energetic particle-hole pairs, which further promotes the chain of ionization processes. The average energy required to create an electron-hole pair is about 3.6 eV for silicon and 3.0 eV for germanium. As a result, many electron-hole pairs are created whose number will be proportional to the total energy absorbed by the medium from the incident ions. The electrons in the conduction band and the holes in the valence band move under the influence of the applied electric field in the opposite direction toward their respective electrodes. Movement of electrons and holes produces a pulse of current with the arrival of electrons and holes to their respective electrodes without recombination or being trapped at impurity sites in the crystal. The resulting current measured in an outer circuit, will be proportional to the energy of the ion if the thickness of the crystal is greater than the range of the ion. Detectors with thicknesses down to 10 μm or less are available for ΔE measurements. In easy cases, such as with ^{14}C , a relatively simple detector system is sufficient. For example, a thin silicon detector used for determining the rate of energy loss and a thick silicon detector for measuring the residual energy give sufficient information to identify the mass and atomic number of ^{14}C and competing ions. Pulse height defect is the main problem in the use of solid-state detectors for heavy ions.

Gas Ionization Detectors

Gas ionization detectors are popular for identification of heavy ions in AMS measurement. They are simple to design and operate, and come in different shapes and sizes. Such a detector is basically a gas-filled enclosure, which contains two electrodes. The electrodes may be of different types: parallel plate, coaxial cylinder, segmented anode, etc. depending up on the purpose of use. When an energetic heavy ion enters the detector, it ionizes gas atoms during its travel. As a result, electron-ion pairs are generated, which are separated and collected by a transverse electric field. The entrance window of the detector is a thin Mylar film ($\sim 150\text{--}300\text{ }\mu\text{g}/\text{cm}^2$),

which separates the detector gas from the other components of the ion beam transport system. Ions enter the detector through the thin film, and then travel through a transverse electric field. Electrons and ions are separated by the electric field and induce voltage signals at the cathode and anodes. The choice of operational gas pressure, which usually varies between 10–200 torr, depends on the energy of the incident ion. In general, argon–methane mixture, isobutene, or propane are used as detector gases. Sometimes, impurities like oxygen or other electronegative species delay the collection of electrons by forming O_2^- . This results in smaller pulse height and poor energy resolution. This problem can be minimized by passing the gas through a purifier with controlled flow from the supply cylinder. Precision control of gas pressure is important to avoid peak shifts and to obtain good resolution.

Segmented anode provides a number of independent signals, which correspond to the energy ΔE deposited in each segment over the ion path. The cathode provides a signal proportional to the total ion energy. A coincidence unit is used to make sure that all electrodes have received a signal. A novel approach is to use of a timing signal between the first and last anode plates to reject anomalous events. A diagram of a segmented anode gas ionization detector is shown in [Fig. 54.5](#).

The radionuclide of interest and the isobars enter the gas ionization detector with equal energies but lose energy at different rates due to their different atomic number and hence have different energies in the gas. It is possible to measure the range of each ion taking information of the energy deposited in the last anode segment with optimized gas pressure.

■ Fig. 54.5

Cross-sectional view of a segmented-anode gas ionization detector

Time-of-Flight Detector

The ion goes through the electrostatic and/or magnetic analyzer and then passes through the time-of-flight region separated by two micro-channel plate detectors called start detector and stop detector. Time of flight provides better mass resolution than the other methods like energy loss, total energy, or range measurements. The start detector consists of a very thin carbon foil (\sim a few $\mu\text{g}/\text{cm}^2$) accompanied by a channel plate. When the ion hits the carbon foil, electrons are produced and scattered. These scattered electrons are then sucked down to the positively charged channel plate. A timer clock starts immediately after the electrons hit the plate. At the end of the flight path region there is another similar plate. When the ion hits the second carbon foil, electrons scatter from it again, are sucked down to the positively charged plate, and the clock stops. Time difference between the start and stop detectors is measured. The second detector is a solid-state detector, which measures the energy of the ion.

The distance traveled by the ions between the start and stop time is determined through precise measurements of the space between the two plates. From the time of flight t and from the flight distance d the absolute velocity of the ion is readily calculated using $v = d/t$. When the ion with energy E hits the second plate, the latter measures the kinetic energy of the ion and stops the clock. Since the velocity and energy of the ion is known, its mass is given by $M = 2E/v^2$. The charge of the ion can also be calculated from the relation, $q = E/(q/E)$ as E is known from the solid-state detector and E/q is found from the electrostatic analyzer placed before the time-of-flight region. The electrostatic analyzer determines the type of ion passed through the instrument and ensures that one type of ion was measured because only the ions with exactly the right combination of mass and energy can pass through it. The disadvantage of the time-of-flight technique is that it cannot distinguish between unwanted and desired ions. Moreover, angular spread of ions sometimes reduces transmission.

54.2.2 Protocols of Sample Preparation and Measurements

Indeed AMS is a *state-of-art* ultrasensitive technique for trace analysis, but the success of AMS depends on many crucial steps before the actual measurement in the AMS system. In fact, sometimes expertise from several areas of science is required to make the AMS experiments reliable. Some of the crucial points are *sample collection*, *pretreatment*, *sample preparation for ion source*, *development of separation methods for isobars*, etc. Like all other analytical techniques, it is also necessary to measure *standard*, *blank*, and *background* simultaneously with the sample. Below some of the crucial steps are described in nutshell.

54.2.2.1 Pretreatment of Samples

Before collecting samples, it is of utmost necessity to decontaminate all sampling equipment prior to use, between the two sampling depth intervals and between each sample collection point. The decontamination of collecting equipment may be done by removing gross contamination by brushing and rinsing with water, washing with detergent or soap solution, and rinsing with alcohol and deionized water. Geological sample material is collected with great care from the layer below a certain depth to avoid exposure of the object to the environment. After the collection of the samples, surface layers are removed because these are most

susceptible to contamination. The samples must be sealed and labeled to show the date and time of sample collection. In all cases, pretreatment procedure depends on the type of sample and the specific interest of measurement.

54.2.2.2 Sample Preparation

Sample preparation is the most crucial for all AMS measurements. The samples for cosmochemical analysis can be various types of raw materials, for example, sediment, lava, rocks, manganese crusts, and ice core. Actually, there is no common or absolute method for the preparation of samples for cosmochemical analysis prior to their introduction to the AMS system. Sample preparation techniques are continuously being developed with the philosophy of reducing isobaric interference, cross contamination, and bulk size. Generally, appropriate carrier is added to the pretreated geological samples (especially if the sample material is precious or available in trace amount only, when addition of carrier becomes mandatory to handle the sample). Samples are then dissolved in the appropriate acid (e.g., stony materials are dissolved in a mixture of HF, HNO₃, and HClO₄). This procedure is followed by evaporation of the solution, and taking up the residue in 1 M HCl (Schaefer et al. 2006). Various methodologies have been developed to separate the radionuclide of interest from the solution and to convert it to a suitable chemical form before putting it into the ion source. The separation method of the radionuclide of interest from bulk sample or from its isobars varies on the chemical properties of the particular radionuclide and the corresponding matrix. Therefore, the separation chemistries have been discussed in the following section individually for each radionuclide. The purpose of chemical treatment is to bring the elements of interest to a specific form to generate high negative ion current from the ion source. Appropriate binders, for example, Ag or Nb powder, having high thermal and chemical conductivity, are used to generate high negative current. Sometimes chemical processing brings the desired atoms in such a favorable form that they become open to ionization and leaves the interfering atoms resistant to ionization. Thus, chemical preparation of the sample helps to minimize interfering background.

In spite of all these advantages, chemical processing sometimes carries its own set of problems by introducing various kinds of contamination into the sample. Very low-conductivity water (resistivity $\sim 18 \text{ M}\Omega \text{ cm}$) and extremely high-purity reagents should be used. Sometimes solvents are distilled before use. One should also be careful about addition of carrier while extracting a very small amount of sample. Even with all precautionary measures, contamination is possible as impurities in solvents and reagents are determined with instruments, which have much higher detection limit than AMS. The quality control requires that these errors must be nullified by using *standards* and *blanks* similar to other methods of measurements in trace analysis. Below some terms related to quality control have been defined (Hotchkis et al. 2000).

54.2.2.3 Quality Control Parameters

Standard: In AMS, standard sample is that where the ratio of the long-lived radioactive isotope to stable isotope is known. The standard samples can be diluted to meet the level desired for AMS analysis. Isotope ratios in the range from 1 to 1×10^{-11} are usually convenient for system calibration.

Blank: In a real blank, the radioisotope of interest should be absent. But in practice, very low isotopic ratio (radioactive/stable) is called blank.

Reagent blank: To reduce the background often reagent blanks are measured. When a blank sample is processed with all the similar pretreatment and chemical steps without addition of the isotope of interest is called reagent blank.

Internal standard: Sometimes standards are not available for all the cosmogenic and SN radionuclides. Therefore, many AMS facilities have embarked on elaborate programs to manufacture their own calibrated standards. In most cases, these materials have been prepared locally with the utmost care using conventional radiometric counting, mass spectrometric methods, and/or standard gravimetric dilution techniques to establish their isotopic ratios. Alternatively, some AMS laboratories have prepared standard materials by series dilutions of primary standards.

Interlaboratory standards: These methods are needed to calibrate in-house standards, which are prepared in sufficient quantity for use in every measurement cycle.

Background: There are two types of contribution to the background, which together limit the reliability of the AMS method. First, other ions may be wrongly identified in the detection system as being the radioisotope of interest. The mass, energy, and charge resolution of the beam transport and detection systems may be insufficient to fully distinguish their signals. For example, while detecting ^{36}Cl some ^{36}S atoms may also reach the detector. Second, the sample may become contaminated from another source of the radioisotope of interest during handling, processing, or analysis. Routine assessment of the background, through measurement of blanks, is an essential part of AMS measurements.

Apart from these samples, some other quality control samples such as *duplicate samples* and *equipment field blanks* are used by different laboratories. Duplicate samples are taken from the same collection site to determine the variability of results for the same sample after the AMS analysis. Generally, one duplicate sample should be collected for every 20 samples. Equipment blanks are collected using laboratory-provided water, which has been run over the decontaminated soil sampling equipment. These samples are used to determine the efficiency of cleaning procedures for soil sampling equipment.

Precision and accuracy: As in all other techniques, precision is a measure of reproducibility while accuracy deals with the closeness of the result with the true value. The precision of an AMS measurement is evaluated from the reproducibility or spread of repeat measurements of the isotopic ratio of a sample. In AMS, stable and radioactive isotopes are measured simultaneously. The precision in AMS is limited by the uncertainty of the counts of the ions arriving in the detector. Precision or uncertainty is also dependent on the sample size. To have a more accurate result all the instruments required in various steps of AMS measurement should be calibrated properly (Hotchkis et al. 2000).

54.2.3 Importance of Cosmogenic and SN Radionuclides and the Required Chemistry for AMS Analysis

The measurement of cosmological and SN produced radionuclides down to subpart per trillion or even less have tremendous impact on various fields of basic and applied sciences. The range includes astrophysics, nuclear physics, biology, pharmacology, toxicology, biomedicine, archeology, geology, meteorology, environment, oceanography, and many other areas (Maiti and Lahiri 2008). The use of cosmogenic radionuclide ^{14}C ($T_{1/2} = 5,730$ years) has

increased dramatically in recent years. There are a number of commercial laboratories available worldwide for the detection of ^{14}C . The AMS determination of ^{14}C is used for radiocarbon dating up to 50,000-year-old samples; to understand the intricacies of prehistorical events, like ancient painting and engravings; for serving human health by tracing the metabolic activities of various drugs in minute scale, and by labeling DNA with ^{14}C . However, in the following discussions, applications of ^{14}C have been deliberately excluded as they can be found elsewhere. Discussion will be focused on the applications of other long-lived radionuclides, like ^{10}Be ($T_{1/2} = 1.5 \text{ Ma}$), ^{26}Al ($T_{1/2} = 0.716 \text{ Ma}$), ^{53}Mn ($T_{1/2} = 3.7 \text{ Ma}$), ^{129}I ($T_{1/2} = 15.7 \text{ Ma}$), (cosmogenic radionuclides); and ^{60}Fe ($T_{1/2} = 1.5 \text{ Ma}$), ^{146}Sm ($T_{1/2} = 103 \text{ Ma}$), ^{182}Hf ($T_{1/2} = 9 \text{ Ma}$), ^{244}Pu ($T_{1/2} = 80 \text{ Ma}$), (SN radionuclides). The discussions will be limited mainly to give an essence of their implication for solving cosmological puzzles. A list of cosmogenic radionuclides measured by AMS is presented in [Table 54.1](#).

54.2.3.1 ^{10}Be

The radionuclide ^{10}Be is mainly produced in the Earth's atmosphere through spallation reactions by cosmic-ray particles on atmospheric N and O atoms. Newborn ^{10}Be atoms get readily attached to the ambient aerosols and are transported and deposited to the Earth via wet and dry deposition after its resident time of 1–2 years in the stratosphere. Owing to its long half-life, the measurement of ^{10}Be in natural archives may reveal several scientific aspects. Both ^{10}Be and ^{26}Al are accumulated in exposed quartz surfaces over a geological timescale. Initially, the abundance of cosmogenic radionuclides in quartz increases as a function of cosmic-ray exposure. However, natural enrichment of radionuclides is limited by landscape erosion and their natural radioactive decay processes. ^{10}Be is extensively used in exposure-dating applications. This is mainly so because a $^9\text{BeO}^-$ current of several milliamperes is easily achieved, which makes possible to get a $\sim 3\%$ ^{10}Be counting statistics for a sample with a $^{10}\text{Be}/\text{Be}$ ratio of 5×10^{-13} in just 5 minutes. Be content in natural samples (e.g., quartz) is exceptionally low, and Be carrier is invariably added before dissolution of the quartz sample to get sufficient amount of BeO for AMS measurement. This allows manipulating the $^{10}\text{Be}/\text{Be}$ ratio either by increasing the amount of quartz to 100 g and/or decreasing the quantity of stable ^9Be to 0.25 mg or less (Fifield et al. 2007).

Recently, ^{10}Be in ice cores has been measured to reconstruct the solar activity during the Holocene (McCracken et al. 2004; Muscheler et al. 2007; Vonmoos et al. 2006).

Table 54.1

Cosmogenic radionuclides measured by accelerator mass spectrometry (AMS)

Radio nuclide	Half-life (year)	Stable isotopes	Stable isobars	Chemical form	Detection limit (atom ratio)
^{10}Be	1.51×10^6	^9Be	^{10}B	BeO	$\sim 10^{-15}$
^{14}C	5,730	$^{12,13}\text{C}$	^{14}N	C (graphite)	$\sim 10^{-15}$
^{26}Al	7.2×10^5	^{27}Al	^{26}Mg	Al_2O_3	$\sim 10^{-15}$
^{41}Ca	1.03×10^5	$^{40,42,43,44}\text{Ca}$	^{41}K	CaH_2 , CaF_2	$\sim 10^{-15}$
^{53}Mn	3.7×10^6	^{55}Mn	^{53}Cr	MnO	$\sim 10^{-13}$
^{129}I	15.7×10^6	^{127}I	^{129}Xe	AgI	$\sim 10^{-14}$

The measurement of ^{10}Be from Greenland and Antarctica reveals that in the Maunder Minimum period, 1645–1715, the mean global ^{10}Be production was 32% higher than today due to low solar activity and colder climate. In the Maunder Minimum period, production of ^{10}Be in the stratosphere was high leading to larger ^{10}Be deposition in the subtropics, where stratosphere–troposphere exchange is strong.

It has been found that the concentrations of ^{10}Be in the deep-sea sedimentation cores vary mostly due to the changes in sedimentation rates. However, climatic changes and the variation of Earth's magnetic field may also be responsible for the changes of ^{10}Be contents in sediments. It has been inferred that global production rates of ^{10}Be have been varied by less than $\pm 30\%$ in the past 2.5 Ma when averaged over periods of 10^5 years (Reddy et al. 1983; Somayajulu 1977; Tanaka and Inoue 1979; Sharma and Somayajulu 1982).

The concentrations of cosmogenic radionuclides ^{10}Be , ^{26}Al , and ^{36}Cl in 120–200 ka old coralline matrix from Barbados and Puerto Rico were measured by Lal et al. (2005). The concentrations of ^{10}Be were measured in the range of 2.3×10^6 to 1.0×10^8 atoms/g coral while ^9Be concentrations lie in the range of 1.6×10^{-9} to 1.6×10^{-7} g Be/g coral. The intrinsic ratio of $^{10}\text{Be}/^9\text{Be}$ atoms were measured between 6×10^{-9} and 3×10^{-8} . The group reported cosmogenic ^{10}Be is suitable for determining the ages of old corals up to about ~ 10 Ma.

In order to distinguish the concentration of ^{10}Be in samples from the corresponding blanks, samples must be prepared using stable isotope carrier with low intrinsic radionuclide concentrations. Precise determinations of $^{10}\text{Be}/^9\text{Be}$ at the level of 10^{-14} need sample preparation to produce the highest ^9Be currents in AMS measurements. Measurements of intrinsic isotopic ratio at different AMS facilities conclude that commercially available ^9Be carriers rarely meet the requirement in geological samples. It has been advised therefore to use ^9Be carriers prepared from Be-containing minerals such as beryl aquamarine ($\text{Be}_3\text{Al}_2\text{Si}_6\text{O}_{18}$ with traces of Fe) beryl morganite ($\text{Be}_3\text{Al}_2\text{Si}_6\text{O}_{18}$ with traces of Mn) and phenakite (Be_2SiO_4) (Merchel et al. 2008).

For the precise AMS analysis of ^{10}Be and ^{26}Al , Hunt et al. (2008) reported an efficient sample preparation method, where quartz was separated from rocks following a sequence of pulverization, size fractionation, acid etching and leaching, and liquid density separation. This protocol yields pure quartz mineral phase, however, trace-level contamination is expected. Most of the time quartz is contaminated due to lattice imperfections with some combination of native Al, Fe, Ti, alkalis, and alkaline earth metals.

Stable Be and Al carrier is added to the quartz before dissolution in a multiacid medium, that is, in the mixture of HF, HClO_4 , HNO_3 , HCl at 120°C for 24 h, following standard US Geological Survey methods (Biggs and Meier 2002). Typically, 30 g quartz is dissolved in the mixture of 80 mL HF, 4 mL HClO_4 , 1 mL HNO_3 , and 2 mL HCl at 120°C . Most of the impurities native to the quartz phase, except Ti, are converted to fluoride under this condition. In the interim, the interfering isobar ^{10}B forms BF_3 and is volatilized. The quartz digest is evaporated to dryness leaving a bead of HClO_4 that contains nonvolatile elements. Fluorides are decomposed in concentrated HClO_4 . Repeated HClO_4 evaporations produce perchlorate salts that are again dissolved in HCl. Insoluble TiO_2 is removed by centrifugation. The resulting chloride solution is eluted from an anion exchange resin (BioRad AG 1-X8, 200 mesh), evaporated to dryness, and redissolved in HCl. Two selective precipitations are carried out from this solution (at $\text{pH} < 4.1$ and at < 8.9) to remove metallic and alkaline earth impurities (Tera et al. 1986).

From the resulting solution Be and Al are separated on a cation exchange resin (BioRad AG 50W-X8, 200 mesh) (Ochs and Ivy-Ochs 1997). Be fraction is then eluted by 1.2 M HCl, while the Al fraction is eluted with 3 M HCl. The Be fraction is evaporated to dryness and fumed with

1 mL of concentrated HClO_4 to expel any trace boron impurities remaining in the sample. $\text{Be}(\text{OH})_2$ and $\text{Al}(\text{OH})_3$ are precipitated from the respective Be and Al fractions by NH_4OH ($8.1 < \text{pH} < 8.9$). The supernatant is discarded by centrifugation and the gel is transferred to quartz vials, which are ignited in a gas flame to produce BeO by thermal decomposition. BeO cathodes are prepared for AMS analysis mixing with niobium powder to enhance ion beam currents.

54.2.3.2 ^{26}Al

^{26}Al is produced by spallation of oxygen or silicon atoms and accumulated in exposed quartz surfaces. In the atmosphere, ^{26}Al is produced by spallation of argon. This radionuclide is also present as extraterrestrial material such as interplanetary dust. ^{26}Al provides information indicating the exposure history of a landscape or, with complementary ^{10}Be data, the burial history of a sample (Granger et al. 2001; Hunt et al. 2007). Like ^{10}Be , the production rate of ^{26}Al is also very low, (e.g., 30 atoms/g of quartz per year) and hence the detection of ^{26}Al is only possible by AMS (Hunt et al. 2008). $^{26}\text{Al}/^{10}\text{Be}$ ratio is often used to dating the climate archived like old ice relicts. The age range that can be addressed by this method is in the order of 1×10^6 years to 5×10^6 years. Recently, Vienna group at VERA laboratory started a project to measure atmospheric ^{26}Al (Auer et al. 2007). For the determination of atmospheric ^{26}Al , aerosol samples and large-volume ice samples have been tested. Aerosol filter samples are leached in 1 M HCl for 1 to 2 h and filtered through 0.45 μm pore size cellulose ester filters. For ice samples, the melt water is acidified to pH 1 with HCl, filtered through 0.45 μm pore size filters, and concentrated by adsorption on cation exchange resin. Prior to filtration, the samples are spiked with 1 mg Al carrier. Fe is separated from the sample. Subsequently Al and Be are separated, precipitated as hydroxides, washed several times with double-distilled H_2O , and converted into the respective oxides at approximately 800°C . However, due to very low production rate of atmospheric ^{26}Al (about 100 atoms/ m^3), one must be careful about the contamination from non-atmospheric ^{26}Al .

The measurement of ^{26}Al has several interesting applications. For example, Pavicevic et al. (2004) measured ^{26}Al in quartz to assess the cosmic-ray background for the geochemical solar neutrino experiment. Nishiizumi et al. (2009) concluded solar cosmic-ray records by measuring the cosmogenic radionuclides ^{10}Be and ^{26}Al . Solar energy drives many processes occurring throughout the solar system, including Earth's climate. The lunar surface is an archive of solar cosmic rays, and studies of lunar surface rocks provide important information on past solar activity (Reddy et al. 1983). Cosmogenic nuclides on the surface of the Moon are produced by both solar cosmic rays (SCR) and galactic cosmic rays (GCR). Nishiizumi et al. (2009) studied the lunar rock erosion rate using ^{10}Be , ^{26}Al , and ^{36}Cl .

Both ^{10}Be and ^{26}Al are the key sources of cosmogenic radionuclides and they are often analyzed in the same matrix like quartz. The chemical extraction procedures for beryllium and aluminum are similar. Unlike Be, ^{26}Al is extracted in AMS as Al^- . The isobaric interference from ^{26}Mg does not exist because Mg does not form Mg^- . The stable ^{27}Al is spiked with the sample to generate higher current in the cathode. However, some authors prefer not to add stable carrier for ^{26}Al determination, especially in quartz as the Al content of even highly purified quartz is typically 100 ppm. Therefore, 10–20 g of quartz yields sufficient Al for an AMS target (Fifield et al. 2007). The separation of quartz from rocks by a sequence of pulverization, size fractionation, acid etching, and leaching is similar to the one that has

been described already in beryllium section (Hunt et al. 2008). In most of the AMS systems, for Al measurements Al_2O_3 is mixed with a small amount of metal powder (e.g., Ag, Cu, or Nb) as a heat and charge conductor.

54.2.3.3 ^{53}Mn

The radionuclide ^{53}Mn is produced by nuclear reactions of cosmic rays (mostly protons) on iron present in Earth's surface minerals or in meteorites and cosmic dusts. Measurements of concentrations of ^{53}Mn in rocks might help to understand Earth's surface processes that occurred in time periods not accessible with any other cosmogenic nuclides. ^{53}Mn with its long half-life (3.7 Ma) records cosmic-rays irradiation time up to 11 Ma (Schnabel et al. 2001). Ability to measure ^{53}Mn expanded the dating timescale and improved analytical precision. The important archive of ^{53}Mn (specially, the extraterrestrial ^{53}Mn , which might have been stored in Kuiper and Asteroids belts) is the ferromanganese crusts and sediments. These crusts and sediments may be collected from the Pacific Ocean, the Antarctic Ice, etc. The abundance of ^{53}Mn in the Earth's crust is scanty and the ratio of $^{53}\text{Mn}/^{55}\text{Mn}$ might be $1/10^{14}$, depending on the location. Only AMS can determine such ultratrace levels of ^{53}Mn .

The main interference in the detection of ^{53}Mn by AMS is its stable isobar ^{53}Cr , which is roughly 10^{12} times more abundant in nature (e.g., in manganese crust, sediment, or lava samples). A prerequisite of any AMS measurement of ^{53}Mn in geological samples is therefore chromium separation by an efficient chemistry. Lahiri et al. (2006) developed a method for the separation of chromium and manganese using radiometric technique. They simulated the condition where a particular isotope of manganese is in scanty amounts but chromium is in much larger amounts, a situation near to the abundance ratio of ^{53}Mn and ^{53}Cr in Earth's surface. The ratio of $^{52}\text{Mn}/\text{Cr}$ produced by the nuclear reaction $^{\text{nat}}\text{Cr}(\text{p},\text{xn})^{52}\text{Mn}$ is similar to this. They consecutively irradiated four types of Cr samples (viz., pure Cr metal, $\text{Cr}(\text{NO}_3)_3 \cdot 9\text{H}_2\text{O}$, $\text{K}_2\text{Cr}_2\text{O}_7$, mixture of Cr(III) and Cr(VI)) with a 12 and a 23 MeV proton beam to produce ^{52}Mn , and ^{51}Cr in the matrix, respectively. The separation procedure was monitored by ^{51}Cr ($T_{1/2} = 27.70$ days) and ^{52}Mn ($T_{1/2} = 5.59$ days), the corresponding radiotracers for chromium and manganese. The separation studies were performed by a liquid–liquid extraction (LLX) technique using trioctyl amine (TOA) diluted in cyclohexane. A high separation factor for Mn and Cr was obtained in optimal conditions of 0.8 M TOA and 9 M HCl, in presence of 0.025 mL octanol. As ^{52}Mn is extracted in the organic phase, it is back extracted into the aqueous phase by shaking with 0.001 M NH_3 . Excess AlCl_3 was added to aqueous solution to precipitate $\text{Mn}(\text{OH})_2$ along with $\text{Al}(\text{OH})_3$. The developed method has been found equally applicable for real geological samples such as manganese crusts, lava, and sediment samples. Therefore, the method offers an important tool to improve ^{53}Mn measurements by AMS.

Schnabel et al. (2001) reported separation of Cr from Mn samples by anion exchange chromatography. They took the sample in 10.2 M HCl, added a few drops of H_2O_2 to the solution. The solution was loaded onto an anion-exchange column. Al, Be, Ni, and most of the Cr were eluted by 10.2 M HCl, followed by the elution by 7.1 M HCl to collect Mn^{2+} and remaining Cr. The procedure was repeated for Mn-bearing fractions a number of times to reduce the amount of Cr. After decontamination of chromium, the Mn fraction was evaporated to dryness, dissolved in 7 M HNO_3 and Mn was precipitated as MnO_2 by addition of KClO_3 . The MnO_2 was redissolved and precipitated, and dried, first at 110°C and then at 250°C .

While measuring ^{53}Mn , it is very difficult to get a standard. Therefore, each laboratory makes its internal standard. For example, Munich AMS laboratory made ^{53}Mn standard by irradiating ^{54}Fe by 19 MeV ^3He to produce ^{53}Mn using the following nuclear reaction:

54.2.3.4 ^{129}I

Iodine-129 is a weak β^- emitter with end-point energy of 152 keV and decays to ^{129}Xe that emits 40 keV γ and X-rays. Due to its long half-life, it is difficult to measure ^{129}I by decay counting. The concentration of ^{129}I in natural samples, for example, seawater, is extremely low ($\sim 10^9$ atoms/g) relative to ^{127}I and can only be measured by AMS, the atom counting technique, as INAA and ICP-MS are limited by lower sensitivity.

In the pre-nuclear era, the total quantity of ^{129}I in the oceans was ~ 100 kg (Raisbeck and Yiou 1999), which is believed to have originated from the cosmic-ray interaction on xenon in the atmosphere and by spontaneous fission of ^{238}U (Fabryka-Martin et al. 1985). In the post-nuclear era, concentration of ^{129}I was found to be enhanced by more than one order of magnitude due to nuclear weapons testing, nuclear reprocessing, Chernobyl disaster, marine discharges, etc.

Raisbeck and Yiou (1999) have shown how ^{129}I can be used as *pathway* and *transit time* tracer in the North Atlantic and Arctic oceans. Santschi et al. (1996) measured profiles of ^{129}I in the Deep Western Boundary Current in the Middle Atlantic Bight. The AMS-measured isotopic ratio of $^{129}\text{I}/^{127}\text{I}$ was as high as 1.0×10^{-10} near the surface, while the ratio in the subsurface peaked at 1,000–1,500 m depth of water giving the value 55×10^{-12} . A steady increase in the ratio was observed below 2,000 m water depth reaching maximum of 80×10^{-12} at 2,600 m depth, which is accredited to the Deep Western Boundary Current. The reason is that the Deep Western Boundary Current in the Greenland Sea is more directly connected to the ^{129}I enriched North Sea water than to the Labrador Sea. The minor maximum at 1,000–1,500 m is due to the Labrador Sea water.

The concentration of ^{129}I and the ratios of $^{129}\text{I}/^{127}\text{I}$ were measured by López-Gutiérrez et al. (2000) in rainwater from Sevilla, Spain, and sea sediment core near the Ringhals coast, Sweden, using AMS to study the environmental effects. The typical ^{129}I concentrations in rainwater in Sevilla zone were 10^7 – 10^8 ^{129}I atoms/L. The ^{129}I concentrations were found to be 10^8 – 10^9 ^{129}I atoms/L in rainwater samples in 1996–1997, which corresponds to the measurements in Europe range (Krupp and Aumann 1999). The enhancement of ^{129}I concentrations occurred due to the emissions from large nuclear reprocessing plants (Paul et al. 1987; Wagner et al. 1996; Muramatsu and Ohmomo 1986).

Buraglio et al. (2000) have reported a sample preparation technique for AMS analysis of ^{129}I , which is the modified procedure of Moran et al. (1995), from natural water. Water samples collected from different sources: oceans, seas, freshwater lakes, rivers, and groundwater are stored securely in a cold dark room. The stored samples are equilibrated to room temperature and filtered through 0.45 μm . Potassium iodide (KI) carrier is added (~ 0.25 – 2.0 mg/100 mL water) to the sample. In order to ensure the complete conversion of iodate into iodide, 2 mL of 0.1 M NaHSO_3 is added to the sample. The sample is then acidified (pH 2) by concentrated HNO_3 and the solution is transferred to a separating funnel. The iodide is oxidized to iodine by adding 30% H_2O_2 and extracted into CCl_4 forming a purple color solution. The remaining

iodate in the aqueous phase is further extracted by adding hydroxylammonium chloride and CCl_4 . The iodine extracted to CCl_4 is back extracted into 0.1 M NaHSO_3 . A few drops of 18 M H_2SO_4 are added to remove excess of sulfite during back extraction of iodine. The iodine is precipitated from the aqueous solution by adding 0.01 M AgNO_3 . The precipitated AgI is then washed with NH_3 to get rid of eventual silver-sulfo compounds or AgCl and with double-distilled H_2O and left at 60°C to dry overnight. The sample (AgI) thus prepared is mixed with silver or niobium powder and pressed in a copper holder for the AMS measurements.

54.2.3.5 ^{60}Fe

The radionuclide ^{60}Fe ($T_{1/2} = 1.5$ Ma) is produced inside the solar system only in minute amounts. Because of spallation reactions with cosmic rays, $^{60}\text{Fe}/\text{Fe}$ ratios in the order of only 10^{-14} have been reported for meteorites. On Earth, a much smaller concentration is expected because of the atmospheric shielding from CRs. However, large amounts of ^{60}Fe are produced by stellar nucleosynthesis, as confirmed by the RHESSI satellite (Smith 2004). The presence of ^{60}Fe in interstellar space reflects ongoing nucleosynthesis in the Galaxy on the timescale of the order of 10^6 years (Rugel et al. 2009). In case of a SN sufficiently close to the solar system, this material can be directly deposited on Earth, leaving a ^{60}Fe signal far above the natural terrestrial level. The half-life of ^{60}Fe is long enough to search for such a signal during the past several millions of years (Ellis et al. 1996; Knie et al. 2004). Therefore, ^{60}Fe is a unique indicator for the detection of SN debris on Earth. One of the earliest attempts to detect ^{60}Fe signal in hydrogenetic ferromanganese crust with a growth rate of only a few millimeter per megannum was carried out in Munich by Knie et al. (1999). They collected a crust sample from South Pacific at a depth of about 1,300 m. Knie et al. (2004) also attempted to measure such SNs' distance from the Earth by the quantification of ^{60}Fe obtained from ferromanganese crusts originating from the equatorial Pacific.

From various layers of ferromanganese crust (each layer is 1–2 mm thick) iron was extracted with diisopropyl ether, purified by ion exchange chromatography with AG1X8 resin and was precipitated with NH_3 . To exclude contaminations during sample preparation, different AMS samples have been independently prepared from each layer. Negative FeO^- ions have been produced in a sputter ion source and were accelerated by the Munich tandem accelerator as Fe^{11+} ions up to an energy of 155 MeV. ^{60}Ni is a stable interfering isobar for the detection of ^{60}Fe . Knie et al. got rid of this interfering nuclide employing physical means of separation using a 135° magnet filled with 6 mbar of nitrogen. Because of the interactions with the gas, the ions assume an average charge state depending on their nuclear charge. Therefore, isobaric ions exit the magnet at different positions (Knie et al. 1999). In the ionization chamber, ^{60}Fe can be identified by position, residual energy, differential energy loss, and angle. In 1999, Knie et al. obtained 1 to 14 ^{60}Fe counts in different layers of ferromanganese crust leading to $^{60}\text{Fe}/\text{Fe}$ ratio of $(0.25\text{--}2.1) \times 10^{-15}$. In 2004, the same group obtained in total 69 ^{60}Fe events in various layers, corresponding to an $^{60}\text{Fe}/\text{Fe}$ ratio of 1.9×10^{-15} .

Fitoussi et al. searched for supernova-produced ^{60}Fe in marine sediment using a different chemical treatment (Fitoussi and Raisbeck 2007). The samples were collected from the North Atlantic Ocean. The sediment was leached with 0.04 M $\text{NH}_2\text{OH}.\text{HCl}$ in HOAc (25% v/v) for 6 h, at 100°C . After centrifugation, the solution was separated, evaporated to dryness, and then dissolved in 10 M HCl . To separate Fe from Ni and Al, an anion-exchange column BioRad AG1X8 was used. The elution of the solution was done by 10 M HCl . Mn was then eluted with

7.1 M HCl. Finally, iron was eluted with water. Fe was precipitated as iron hydroxide. The precipitate was redissolved in HCl for purification and reprecipitated with NH_3 , centrifuged and dried at 80°C . The AMS measurement of $^{60}\text{Fe}/\text{Fe}$ ratio shows inconsistency with the traversal of the solar system by a young SN shock wave having the ^{60}Fe -calculated fluence. Therefore, further experiment is required with samples collected from other locations of the globe.

The age of the crust (from where samples are taken to measure ^{60}Fe) is an important parameter since it defines the time span of ^{60}Fe accumulation in the sample. For almost all the measurements discussed above, dating of the crust has been simultaneously done by ^{10}Be measurement (Fitoussi et al. 2008a).

54.2.3.6 ^{146}Sm

Most of the unstable nuclides, present at the beginning in the solar system have faded away. However, some of them with sufficiently long half-lives are still around. Measurement of specific radioactive nuclei on Earth synthesized before the formation of the solar system is a new approach to understanding these processes. ^{146}Sm ($T_{1/2} = 1 \times 10^8$ years), and ^{244}Pu ($T_{1/2} = 82.6 \times 10^6$ years) are such long-lived radionuclides, which have been produced in significant amounts and should still be around in measurable quantities (Wallner et al. 2004).

No measurement or attempted measurement has been performed so far to detect ^{146}Sm in natural samples. The obstacle, until now, is the lack of a method to detect such low concentrations. Because of the long half-life, any attempt to count directly the decay of ^{146}Sm is out of the scope of present detector technology. The measurement of ^{146}Sm through AMS is also a big challenge. Any attempt to measure ^{146}Sm by AMS must ensure that the sample is free from its naturally occurring and million times more abundant stable isobar ^{146}Nd . However, this is a serious problem, because samarium and neodymium, due to their similar chemical properties, always occur together in nature. The phenomenon of lanthanide contraction is mainly responsible for this similarity; introducing a colossal challenge for their mutual decontamination. Therefore as a first step of AMS detection of ^{146}Sm , separation of samarium and neodymium is of utmost importance.

There are many reports on chromatographic techniques describing the separation of samarium and neodymium (Stray and Dahlgren 1995; Arai et al. 2006; Miranda et al. 2002; Pin and Zalduogui 1997; Schwantes et al. 2006; Tsuyoshi and Akiba 2000). Compared to chromatographic techniques LLX is easy to handle, simple and much faster. A larger sample volume can be handled at a time. Recently, a publication coauthored by the senior author of this chapter reported an efficient separation of Sm and Nd with a very high separation factor through LLX so that the result can be directly applied to decontaminate ^{146}Sm from ^{146}Nd for measurement of the former through AMS (Maji et al. 2006b).

The separation of samarium and neodymium was simulated radiometrically using the radioisotopes ^{153}Sm ($T_{1/2} = 46.28$ h) and ^{147}Nd ($T_{1/2} = 10.98$ days). Di-2-(ethylhexyl)phosphoric acid (HDEHP) was used as organic extractant and cyclohexane was used as diluent. As samarium also exhibits a +2 oxidation state, hydroxylamine hydrochloride was added to the radioactive solution containing samarium and neodymium. In optimal conditions, that is, at 0.025 M HCl and 0.1% HDEHP in the presence of hydroxylamine hydrochloride, a separation factor as high as 10^6 has been achieved, where Sm goes to the organic phase along with slight Nd contamination. The metals extracted in the organic phase are stripped back completely into

the aqueous phase with the help of 0.1 M HCl. The aqueous phase was diluted to 0.025 M HCl and the process of extraction was repeated again. After third time extraction, 99% Sm is extracted by the organic phase contaminated with only 0.01% Nd. The developed process for the separation of samarium and neodymium not only offers a very high separation factor but also ensures the suppression of neodymium contamination of samarium by a factor of 10^6 at least after multiple extraction and back extraction processes. Therefore, the developed method might be highly helpful for the pretreatment of samarium samples for the AMS measurement of ultratrace amounts of ^{146}Sm in nature to study nuclear synthesis.

54.2.3.7 ^{182}Hf

Several observations indicate that one or even more supernova (SN) explosions occurred rather close to the solar system during the past several million years. ^{182}Hf ($T_{1/2} = 9 \times 10^6$ years) is believed to be formed by two distinct types of r-process at different rates (Qian 2003) during a supernova explosion. In contrast, according to Meyer and Clayton (2000), a kind of fast “s” process in carbon and helium burning shell is responsible for the production of ^{182}Hf . It is one of the examples of an “extinct” radionuclide with a high abundance in the early solar system, which has led to a powerful application as a geochronometer for dating the formation of objects in the inner solar system (Vockenhuber et al. 2005). ^{182}Hf is expected to be present in the interstellar medium (ISM) as a result of recent nucleosynthesis. Gamma-ray detection of ^{182}Hf through γ -ray telescope is unfeasible due to its overall low activity. However, deposition of ISM grains by accretion onto Earth could make a direct detection of live ^{182}Hf possible in slow-accumulating reservoirs such as deep-sea sediments. Finding of live ^{182}Hf on Earth is also a strong proof for the introduction of material from recent nucleosynthesis, that is, from nearby supernovae.

The average concentrations of hafnium and tungsten in deep-sea sediment are 10 ppm, while the ratio $^{182}\text{Hf}/^{180}\text{Hf}$ has been estimated 1×10^{-12} (Vockenhuber et al. 2004b). The success of an AMS measurement of such minute level of ^{182}Hf relies on two main properties: (1) high mass resolution to separate neighboring isotopes; (2) an efficient suppression of the stable isobar ^{182}W . Because of the natural abundance of ^{182}W , its concentration might be a million times higher in a sample than that of the ultra trace analyte ^{182}Hf . Therefore, prerequisite of ^{182}Hf measurement by AMS is that the sample must be free (until the limits of a chemical separation) of ^{182}W . Again, elements such as hafnium and tungsten, due to lanthanide contraction, always occur together in nature. Their mutual decontamination is always a challenge to the analytical chemist.

There are a few reports available dealing with the decontamination of tungsten from hafnium samples to measure ^{182}Hf by AMS. Attempt was made by Maji et al. (2006a) to develop a method of decontamination of ^{187}W (23.9 h) from ^{175}Hf (70 days) (both produced in a nuclear reactor by irradiating natural tungsten and hafnium salts). The separation studies were performed using LLX technique. Trioctylamine (TOA) dissolved in cyclohexane and HCl were used as organic and aqueous phase respectively. It was observed that tungsten could be quantitatively extracted in the organic phase along with only 2% of hafnium when 6 M HCl in the presence of H_2O_2 and 0.3 M TOA were used as aqueous and organic phase, respectively. The separation factor achieved in this condition was as high as 1.6×10^6 , indicating the possibility of getting ultrapure hafnium without contamination from tungsten. After developing the radiochemical method, the same procedure for stable isotopes of hafnium and tungsten

was checked with AMS facility at Munich. It was found that the developed method alone was responsible for reduction of ^{182}W with a suppression factor of 5–6 orders of magnitude. This finding together with the suppression in the ion source by 3–4 orders of magnitude by using $^{182}\text{HfF}_5^-$ (Vockenhuber et al. 2004a, b), and the additional suppression of 2–3 orders of magnitude by Delta TOF results in a total suppression of around 10^{-11} or 10^{-12} . That value might be further pushed by 2–3 orders of magnitude with an improved chemistry and the appliance of more rigid software cuts at the spectra of the AMS measurements. By this view, a measurement of ^{182}Hf seems to be feasible at an extremely low level as is expected in the case of a supernova-related signal.

Vockenhuber et al. (2007) separated tantalum and hafnium by ion exchange. Strongly basic anion exchange resin Dowex 1X8 (mesh 200–400) was prepared by immersion in a 1:1 mixture of 1 M hydrofluoric and 1 M nitric acid overnight. The same acid mixture was used as eluant and it was possible to eluate out pure Hf fraction free from tantalum.

Earlier the same group (Vockenhuber et al. 2004b) also separated Hf from Ta by dissolving it in HF acid and thereby converting Ta into heptafluorotantalate ions $[\text{TaF}_7]^{2-}$, which could be removed easily by LLX with tributyl phosphate (TBP) in *n*-heptane. The purified Hf solution was mixed with commercial HfF_4 . Finally, HfF_4 was precipitated and dried. The sample material was mixed with silver powder to make the ion source.

Qiu et al. (2007) also followed a similar method to separate Ta and W from hafnium sample. HfO_2 standard sample was dissolved in conc. HF and conc. HNO_3 mixed solution. The sample was roasted in oven for 2 h at 120°C to obtain desiccated HfF_4 powder, which was redissolved in 1 M HF solution. The sample solution was loaded onto an anion-exchange column. Hf was then eluted by 0.01 M HF 9 M HCl, while W and Ta retained on the column. However, through tracer experiments, the author found that the decontamination factors for W and Ta were only in the order of 1,000. The Hf sample purified with this procedure was transformed to HfF_4 powder again and was mixed with 1:1 w/w silver powder and pressed firmly for making ion source. The silver powder served as both an electrical and thermal conductor.

54.2.3.8 ^{244}Pu

After the detection of interstellar ^{60}Fe in deep-sea ferromanganese crust, thrust for searching ^{244}Pu ($T_{1/2} = 8.3 \times 10^7$ years) has been increased many folds (Wallner et al. 2000). ^{244}Pu is produced in recent supernova exclusively by the r-process. They are also present in the interstellar medium. By measuring the current abundance of ^{244}Pu and comparing it to the longer-lived ^{238}U , one may deduce the portion of r-process material from the last nucleosynthesis process that has contributed to the protosolar cloud before the formation of the Earth (Lachner et al. 2009). The Munich AMS group has set up a time-of-flight system for the detection of actinides. This setup was used by Wallner et al. (2004) to measure ^{244}Pu in deep-sea ferromanganese crust. They found about 4,000 atoms/cm² in the surface of such crust, which is believed to be 1–14 Ma old. It should be kept in mind that ^{244}Pu is also generated by atmospheric weapon tests, though it is unlikely to be deposited in deep-sea sediments and crust.

AMS measures the ratio of a long-lived radionuclide to its stable isotope (e.g., $^{14}\text{C}/^{12}\text{C}$). However, in the case of plutonium, there is no stable isotope. Hence, it is necessary to add a “spike” of a known amount of one of the long-lived isotopes, generally ^{242}Pu (3.75×10^5 years) or ^{239}Pu (2.4×10^4 years), to the sample in order to quantify the concentrations of the

isotopes of interest (Fifield 2008). Lack of stable isotopes and stable isobars offers favorable conditions for the AMS measurement of plutonium. As there are no isobaric interferences, it is not required to develop elaborated chemistry for isobar separation. These are the reasons for the success of ^{244}Pu detection by AMS though the production rates of the actinides in supernovae are a few orders of magnitude lower than that of ^{60}Fe .

The chemical extraction of plutonium helps to reduce the matrix (crust) material from kilogram range to below 1 mg. After dissolving the manganese crust in aqua regia, plutonium is recovered by passing the solution through anion exchange resin followed by co-precipitation with calcium oxalate. In the case of plutonium, only picogram quantities of the element are available, whereas the Cs sputter ion sources require sample masses of 1–10 mg. The extra bulk is achieved by dispersing the plutonium in an iron oxide matrix. Typically, 1–2 mg of $\text{Fe}(\text{NO}_3)_3$ is added to the plutonium-containing solution. The solution is then either evaporated to dryness, or precipitated as $\text{Fe}(\text{OH})_3$ by making the solution alkaline. The resulting solid is converted to Fe_2O_3 by baking at 800°C , mixed with a conductor like aluminum, silver, copper, or niobium, and pressed into a sample holder (Wallner et al. 2000, 2004). In the ion source PuO^+ molecular ions are preferred as intensity of this ion is higher than that of the Pu^+ ions.

54.3 Other Mass Spectrometric Techniques Related to Cosmochemical Analysis

AMS is the most reliable and ultra sensitive technique for measuring cosmogenic radionuclides. However, with the advent of analytical sciences, some other mass spectrometric techniques became potential competitors of the AMS system. Nowadays resonance ionization mass spectrometry (RIMS) is also considered as a sensitive and selective method for cosmochemical analysis in ultra trace scale. It provides extremely high isobaric suppression and good overall efficiency. The determination of naturally occurring and cosmogenic radionuclides by inductively coupled plasma-mass spectrometry (ICP-MS) has gained recognition over the last 15 years. With the increase in instrumental sensitivity, it is now possible to measure ultratrace levels (fg range) of many radionuclides by ICP-MS without requiring very complex sample pre-concentration schemes. The abundances and isotopic compositions of some long-lived radionuclides can also be measured by the thermal ionization mass spectrometry (TIMS). In this section, the principle and instrumentation of ICP-MS, TIMS, and RIMS will be discussed briefly together with their use in cosmochemical analysis.

54.3.1 Inductively Coupled Plasma-Mass Spectrometer (ICP-MS)

54.3.1.1 Components of ICP-MS

The most widely used mass spectrometric technique in the last couple of years is the inductively coupled plasma-mass spectrometry (ICP-MS), which is a highly sensitive mass spectrometry and is capable of determining a range of metals and several nonmetals at concentrations below one part in 10^{12} . It is based on coupling together with inductively coupled plasma, a method of producing ions, with a mass spectrometer as a method of separating and detecting the ions. ICP-MS is also capable of monitoring isotopic speciation for the ions of choice. Being a powerful tool, ICP-MS has opened up new applications for isotope ratio measurements of

elements, which are difficult to analyze (e.g., Mo, Hf, and Fe). Because of multielement handling capability, very low detection limits, good accuracy and precision measurements, ICP mass spectrometers are preferred among other comparing mass analysis techniques. A detailed description of the instrument and the functions of each component of ICP-MS can be found in the handbook by Nelms (2005). An ICP-mass spectrometer consists of the following components:

- Sample injection system
- Inductively coupled plasma formation
- Plasma sampling interface
- Mass analyzer
- Detector

A flowchart of the various steps of ICP-MS is given in [Fig. 54.6](#).

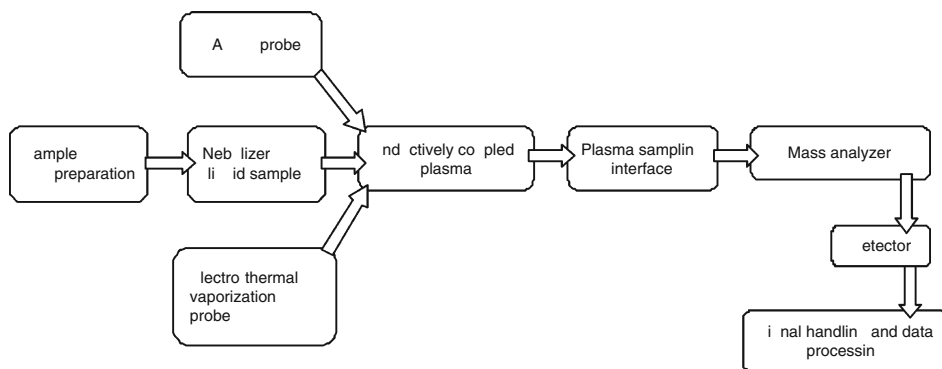

Sample Introduction System

The mostly liquid samples are introduced into an ICP-mass spectrometer by different techniques. Each of these techniques aims to generate fine aerosol of the liquid sample to achieve efficient ionization of the sample atoms in the plasma. However, only 1–2% of the sample can find way into the plasma; hence, the sample introduction system is considered as the weakest component of an ICP-MS. The introduction system works in two steps, namely, aerosol generation using nebulizer and droplet selection by the spray chamber. Most commonly, the liquid sample is pumped into the nebulizer by a peristaltic pump at a speed of ~ 1 mL/min. When the liquid sample enters the nebulizer, it is transformed into fine aerosol under the pneumatic action of the nebulizer gas flow (~ 1 L/min). However, some pneumatic nebulizers do not use a pump. They suck the sample through the tubing through the action of positive pressure of the nebulizer gas.

The spray chamber restricts the movement of large droplets (~ 10 μm in diameter or more) toward the plasma allowing only fine droplets (~ 5 – 10 μm diameter) to enter the plasma. The reason is that the plasma is not efficient enough to dissociate large droplets. The spray chamber also smoothes out the pulses that form during the nebulization process due to the pumping.

■ Fig. 54.6

Block diagram of the sample analysis in inductively coupled plasma-mass spectrometry (ICP-MS)

The fine droplets inserted into the plasma proceed through the process of dissociation, atomization, and finally ionization of the sample elements.

ICP Formation

Inductively coupled plasma forms when argon gas passes through a quartz torch placed in an induction coil, commonly called load coil, where radio frequency (RF) power of 750–1,700 W is applied. As a result, an alternating current oscillates within the field and the frequency of oscillation is governed by the RF generator. These oscillations generate electric and magnetic fields at the top of the torch. A high-voltage spark is introduced in order to strip electrons from the argon atoms. Stripped electrons are trapped in the surrounded magnetic field and accelerated in closed circular loop. Rapidly moving electrons collide again with neutral argon atoms stripping a new set of electrons and thus a chain reaction is sustained. High temperature of the plasma is governed by this collision process. The plasma flame is therefore the assembly of neutral argon atoms, positively charged argon ions, and electrons. Plasma remains alive until the radio frequency power is supplied through the inductive coil. In general, the temperature of plasma varies between 6,000 and 10,000 K, depending on the region of the plasma. The sample aerosol that enters the plasma is immediately de-solvated, vaporized, atomized, and finally partially ionized. It has already been established that most of the elements in the Periodic Table produce predominantly singly charged ions at yields ranging from 5% to 100%.

In most cases, plasmas are formed entirely of argon gas. However, the introduction of alternative gases may also have beneficial effects. For example, nitrogen can be introduced either as coolant gas or as a nebulizer gas flow to overcome various interferences including that of $^{40}\text{Ar}^{35}\text{Cl}^+$ on $^{75}\text{As}^+$ and oxide-based interferences. The introduction of nitrogen has substantial effect on the physical and electrical properties of plasma. If it is introduced as nebulizer gas flow, annular width of the plasma increases significantly though electron temperature decreases to 3,000–5,000 K along with the decrease in the gas kinetic temperature. As a result, interference effect decreases significantly, and at the same time sensitivity of the measurement also decreases.

Plasma Sampling Interface

The sampling interface consists of two sample cones with a small orifice in the center and is designed to extract the analyte ions from the ICP and transport them to the mass spectrometer for analysis. Analyte ions are generated in the ICP at high temperature ($\sim 7,500$ K) and atmospheric pressure. During the transportation, extracted analyte ions travel from the ICP to the mass spectrometer and detector, which are operating at room temperature (~ 300 K) and reduced pressures (10^{-5} – 10^{-9} mbar). Pressure gradient between the plasma and specially designed cone shapes, namely, sample cone and skimmer cone, of the sampling interface strongly influence the analyte sensitivity and the degree of the possible molecular interferences. An expansion chamber operated at 2–5 mbar pressure is located just behind the sample cone. Consequently, a significant portion of the plasma drives through the sample cone aperture into the expansion chamber. Argon ICP is a weakly ionized plasma, and therefore the bulk of the argon gas drawn through the sample orifice remains unionized. The cloud entering the expansion chamber is a mixture of gas atoms, molecules, ions, and electrons. Each constituent of the cloud gains speed quickly and expands outward under the influence of reduced pressure, generating a free jet. The supersonic expansion of gas is observed in the interface region. Rapid increase of gas velocity is due to the conversion of thermal energy of gas into the kinetic energy,

resulting in a reduction of gas temperature to 100–200 K. However, the gas does not attain thermal equilibrium in the interface as the electron temperature remains close to the source temperature, but ion–electron recombination is prevented due to the rapid drop in density. This process is known as adiabatic expansion, which is fundamental to ICP-MS analysis.

Ion Extraction and Ion Optics

ICP-MS is divided into two distinct regions, which are separated from each other by a gate valve. The first part of the instrument combines ICP generation system and expansion chamber, which readily attains atmospheric pressure when ICP is not functioning. The high vacuum, $\sim 10^{-7}$ – 10^{-8} mbar, is maintained for the ion optics, quadrupole, and detector. The gate valve between these two parts only opens when the ICP is operational and the expansion chamber is pumped out to the required operating pressure. Analyte ions travel through the interface region as they tend to achieve high velocity of the bulk argon gas, but the ion kinetic energies (E) exhibit a mass dependence as soon as the ions cross the sampling interface following the equation, $E = Mv^2/2$, where M is the ion mass and v is the ion velocity. The first charge separation takes place just behind the skimmer cone orifice, even in the absence of any applied external electric field. This action leads to a typical energy spread of 0.5–10 eV for the total mass range of Li to U. In the skimmer region, difference in mobilities between ion and electron occurred due to the drop of pressure and relative size difference. The high temperature of electron creates net negative charge diffusion readily toward the inner wall of the skimmer cone and this leaves a net positive charge along the axis with the bulk neutral gas flow. In the ICP, most elements of the Periodic Table efficiently produce positive ions, which survive long enough allowing mass selection and detection in the mass spectrometer. Positive ions are therefore favored for ICP-MS.

Application of an electric field in the interface can enhance the charge separation process and that means positive charge concentration increases largely in a comparatively small volume. Naturally, positive ions in the gas beam start repelling each other. This effect produces a self-defocused beam and the phenomenon is known as space charge effect. The maximum achievable sensitivity is limited by the space charge effect, which not only resists transmission of low-mass ions, but also sometimes suppresses the whole matrix. It strongly influences the operation of the ion optics. The “extraction” of ions usually means the selection of only positive ions applying electric field from the gas beam, which contains positive and negative ions, electrons, and uncharged species. Ions are generally extracted by a circular metal tube placed behind the skimmer cone. A negative voltage is applied to the metal tube to accelerate the positive ions from the gas beam toward the ion optics repelling electrons. Several important factors like plasma operating conditions, pressure of the expansion chamber, skimmer cone shape, ion current are considered to decide the magnitude of extraction voltage to be applied. In general, high extraction voltage helps to achieve high sensitivity for high-mass elements ($A > 80$), while lower extraction voltages favor sensitivity for low-mass elements ($A \leq 80$).

The objective of using ion optics is to transport the positive ions from the rear of the skimmer cone to the quadrupole, where they are separated according to their mass-to-charge ratio for analysis. Ion optics acts as an ion–energy filter, which must be compatible with the range of ion kinetic energies that emerge from the plasma sampling interface.

Mass Analyzer

The nucleus of ICP-MS is the mass separation device, generally called mass analyzer, is positioned between the ion optics and the detector. The task of this device is to separate the

ions of interest from the non-analyte and argon-based ions. Ions are traveling through the mass analyzer are separated according to their mass-to-charge ratio (M/q). However, the mass separation is performed in various ways depending upon the mass separation device used in ICP-MS. Various analyzers are used in the ICP-MS depending upon the application and are named accordingly. Among others, quadrupole (ICP-QMS), magnetic sector combined with electrostatic analyzer (High Resolution, HR-ICP-MS or Multi Collector, MC-ICP-MS), time-of-flight analyzers (TOF-ICP-MS) are commonly used for trace element analysis (Aggarwal 2010). Ions are routinely detected by using either Faraday cups or secondary electron multiplier. However, all above-discussed mass analyzers carry their own advantages and shortcomings.

The most common among the analyzers is the quadrupole mass filter that uses time-varying electric fields. In all these instruments, electric fields are varied rapidly compared to the transit time of the ions, hence these spectrometers are known as *dynamic* mass spectrometers. Potential energy of the ions is governed by the plasma potential. This potential energy is converted to equivalent kinetic energy when the ions are accelerated entering a grounded surface. Ion velocity (v) is calculated equating the potential energy and the kinetic energy expressions.

In ICP-QMS, the quadrupole consists of four cylindrical rods, typically made of stainless steel or molybdenum of equal length (~ 15 – 20 cm) and diameter of about 1 cm, enclosed in a cylinder of fixed radius (r_0). A fixed (DC) potential is applied on one diagonal pair of rods; and a radio frequency field on the opposite pair selects the ions by mass, which are allowed to pass through the quadrupole, while the rest eventually strike the quadrupole rods, where they are neutralized and stay until the rods are cleaned. The potential ϕ in the quadrupole mass filter is expressed as

$$\phi = \phi_0 \frac{(x^2 - y^2)}{2r_0^2} \quad (54.8)$$

The components of electric field along the axes are

$$E_x = -\phi_0(x/r_0^2), \quad E_y = \phi_0(y/r_0^2), \quad E_z = 0 \quad (54.9)$$

The potential, ϕ_0 , consists of a direct and an alternating component as

$$\phi_0 = V_{DC} - V \cos \omega(t - t_0) \quad (54.10)$$

where V_{DC} is the direct potential (constant), V is the amplitude of the RF potential, $\omega = 2\pi f$ is the angular frequency, f is the frequency of the RF supply, t is the time, and t_0 is the initial phase of the RF component. Ion motion can be obtained by solving the differential equation in each direction. There will be no acceleration along the axis of the cylinder; therefore, ions are transmitted with a constant axial velocity. This velocity is obtained from the difference between the ion's kinetic energy and the constant potential along the axis of the quadrupole mass filter. The electric field along the z -axis is zero, but often a constant unipolar potential is superimposed. This is known as fixed axis potential. The fixed axis potential controls the motion of ions (speed up or slow down) within the field, so that they can be transmitted with optimal axial velocity. Ions may speed up or slow down when they cross the intermediate lenses before the quadrupole mass filter. In practice, fringing field, which gives rise to nonzero field components in the axial (z) direction, always exists near the entrance and the exit of the quadrupole mass filter. Ions are lost at the entrance and the exit of the mass filter. Loss of ions is more near the entrance of the mass filter than at the exit end. It is therefore

usual to minimize the loss of ions in the entrance of mass filter by controlling carefully the ion entry conditions.

A set of DC-RF voltage on the rods will steer the analyte ions of interest electrostatically through the center of the quadrupole mass filter until the exit and they will be converted to an electrical pulse by the detector while other ions of different mass-to-charge ratios will stop in the quadrupole. In a multielemental analysis, the mass scan process is repeated one after another for all analyte ions of different mass-to-charge ratio until all the analytes in a multielement analysis have been measured. Quadrupole scan rates are typically on the order of 2,500 atomic mass units (amu) per second and can cover the entire mass range of 0–300 amu in about 0.1 s. However, real-world analysis speeds are much slower than the above.

Detectors

The detection system of ICP-MS counts the number of ions coming out from the mass analyzer. The detector converts the ions into electrical pulses that are counted by the integrated circuitry. The measure of the electrical pulses correlates the concentration of analyte ions in a matrix. The quantification of trace element is obtained comparing the ion signature with respect to the reference standards.

The ultratrace analysis in ICP-MS involves the use of sophisticated detectors such as active film or discrete dynode electron multiplier that efficiently converts the ion current to the electrical signal. The detector is kept off the axis of the mass analyzer in order to minimize the background. Consequently, the ion emerges from the mass analyzer, traverses through a curved path, and hits the first dynode creating lots of secondary electrons. The design of the dynodes is made in such a way that the secondary electrons are accelerated to the next dynode, where they generate more electrons. The electron multiplication process is continued in each dynode creating a pulse of electrons and is collected by the anode placed at the end. Though the discrete dynode detector is in general more sensitive than the old channeltron multiplier, the function of the measurement circuitry is also important in handling the low and high ion count rate.

In general, quadrupole-based ICP-MS allows isotope ratios to be measured in a few minutes with a precision between 0.1% and 0.5% and detection limits in the nanogram per liter range and below in aqueous solutions. The factor, which deteriorates the accuracy and precision of the isotope analysis, is the occurrence of isobaric interferences (atomic ions or molecular ions at the same mass/charge ratio) of analyte ions. The precision of isotope ratio measurements and the detection limits for selected elements (e.g., Ca, Fe, S, I, and Se) were improved by the insertion of a collision/reaction cell in quadrupole-based ICP-MS. Due to the collisions of ions formed in the ICP with gas atoms (He, Xe, Ar) or molecules (H_2 , O_2 , CH_4 , NH_3) introduced into a collision cell (CC), the kinetic energy spread of ions is reduced from several eV to <0.1 eV, which results in an increasing sensitivity of analyte ions. Moreover, isobaric interferences from disturbing atomic or molecular ions are significantly reduced by the interaction between collision gas and ions in the collision cell. For instance, the determination of $^{80}\text{Se}^+$ or $^{40}\text{Ca}^+$ isotope abundance is almost impossible even in a high mass-resolution sector-field ICP-MS. The problem can easily be solved by ICP-QMS with a collision cell, because the interfering Ar dimer ions ($^{40}\text{Ar}_2^{2+}$) are dissociated or atomic plasma gas ions ($^{40}\text{Ar}^+$) are neutralized via collision-induced reactions (Tanner et al. 2002; Boulyga and Becker 2001). Sometimes, molecular ions are also formed in the collision cell to be used as analyte ions to avoid interference. For example, $^{31}\text{P}^+$ or $^{32}\text{S}^+$ determination is carried out via the oxide ions $^{31}\text{P}^{16}\text{O}^+$ and $^{32}\text{S}^{16}\text{O}^+$, which are interference-free at mass/charge = 47 and 48, respectively,

formed with maximum ion intensities in the collision or reaction cell under optimized experimental conditions (Boulyga et al. 2003).

The other type of mass spectrometer that is used in isotope analysis is the double-focusing sector field ICP-MS. It allows a determination of isotope ratios with a precision between 0.02% and 0.2% and detection limits from nanogram per liter to sub-nanogram per liter range.

In order to overcome the limitation of the mass spectrometer having single ion collector, multiple ion collector is used for simultaneous measurements of mass-separated ion currents of several isotopes. Insertion of multiple ion collectors in sector field mass spectrometers improved the precision of isotope ratio measurements down to 0.001–0.002%.

54.3.1.2 Application of ICP-MS in Long-lived Analysis

ICP-MS is advantageous over RIMS and AMS due to fast and relatively inexpensive multielement determination, precise and accurate isotopic analysis at the trace, and ultratrace concentration levels in any material. Another advantage of ICP-MS compared to other atomic mass spectrometric techniques is the simple sample preparation and introduction of aqueous solutions into the normal-pressure inductively coupled plasma ion source.

Measurements of isotopic ratios of certain elements using ICP-MS combined with other attachments are described in the review of Becker (2005). A sensitive analytical technique for ^{129}I determination in soil and sediments was proposed by Izmer et al. (2003). Hot extraction (at 1,000°C with oxygen) of volatile analyte iodine was carried out in an oven coupled to ICP-CC-QMS. Oxygen was used as the extraction and collision gas and also for eliminating the isobaric interference of $^{129}\text{Xe}^+$, which disturbs ^{129}I detection. A cold finger for the collection of iodine between the oven for hot extraction and ICP was introduced and achieved a significant improvement of the detection limit for ^{129}I in sediments (0.4 pg/g instead of 30 pg/g, without cooling). $^{129}\text{I}/^{127}\text{I}$ isotope ratios of about 10^{-6} were measured in sediments at the ultratrace level with a precision <10% (Izmer et al. 2004). The abundance sensitivity for $^{236}\text{U}/^{238}\text{U}$ was also determined by ICP-CC-QMS, using helium as collision gas, as 6.3×10^{-8} (Boulyga and Becker 2002).

An ultratrace level Pu isotope analysis was performed in MC-ICP-MS by Becker et al. (2004) after separation on TEVA resin and enrichment of Pu from 100 L lake water from the Sea of Galilee. Studies of the separation procedure for 2.1 pg ^{242}Pu spiked to 100 L of lake water have resulted in a yield of 62%. The detection limit for Pu measurement by MC-ICP-MS was 3×10^{-20} g/mL. ^{239}Pu was detected in 100 L lake water at a concentration level of about $\sim 3.6 \times 10^{-19}$ g/mL. Hence, the measured $^{240}\text{Pu}/^{239}\text{Pu}$ isotope ratio by MC-ICP-MS of 0.17 is a clear evidence of plutonium contamination from the global nuclear fallout in the 1960s.

A direct determination of plutonium isotopes in soils and sediments was proposed by Boulyga et al. (2004) by Laser Ablation (LA)-ICP-MS. To minimize uranium hydride formation and peak tailing of $^{238}\text{U}^+$ on mass/charge = 239, LA-ICP-MS measurements were carried out at the optimum condition of the spectrometer. Isotope ratio of $^{240}\text{Pu}/^{239}\text{Pu} \approx 0.4$ was measured in contaminated Chernobyl soil samples, wherein the detection limit for Pu was determined as 0.3 pg/g.

Though the above-discussed samples are not directly of cosmogenic origin, the technique used is similar.

Wolfa et al. (2005) have developed a method for the quantification of a large number of trace elements, from moderately volatile to highly volatile (Cu, Zn, Ga, Se, Rb, Ag, Cd, In, Sn,

Sb, Te, Cs, Tl, and Bi) in chondritic meteorites by ICP-MS. The method allows for a rapid and accurate determination of the cosmochemically important volatiles in chondritic meteorites providing the means for an even more comprehensive elemental analysis of a single sample of chondritic material.

54.3.2 Resonant Ionization Mass Spectrometry (RIMS)

Resonant ionization mass spectrometry (RIMS) is a promising analytical technique that can accomplish distinct identification of low elemental concentrations in bulk materials. The technique offers high sensitivity and selectivity, which helps to determine low-concentration elements at and below the parts-per-billion (ppb) level. Moreover, such determinations can be quantitative even in complex matrices.

The high selectivity of the technique is due to sequential optical excitations combined with mass spectrometry coupled with high-efficiency ion detection. Several experimental combinations of RIMS have been studied aiming individual application. Nevertheless all individual techniques share a common goal.

54.3.2.1 Working Principle

Conventional chemical extraction of the sample is carried out before introducing it into an atomic beam source and thermally evaporated into high vacuum ($<10^{-6}$ torr). Single or multistep resonance excitation and ionization takes place upon irradiation with precisely tuned laser light onto individual optical resonance of the selected isotope. In most cases, excitation starts from the atomic ground state, passes through intermediate bound states, and ends at high-lying or auto-ionizing states for the final ionization. The resulting ions are accelerated in an electric field and transmitted through a mass spectrometer to a low-background ion detector. The overall isotopic selectivity is achieved through proper optimization of the instrumental parameters, suppressing neighboring masses by as much as a factor of 10^8 .

54.3.2.2 Components of RIMS

The simplest version of RIMS is composed of a source of atoms or molecules, one or more tunable lasers, and a mass analyzer or detector. A detail of instrumentation is discussed by Young et al. (1989).

Atom Source

Atoms are generated in gas phase using thermal sources, heated filament, and graphite furnace. Atom generation by a filament or in furnace is normally continuous in time, which may yield coupling inefficiency between such an atom source and a pulsed laser. In order to overcome the problem, two types of pulsed atom sources have been developed that use either a pulsed laser or a pulsed particle beam to generate an atom cloud. Either of these types of atom sources is coupled to pulsed-laser excitation. Glow discharge is another useful atom-generating source used in RIMS.

Lasers

Commonly, either of two types of lasers, continuous-wave or pulsed, have been applied to RIMS. Resonant optical processes have typically included one, two, or more laser energies delivered by one or more lasers. For analytical simplicity, one laser is desirable. Application of one laser wavelength (single-color RIMS), requires the absorption of two or more photons, of which at least one transition must be a bound-bound transition. All kinds of tunable lasers are commercially available and the wavelength ranges available to tunable lasers are very broad. Among them, dye lasers pumped by a Nd:YAG laser, excimer laser, flash-lamp laser, and semiconductor diode lasers are easy to operate. Continuous-wave or pulsed lasers are used alone or in a variety of combinations to produce ionization. An ideal arrangement that was found to be satisfactory is the use of relatively low-power continuous-wave lasers for the bound-bound steps and a high-power CO₂ laser as additional energy source or electric field for the ionization step. Another combination in RIMS is the use of semiconductor diode laser in combination with another high-power laser for excitation and ionization, respectively.

Optical resonance excitation from the atomic ground state up to final ionization can follow a number of different pathways (► Fig. 54.7). Typical ionization potential is ~ 6 eV for all the alkaline earths, rare earths, and actinides. Due to the high optical cross section ($\sigma = \lambda^2/2\pi$) of the order of $\sim 10^{-10}$ cm², all resonant optical excitation steps between bound atomic states (typical excited state lifetime of 10^{-8} s) can be saturated with continuous-wave as well as pulsed laser systems. Nonresonant ionization into the continuum has a relatively low cross section in the range of $\sim 10^{-17}$ – 10^{-20} cm² and is thus difficult to saturate with continuous-wave lasers. This blockage of the process can often be avoided for elements with more than one valence electron, by tuning the ionization laser to an auto-ionizing state, which decays rapidly within its lifetime of far less than 1 ns into an ion and a free electron. This is particularly effective for lanthanide and actinide elements, which have a high density of auto-ionizing states near the

■ Fig. 54.7

Resonance excitation methods followed in resonant laser ionization mass spectrometry(RIMS)

threshold. Otherwise, efficient excitation into high-lying Rydberg states and subsequent electric field- or infrared-ionization can be used to increase the ionization probability. Even with these additional processes, which increase the ionization probability by 2–3 orders of magnitude, the ionization step still requires the most intense laser light provided by a high-power laser system. As isotope shifts are usually not resolved with pulsed lasers, a compromise between isotopic selectivity (requiring narrow-bandwidth continuous-wave lasers) and efficiency (requiring high repetition rate pulsed lasers) must be done. High isotopic selectivity requires multistep excitation and experimental arrangements capable of avoiding or at least minimizing the Doppler-broadening of optical resonance, which usually overshadows the small effects of isotope shift and hyperfine structure, while isobaric selectivity is obtained in a single optical excitation (Ott et al. 2004; Wendt et al. 2000; Wendt and Trautmann 2005; Becker 2005).

Mass Analyzer/Detector

All kinds of mass analyzers, such as magnetic sector, quadrupole, and time-of-flight instruments, have been used in RIMS studies. Each of these mass analyzers carries its own advantages and disadvantages. The combination of a time-of-flight analyzer with a pulsed laser is an ideal system in terms of matching duty cycle to the characteristics of the mass analyzer. The pulsed laser is capable of generating a burst of ions in a short period suitable for time-of-flight separation. However, in terms of mass resolution, magnetic sector instruments are superior to time-of-flight analyzers. New improved quadrupole mass analyzers are also found efficient with regard to several important mass spectrometric parameters. Moreover, these analyzers are compact and less costly than sector instruments.

The decision of using continuous-wave or pulsed lasers for ion generation depends on the choice of mass analyzer that will be used in RIMS. This is because, compared to the pulsed lasers, the probability of ion generation is poor in continuous-wave lasers and an independent source of energy is required to improve the situation.

In case of pulsed lasers, the probability of ion generation approaches unity per pulse, but detector dead time can result in errors if too many ions arrive at the detector in a short time. However, pulsed-laser approach is ideal in detecting extremely small numbers of atoms.

54.3.2.3 Application of RIMS

A few reports are available till date on cosmochemical analysis using RIMS though the performance of each individual combination has been studied using several laser systems for the atomic excitation and mass analyzers for isotope selection. Commonly it is used in the analysis of environmental and biomedical samples. Wendt et al. (2000) demonstrated the measurement of $^{41}\text{Ca}/^{40}\text{Ca}$ ratio using the promising technique of coherent multistep RIMS, which achieved high isotopic selectivity with values of 10^{13} and higher. Improved method is needed for the cosmogenic analysis, which demands isotopic selectivity greater than 10^{14} . The measurement of $^{236-244}\text{Pu}$ was also reported by Wendt et al. (1999) in environmental samples with experimental detection limit as low as 10^6 per sample.

Lu and Wendt (2003) described the performance of laser-based ionization spectroscopy with quadrupole mass analyzer. The expected neighboring mass suppression factor could not be achieved in the experiment due to backgrounds arising from photo-induced Ca dimmers and Ca hydrides, surface ionized ^{41}K and highly excited neutral Ca that pass through the mass

spectrometer, scattered photons, and detector dark counts. These effects limit the isotopic selectivity of high-resolution RIMS at about 5×10^{12} for ^{41}Ca against ^{40}Ca , and limit the isobaric selectivity at 10^8 for ^{41}Ca against ^{41}K . Environmental, cosmochemical samples, where relative abundances of ^{41}Ca lies in the range of 3×10^{-10} – 3×10^{-11} , were analyzed with a precision of 5% and overall efficiency of 5×10^{-5} .

The expected source of ^{244}Pu is the interstellar medium (ISM) from fresh r-process nucleosynthesis or in direct ejecta from supernovae. Deposition onto Earth may result in traces of live ^{244}Pu in suitable reservoirs. Ofan et al. (2006) developed a method for ^{244}Pu detection based on RIMS. Gd was chosen as a proxy, because its chemical properties, excitation and ionization schemes, and wavelengths are similar to those of Pu. The Pu detection efficiency achieved for by RIMS was found to be smaller than that obtained by AMS (10^{-6} – 10^{-5}) by a factor of $\sim 1,000$. However, a value of the order of 0.5%, as obtained here for Gd, is believed to be feasible for Pu detection as well. This efficiency would allow the determination of the abundance of ^{244}Pu continuously accreted from the ISM or deposited in a single supernova event such as the one occurred 3 Ma before present, as evidenced by the ^{60}Fe anomaly reported in a deep-sea manganese crust.

54.3.2.4 RIMS and AMS

RIMS technique has been established as a well-suited method in determining certain trace and ultratrace isotopes. Isobaric suppression interferences and the ability to effectively combine optical isotopic and mass spectrometric selectivity are the major advantages of RIMS. Measurement of extremely rare isotopes is possible by enhancing the efficiency and hence increasing the effective dynamic range by the easy adjustment of laser intensities. However, the variety of problems tackled by the RIMS is not comparable with the vast application of AMS. Developments are in progress to achieve isotopic selectivity above 10^{13} , detection limits of isotopic ratios below 10^6 atoms, as it is the characteristics of AMS in commonly measured isotopes. Nevertheless, RIMS can be a good alternative technique for many ultratrace isotopes, where AMS encounters fundamental limitations, such as insufficient or no production of negative ions, strong isobaric interferences, or other sources of background. Hence, RIMS should be treated as complementary technique of AMS, rather than as competitive.

54.3.3 Thermal Ionization Mass Spectrometry (TIMS)

54.3.3.1 Principle and Components: A Quick Look

Thermal ionization mass spectrometry (TIMS) is an analytical technique for precise measurements of isotope ratios of elements that can be ionized thermally. TIMS is essentially a magnetic sector mass spectrometer that is used in geochemistry, geochronology, and cosmochemistry. Generally, ions are created on a thin metal ribbon by passing current through the metal ribbon in vacuum. Ions are accelerated across an electric potential gradient up to ~ 10 kV and focused into a beam passing through a series of slits and electrostatically charged plates. The focused ion beam is then allowed to traverse through a bending magnetic field in order to achieve dispersion of the original ion beam into separate beams based on their mass to charge (M/q) ratio. The mass-resolved ion beams are directed to the collectors, where the ion beam is

converted into voltage. Precise isotope ratios are obtained by comparing voltages corresponding to the individual ion beams.

TIMS consists of the following components:

1. Ion source and ion optics: the region where positive or negative ions are produced, accelerated, and focused into a single ion beam.
2. Mass analyzer: the equipment splits a single ion beam into separate ion beams according to the ion's mass/charge ratio.
3. Collector: it measures the ion beams either sequentially or simultaneously. TIMS is able to measure the isotopic ratios with a precision to 0.01–0.001%.

TIMS is able to ionize and evaporate samples at different temperatures by using multiple filament assemblies and allows complete transmission of ions from source to collector that yields highly precise measurement (e.g., Sr and Nd is measured with a precision better than 10^{-5} using sample sizes of a nanogram or less). Switching between positive and negative ion mode is easy; however, the technique is limited by its ionization efficiency for some elements and because rigorous sample preparation is needed to avoid isobaric interference.

54.3.3.2 Application of TIMS in Cosmochemical Analysis

The major application of TIMS is to the geochronology and tracer studies using terrestrial radiometric systems, for example, U–Th–Pb, Rb–Sr, Sm–Nd, and Lu–Hf. Geochronology exploits the radioactive decay in closed systems to obtain the date of a specific geological event. Tracer studies use the growth of daughter nuclides from radioactive decay to evaluate the interaction between geochemical systems and/or reservoirs. The application of TIMS in cosmochemical analysis is limited; however, it is used to measure the isotopic compositions as tracers of nucleosynthesis processes. This includes the measurement of radionuclides observed mainly in meteorites, for example, Mn–Cr, Al–Mg, Fe–Ni, and Ca–K system in addition to the above-mentioned systems.

A few reports are available where TIMS has been used for cosmochemical analysis. The recent report of Yamakawa et al. (2009) deals with sequential chemical separation technique for Cr, Fe, Ni, Zn, and Cu in terrestrial and extraterrestrial silicate rocks for precise and accurate determination of elemental concentration. The chemical technique uses a combination of cation–anion exchange chromatography and Eichrom nickel specific resin. The developed method was tested to a variety of matrixes; bulk meteorite (Allende), terrestrial peridotite (JP-1), and basalt (JB-1b). Concentrations of each element were determined by TIMS. The analytical procedure was further extended to obtain high-precision isotope data for Cr. The method is capable to determine the isotopic ratios of $^{53}\text{Cr}/^{52}\text{Cr}$ and $^{54}\text{Cr}/^{52}\text{Cr}$ with precision of 5×10^{-6} and 1×10^{-5} , respectively. The method can be equally applicable in cosmochemical studies, like Mn–Cr chronology and investigation of nucleosynthetic isotopic anomalies in meteorites. The elemental concentrations measured by TIMS in Allende are, for example, Cr: $3,600 \pm 0.007$ ppm, Fe: $233,400 \pm 0.009$ ppm, Ni: $14,020 \pm 0.006$ ppm, Cu: 107 ± 0.013 ppm, and Zn: 117.8 ± 0.01 ppm. The detection of ^{26}Al (0.7 Ma) in the Allende meteorite proves that nucleosynthesis is still active in the Milky Way as the half-life of ^{26}Al is much less than the timescale of galactic evolution (10^9 years).

Harvey and Baxter (2009) reported very high-precision (<10 ppm) isotopic measurement of Nd using TIMS. Nd isotopic measurements are important in view of geological,

cosmochemical, and environmental materials that yield only a few nanograms of Nd. Nd isotopes are commonly analyzed as oxide (NdO^+) involving an oxygen bleed valve and/or silica gel. The authors reported a method that uses a slurry containing tantalum oxide (Ta_2O_5) and phosphoric acid, which provides the oxygen source. The Ta_2O_5 loading method is of great use in refining Sm/Nd garnet geochronology, making possible the analysis of small garnet samples in which Nd concentrations are very low (<1 ppm). Garnet $^{143}\text{Nd}/^{144}\text{Nd}$ from several field areas was measured with Ta_2O_5 loading method resulting internal precisions of 8–42 ppm with garnet Nd load sizes ranging from 2.3 to 12 ng Nd. Garnet analysis yields age precisions of 0.4–4.6 Ma depending on the $^{147}\text{Sm}/^{144}\text{Nd}$ ratio. With the help of efficient chemistry and sufficiently low blanks, this method allows high-precision (13–21 ppm) analysis of potentially small sample (~ 4 ng) aliquots of Nd separated from natural samples.

Extensive report of Qin et al. (2010) deals with the measurement of Cr isotopic compositions of a broad range of meteorites using TIMS. They reported high-precision survey of the Cr isotopic compositions of primitive chondrites, along with some differentiated meteorites. Carbonaceous chondrites exhibit excesses in $^{54}\text{Cr}/^{52}\text{Cr}$ from $0.4\text{--}1.6 \times 10^{-4}$, and ordinary chondrites display a common $^{54}\text{Cr}/^{52}\text{Cr}$ deficit of $\sim 0.4 \times 10^{-4}$ when measured against the NIST Cr standard (SRM 3112a). This is because carbonaceous and ordinary chondrites share a common ^{54}Cr -enriched carrier, which is characterized by a large excess in $^{54}\text{Cr}/^{52}\text{Cr}$ (up to 200×10^{-4}) associated with a very small deficit in $^{53}\text{Cr}/^{52}\text{Cr}$ ($<2 \times 10^{-4}$). The eucrite and Martian meteorites studied exhibit small deficits in $^{54}\text{Cr}/^{52}\text{Cr}$. The $^{54}\text{Cr}/^{52}\text{Cr}$ variations among different meteorite classes suggest that there was a spatial and/or temporal heterogeneity in the distribution of a ^{54}Cr -rich component in the inner solar system.

They confirmed the excesses in $^{54}\text{Cr}/^{52}\text{Cr}$ and $^{53}\text{Cr}/^{52}\text{Cr}$ for bulk carbonaceous chondrites, which may affect the use of the Mn–Cr chronometer in carbonaceous chondrites, reported by Shukolyukov and Lugmair (2004, 2006). Bulk chondrites have small $\epsilon^{53}\text{Cr}$ (1 ϵ unit is 1 part in 10^4) excesses (up to 0.3) relative to the Earth, most likely reflecting the subchondritic Mn/Cr ratio of the Earth. The $\epsilon^{53}\text{Cr}$ variations in chondrites probably correlate with Mn/Cr and yield an initial solar system $^{53}\text{Mn}/^{55}\text{Mn}$ value of $5.4(\pm 2.4) \times 10^{-6}$, corresponding to an absolute age of $4,566.4(\pm 2.2)$ Ma. Interactions of cosmic rays result in excesses of $\epsilon^{54}\text{Cr}$ and $\epsilon^{53}\text{Cr}$ with $\sim 4:1$ ratio in phases with high Fe/Cr. These are most dramatically verified in the iron meteorite Carbo. Hence, the Mn–Cr chronometer should be used with caution in samples/minerals with high Fe/Cr and long cosmic-ray exposure ages.

54.3.4 Secondary Ion Mass Spectrometry (SIMS)

When the surface of a solid is bombarded by energetic *primary* particles, usually, electrons, ions, neutrals, or photons, and *secondary* particles are emitted. The *secondary* particles are mainly electrons, neutral species, atoms or molecules, atomic and cluster ions. The majority of *secondary* particles are neutral species. The secondary ion mass spectrometry (SIMS) is a kind of mass spectrometry, where only secondary ions are detected and analyzed by the mass spectrometer. The process yields a mass spectrum of a surface and thus the method enables a detailed chemical analysis of a surface or solid. SIMS is such a powerful technique of surface analysis and microstructural characterization of solids that a very low primary particle flux density of ~ 1 nA/cm² or even less can generate spectral data in a timescale, which is very short compared to the lifetime of the surface layer. SIMS is particularly well known for its outstanding sensitivity of chemical and isotopic detection. Quantitative or semiquantitative analysis can

be performed for small concentrations of most elements in the Periodic Table, including the lightest; however, deficiencies exist in the capability of SIMS for quantitative elemental analyses compared to other surface techniques (Auger, X-ray photoelectron spectroscopy, electron microprobe techniques, etc.). Use of high-resolution mass analyzers ($M/\Delta M > 3,000$) may reduce the commonly occurring isotopic and molecular interferences, like, hydrocarbons, oxides, and hydrides, in the mass analysis of secondary ions. A review of Betti (2005) describes SIMS technique in details.

54.3.4.1 Principle of SIMS

The SIMS technique follows three important steps:

1. Bombardment of the sample surface by focused primary ions, with sputtering of the outmost atomic layers;
2. Mass spectrometric separation of the ionized secondary species, which are sputtered atoms, molecules, clusters, according to their mass-to-charge ratios;
3. Collection of separated secondary ions as quantifiable mass spectra, as in-depth or along-surface profiles, or as distribution images of the sputtered surface.

The primary ions are produced in a number of ways, for example, by duoplasmatron gas source (O_2^+ , O^- , N_2^+ , Ar^+); surface ionization (Cs^+ and Rb^+); or by liquid-metal field ion emission (Ga^+ and In^+). The common primary ions used in SIMS are the oxygen ions, Cs^+ , and Ga^+ . Ions are accelerated and focused to a selected impact area on the specimen. The collision of a primary ion results in the implantation of the primary particle on the impact area, reshuffling of ~ 50 – 500 matrix atoms, and emission of neutral or ionized secondary particles. Secondary ions from the specimen are transmitted into the mass spectrometer to be separated according to their mass-to-charge ratio. The mass spectrometer can be either of the following designs: electrostatic/magnetic analyzer; quadrupole; and time-of-flight type. Secondary ions of specific mass-to-charge ratio and having kinetic energy within a certain interval are collected for pulse/current measurement, ion-optic imaging, and data processing.

Generally, SIMS instruments are operated in two modes: microscope mode and microprobe mode. A defocused primary ion beam (~ 5 – $300\ \mu m$) is used for investigating a large surface in the microscope mode. The secondary ions are then transmitted to the mass spectrometer and generally detected by imaging. In the microprobe mode, a focused primary ion beam ($< 10\ \mu m$) is used to investigate a small portion of the surface and detected usually in an electron multiplier.

54.3.4.2 NanoSIMS 50

The name, nanoSIMS 50, stands for a new-generation SIMS instrument. The unique feature of the instrument is that it combines high sensitivity with a high lateral resolution of $\sim 50\ nm$ when operated with the Cs^+ primary beam. This is achieved by using a specific design of ion optics where the primary and secondary ion optics are coaxial and the primary beam hits the sample surface at an angle of 90° . Compared to the old SIMS, the transmission of the new instrument for secondary ions is a factor of ~ 20 – 30 better in typical measurement conditions.

Apart from the design, the nanoSIMS has six detectors, out of which four are movable, for simultaneous ion collection, resulting in the increase in effective detection efficiency. These detectors can cover a wide mass range and therefore, elements with large difference in mass can be analyzed in a single run.

54.3.4.3 Application of nanoSIMS

Various potential applications of nanoSIMS in characterization of solids have already been recognized. Though the technique seems to be promising in cosmochemical analysis, its real application is still limited due to the strong isobaric interference. However, nanoSIMS is a more flexible alternative for elements that are ionized easily (Hoppe et al. 2004; Marhas et al. 2003) when compared with RIMS or TIMS. Hoppe et al. (2004) of MPI for Chemistry, Mainz, reported the measurement of extinct ^{26}Al , ^{53}Mn , and ^{60}Fe in meteoritic minerals formed early in solar system history. They also measured extinct ^{44}Ti and ^{49}V , and s-process Ba in pre-solar silicon carbide grains of supernova origin.

NanoSIMS measurements were carried out for $^{26}\text{Al}/^{27}\text{Al}$ ratio on plagioclase grains in two different ordinary chondrites (Zinner et al. 2002). Polished thin sections, in which the grains were located by automatic energy dispersive X-ray mapping, were analyzed. The size of the grains as found was large; therefore, high spatial resolution of the nanoSIMS proved effective in avoiding numerous tiny Mg-rich grains within the plagioclase during measurement. The $^{26}\text{Al}/^{27}\text{Al}$ ratio of 1.6×10^{-7} is inferred for the time when the feldspar in Forest Vale formed. An absolute age was calculated by comparing this value with the canonical value and found to be in agreement with Pb–Pb ages of phosphates in the same meteorite. Analysis concluded that ^{26}Al was indeed widely and uniformly distributed in the early solar system and can be used as a potential chronometer.

Primitive meteorites, in particular carbonaceous chondrites, show evidence for aqueous alteration. It is of great interest to ascertain when this aqueous activity occurred on the meteorite parent body. I–Xe analyses of halite in ordinary chondrites indicate that this formed very early in solar system history (Whitby et al. 2000); however, the time resolution of the I–Xe chronometer is limited because of its rather long half-life. The Mn/Cr ratios in the carbonate products of aqueous alteration are rather high and therefore, ^{53}Mn – ^{53}Cr can be a superior chronometer. The Mainz nanoSIMS was useful to exclude Cr-rich inclusions and to analyze spots with $^{55}\text{Mn}/^{52}\text{Cr}$ ratios up to $\sim 50,000$ because of the small beam diameter. The inferred $^{53}\text{Mn}/^{55}\text{Mn}$ ratios of $\sim 3 \times 10^{-6}$ found for five carbonate grains from Orgueil correspond to the absolute time of carbonate formation and aqueous activity on the meteorite parent body $\sim 4,563$ Ma.

^{60}Fe is a potential heat source for melting asteroidal bodies in the early solar system like, ^{26}Al . Because of long lifetime it is of special interest to know the early development of solar system bodies. The first demonstration of the existence of ^{60}Fe in the early solar system was obtained by Shukolyukov and Lugmair (1993) while studying the HED meteorites, which were planetary differentiation and therefore relatively young. The measured $^{60}\text{Fe}/^{56}\text{Fe}$ ratio was $\sim 4 \times 10^{-9}$ at the time of their formation. Using nanoSIMS, analyses were performed on one of the most primitive ordinary chondrites, Semarkona (Mostefaoui et al. 2003). The studied mineral was troilite, iron sulfide, which has a suitably high Fe/Ni ratio. The inferred initial $^{60}\text{Fe}/^{56}\text{Fe}$ ratio of $\sim 1 \times 10^{-6}$ is several times higher than the $1\text{--}2 \times 10^{-7}$ found by Tachibana and Huss (2003) in troilite from two other ordinary chondrites.

54.4 Conclusion and Future Scope

Cosmochemical analysis has become easier nowadays than it was in the past due to huge development of instrumentation and technology. Apart from the ultrasensitive AMS technique, several other techniques such as ICP-MS, RIMS, TIMS, nanoSIMS emerged as potential tools to measure cosmogenic radionuclides, though they still could not reach the sensitivity of AMS. However, they are found to be suitable in specific applications, especially when there is a significant amount of radionuclide present in the sample. In isotope analysis, RIMS can be viewed as an alternative of AMS rather than competitive for elements where AMS has limitations, for example, severe chemical treatment of sample, isobaric interference, and negative ion current. Precise and accurate multielemental analysis is possible by ICP-MS and it is the most used mass spectrometer at present. The sector field or collision cell-based ICP-MS can achieve the sensitivity of AMS for some elements. Revolution in technology has already simplified the AMS instrumentation; therefore, it is now a tabletop machine for regular analysis. However, the instrumental development of the technique is still a real challenge. A limited number of radionuclides are measured by AMS. A long list of radionuclides, which may have potential applications in various fields, is still untouched by any of these techniques including AMS. Half-life measurement of long-lived (\sim Ma) radionuclides is also a big challenge, as limited literature is available for them.

Cosmogenic radionuclides have enriched the idea about the surface stability and integral cosmic-ray exposure on the Moon. The exposure history and infall rate of meteorites have been learned from their radionuclide compositions. The measurement of radionuclides in ultra-small samples of Martian atmospheric CO₂, ice, and rock may also become important; hence, refinement of AMS equipment and sample chemistry should be developed in advance of sample-return missions, expected by 2015 (Jull and Burr 2006). *Sample-return missions* from other bodies, as well as Mars, are also expected. Measurement of cosmogenic radionuclides, especially ¹⁴C, in the Martian atmosphere and other reservoirs will be of particular interest because of the recent evidence of water on Mars in the past. Atmospheric samples from Mars, surface sediments, and carbonates, along with polar ice-cap material, would allow developing a good model of the carbon cycle and size of exchangeable reservoirs on Mars. AMS measurements of cosmogenic radionuclides in these materials would allow establishing a *Martian carbon cycle*. Jakosky et al. (1996) have discussed the expected sizes of various reservoirs and using this information, one can devise a prototype Mars carbon cycle. Studies of cosmogenic nuclides (whose production rate is much higher on Mars) may provide information on Martian geomorphology. The discussion on the possibility of measuring radiocarbon by Lorenz et al. (2002) in Titan sample may be helpful in this context.

Abstract: The environmental distribution of radionuclides, released from nuclear facilities and other sources, and the principles of the emergency countermeasures for radiation protection of the public and workers are discussed in this chapter. The concentration levels of radionuclides in various aquatic and terrestrial environments and the exposure levels of the population due to the various sources of radiation (natural and artificial radionuclides, cosmic radiation, diagnostic medical examinations, atmospheric nuclear tests, etc.) are presented.

55.1 Introduction

The main objective of the current system of radiation protection is to provide humans with adequate protection from the unacceptable effects of ionizing radiation; therefore, it requires the assessment of pathways leading to their exposure. A certain level of contamination in the environment will imply a certain dose in humans. Environmental radiation protection therefore deals with those pathways that originate from environmental media and edible biota in areas liable to contamination by artificial radionuclides (or enhanced levels of natural radioactive materials).

Since the dose to humans is strictly controlled and there are usually efforts to reduce it further, this practice also results in the control and reduction of contamination in the environment. The system for protecting humans is therefore still believed to implicitly protect other species in the environment as well. This safety measure was outlined in the Publication 60 of the International Commission on Radiological Protection (ICRP): “The Commission believes that the standards of environmental control needed to protect man to the degree currently thought desirable will ensure that other species are not put at risk. Occasionally, individual members of nonhuman species might be harmed, but not to the extent of endangering whole species or creating imbalance between species. At the present time, the Commission concerns itself with mankind’s environment only with regard to the transfer of radionuclides through the environment, since this directly affects the radiological protection of man.” (ICRP 1991)

Although most experts consider that the environment receives a sufficient level of protection against radiation from the nuclear industry, some also believe that the current approach should be reviewed. Although ICRP continues to believe that the standards of environmental control needed in order to protect the public would ensure that other species are not put at risk, ICRP has been revising their recommendations to explicitly cover protection of the environment from ionizing radiation (ICRP 2007). A set of Reference Animals and Plants has been elaborated representing a few types of organisms that are typical of the major environments. They will form the basis of a more structured approach to understanding the relationships between exposures and dose, dose and effects, and the potential consequences of these effects in the environment (ICRP 2008).

Because this is still an ongoing process, this chapter follows the traditional concept of environmental radiation protection; therefore, focus is given on the various sources, the transport of radionuclides in the environment, and the concentration levels of radionuclides in environmental media and edible biota. The exposure levels of the population due to the various sources of radiation (natural and artificial radionuclides, cosmic radiation, diagnostic medical examinations, atmospheric nuclear tests, etc.) are presented and the principles of the emergency countermeasures for radiation protection of the public and workers are briefly discussed based on ICRP Publication 60 and 63 (ICRP 1991, 1991a).

55.2 Monitoring Methods of Environmental Radioactivity

Environmental monitoring must be vigilant with sensitive measurement techniques and is needed for early warning of breaches of containment. Mathematical modeling of processes is used to support decisions related to a response in an emergency, facility design to comply with safety regulations, and selection of a suitable site for a facility. Accurate models are also used to help better understanding of the world and to increase scientific knowledge or processes.

The methods for the collection and pretreatment of environmental and dietary samples and materials are described in several papers (RSDJ 2002; L'Annunziata 2003). To keep reliable data that can be compared with other measurement methods, samples collected by a standardized sampling method and prepared with a standardized pretreatment are necessary. Measurement of the radioactivity of γ -ray emitters is carried out by high-resolution gamma spectrometry (HRGS), using usually a high-purity germanium (HPGe) detector with a lead shield. Spectra are analyzed automatically using a suitable γ -spectrum analysis program provided that counting efficiency (geometry), energy, and resolution calibration are carried out with Standard Reference Materials (SRM) following standard procedures. Radioactivity of β -ray emitters is measured using a low-background anticoincidence β counter.

Accelerator mass spectrometry (AMS) is useful to measure extremely low-abundance nuclides (isotope ratio of 10^{-12} to 10^{-16} relative to its stable isotope), such as ^{10}Be , ^{14}C , ^{26}Al , ^{36}Cl , ^{41}Ca , and ^{129}I , in natural samples. Small amounts of ^{14}C and ^{129}I can be measured by AMS on mg size samples of carbon and iodine extracted from 500-ml seawater samples (Povinec et al. 2000). Neutron activation analysis (NAA), radiochemical neutron activation analysis (RNAA), and inductively coupled plasma mass spectrometry (ICP-MS) are useful for the determination of ultra-trace Th and U in geological and cosmochemical samples, and for determination of the concentration of ^{239}Pu and ^{240}Pu .¹ Reference marine-biological samples are necessary to test the performance of the analytical methods employed in surveying and monitoring radioactive materials in the sea. An ocean shellfish composite material containing 0.1% w/w Irish Sea mussel, 12% w/w White Sea mussel, and 87.9% w/w Japan Sea oyster has been prepared as the NIST SRM 4358 (The National Institute of Standards and Technology, SRM) in the natural-matrix, environmental-level radioactive SRM series (Altitzoglou 2000). This NIST SRM 4358 sample will be useful for the determination of the activity of ^{40}K , ^{137}Cs , ^{210}Pb , ^{226}Ra , ^{228}Th , ^{238}U , and ^{241}Am .

55.3 Radionuclides in the Environment

Chemists are required to solve environmental problems: transport and biogeochemical cycling of stable and radioactive nuclides through the environment, and the effects of ionizing radiation on biota. The knowledge of the biogeochemical cycles is critical to future global development. It is difficult to make decisions concerning the allowable releases of specific radioactive materials without a good knowledge of the fate and transport of nuclides in the environment. The atmospheric nuclear weapon tests and the accident at Chernobyl in 1986 provided important knowledge concerning the transport of radionuclides and the complexity of radionuclide cycling in the environment.

Naturally occurring radionuclides are composed of three distinct chains of ^{238}U , ^{235}U , ^{232}Th , and their daughter nuclides, ^{226}Ra , ^{210}Po , ^{222}Rn , and long-lived radionuclides such as ^{40}K and ^{87}Rb , which were already present at the birth of the earth.² The relative abundance of

the isotopes present on the earth is derived from the isotopic ratios produced shortly after the universe was formed, although all the short-lived isotopes have disappeared by now.³ Furthermore, there are some induced radionuclides such as ^3H , ^7Be , ^{10}Be , ^{14}C , ^{22}Na , ^{32}P , ^{35}S , and ^{39}Cl , which are created by the interaction of cosmic rays with nuclei in the atmosphere. The natural rate of production of ^{14}C over the surface of the earth is estimated to be $1.6 \text{ atoms cm}^{-2} \text{ s}^{-1}$ and the equilibrium specific activity of ^{14}C in living biological substances is estimated to be $(0.28 \pm 0.10) \text{ Bq/g}$ of carbon.⁴

^3H and ^{14}C are very mobile and are readily incorporated into biological materials (Boyera et al. 2009). ^{129}I (16 million years of radiological half-life) is not very radiotoxic, but constitutes a special problem in the disposal of high- and low-level radioactive waste⁵ and is mobile.

The artificial nuclides ^{90}Sr , ^{85}Kr , ^{137}Cs , ^{239}Pu , etc., were released from nuclear facilities and explosions of atomic bombs in the past. The concentration of the radionuclides from nuclear tests in the ocean has decreased to fallout level by now except in special areas (Livingston and Povinec 2000). The most abundant nuclear fission product radionuclide present in the environment is ^{137}Cs , which was generated as a product of the nuclear weapons testing or from nuclear accidents (e.g., Chernobyl). The weapons tests released ^{137}Cs into the stratosphere, which was distributed globally, while the fallout of ^{137}Cs released into the troposphere by nuclear accidents had a more heterogeneous distribution, reflecting the atmospheric circulation and precipitation distribution immediately following the release. In recent decades, ^{137}Cs has been commonly used as a tracer of soil erosion and sedimentation, particularly in the Northern Hemisphere where atomic deposition was three times as great as in the Southern Hemisphere (Mabit et al. 2008). Its mean specific activities in Japan are reported to be $(13 \pm 12) \text{ Bq/kg}$ for soil, $(2.0 \pm 2.1) \text{ Bq/kg}$ for grass, 0.06 Bq/kg for hinoki, and 5.6 Bq/kg for broadleaf trees in 2001.

55.3.1 Aquatic Environment (Oceans, Rivers, Lakes)

55.3.1.1 Oceans

Near-surface water of the oceans, from 100 m to 300 m in depth, undergoes rapid mixing as a result of wind action. The intermediate zone of the ocean may be as much as 1,000 m in depth, being known as the thermocline or pycnocline. The characteristic speed of movement of the ocean surface layer is as much as 14–150 km/day dependent on the current. The movement and characteristic of the oceans have become well known by the development of recent technology such as the Advanced Earth Observing Satellite. Transport, potential vorticity, and related dynamical properties of the Florida Current have been studied by three-dimensional analysis (Wang and Mooers 1997; Stewart et al. 1957). The coupling between the wind stress and the ocean surface currents has also been modeled on the global scale (Deng et al. 2009). Since the first nuclear weapons tests in the 1940s, pulsed inputs of plutonium isotopes have served as excellent tracers for understanding sources, pathways, dynamics, and the fate of pollutants and particles in the marine environment (Lindahl et al. 2009). Activity concentrations of some radionuclides in the oceans are summarized in [Table 55.1](#).

Body burdens of $^{239+240}\text{Pu}$ (i.e., ^{239}Pu and ^{240}Pu together) in zooplankton and juvenile squid collected in the Sea of Japan and in the Northwest Pacific for the period of 1993–1996 have been reported. The specific activity concentration of $^{239+240}\text{Pu}$ in mixed populations of zooplankton living in seawater varies from $(0.08 \pm 0.01) \text{ Bq/kg}$ to $(0.39 \pm 0.08) \text{ Bq/kg}$

■ Table 55.1

Activity concentration of some radionuclides in Ocean (Bq/m³)

	²²⁶ Ra	¹³⁷ Cs	⁹⁰ Sr	⁹⁹ Tc	Reference
Indian and Atlantic Ocean	2.96				
Pacific Ocean		5.55			
Mediterranean Sea		0–36			Sanchez-Cabeza et al. (2002)
Southeastern part of the Baltic Sea			60–92	15–64	Styro et al. (2001)
Spanish Mediterranean coast			4.8		Molero et al. (1999)
Western Irish Sea				21–45	Smith et al. (2001)
South coast of Norway				0–0.44	Smith et al. (2001)
Brazilian coast			1.4	1.8	Cunha et al. (1999)

(dry mass). That in the southwestern part of the East Sea (Sea of Japan) varies from (0.07 ± 0.02) Bq/kg dry wt. to (0.11 ± 0.01) Bq/kg dry wt., being lower than that in the northwestern part of the East Sea. The ²³⁹⁺²⁴⁰Pu specific activity varies from (0.08 ± 0.06) Bq/kg dry wt. to (0.26 ± 0.05) Bq/kg dry wt. for the Sea of Okhotsk and varies from (0.05 ± 0.01) Bq/kg dry wt. to (0.29 ± 0.03) Bq/kg dry wt. in the subarctic region of the Northwest Pacific off the Kamchatka Peninsula. In the Northwestern Pacific, off the central Honshu Island, the ²³⁹⁺²⁴⁰Pu concentration varies from (0.03 ± 0.01) Bq/kg dry wt. to (0.17 ± 0.04) Bq/kg dry wt. ²³⁹⁺²⁴⁰Pu concentration of the samples from the Bransfield Strait of the Antarctic Ocean is very low and constitutes levels due only to atmospheric bomb fallout. In the Northwest Pacific, ²³⁹⁺²⁴⁰Pu specific activity in zooplankton increase at the higher latitudes, and smaller-sized copepods contain the highest body burdens of ²³⁹⁺²⁴⁰Pu. The concentration factor (R_c) of ²³⁹⁺²⁴⁰Pu for zooplankton living in the East China Sea was 2.7×10^3 and that in the Bransfield Strait was 1.4×10^3 (Hong et al. 2002).⁶ The concentration of ¹³⁷Cs for walleye pollock (*Theragra chalcogramma*) was similar to those reported in other studies. The concentration factors of ¹³⁷Cs for fresh squid in the East Sea varies from 1 to 60 and that for fresh walleye pollock was estimated to be 11, 18, and 14 in the East Sea, the Pacific coast off Hokkaido, and the Sea of Okhotsk, these values being within the range of values reported by IAEA (1985).

Seawater samples and sea grass *Posidonia oceanica* were collected along the Spanish Mediterranean coast. The mean activity concentrations for ¹³⁷Cs and ¹³⁴Cs in surface waters collected from the Spanish Mediterranean shoreline were (4.8 ± 0.2) Bq/m³ and (0.27 ± 0.01) Bq/m³ (1987–1991), respectively. Because of its short radioactive decay period, ¹³⁴Cs has not been detectable in the Western Mediterranean waters. From 1987 to 1991, the enhancement of radiocesium levels in the Spanish Mediterranean marine environment was observed after the Chernobyl accident. The ¹³⁴Cs/¹³⁷Cs isotopic ratio in Chernobyl fresh deposition was used to identify the weapon-test fallout and Chernobyl deposition components. The mean isotopic ratio ¹³⁴Cs/¹³⁷Cs is 0.057 ± 0.003 . The mean ¹³⁴Cs/¹³⁷Cs isotopic ratio of *Posidonia oceanica* is 0.20 ± 0.04 . This value is twice that of the ¹³⁴Cs/¹³⁷Cs ratio (0.11 ± 0.01) observed for water samples from the vicinity of Vandellos NPP. The activity concentration of ¹³⁷Cs input into Mediterranean waters as a consequence of the post-Chernobyl deposition is estimated to be (1.16 ± 0.04) Bq/m³, which brought about an increase of $(33 \pm 3)\%$ over the previous levels. Activation and fission products ¹⁰⁶Ru, ^{110m}Ag, ¹³⁴Cs, ¹³⁷Cs, and ¹⁴⁴Ce are detected in all samples of *Posidonia oceanica*. Mean radiocesium levels in the bioindicator were (1.02 ± 0.25) Bq/kg

for ^{137}Cs and $(0.20 \pm 0.03) \text{ Bq/kg}$ for ^{134}Cs , corresponding to a mean isotopic ratio $^{134}\text{Cs}/^{137}\text{Cs} = 0.20 \pm 0.04$ (1987). ^{137}Cs specific activity incorporated by *Posidonia oceanica* after the Chernobyl deposition over the Mediterranean Sea is estimated to be $(0.51 \pm 0.08) \text{ Bq/kg}$ (Molero et al. 1999).

Radioactivities for ^{134}Cs , ^{137}Cs , ^{238}Pu , and $^{239+240}\text{Pu}$ of tissues from seals and porpoises in the marine environment around the UK were measured (Watson et al. 1999). Multifactor analysis of variance indicate that for radiocesium there was no significant difference for harbor seals, gray seals, or porpoises in terms of species or gender; however, activity concentration of the tissue increased with body mass, and decreased with distance from Sellafield. The marine mammals concentrate radiocesium by a factor of 300 relative to the concentration in seawater. The highest activity, 0.037 Bq/kg ($^{239}\text{Pu} + ^{240}\text{Pu}$), was detected in a gray seal stranded at Rathlin Island in Northern Ireland.

There was information that high-level radioactive wastes had been dumped in the shallow waters of the Kara Sea in 1993 and several assessment and research programs were started. The $^{238}\text{Pu}/^{239+240}\text{Pu}$ activity ratio ranged from 0.3 to 0.7, and is over one order of magnitude higher than the global fallout ratio, confirming that the contamination is derived from the waste (Osvath et al. 1999). The maximum activity concentration levels measured in water were 1 kBq/m^3 for ^3H , 2.5 Bq/m^3 for ^{90}Sr , 7 Bq/m^3 for ^{137}Cs , and 5 mBq/m^3 for $^{239+240}\text{Pu}$ in 1994. The latest estimate of the International Atomic Energy Agency (IAEA) indicates that no radiologically significant contamination has occurred outside of the dumping sites in the Novaya Zemlya bays in the Kara Sea. High levels of radioactivity in sediment are observed only in Abrosimov and Stepovoy Bays, very close to the dumped containers. Radionuclide inventories in water and sediment of the open Kara Sea and Novaya Zemlya bays, as well as soil from the shore of Abrosimov Bay are mainly due to global fallout, with smaller contributions from the Sellafield reprocessing plant, the Chernobyl accident run-off from the Ob and Yenisey rivers, and local fallout. From the result of computer modeling, maximum annual doses of approximately 1 mSv are expected for a hypothetical critical group subsisting on fish caught in the Novaya Zemlya bays whereas populations living on the mainland are expected to receive doses at least three orders of magnitude lower than the worldwide average.

$^{129}\text{I}/^{127}\text{I}$ ratios in marine systems were about 10^{-12} before the nuclear era, reflecting natural sources of the long-lived radionuclide ^{129}I from cosmic ray spallation of atmospheric xenon and natural uranium fission.⁷ However, the contribution of ^{129}I to the North Atlantic Ocean from nuclear fuel reprocessing facilities reaches detectable levels. Pacific Ocean burdens of ^{129}I are relatively low in the Pacific-influenced Arctic, particularly compared to high-latitude waters influenced by the North Atlantic. The concentration of ^{129}I for near-surface seawater ranges from $12 \times 10^6 \text{ atoms/kg}$ to $31 \times 10^6 \text{ atoms/kg}$. ^{129}I concentrations in the Bering Strait in 1993 show concentrations of 62×10^6 – $82 \times 10^6 \text{ atoms/kg}$ and that in the Long Strait between the East Siberian and Chukchi Seas is 44×10^6 – $76 \times 10^6 \text{ atoms/kg}$ (Cooper et al. 2001).

Samples collected in the eastern subtropical North Atlantic in 1969 were used in order to measure the impact of weapons-fallout ^{129}I in the oceans (Edmonds et al. 1998). The measured $^{129}\text{I}/^{127}\text{I}$ ratio of the sample was $(0.53 \pm 0.08) \times 10^{-10}$, being ten times higher compared with the pre-anthropogenic ratio of about 10^{-12} . The ratio of ^{129}I to ^{137}Cs was 2.0 ± 0.6 (atom ratio), 1.6 ± 0.6 when corrected for the 7-year radioactive decay from the bomb-input peak.

The ratios $^{129}\text{I}/^{127}\text{I}$, $^{129}\text{I}/^{137}\text{Cs}$, and $^{129}\text{I}/^{99}\text{Tc}$ in seaweeds sampled at two locations along the Norwegian Coastal current from 1990 to 1998 were measured to estimate “transit time” in the thermohaline circulation of the Arctic and North Atlantic oceans (Yiou et al. 2002). ^{129}I , ^{99}Tc , and ^{137}Cs are discharged from nuclear fuel reprocessing facilities into the Irish Sea and the

English Channel. Most of these discharges are transported into the Arctic Ocean by the Norwegian Coastal Current. The ratios $^{129}\text{I}/^{127}\text{I}$, $^{129}\text{I}/^{137}\text{Cs}$, and $^{129}\text{I}/^{99}\text{Tc}$, which vary up to two orders of magnitude over this period, are potentially very interesting for determining “transit times” in the Arctic and North Atlantic oceans.

Surface and bottom seawater samples from three locations in the Kattegat and Baltic Sea were analyzed for ^{129}I and ^{127}I in both iodide and iodate species, and total inorganic iodine by neutron activation analysis using nuclear reactions of $^{129}\text{I}(\text{n},\gamma)^{130}\text{I}$ and $^{127}\text{I}(\text{n},\gamma)^{128}\text{I}$ (Hou et al. 2001). Levels of 2.3×10^{-15} mol/l for ^{129}I and 7×10^{-9} mol/l for ^{127}I are obtained. Therefore, these isotopes of iodine are promising tracers of physical and biochemical process in the ocean, and research about the chemical speciation of ^{129}I and ^{127}I in ocean will be developed.⁸

55.3.1.2 Sediments

The specific activities of radionuclides contained in sediments collected in uncontaminated areas are listed in [Table 55.2](#).

Continental margins are important areas to study concerning the distribution and deposition of pollutants, because coastal sediments accumulate most of those contaminants. The main source of radioactive pollutants is fallout from stratospheric nuclear testing performed from the late 1950s until the early 1960s. Northeastern Spain has also been affected by the 1986 Chernobyl accident, as the $^{134}\text{Cs}/^{137}\text{Cs}$ ratio calculated for seawater samples has proven. However, no sign of ^{134}Cs has been detected in sediments collected in the area. In the Mediterranean Sea, the mean residence times in shallow waters are estimated as 11 years for plutonium and 5.5 years for americium. The $^{239+240}\text{Pu}$ inventory ranges from 9 Bq/m² to 120 Bq/m², ^{241}Am varies from 15 Bq/m² to 44 Bq/m², and cesium accumulation varies from 161 Bq/m² to 727 Bq/m² (Gasco’ et al. 2002).

The marine surface sediments collected in Ghazaouet, a small bay on the western coast of Algeria, contain measurable amounts of radioactivity: from 0.02 Bq/kg ash to 0.05 Bq/kg ash for ^{238}Pu , from 0.3 Bq/kg ash to 0.6 Bq/kg ash for $^{239+240}\text{Pu}$, from 6.9 Bq/kg ash to 8.5 Bq/kg ash for ^{137}Cs , and from 1.4 Bq/kg ash to 7.4 Bq/kg ash for ^{90}Sr (Nouredine and Baggoura 1997).

Table 55.2

The concentration of radionuclides contained in sediments that are collected in uncontaminated areas (Bq/kg)

Radionuclide	Red sea	Ghazaouet	Brazilian coast
^{238}U	29.6 ± 16.3		
^{226}Ra	11.6 ± 15.2	31–133	
^{210}Po	33 ± 29.1		
^{230}Th	6.6 ± 4.6		
^{212}Pb		6–32	
^{228}Th	48.4 ± 20.9		
^{137}Cs	0–10	0.7–9	
^{40}K	158.4 ± 161.9	184–632	0.4–1.8
Reference	Sam et al. (1998)	Nouredine et al. (1998)	Cunha et al. (1999)

Concentration ratios $^{238}\text{Pu}/^{239+240}\text{Pu}$ and $^{137}\text{Cs}/^{239+240}\text{Pu}$ obtained for these samples confirm that these artificial radioactivities are mainly due to nuclear-testing fallout. The radioactivities of ^{238}U , ^{232}Th daughters, ^{40}K , and ^{137}Cs are detected in different types of sediments; fine or muddy sand and mud, and decrease from very fine grain to larger pore-size particles as shown in [Table 55.3](#).

^{210}Po and ^{210}Pb cycling in a hydrothermal vent zone in the coastal Aegean Sea was studied. ^{210}Pb levels in sinking particles from the control site tend to be higher than those measured in the vent zone, as demonstrated by the lower $^{210}\text{Po}/^{210}\text{Pb}$ ratios (3.3–8.5) observed on particles in the control site. These ^{210}Pb levels (0.01–0.23 Bq/g) are comparable with data reported for the northwestern Mediterranean Sea. The hydrothermal emissions in the shallow Aegean Sea off Milos Island do not have any major effect on the biogeochemical cycling of the natural radionuclides ^{210}Po and ^{210}Pb in the water column (Boisson et al. 2001).

The concentration of ^{239}Pu , ^{240}Pu , ^{241}Pu , ^{242}Pu , and ^{237}Np isolated from oceanic estuarine and riverine sediments in the Arctic Ocean Basin indicates that the Pu in these sediments, as well as that in the deep basins (Amerasian and Eurasian) of the Arctic Ocean, has its origin in stratospheric and tropospheric fallout (Cooper et al. 2000).

Activity levels of uranium isotopes, thorium isotopes, ^{226}Ra , ^{210}Po , ^{40}K , and ^{137}Cs were determined in marine surface sediments, sea grass, and algae collected from the Sudanese coastal waters of the Red Sea, 30-km offshore. The anthropogenic and terrestrial influx from the hinterland is negligible. However, values for ^{226}Ra and ^{210}Po are higher in the sediments of Port Sudan harbor relative to those from the adjacent fringing reefs. The $^{228}\text{Th}/^{232}\text{Th}$ ratio in sediments is in disequilibrium, indicating a rapid rate of sedimentation at the sampling sites. The activity levels of ^{137}Cs in sediments collected in the Port Sudan harbor area are fairly high as compared with values in other sampling locations. Specific activity for ^{137}Cs in algae (*Sargassum*) is high, 0.33–1.32 Bq/kg (Sam et al. 1998).

Host phases of fallout $^{239,240}\text{Pu}$ and ^{241}Pu were studied in the surface sediments obtained in 1994 from abyssal basins of the western North Pacific (Haque and Nakanishi 1999). An analytical procedure involving sequential chemical extraction was employed for partitioning the host phases of the nuclides in the sediment into five fractions: (1) exchangeable, (2) bound to carbonate, (3) bound to hydrous Fe–Mn oxides, (4) bound to organic matter, and (5) residual. Decrease of total $^{239,240}\text{Pu}$ concentration with decreasing association of $^{239,240}\text{Pu}$ with organic matter, high $^{241}\text{Am}/^{239,240}\text{Pu}$ activity ratio in the carbonate phase, and somewhat high proportion of oxidized $^{239,240}\text{Pu}$ in the reachable phases suggest the possibility of post-depositional diagenetic remobilization of Pu from the sediment to the water column.

55.3.1.3 Fish

Anthropogenic radioactivity was measured in Cienfuegos Bay in the vicinity of the first Cuban nuclear power station while under construction. In this area, the main contribution to the radiation dose received by marine fauna comes from naturally occurring uranium-series radionuclides accumulated in the body. ^{210}Po belongs to the natural uranium series, being constantly supplied to the marine environment. ^{137}Cs was released mainly during atmospheric nuclear weapon tests in the late 1950s and early 1960s, from nuclear-fuel reprocessing plants and the Chernobyl accident in 1986. The highest value and mean value of ^{210}Po in dissected edible parts of fish, mollusks, and crustaceans are on the order of 25 Bq/kg wet wt. and 19.5 Bq/kg wet wt., respectively. The polonium concentrations found in mollusks are

Table 55.3
Specific activities in Bq/kg dry weight for different classes of sediment (Noureddine et al. 1998)

Sediment	Grain-size/ μm	^{226}Ra	^{214}Pb	^{214}Bi	^{228}Ac	^{212}Pb	^{40}K	^{137}Cs
Sand	800 to 200	32.4 ± 10.5	4.8 ± 0.8	4.8 ± 0.9	5.2 ± 1.1	6.6 ± 0.9	57.4 ± 8.6	0.7 ± 0.2
	200 to 100	23.7 ± 7.7	6.0 ± 0.9	6.4 ± 1.3	6.2 ± 1.3	6.3 ± 0.9	65.6 ± 8.3	0.6 ± 0.2
	<100	59.3 ± 14.6	12.5 ± 2.0	12.4 ± 2.1	14.8 ± 2.9	21.4 ± 2.9	290 ± 41	8.1 ± 1.4
Fine mud, sand	800 to 200	20.7 ± 8.9	4.2 ± 0.8	3.1 ± 0.7	4.1 ± 1.1	5.6 ± 0.8	67.1 ± 10.3	0.5 ± 0.2
	200 to 100	29.3 ± 8.7	6.4 ± 1.0	6.2 ± 1.0	6.3 ± 1.3	8.2 ± 1.1	91.5 ± 13.5	0.5 ± 0.1
	<100	70.9 ± 8.5	23.4 ± 1.7	22.6 ± 1.7	31.9 ± 2.4	32.5 ± 2.0	608 ± 31	11.4 ± 0.8
Mud	800 to 200	42.2 ± 9.8	7.7 ± 1.2	7.6 ± 1.3	5.9 ± 1.2	7.1 ± 0.9	81.6 ± 12.1	1.1 ± 0.2
	200 to 100	39.9 ± 6.9	14.3 ± 1.2	14.5 ± 1.1	13.2 ± 1.5	17.8 ± 1.4	234 ± 13	3.0 ± 0.4
	<100	60.1 ± 8.1	21.6 ± 1.6	17.9 ± 1.4	29.5 ± 2.7	28.3 ± 1.9	364 ± 20	6.3 ± 0.5

comparable to the available data on bivalves inhabiting different marine systems, but the mean concentration of ^{210}Po in fish is high in comparison to those reported by the United Nations Science Committee on the Effects of Atomic Radiation (UNSCEAR 1996). ^{137}Cs levels are in the range from 0.1 Bq/kg wet wt. to 0.9 Bq/kg wet wt., and are in good agreement with ^{137}Cs concentrations of marine species originating only from global fallout. The mean ^{137}Cs activity concentration in edible parts of the analyzed organisms is two orders of magnitude lower than those observed for ^{210}Po (Alonso-Hernandez et al. 2002).

The concentrations of ^{40}K , ^{232}Th , ^{238}U , ^{137}Cs , and ^{134}Cs in different marine fish samples caught in the Bay of Bengal in Bangladesh were determined (Alam et al. 1995). The specific activities for ^{137}Cs ranged from 0.06 Bq/kg (Foli Chanda) to 1.98 Bq/kg (Hail Chanda), being below the detection limit for many of the fish samples. ^{134}Cs was below the detection level for all samples. ^{238}U specific activities ranged from 0.11 Bq/kg (whole Chaka Chingri) to 1.94 Bq/kg (head of Hail Chanda) and ^{232}Th ranged from 0.24 Bq/kg (Rup Chanda) to 0.28 Bq/kg (Bom Maittya).

The concentration of natural and artificial radionuclides in two types of fresh water fish and four types of marine fish consumed by the Hong Kong population were measured (Yu et al. 1997). The two types of fresh water fish are gray mullet (*Mugil cephalus*) and grass carp (*Ctenopharyngodon idellus*), and the four types of marine fish are white pomfret (*Pampus argenteus*), red bullseye (*Priacanthus macracanthus*), golden thread (*Nemipterus*), and naked-headed sea bream or ginkgo (*Gymnocranius griseus*). The concentrations of U and Th chain radionuclides in the samples have values below the minimum detectable activities (MDA) except for positive detection of ^{228}Ra (assuming ^{228}Ra to be in equilibrium with ^{228}Ac) in gray mullet and red bullseye. ^{40}K of 0.01–0.2 Bq/kg and ^{137}Cs of 41.23–111.47 Bq/kg were detected in the samples. Authors say that the different levels of radioactivity in different species of fish are due to differences in metabolism and feeding patterns.

$^{108\text{m}}\text{Ag}$ is detected in oysters (*Crassostrea gigas*) on the Japanese coast and its specific activity decreased from the initial value of about 30 mBq/kg fresh weight (fw) in the early 1980s to the value of about 10 mBq/kg fresh in the early 1990s (Ishikawa et al. 1995).

55.3.1.4 River

The natural radionuclides ^{234}Th and ^7Be are good tracers for the transport and sources of particles in the suspended sediment reservoir. In the Hudson River estuary, ^{234}Th is produced from the decay of dissolved ^{238}U , which varies linearly with salinity, while ^7Be is added directly to the estuary from the atmosphere (Feng et al. 1999). Samples in the Hudson under conditions of low and high river flow show that $^{234}\text{Th}/^7\text{Be}$ activity ratio in suspended sediment increases from low salinity to higher salinity waters. The distribution of heavy metals in the suspended sediment reservoir can be compared with that of $^{234}\text{Th}/^7\text{Be}$ activity ratio by normalizing the metals to Fe, and therefore iron and aluminum in suspended sediments of the Hudson can be used to normalize grain-size effects on specific concentrations of metals.

Concentrations of ^{238}Pu , $^{239,240}\text{Pu}$, ^{137}Cs , and excess ^{210}Pb in biological samples (five isopods, ten bivalves, two amphipods, two mussels, one fish fat, six fish liver, and two worm tubes) from the Ob and Yenisey Rivers and Kara Sea, and sediment samples from the Pechora Sea of the Russian Arctic were measured (Baskaran et al. 2000). In surface sediment samples (upper 3 cm) of the Pechora Sea, the $^{239,240}\text{Pu}$ specific activities ranged from 38 mBq/kg to 877 mBq/kg (mean = 193 mBq/kg). ^{238}Pu concentrations were below the detection limit.

The $^{238}\text{Pu}/^{239,240}\text{Pu}$ activity ratios in the sediment samples of the Pechora Sea vary between 0.015 and 0.056, which shows that there is no detectable input either from the European nuclear effluents or from the dumped nuclear reactors in the Kara and Barents Sea. The specific activities for ^{137}Cs (27 surface sediments of the Pechora Sea) vary between below detection limits and 10.4 Bq/kg (mean = 3.13 Bq/kg). The mean values of ^{137}Cs and $^{239,240}\text{Pu}$ are lower than those for the sediments from the Ob and Yenisey Rivers and Kara Sea.

On the other hand, sediments from the Ob and Yenisey Rivers show the presence of weapons-grade Pu originating from nuclear fuel reprocessing. The data are distinctly different from those of northern-hemisphere stratospheric fallout (see references in Haque and Nakanishi 1999).

Artificial radionuclides in bottom sediments of the Don River Estuary-Azov Sea (Black Sea) were measured to examine the storage and migration of radionuclides within this inland sea and to estimate the annual dose received by individuals in the local population who regularly consume fish (Matishov et al. 2002). The specific activity of surface sediments was 0.5–100 Bq/kg dry wt. [mean = (33.8 ± 25.9) Bq/kg dry wt., the number of samples = 57] for ^{137}Cs , 0.2–5.7 Bq/kg dry wt. [mean = (2.1 ± 1.4) Bq/kg dry wt., the number of samples = 34] for ^{90}Sr and 0.31–0.51 Bq/kg dry wt. (the number of samples = 2) for $^{239,240}\text{Pu}$ in 1997–1999. ^{137}Cs specific activities increase with distance from the mouth of the Don River and correlate negatively with the sediment grain size (square of the correlation coefficient, $r^2 = 0.77$, the number of data points, $n = 21$). The annual ^{137}Cs -derived dose received by an individual through the tropic chain: water–fish–humans (approximately 10^{-6} Sv/a) is well below regulatory recommended limits.

Uranium, plutonium, and americium in fish, mussels, and sediments from the Peconic River system on Long Island, NY were analyzed (Rapiejko et al. 2001). Sediments were cored in four sections to 0.37-m depth, whole fish were analyzed, and mussels were separated into flesh and shells. Radioisotopes of the cited elements were detected in sediments, some of the fish contained ^{137}Cs , ^{241}Am , and uranium, and mussel flesh contained ^{137}Cs and uranium. All of the ^{60}Co , ^{233}U , and enriched uranium, and some of the ^{137}Cs and ^{241}Am , can most likely be attributed to Brookhaven National Laboratory. The other radionuclides (and some of the ^{137}Cs and ^{241}Am) are believed to have either fallout or nature as their origin. The New York State Department of Health (NYSDOH) determined that the added radiation doses, which result from eating such fish are a small fraction of the radiation dose that normally results from radionuclides present in the body.

Aquatic biota in the Rhone River downstream of the Marcoule nuclear complex in France are exposed to natural sources of radiation and to radioactivity released from the Marcoule complex (St-Pierre et al. 1999). Radioactivity of five categories of aquatic organisms, i.e., submerged aquatic plants (phanerogam), non-bottom-feeding fish, bottom-feeding fish, mollusca, and fish-eating birds were studied. The dose rates range over three orders of magnitude, with maximum dose rates of 1–10 $\mu\text{Gy/h}$. These maximum dose rates are a factor of 40 or more below the international guideline intended to ensure the protection of aquatic populations (about 400 $\mu\text{Gy/h}$).

55.3.1.5 Lakes

The distribution of ^{90}Sr and ^{137}Cs in lake ecosystems in the southern Urals, which were affected by the 1957 radiation accident, was studied (Kryshev 1997; Kryshev et al. 1997; Aarkrog et al. 1997). The levels of ^{90}Sr in the most highly contaminated lakes in 1992 were as follow: 17–120 Bq/l in water, 70–110 kBq/kg in fish, and 2.9–5.2 kBq/kg in aquatic plants. At the

present time, the levels of ^{90}Sr have decreased to 0.05–0.5 Bq/l in water and 4–550 Bq/kg in fish. The levels of ^{137}Cs in these lakes have decreased to 0.03–0.06 Bq/l in water and 2–33 Bq/kg in fish. In the first few years following the accident, a dose rate level of 10^{-2} Gy/day to mollusks, bottom-dwelling fish, and aquatic plants exceeded that in the most highly contaminated lakes of Uruskul' and Berdyandish. In 1992, the background exposure level for fish in these lakes is still exceeded by a factor of 1,000. Doses to the population from lake fish consumption do not exceed 10^{-3} Sv/year.

Geochemical coexistence of ^{137}Cs and $^{239,240}\text{Pu}$ in the surface sediments from two oligotrophic and mesotrophic lakes in Japan was studied by sequential chemical extractions (Nagao et al. 1999). The fractions separated were exchangeable and bound to carbonate, bound to oxides, bound to organic matter-sulfides, and residual. The ^{137}Cs and $^{239,240}\text{Pu}$ were mainly associated with the organic matter-sulfides and residual fractions, but exhibited different vertical profiles in both lakes.

55.3.2 Terrestrial Environment

The following three sources of radionuclides in the environment need to be considered.

1. Fallout from the atmospheric bomb tests from the 1950s to the 1960s.
2. Routine emissions to the atmosphere from reprocessing plants and nuclear power stations.
3. Accidents at nuclear facilities, the most prominent being Chernobyl.

The effects of atmospheric bomb tests and the Chernobyl accident are no longer considered to be of radiological importance. The reprocessing plants and nuclear power stations during routine operation release radionuclides in airborne and liquid effluents, the level of which is usually higher for the reprocessing plants than of the power reactors. Radionuclides released from the Calder Hall reactor in 1997 are listed as examples: ^{41}Ar (2.6×10^3 TBq/a), ^{14}C (3.2×10^{-1} TBq/a), ^{60}Co (6.0×10^{-2} TBq/a), ^3H (4.4×10^0 TBq/a), and ^{35}S (8.9×10^1 TBq/a). The total critical group annual effective dose was estimated to be $4.56 \times 10^1 \mu\text{Sv}$. Even this dose is negligible compared to the annual dose received from the natural background (~ 2.4 mSv/a), routine releases from reprocessing and reactor sites require continued monitoring for radiation protection control purposes.

Noble gases are released to the atmosphere, however they are not considered to be biological material. If one considers the radionuclides released from reprocessing plants, ^3H , ^{14}C , ^{35}S , ^{85}Sr , ^{90}Sr , ^{129}I , ^{131}I , ^{134}Cs , ^{137}Cs , and actinides are of potential interest. Fruit Working Group (FWG) in the UK suggests that ^{36}Cl and ^{45}Ca should be added to a group of monitored nuclides in the future because both nuclides are very mobile (Ould-dada et al. 2001).

A little information is available on the chemical forms of radionuclides in routine emissions from nuclear facilities and on chemical speciation in the atmosphere. The chemical identity of radionuclides affecting their mobilities and biological effects in environmental media must be made clear.

55.3.2.1 Atmosphere

Tritium may be released to the atmosphere as HTO, HT, and CH_3T . These species are transferred to other chemical species through many complex processes in atmosphere.

For example, HT released from a plant is rapidly oxidized to HTO. Tritium water may be incorporated in organic matter as organically bound tritium (OBT) within tissues. The specific radioactivity of tritium in the form of CH_3T in the atmosphere is very high, but the reason is not understood. ^{14}C may be released to the atmosphere as CO , CO_2 , CH_4 , HCHO , and COS . $^{14}\text{CO}_2$ released becomes incorporated into crops via photosynthesis leading to enhanced levels of ^{14}C in crops.

The background level of tritium in Cernavoda in Romania, before the nuclear power plant was operational, was measured in 1996. The mean values determined are (7.4 ± 5.5) Bq/l in humid air, (3.1 ± 1.0) Bq/l in water, (3.5 ± 0.7) Bq/l in tissue water from vegetables, and (4.9 ± 1.7) Bq/l in tissue water from cereals. The transfer parameters for deposition from the atmosphere to forage and crops, and for the contamination of land and vegetation by spray-irrigation water found to be $29\text{--}49$ and (0.90 ± 0.27) , respectively (Paunescu et al. 1999). A background level of tritium was measured for rain collected at Fukuoka in Japan between 1984 and 1995 (Hayashi et al. 1999) and Kumamoto, Japan during 2003–2005 (Momoshima et al. 2007) with average results of 0.85 Bq/l and 0.69 Bq/l, respectively. On the other hand, an average tritium activity concentration of atmospheric water vapor is (1.88 ± 0.26) Bq/l, showing a higher level than that of the rain. Surface seawater and water vapor about 10 m above the sea level were collected in the Pacific and Indian Oceans during the expedition of KH-96-5 to examine tritium concentrations in the open sea. The tritium concentration in the water vapor was one order of magnitude higher than that in the surface seawater, attributed to a downward movement of naturally occurring tritium from the stratosphere to the troposphere (Kakiuchi et al. 1999).

^7Be produced by cosmic-ray-induced nuclear reactions is useful for studying atmospheric transport mechanisms. Since the production of ^7Be and other cosmogenic nuclides is directly dependent on the cosmic-ray intensity, a relationship between the production rate of these nuclides and the 11-year solar cycle has been found (Kulan et al. 2006). It is known that the galactic cosmic-ray intensity at the earth's orbit is inversely related to solar activity (Hotzl et al. 1991).

Average ^{35}S levels were $110 \text{ mBq m}^{-2} \text{ d}^{-1}$ for atmospheric deposition, 0.078 mBq/m^3 for aerosol in surface air, and 45 mBq/l for rainwater at Fukuoka in Japan. The $^7\text{Be}/^{35}\text{S}$ ratios are abnormally low, although most of $^{32}\text{P}/^7\text{Be}$ ratios show reasonable values corresponding to residence times of 10–60 days. The excess ^{35}S suggests an external source of ^{35}S (Osaki et al. 1999).

Historical data on radioactivity in air and precipitation samples have been collected and analyzed at study sites in Norway to investigate the correlation between air concentration, precipitation and deposition, and to identify areas with high deposition rates. The base line data are obtained from the measurements of total β -ray activities in air and precipitation on a daily basis for the period 1956–1982. Radioactive fallout correlates strongly with annual precipitation, which varies from 280 mm per year to 4,200 mm per year in Norway. The deposition of ^{137}Cs was calculated to be $(3.23 \pm 1.20) \text{ kBq/m}^2$ per 1,000 mm precipitation for the period 1955–1975. The age of fallout in Norway ranges from 3 months to 9 months during the test periods, which is considerably shorter than the global average, where the mean residence time for debris in the lower stratosphere is estimated to be 1.3 years. There is no evidence of local fallout reaching Norwegian areas from tests on Novaya Zemlya (Bergan 2002).

Atmospheric radioactivity is monitored globally for the verification of the Comprehensive Nuclear-Test-Ban Treaty (CTBT), with xenon isotopes $^{131\text{m}}\text{Xe}$, ^{133}Xe , $^{133\text{m}}\text{Xe}$, and ^{135}Xe serving as important indicators of nuclear explosions. The interpretation of atmospheric concentrations of radioxenon has been enhanced by quantifying radioxenon emissions released from

civilian facilities, which resulted in the first global radioxenon emission inventory for nuclear power plants, based on North American and European emission reports for the years 1995–2005 (Kalinowski and Tuma 2009). Based on new, more sensitive technologies with higher time resolution, recent studies have shown that regions with nuclear facilities have a background of few mBq/m^3 of ^{133}Xe with short spikes up to few hundred mBq/m^3 . These spikes could not in general be explained by normal nuclear power plant operations. Based on several years of measurements, combined with advanced atmospheric transport model results, it was shown that the main source of radioxenon observations are strong and regular batch releases from a very limited number of radiopharmaceutical facilities in the northern and southern hemisphere. These releases can be up to several orders of magnitude above those attributed to nuclear power plants (Saey 2009).

It is customary to concentrate the major gaseous fission products (krypton, xenon, and iodine) by cryogenic adsorption. Schell et al. (1997) made the initial efforts to develop an automated portable system for online separation and concentration, with the potential for measuring environmental levels of radioactive gases, including ^{85}Kr , $^{131,133,135}\text{Xe}$, ^{14}C , ^3H , ^{35}S , and $^{125,131}\text{I}$, without using cryogenic fluids. There is now the ability to measure amounts of fission-produced xenon isotopes that decay by internal conversion electrons and beta radiation with short half-lives, namely ^{131}Xe ($T_{1/2} = 11.8$ days), ^{133}Xe ($T_{1/2} = 2.2$ days), and ^{135}Xe ($T_{1/2} = 9.1$ h).

According to the model proposed by Stewart et al., air enters the stratosphere in the tropical regions where it is heated and rises to an altitude of about 30 km, at which level it begins to move toward the poles. The mean residence time of stratospheric debris depends on altitude, time of year, and latitude. Debris injected into the lower polar stratosphere in Russia has been found to have a mean residence time of less than 6 months, whereas in tropical latitudes residence time has been found to be 2–3 years for the middle stratosphere and 5–10 years for debris injected at 100-km altitude.

55.3.2.2 Soil

The cumulative deposition of anthropogenic radionuclides shows a typical latitudinal distribution, with high levels in the mid-latitude regions of the Northern Hemisphere, reflecting the stratosphere–troposphere exchange of air masses in the mid-latitude region (UNSCEAR 2000a).

Analysis of the 50-year records of the atmospheric deposition of long-lived radionuclides (^{137}Cs , ^{90}Sr , and Pu isotopes) has been carried out in Japan (Hirose et al. 2008). The maximum annual deposition occurred in 1963 after the large-scale atmospheric nuclear weapons testing of 1961–1962. In the 1980s, the fallout from the Chinese nuclear weapons tests was observed and the released radionuclides from the Chernobyl accident affected radioactive deposition in Japan until the early 1990s. The recent deposition samples in Japan showed varying behavior although they all primarily originate from the resuspension of radionuclide-bearing particles deposited on land surfaces. These radionuclides may be useful tracers of environmental changes, such as desertification and erosion, in terrestrial regions. The mean annual deposition of ^{90}Sr and ^{137}Cs is estimated to be $150 \text{ mBq m}^{-2} \text{ a}^{-1}$ and $300 \text{ mBq m}^{-2} \text{ a}^{-1}$ in Japan and are almost the same as observed in England (Igarashi et al. 1999).

The cumulative depositions of ^{137}Cs , ^{90}Sr , and fallout Pu in the volcanic ash soil of Korea were determined. From depth profiles, it was found that ^{137}Cs , ^{90}Sr , and $^{239,240}\text{Pu}$ in the

volcanic soil are more mobile than those in other forest sites of Korea and the downward movement of ^{90}Sr is faster than that of ^{137}Cs and $^{239,240}\text{Pu}$. The activity ratios of $^{238}\text{Pu}/^{239,240}\text{Pu}$ and $^{241}\text{Pu}/^{239,240}\text{Pu}$ in the soils are close to those observed in the cumulative deposit from the global fallout of nuclear weapon testing (Lee and Lee 1999).

Soils in Japan have been monitored by the National Institute of Radiological Science. The average level of ^{90}Sr in rain and dry fallout was 0.01866 MBq/km^2 and that of ^{137}Cs was 0.00895 MBq/km^2 in 1999. The average activity of ^{90}Sr of soils is 0.26 Bq/km^2 and that of ^{137}Cs is 0.8275 Bq/km^2 (RSDJ 2002). The $^{240}\text{Pu}/^{239}\text{Pu}$ atom ratios observed in Japanese soil samples are estimated to be around 0.17 (in the range of 0.15–0.19) (Muramatsu et al. 2001).

The activity concentration of ^{238}Pu , $^{239/240}\text{Pu}$, and ^{241}Pu was also measured recently in Hungary (Varga et al., 2008). The $^{239/240}\text{Pu}$ concentration is in the range of $0.01\text{--}0.84 \text{ Bq/kg}$ dry soil with the average of 0.10 Bq/kg . ^{238}Pu could be detected only in few moss samples and the $^{238}\text{Pu}/^{239/240}\text{Pu}$ ratio is close to the value of the global fallout. The activity concentration of ^{241}Pu was between 0.04 Bq/kg and 3.74 Bq/kg with the average of 0.82 Bq/kg , while in the moss is also similar $0.01\text{--}2.07 \text{ Bq/kg}$ fresh mass with the average of 0.43 Bq/kg . The isotope ratios $^{241}\text{Pu}/^{239/240}\text{Pu}$ prove that the origin of the plutonium in Hungary is the global fallout determined by the atmospheric nuclear weapon tests.

Transport, speciation, and sources of plutonium in the Ob and Yenisey river systems (Siberia, Russia) and the adjacent Kara Sea was studied showing a clear difference in speciation between high $^{240}\text{Pu}/^{239}\text{Pu}$ atom ratio Pu derived from global weapon fallout and low $^{240}\text{Pu}/^{239}\text{Pu}$ atom ratio Pu, presumably originating from weapons grade Pu (Lind et al., 2006). In particular, the $^{240}\text{Pu}/^{239}\text{Pu}$ atom ratios (mean 0.18 ± 0.06) for particles ($>0.45 \mu\text{m}$) could not be distinguished from global fallout Pu ($0.17\text{--}0.19$), whereas for low molecular mass (LMM; $<8 \text{ kDa}$) species the Pu ratio was much lower than for global fallout Pu in both rivers.

55.3.2.3 Vegetation

Activity concentrations of ^7Be , ^{210}Pb , and ^{210}Po in precipitation (rain, throughfall, and stemflow), wood, and soil were determined to estimate the migration behavior of these radionuclides in the forest canopy (Sugihara et al. 1999). Output/input ratios of precipitation for the forest canopy were 0.53 for ^7Be , 0.79 for ^{210}Pb , and 1.5 for ^{210}Po in *Pasania edulis* forest. Mean residence times of the radionuclides were estimated to be 56 days for ^7Be , 765 days for ^{210}Pb , and 653 days for ^{210}Po for *Pasania edulis* forest.

55.3.2.4 Foodstuffs and Algae

Studies of the transfer, uptake, and retention of radionuclides in foodstuffs have been mainly concerned with ^{137}Cs , ^{90}Sr , ^3H , ^{14}C , and ^{35}S because these nuclides have relatively long half-lives and represent biologically important elements.

The concentration and temporal variation of ^{55}Fe in seaweed, shellfish, crab, and lobster collected in Weymouth Bay, adjacent coastal areas, and southern England were measured (WAWICK et al. 2001). Significant quantities of ^{55}Fe have been released into the environment following the atmospheric testing of nuclear weapons as well as through authorized discharges of radioactivity from nuclear power and reprocessing sites. These areas have received authorized discharges of radionuclides originating from the operation of a now-decommissioned

steam-generating, heavy-water-type reactor at AEE Winfrith. The highest activities of ^{55}Fe are found in marine sediments collected near the discharge pipeline and a rapid decline occurs away from the pipeline. This is consistent with rapid sorption of ^{55}Fe by the sediment.

Potted plants were exposed to D_2O vapor in a greenhouse and the uptake of D_2O by leaf and deposition of D_2O in pot soil were examined (Momoshima et al. 1999). Although the variation of D_2O concentration in leaves followed that in air, showing a time delay, D_2O concentration in leaves did not reach the same level as that in air, and veins showed a lower concentration than lamina. The D_2O concentration in the pot soil increased slowly with diffusion to deeper layers.

Edible seaweed products have become popular in the food industry, especially in Japan. Elements of 15 seaweed samples collected on the coasts of British Columbia (Canada), Japan, and Norway were analyzed, and the radioactivity were measured. The iodine content of algae was found to vary widely, with the highest concentrations in wakame from Japan. The analysis shows little activity above background; only traces of ^{137}Cs were found in a product from Norway, and traces of ^{226}Ra were found in a product from Japan. Arsenic levels are found to be elevated (van Netten et al., 2000).

Collective and individual dose rates to humans were estimated from the consumption of seafood harvested in the Arctic Seas. The actual collective dose rates to the world population are estimated to be 2.7–4.5 man-Sv/a due to the consumption of seafood from the Barents Sea, and 0.03 man-Sv/a due to seafood from the Kara Sea. The contribution of ^{137}Cs to the collective dose rate is estimated to be about 90% (Sazykina and Kryshev 1997).

Radioactivity levels of natural ^{210}Po and anthropogenic ^{137}Cs in seawater and biota (fish and shellfish) were estimated for the FAO fishing areas. Collective doses resulting from seafood consumption are calculated for each FAO area using radioactivity data for water and biota. Good agreement is observed between the results calculated by these two methods, with the exception of the doses from ^{210}Po via shellfish consumption. The effective dose due to the anthropogenic ^{137}Cs (mainly originating from nuclear weapons tests) in marine food in 1990 is estimated to be two orders of magnitude less than the corresponding dose from ^{210}Po , the latter being the dominant contribution to the doses due to fish and shellfish and the contribution from ^{137}Cs is negligible (Aarkrog et al. 1996).

The radioactivity of ^{226}Ra in fish, pork, rice, flour, chicken, vegetable, milk, fruit, egg, and water samples in Taiwan was measured. The ^{226}Ra activity concentration of groundwater is 12.0 mBq/l and ^{226}Ra specific activities of the food range from 0.02 Bq/kg fresh to 0.17 Bq/kg fresh. The annual internal dose due to ingestion of ^{226}Ra in food and drinking water per capita is evaluated to be 7.5 μSv (Kuo et al. 1997).

A region between Chelyabinsk and Ekaterinburg in the Southern Urals has been heavily contaminated due to operational and accidental releases from the first Soviet plutonium production facility, Mayak, during the late 1940s and 1950s. Environmental samples were collected in areas affected by the explosion of a fission product storage tank in 1957. Soil, sediments, water, milk, and food samples were analyzed for ^{90}Sr , ^{137}Cs , and plutonium. The highest contamination of an area accessible to the local population is found in the vicinity of the Tcha river around Muslumovo. Specific activity of food samples in 1992–1993 reached 37,000 Bq/kg for ^{137}Cs , 5,600 Bq/kg for ^{90}Sr , and 9.9 Bq/kg for Pu. ^{90}Sr and ^{137}Cs specific activities in vegetables in Muslyumove are listed in [Table 55.4](#). Milk and potatoes in Muslumovo show low levels in the range from 0.7 Bq/kg to 25 Bq/kg for ^{90}Sr , respectively (Winkelmann et al. 1998).

■ **Table 55.4**

⁹⁰Sr and ¹³⁷Cs specific activities in vegetables in Muslyumove

Products	n	⁹⁰ Sr/Bq kg ⁻¹		¹³⁷ Cs/Bq kg ⁻¹	
		Mean ± SD	Range	Mean ± SD	Range
Potatoes	15	0.63 ± 0.59	0.1–2.4	0.57 ± 0.59	0.05–2.8
Beetroot	4	1.50 ± 0.52	0.96–1.92	0.42 ± 0.51	0.07–1.19
Carrots	4	3.2 ± 2.9	1.4–7.1	2.7 ± 2.3	0.6–3.0
Cucumbers	4	0.67 ± 0.29	0.34–0.91	0.74 ± 0.76	0.11–1.59
Tomatoes	1	0.58		1.1	
Peppers	1	1.20		13.0	
Dill	9	29 ± 14	11.3–40.9	4.6 ± 2.0	1.6–6.8
Spring onions	8	49.0 ± 30.2	0.21–92.7	8.4 ± 8.7	0.13–27.4
Onions	1	4.70		0.80	
Garlic	2	4.4 ± 1.8	3.2–5.7	0.85 ± 1.10	0.10–1.65
Currants	3	2.0 ± 0.6	1.39–2.54	1.7 ± 1.0	0.93–2.8

The current radioactive contamination of soil, vegetation, and foodstuffs in the two remaining villages closest to the Mayak site, Muslyumovo, and Brodokalmak were examined. The highest contamination levels in soil are 5.5 MBq/m² for ¹³⁷Cs and 1.0 MBq/m² for ⁹⁰Sr and are found in the floodplain. Radionuclide contamination in the soil of the villages is much lower, but exceeded the level expected from global fallout.

Significantly, higher ¹³⁷Cs activities are found in milk sampled from cows housed in winter period in Muslyumovo compared with the grazing summer period. The highest measured activities in food products for ¹³⁷Cs and ⁹⁰Sr are found in river fish, waterfowl, poultry, and milk. The activity concentrations of ¹³⁷Cs and ⁹⁰Sr in some animal products are higher than that expected for soil and vegetation from fields and pasture in the villages (not including the floodplain). The ¹³⁷Cs specific activity of milk ranges 0.1–174 Bq/kg during May–October and 0.03–200 Bq/kg during November–April in Muslyumove, and 0.1–38 Bq/kg during May–October and 0.01–66 Bq/kg during November–April in Brodokalmak. The ⁹⁰Sr level of milk ranges 0.1–37 Bq/kg during May–October and 0.1–34 Bq/kg fresh weight (fw) during November–April in Muslyumove, and 0.1–5.6 Bq/kg during May–October and 0.1–4.7 Bq/kg during November–April in Brodokalmak (Shutov et al. 2002).

The average specific activity of ⁹⁰Sr (69 samples) of milk produced in Japan is 0.287 Bq/kg fw and that of ¹³⁷Cs of milk is 0.0225 Bq/kg fw. The specific activities related to homologous chemical elements common in milk are as follows. ⁹⁰Sr: 0.02519 Bq per 1 g of Ca, ¹³⁷Cs: 0.01364 Bq per 1 g of K. The specific activities in vegetables are 0.145 Bq/kg fw and 0.00498 Bq/g Ca for ⁹⁰Sr, and 0.0865 Bq/kg fw and 0.03798 Bq/g K for ¹³⁷Cs. The activities in tea (19 samples) are 0.5968 Bq/kg fw and 0.2744 Bq/g Ca for ⁹⁰Sr, and 0.4895 Bq/kg fw and 0.02679 Bq/g K for ¹³⁷Cs. The activities in tea are higher than in other vegetables. The specific activities in fish (12 samples) are 0.00428 Bq/kg fw and 0.00318 Bq/g Ca for ⁹⁰Sr, and 0.1123 Bq/kg fw, and 0.0316 Bq/g K for ¹³⁷Cs. The specific activities in shellfish (six samples) are 0.0041 Bq/kg fw and 0.00505 Bq/g Ca for ⁹⁰Sr, and 0.0222 Bq/kg fw and 0.00937 Bq/g K for ¹³⁷Cs. The specific activities in seaweeds (five samples) are 0.226 Bq/kg fw and 0.0224 Bq/g Ca for ⁹⁰Sr,

and 0.0236 Bq/kg fw and 0.00366 Bq/g K for ^{137}Cs . It should be noted that the activity of ^{137}Cs is higher in fish than in shellfish or seaweed and it is well known that the concentration factor R_c of fish for ^{137}Cs is high (RSDJ 2002).

55.4 Environmental Transport of Radioactive Effluents; Routine and Accidental Releases

The prediction of fluid motions in the atmosphere, ocean, ground water, and surface water is often not accurate enough, showing that these processes are still not completely understood. Beside the knowledge of the physical half-lives of the radionuclides and the basic *physical transport processes*, it is important to understand the general circulation modes of the atmosphere to improve the accuracy of estimations of the transport of all nuclides. In order to understand the chemistry and transport of atmospheric pollutants, it is indispensable that the applied models include coupling between different components of the global environment, such as atmosphere, hydrosphere, cryosphere, and the soil system. One possible solution is the application of *box modeling*, where for instance the dispersion of radionuclides in marine systems relates to instantaneous mixing in each box. A new approach to box modeling, which includes dispersion of radionuclides as a function of time, has been developed by Iosjpe et al. (2002) in order to provide a better and more realistic approximation.

The process of assessing risk to the environment following a given release of radioactivity requires the quantification of activity concentrations in environmental media and in the food chain. In some cases, the radiological impact, i.e., the level and significance of the radiation exposure, can be estimated from measurements of radioactivity concentration in the environment. In many cases however, suitable measured values will not exist, and in these cases models are needed to provide estimates of the values. Some of these models attempt to relate a measured or estimated discharge of a radionuclide from a particular source to the resulting activity concentration of the radionuclide in air at the point of interest and its level of deposition to the ground. These models, known as atmospheric dispersion models, are mathematical representations of the transport and dilution of material in the atmosphere and they are reviewed in detail elsewhere (Mavall 2003).

Similarly, the methodologies implemented in state-of-the-art models for predicting the physical processes of radionuclide migration through the aquatic environment are not discussed here. A review of the methodologies, including transport due to water currents, diffusion, settling, and resuspension has recently been published by Monte et al., where the models are briefly described, model parameter values reviewed, and values recommended (Montea et al. 2009).

The dose to man from radionuclides released to the environment is also assessed with mathematical models that require transfer factors as input parameters to predict the concentration of radionuclides in foodstuffs. For the assessment and management of environmental risks from ionizing contaminants an integrated approach has been developed (ERICA Integrated Approach), which involves the application of concentration ratios and distribution coefficients for aquatic systems (Larsson 2008). Hosseini provides the description of the methodologies applied to derive default transfer parameters, collated within the ERICATool databases (Hosseini et al. 2008).

Because naturally occurring and artificially produced radionuclides in the environment may be present in different physicochemical forms (i.e., radionuclide species) varying in size

(nominal molecular mass), charge properties and valence, oxidation state, structure and morphology, density, and degree of complexation, the understanding of the transfer process becomes more complicated. To assess the environmental impact from radionuclide contamination, information on radionuclide species deposited, interactions within affected ecosystems, and the time-dependent distribution of radionuclide species influencing mobility and biological uptake is essential (Salbu 2009).

55.4.1 Radionuclides Released to Aquatic Systems

The water around Greenland has received radioactive contamination from three major sources: global fallout, discharges from the nuclear fuel reprocessing plant at Sellafield in the UK, and the Chernobyl accident in the former Soviet Union. The *global fallout* peaked in the early 1960s. The radiologically most important radionuclides of this source are ⁹⁰Sr and ¹³⁷Cs. The waterborne discharges from Sellafield, which were at a peak between 1974 and 1981, consist mainly of ¹³⁷Cs. The Chernobyl accident in 1986 was characterized by its substantial atmospheric release of ¹³⁴Cs and ¹³⁷Cs. Other sources may be La Hague, France, and radioactive discharge to the great Siberian rivers (Ob, Yenisey, and Lena) from nuclear activities, local fallout from the Novaya Zemlya nuclear weapons test site, or dumping of nuclear waste in the Kara and Barents Seas. The time integral activity concentrations of seawater were estimated to be (164 ± 18) Bq/m³ for ⁹⁰Sr and (239 ± 32) Bq/m³ for ¹³⁷Cs from 1962 to 1980 and (64 ± 7) Bq/m³ for ⁹⁰Sr and (117 ± 64) Bq/m³ for ¹³⁷Cs from 1980 to 1997. The transport of ⁹⁰Sr and ¹³⁷Cs by the East Greenland Current from the Arctic to the Atlantic Ocean has been calculated to be (24 ± 3) PBq/a and (40 ± 9) PBq/a, respectively (Aarkrog et al. 1999). Concentration factors – R_c as defined by ▶ Eq. (55.3) – for Greenland marine shrimp, fish, and mammals are collected in ▶ Table 55.5.

The civilian nuclear icebreaker facility, RTP “ATOMFLOT,” is located in Kola Bay, Northwest Russia, where several nuclear installations are operated by the Russian Northern Fleet. The Atomflot facility discharges purified nuclear waste into the bay at an annual rate of 500 m³. The mean ¹³⁷Cs activity concentration of seawater at the mouth of the Kola Bay was (8.0 ± 0.8) Bq/m³ at 1994, showing no indication of contamination. In 1986, ¹³⁷Cs levels in seaweed were increased by the Chernobyl release, but in the 1990s, ¹³⁷Cs levels decreased to less than 2 Bq/kg from 8 Bq/kg earlier in the 1980s. However, one exceptional seaweed sample, which shows ¹³⁷Cs level of (46 ± 5) Bq/kg wet wt. and additional radioactivities of ¹³⁴Cs, ¹⁰³Ru, Co, and Eu, is found in the Atomflot area (Matishov et al. 2000).

The quantity of ¹²⁹I in the pre-nuclear age ocean is estimated to be about 10 kg and the quantity increased by one order of magnitude due to various nuclear fuel reprocessing plants.

■ Table 55.5

Concentration factors for Greenland marine shrimps, fish, and mammals (Aarkrog et al. 1999)

Species	⁹⁰ Sr	¹³⁷ Cs
Shrimps	6 ± 3	25 ± 10
Fish	4.6 ± 1.3	78 ± 23
Seal and whales	2.2 ± 0.5	108 ± 23

The two largest commercial reprocessing facilities are at Sellafield (UK) and La Hague (France). A pathway and transit time of tracers in the North Atlantic and Arctic ocean were examined. Atmospheric testing of nuclear weapons is estimated to have produced ~ 50 kg (325 GBq) of ^{129}I , mainly in the early 1960s. Assuming all of this ^{129}I has been deposited and mixed in an ocean surface layer of 100 m depth, it would be expected to raise the $^{129}\text{I}/^{127}\text{I}$ atomic ratio in this layer to $\sim 2 \times 10^{-11}$ (Yiou et al. 2002). At these facilities, special steps have been taken to trap most ($>90\%$) of the iodine, and iodine is discharged to the NE Irish Sea and the English Channel through the steps, respectively, as part of their authorized liquid discharges. The current discharge rates are thus ~ 330 kg/year, with approximately 75% coming from La Hague. The integrated discharge from La Hague is estimated to be $\sim 2,360$ kg (Raisbeck and Yiou 1999).

Iodine and ^{129}I concentrations as well as $^{129}\text{I}/\text{I}$ ratios were measured in lakes and rivers in order to report the global distribution of anthropogenic ^{129}I (Snyder and Fehn 2004). The highest values in ratios and ^{129}I concentrations were found in the mid-latitudes of the Northern Hemisphere, but levels above pre-anthropogenic were found in all samples, including those from the high Arctic and from Antarctica. Low values are observed in equatorial regions, but another maximum is present in the mid-latitudes of the Southern Hemisphere, although it is smaller than that in the Northern Hemisphere. The distribution demonstrates on a global scale the rapid atmospheric transport of ^{129}I from its sources, reprocessing plants located in the Northern Hemisphere. The minimum in ^{129}I concentrations observed at low latitudes probably indicates that the overall remobilization of iodine is a function of regional soil ecosystems.

The International Atomic Energy Agency (IAEA) carried out an international project: "The Study of the Radiological Situation at the Atolls of Mururoa and Fangataufa." Marine radioactivity of present radionuclide concentrations in water, sediment, and biota of the Mururoa and Fangataufa lagoons, and the surrounding ocean were studied. The dominant radionuclide in both lagoons is Pu in sediments (the total inventory is approximately 30 TBq). A decline in radionuclide concentrations has been observed in recent years in lagoon water, with the exception of ^3H and ^{90}Sr . With respect to ^3H and ^{90}Sr , a contribution from underground sources is expected. Radionuclide concentrations in biota from the lagoons and the surrounding ocean are low and consistent with previous measurements. The observed radionuclide concentrations in both lagoons show that no radiological risk exists for hypothetical inhabitants of Mururoa and Fangataufa Atolls (Povinec et al. 1999).

During 1971–1977, the highest specific activities of ^{241}Am and $^{239,240}\text{Pu}$ in Bikini were 2.85 Bq/g and 4.44 Bq/g, respectively, in surface sediments in the northwest part of the lagoon, respectively. Concentrations of soluble and particulate Pu and Am in surface and deep water samples show distributions similar to the sediment samples. Continuous circulation of water in the lagoon and exchange of water with the open ocean results in removal of 111 GBq/a for ^{241}Am and 222 GBq/a for $^{239,240}\text{Pu}$ into the North Equatorial Current (Donaldson et al. 1997).

The behavior and distribution of actinide radionuclides in the estuarine and marine sediments of the NE Irish Sea are significantly influenced by the releases of nonradioactive industrial wastes. There are many industrial activities in the Cumbrian coastal region: hematite mining, diversion-ferric metal extraction industries, coal mining, and a large number of blast furnaces for the manufacture of iron. Large quantities of liquid and solid waste were discharged into the eastern Irish Sea from the Albright & Wilson phosphoric acid production plant between 1954 and 1992, and are a local source of natural series radionuclides entering the eastern Irish Sea. The phosphate ore mix used at the plant before June 1992 contains activity of $(1,377 \pm 34)$ Bq/kg of ^{238}U , (56 ± 4) Bq/kg of ^{235}U , and (13 ± 2) Bq/kg of ^{232}Th .

The radionuclides ^{230}Th and ^{226}Ra are almost in equilibrium $[(1,508 \pm 57) \text{ Bq/kg}$ and $(1,477 \pm 36) \text{ Bq/kg}$, respectively]. ^{210}Pb and ^{210}Po have lower specific activity than ^{226}Ra , but are in equilibrium with each other $[(837 \pm 55) \text{ Bq/kg}$ and $(835 \pm 29) \text{ Bq/kg}$, respectively] (Poole et al. 1995; Hamilton 1999).

The radioactivity in tobacco leaves collected from 15 different regions of Greece was studied. The activities of radium, ^{226}Ra and ^{228}Ra , in the tobacco leaves reflect their origin from the soil by root uptake rather than from fertilizers used in the tobacco cultivation. ^{210}Pb originates from the air and is deposited onto the tobacco leaves and trapped by the trichomes. ^{40}K in the tobacco leaves is due to root uptake either from soil or from fertilizer. ^{137}Cs and ^{134}Cs in the tobacco leaves is due to root uptake and not due to deposition onto the leaf foliage as these isotopes of Cs still remained in the soil 4 years after the Chernobyl reactor accident but were absent from the atmosphere in *rain washout* (precipitation) and *gravitational settling* (Papastefanou 2001).

Results pertaining to ^{226}Ra in thermal and mineral water springs, mostly spas and health resorts, in the Republic of Croatia have been presented. The ^{226}Ra activity concentration of thermal and mineral waters range from 0.07 Bq/l to 4.40 Bq/l. In the spas, water is used both for bathing and for drinking purposes. ^{226}Ra activity concentrations in some springs have been found to exceed the maximal permissible level of 1 Bq/l for drinking water (Marovi et al. 1996). Activity concentrations of naturally occurring alpha-emitter radionuclides, ^{226}Ra , ^{224}Ra , ^{234}U , ^{238}U , and ^{210}Po were determined in 30 frequently visited and regularly consumed spring waters in the Balaton Upland region of Hungary. The average concentration (mBq L^{-1}) was in the range of 2–600, 1–66, 4–742, 0.4–275 and 2–15, respectively. The doses due to the consumption of spring water are in the range $3.5\text{--}167 \mu\text{Sv a}^{-1}$ with an average of $18.2 \mu\text{Sv a}^{-1}$ (Jobbágy et al. 2010). This is well below the $100 \mu\text{Sv a}^{-1}$ reference level of the committed effective dose recommended by World Health Organization (WHO).

55.4.2 Radionuclides in the Food Chain

Brown trout were exposed to ^{32}P in their tank water (7.4 Bq/l) and the uptake to muscle was followed over 6 weeks. A steady-state concentration factor of 1.7 and a biological half-life for clearance of 45 days are calculated (Winpenny et al. 1998).

On the other hand, juvenile rainbow trout (*Oncorhynchus mykiss*) were subjected to a 2-day radioactive pulse of $^{110\text{m}}\text{Ag}$ at 11.9 g/l (as AgNO_3), followed by a 19-day post-tracer exposure to nonradioactive Ag(I) (3.8 g/l). The distribution of $^{110\text{m}}\text{Ag}$ in the gills, liver, intestine, kidney, brain, and remaining carcass was investigated over a 19-day post-tracer period. Initially, the intestine contains the highest proportion of the $^{110\text{m}}\text{Ag}$ burden (34%); however, by day 8, less than 5% of the total radioactivity remains in this tissue. The majority of the $^{110\text{m}}\text{Ag}$ eliminated from the intestine moves to the liver and as much as 65% of the total radioactivity of the $^{110\text{m}}\text{Ag}$ in the fish are found in the liver (Galvez et al. 2002).

Dietary uptake, retention, and tissue distribution of ^{54}Mn , ^{60}Co , and ^{137}Cs in the rainbow trout have been studied, because this fish is widely distributed in European waterways. These radionuclides present a special interest from a biological standpoint, because Cs is biochemically analogous to K; and Mn and Co are classified among the ten vital elements for life. The theoretical values of the steady-state trophic transfer factor (TF) were significantly lower than one for ^{54}Mn and ^{60}Co , indicating that these radionuclides are not being biomagnified in their transfer to trout, while ^{137}Cs showed the opposite. At the end of the uptake phase (42 days), the

highest concentrations of ^{54}Mn were found in the liver, ^{60}Co in the kidneys, and ^{137}Cs in the digestive tract. After 73 days of depuration, the highest concentrations of ^{54}Mn were detected in the fins, ^{60}Co in the kidneys, and ^{137}Cs in the muscles. In general, ^{54}Mn was concentrated in the bony and cartilaginous tissues, ^{60}Co in skin, head, bone, and muscle, and ^{137}Cs in muscle (Baudin et al. 2000).

It is widely believed that iodine in soil is derived from iodine in the ocean rather than from iodine in the rock. This implies that the specific activity of ^{129}I in the iodine of human thyroids should be the same as that in the oceans. If, however, the iodine in soil originates from weathering of rocks (as is the case with other heavy trace elements), then the ^{129}I specific activity in thyroids should be much lower. It now appears that only a small fraction of the iodine in soil is of oceanic origin. Most calculations of very long-term effects of ^{129}I on human health are therefore considered to have resulted in overestimated figures (Cohen 1985).

Rice is a staple food in Japan and other Asian countries. Transfer of ^{137}Cs and stable Cs from paddy soil to polished rice in Aomori, Japan was measured. The specific activity of ^{137}Cs derived from fallout depositions and the mass fractions of stable Cs and K in paddy soils are 2.5–21 Bq/kg, 1.2–5.3 mg/kg, and 5,000–13,000 mg/kg, respectively. The respective values in polished rice are 2.5–8.5 mBq/kg dry wt., 0.0005–0.0065 mg/kg, and 580–910 mg/kg. The geometric mean of soil-to-polished rice *transfer factor* (TF) of ^{137}Cs is estimated to be 0.0016, being approximately three times higher than that of stable Cs, 0.00056. Here, TF is defined as follows:

$$\text{TF} = \frac{C_{\text{pr}}}{C_{\text{s}}} \quad (55.1)$$

where C_{pr} denotes the specific activity/mass fraction of a radionuclide/element in polished rice (Bq/kg dry mass for radionuclide or mg/kg dry wt. for stable element), and C_{s} stands for the specific activity/mass fraction of the same radionuclide/element in soil (Bq/kg dry wt. for radionuclide or mg/kg dry wt. for stable element).

Fallout ^{137}Cs , mostly deposited up to the 1980s, is more mobile and more easily absorbed by plants than stable Cs in the soil. Potassium in the soil is reported to be a competitive factor for the transfers of both ^{137}Cs and stable Cs from soil-to-polished rice. A similar difference between the transfer of ^{137}Cs and stable Cs was reported for polished rice (TF is about 40), wild mushrooms (4), and potato tubers (about 3) (Tsukada et al. 2002).

Radium is similar to calcium in chemical behavior and is absorbed from soil by plants and is passed up the food chain to man. Chemical factors such as the amount of exchangeable calcium in the soil will determine the rate at which radium will be absorbed by plants. The radium in food transferred from soil is known to be as variable as ^{137}Cs contents of food.

It is very important to understand how each radionuclide behaves in passing from the root to the edible portion of the plant and through the body of the stock animal and into the meat and/or milk consumed by man. The metabolisms of ^{90}Sr , ^{137}Cs , and ^{131}I have been studied in detail.

To understand the metabolism of radionuclides in relation to the congeners, the observed ratio (R_{obs}) defined as follows is used:

$$R_{\text{obs}} = \frac{(C_{\text{e}}/C_{\text{c}})_{\text{sample}}}{(C_{\text{e}}/C_{\text{c}})_{\text{precursor}}} \quad (55.2)$$

where C_{e} and C_{c} are the concentrations of the element and its congener, respectively. For the purpose of  Eq. (55.2), the concentration C_{e} can be replaced by the specific activity. For example, if a cow ingests 1,000 Bq of ^{90}Sr activity per 1 g of Ca and the cow's milk contains 100

Bq ^{90}Sr /g Ca, R_{obs} will be 0.1. However, the application of R_{obs} to ^{90}Sr is often not useful because ^{90}Sr is not homogeneously mixed throughout the soils.

Pyle and Clulow have reported the R_{obs} [(Bq ^{226}Ra /g Ca in fish tissue)/(Bq ^{226}Ra /g Ca in water)] in Quirke Lake white sucker (*Catostomus commersoni*) bone (mean = 0.07) and muscle (mean = 3.60), and these values correspond well to those reported by Rope and Whicker and show that bone could discriminate against ^{226}Ra in the water, but muscle does not (Pyle and Clulow 1998).

There are a number of hypotheses concerning the rates of uptake and elimination of radiocesium in fish. The level of radioactive concentration of aquatic biota is commonly defined in terms of a *concentration factor* (R_c) as follows:

$$R_c = \frac{\text{Activity per kg of aquatic biota (wet wt)}}{\text{Activity per liter of water}} \text{ l/kg.} \quad (55.3)$$

Smith et al. (2002) have obtained the following results from a considerable number of data measured for radiocesium in lakes:

1. Fish-water concentration factors are inversely proportional to $[\text{K}^+]$ of the lakes.
2. The uptake rate of ^{137}Cs in fish is negatively correlated with lake $[\text{K}^+]$.
3. The excretion rate of ^{137}Cs in fish is not positively correlated with lake $[\text{K}^+]$.
4. Lake pH or $[\text{Ca}^{++}]$ may reduce accumulation of ^{137}Cs .

It is assumed that the Sellafield plutonium reprocessing plant discharges large amounts of ^{99}Tc : a total of about 3,000 TBq of ^{99}Tc by the year 2015, weighing about 5 tons. Levels of ^{99}Tc in Norwegian coastal waters increased by a factor of ten between 1991 and 1996. ^{99}Tc is concentrated in seaweed, winkles, and mussels. A concentration factor of 120,000 is reported in seaweed and one of 650,000 has been measured in the green gland of lobster (Barnaby and Boeker 1999). Recent studies have shown that accumulation of ^{99}Tc in seabed sediments labeled by authorized radioactive liquid discharges into the NE Irish Sea from the Sellafield reprocessing complex is greater than previously thought. New data on ^{99}Tc concentration profiles in subtidal and intertidal sediments from the eastern and western Irish Sea show that substantial amounts of ^{99}Tc have accumulated in the fine-grained subtidal sediments off the Cumbrian coast, particularly after increased releases from Sellafield following the commissioning of the Enhanced Actinide Removal Plant (EARP) in 1994 (Finegan et al. 2009).

^{99}Tc activity concentration factors were measured in fish in the Irish marine environment. The mean annual ^{99}Tc level in filtered seawater ($<0.45 \mu\text{m}$) is 21–45 mBq/l for seawater from the western Irish Sea in 1995–1998, and 0–0.44 mBq/l from the south and west coasts in 1998. In seawater, technetium exists predominantly as the pertechnetate ion (TcO_4^-), which is highly soluble. Weighted mean ^{99}Tc specific activities in fish, prawns, and mussels landed at northeast ports in 1996–1998 are 0.15–0.37, 63–88, and 18–37 Bq/kg wet weight, respectively. Concentration factors for ^{99}Tc in seafood from the western Irish Sea are 6,850 for lobster (tail meat), 2,800 for prawns (edible), 970 for mussels (edible part), 280 for oysters (edible part), and 12 for fish (edible part) (Smith et al. 2001).

Reported values of ^{137}Cs specific activity (A_{sp}) and concentration factor (R_c) for fish in reservoirs close to the Mayak Production Association (PA) in Russia in 1994 are as follows. A_{sp} = 80 kBq/kg and R_c = 800 for pike (*Esox lucius*) (7.2 kg), A_{sp} = 120 kBq/kg and R_c = 1,200 for perch, A_{sp} = 0.3 and R_c = 240 for roach, and A_{sp} = 1.3 and R_c = 1,000 for pike (1.7 kg). Activity concentrations of ^{137}Cs and ^{90}Sr are reported to be 100 Bq/l and 8.4–14.0 kBq/l, respectively, in

Reservoir 10, and those in Reservoir 11 are in the range of 1.1–1.5 Bq/l for ^{137}Cs , and 1.9–2.4 kBq/l for ^{90}Sr (Strand et al. 1999).

Data on the concentrations of ^{210}Pb in water, sediment, and biota of the Kaveri River ecosystem at Tiruchirappalli in South India are presented. The highest level of ^{210}Pb was observed in the sediment (15.5 Bq/kg dry) and the lowest level in water (2.7 mBq/l). The concentration factors of ^{210}Pb in biotic components range from about 10^1 to about 10^3 . The high R_c is observed for shells and bones (Hameed et al. 1997).

55.5 Sources of the Effective Dose to the Population in the Environment

Everyone is exposed to natural radiation and globally dispersed radionuclides from atmospheric nuclear tests and accidents, and almost all people are exposed to medical radiography. The annual average doses in the world are estimated by the United Nations Scientific Committee on the Effects of Atomic Radiation (UNSCEAR) and listed in [Table 55.6](#).⁹

UNSCEAR has globally and extensively surveyed the sources of radiation, human exposure, and the effects of radiation, and the reports have been published successively since 1958. The most recent report was published in 2008. In this chapter, almost all data come from the UNSCEAR reports, especially those published in 1988, 1993, 2000, and 2008.

55.5.1 Exposure to Natural Sources

As shown in [Table 55.6](#), exposure to natural sources is predominant in all exposures, and covers a wide range. Natural sources are divided into cosmic and terrestrial sources. The external exposures to the two sources are similar as shown in [Table 55.7](#) and the inhalation of radon is the maximum source of human exposure, and varies widely depending on environmental conditions.

Table 55.6

Annual average doses and ranges of individual doses of ionizing radiation by source (UNSCEAR 2008)

Source	Annual per capita effective dose/mSv	Range or trend in exposure
Natural background	2.4	Typical range 1–13 mSv
Medical diagnosis (not therapy)	0.4	Range from 0.04–1.0 mSv
Atmospheric nuclear tests	0.005	Maximum of 0.15 mSv in 1963
Chernobyl accident	0.002 ^a	The average in the northern hemisphere has decreased from a maximum of 0.04 mSv in 1986
Nuclear power production	0.0002 ^a	Doses are up to 0.02 mSv for critical groups at 1 km from some nuclear reactor sites. Decreased with improved practice

^aGlobally dispersed radionuclides.

■ **Table 55.7**
Average radiation dose from natural sources (UNSCEAR 2008)

Source	Worldwide average annual effective dose/mSv	Typical range/mSv
External		
Cosmic rays	0.39	0.3–1.0
Terrestrial gamma rays	0.48	0.3–1.0
Internal		
Inhalation (mainly radon)	1.26	0.2–10
Ingestion	0.29	0.2–1.0
Total	2.4	1–13

55.5.1.1 Cosmic Radiation

Cosmic Rays

Ground level The components of galactic cosmic rays incident at the top of the atmosphere are primary protons (87%), alpha particles (10%), heavier nuclei (1%), and electrons (2%). The high-energy particles impinging on the atmosphere interact with atoms in the air and generate a complex set of secondary charged or uncharged particles. At ground level, the dominant components of the cosmic-ray secondaries are muons with energy mostly between 1 GeV and 20 GeV. About 80% of the absorbed dose rate in free air comes from the directly ionizing radiation of muons, and the remainder comes from electrons produced by the muons. A representative value for ionizing radiation for this dose rate at the sea level is 32 nSv h⁻¹. The geomagnetic latitude effect is about 10%, so that a value of 30 nSv h⁻¹ is appropriate for latitude below 30°. Since the radiation factor of muons is mostly unity, the effective dose rate is 31 nSv h⁻¹ or 270 μSv a⁻¹.

The effective dose rates for cosmic-ray neutrons were measured to be 4 nSv h⁻¹ at 24°N and 9 nSv h⁻¹ at 50°N, and the latitude variation at sea level was estimated from calculations and listed in ► [Table 55.8](#).

There are substantial altitude effects for both the directly ionizing and photon components and the neutron component of cosmic rays. The annual effective doses from cosmic ray for some high altitude cities are listed in ► [Table 55.9](#). At the altitude of 3,900 m of Lapaz, Bolivia, the average effective dose is 2,020 μSv a⁻¹, i.e., 5.3 times higher than the population-weighted average of the world, 380 μSv a⁻¹.

Aircraft altitudes Aircraft passengers and crews are subject to cosmic radiation exposure rates much higher than the rates at ground level. Estimation of doses to passengers and crews depends on the particular path taken through the atmosphere in terms of altitude and geomagnetic latitude, and on the duration of the exposure. For altitude of 9–12 km at temperate latitudes, the effective dose rates are in the range of 5–8 μSv h⁻¹, and at equatorial latitudes, the dose rates are lower and in the range of 2–4 μSv h⁻¹. For a transatlantic flight from Europe to North America, as an example, the route dose would be 30–45 μSv.

■ Table 55.8

Latitude distribution of cosmic ray dose rates outdoors at sea level. Population-weighted average in the world: ionization 30.9 nSv h⁻¹, neutron 5.5 nSv h⁻¹ (UNSCEAR 2000c)

	Latitude	80–90°	70–80°	60–70°	50–60°	40–50°	30–40°	20–30°	10–20°	0–10°

¹⁴ C	1.52	2,000	12
²² Na	0.12	50	0.15

Cosmic Radionuclides

The cosmic radionuclides, ³H, ⁷Be, ¹⁴C, ²²Na, etc., are produced by the interaction of cosmic ray particles with the atoms in the atmosphere, and the production rates are 72 PBq a⁻¹, 1,960 PBq a⁻¹, 1.54 PBq a⁻¹, and 0.12 PBq a⁻¹, respectively. The ingestion and the effective doses of an average person are listed in ▶ Table 55.10. Only ¹⁴C contributes slightly to the total effective doses of 2,400 μSv a⁻¹.

55.5.1.2 Terrestrial Radiation

External Exposure

Outdoors Only the ^{238}U series, ^{232}Th series, and ^{40}K contribute significantly to the exposure of the human body to terrestrial radiation. Other long-lived radionuclides, such as the ^{235}U series, ^{87}Rb , ^{138}La , ^{147}Sm , and ^{176}Lu exist in small amounts and do not contribute to the exposure dose. Therefore, the external radiation exposure depends on the abundance of the first group of nuclides in soil and rock. Generally igneous rocks, such as granite, contain much uranium and thorium, while the sedimentary rock contents are lower. The population-weighted average specific activities are 420 Bq kg^{-1} , 33 Bq kg^{-1} , and 45 Bq kg^{-1} for ^{40}K , ^{238}U , and ^{232}Th , respectively. The above values correspond to the absorbed dose rates in air of 18 nGy h^{-1} , 15 nGy h^{-1} , and 27 nGy h^{-1} , respectively, and the average absorbed dose rate calculated from terrestrial radionuclides in soil is 60 nGy h^{-1} . The distribution of terrestrial radionuclides shows large fluctuation in the world, and the average absorbed dose rates in countries range from 18 nGy h^{-1} (Cyprus) to 93 nGy h^{-1} (Australia).

Indoors Indoor exposure to gamma rays depends on the materials of the construction of houses. Some national average indoor exposure rates are listed in [Table 55.11](#). The lower-rate countries such as the USA and Thailand mainly use wood-frame houses, and the higher-rate countries, such as Iran and Sweden, reflect the wide use of stone or masonry materials in buildings. The ratios of indoor and outdoor exposure in the table show these conditions. There are some areas of high natural radiation background as shown in [Table 55.12](#). The higher radiation rates mainly derive from U- and/or Th-rich minerals in the soil. Monazite, (Ce, La, Y, Th) (PO_4), is such a mineral, which tends to concentrate by weathering with a higher density

Table 55.11

External exposure rates from terrestrial gamma radiation in some countries (UNSCEAR 2000e)

Country	Population (10^6)	Absorbed dose rate in air/ nGy h^{-1}		
		Outdoors	Indoors	Ratio I/O
USA	269.4	47	38	0.8
Chile	14.42	51	61	1.2
China	1,232	62	99	1.6
Japan	125.4	53	53	1
Thailand	58.7	77	48	0.6
Iran	69.98	71	115	1.6
Sweden	8.82	56	110	2
Germany	81.92	50	70	1.4

Effective dose/mSv	0.48	0.4	0.65	0.35	0.28	0.32	0.48

of 4.6–5.4. The estimation of average annual effective doses in countries by terrestrial gamma rays is listed in ● Table 55.13.

Radon and Its Decay Products

Source of radon Radon and its decay products are the most important for human exposure from natural sources. There are two important radon isotopes, ²²⁰Rn (referred to later as “thoron”) in the ²³²Th series and ²²²Rn (referred to later as “radon”) in the ²³⁸U series.¹⁰ The half-lives of ²²²Rn and ²²⁰Rn are 3.82 days and 55.6 s, respectively. The half-life of ²²⁰Rn is so short that ²²⁰Rn itself does not travel a long time, but ²¹²Pb, one of its descendants, has a rather

long half-life (10.6 h) and can transfer as an attachment of aerosol. ^{222}Rn can migrate for a long time as a gaseous component and change to short-lived decay products, ^{218}Po (3.05 min), ^{214}Pb (26.8 min), ^{214}Bi (19.9 min), and ^{214}Po (164 μs) and then change to a long-lived decay product, ^{210}Pb (21.3 a).

The evaluation of exposures to radon and its decay products must take account of the actual activity concentrations of the various alpha-emitting radionuclides in the two series in the air that is breathed.

The fraction of radon atoms released into rock or soil pore space from a radium-bearing grain is called the emanation coefficient (also called emanation factor or emanating power). Typical emanation coefficients for rocks and soils range from 0.05 to 0.7. The grain size, the shape, and the soil moisture are important factors.

Concentrations of “radon” and “thoron” in air and their doses Diffusion and advection from the ground and building materials, the entry of outdoor air, and radon released from water and natural gas affect the radon entry rates into structures. The estimation of effective doses for indoor and outdoor inhalation of “radon” (^{222}Rn), “thoron” (^{220}Rn), and their decay products by members of the public are shown in [▶ Table 55.14](#).

Their average activity concentrations outdoors are the same (10 Bq m^{-3}), but indoors the average activity concentration of “radon” (40 Bq m^{-3}) is larger than that of “thoron” (3 Bq m^{-3}). Indoors, “radon” is concentrated, but “thoron” decays due to its short half-life. The equilibrium equivalent activity concentrations are the product of the activity concentration of “radon”/“thoron” and the equilibrium factor. The equilibrium factor is defined as the ratio of the actual PAEC (the Potential Alpha Energy Concentration) to the PAEC that would prevail if all the decay products in each series were in equilibrium with the radon present, and is 0.6 outdoors and 0.4 indoors for “radon.” Those factors for “thoron” were obtained from the average of measured values. The global average annual effective dose from “radon” and its daughters is $1,200 \mu\text{Sv a}^{-1}$ and that for “thoron” and its daughters is $73 \mu\text{Sv a}^{-1}$. As shown in [Table 55.14](#), the annual effective doses due to “radon” daughters are very high, especially the indoor value ($1,000 \mu\text{Sv}$).

Table 55.14

Average activity concentration of "radon" (^{222}Rn), "thoron" (^{220}Rn), and their daughters in air, and annual effective doses (UNSCEAR 1993c)

Radionuclides	Place	Activity concentration/ Bq m ⁻³		Effective dose equivalent Concentration factor/ nSv Bq ⁻¹ h ⁻¹ m ³		Annual effective dose/ μ Sv	
		Radon Thoron gas	Equilibrium equivalent	Radon Thoron gas	Equilibrium equivalent	Radon Thoron gas	Equilibrium equivalent
Radon	Outdoors	10	6	0.17	9	3.0	130
	Indoors	40	16	0.17	9	48	1,000
Total (rounded)							1,200
Thoron	Outdoors	10	0.1	0.11	10	1.9	1.8
	Indoors	3	0.3	0.11	32	2.3	67
Total (rounded)							73

■ **Table 55.15**

Annual effective doses from ingestion of uranium and thorium radionuclides (UNSCEAR 2000g)

	Effective dose rate/ $\mu\text{Sv a}^{-1}$						
	$^{238}/^{234}\text{U}$	^{230}Th	^{226}Ra	$^{210}\text{Pb}/^{210}\text{Po}$	^{232}Th	$^{228}/^{224}\text{Ra}$	Total
Dose from body	7	6	7	80	4	18	120
Dose from food intake	0.5	0.6	6	91	0.4	11	110

Other than radon Internal exposures due to sources other than radon arise from the intake of terrestrial radionuclides by inhalation and ingestion mainly due to ^{40}K , the ^{238}U series, and ^{232}Th series nuclides present in foods and drinking water.

The dose rate from ^{40}K can be determined directly and accurately from external measurements of its concentration in the body, and the average dose rate is $170 \mu\text{Sv a}^{-1}$.

The estimation of dose rates from the internal exposure to the ^{238}U series and ^{232}Th series is more difficult. UNSCEAR (2000a) surveyed their contents in the human body and their dietary intake, and estimated annual effective doses from ingestion of the radionuclides from uranium- and thorium- series are shown in ▶ [Table 55.15](#). The exposure due to these radionuclides contained in the body ($120 \mu\text{Sv a}^{-1}$) is almost the same as that from food intake, $110 \mu\text{Sv a}^{-1}$. In the series of ^{238}U and ^{232}Th (disregarding “radon,” “thoron,” and their short-lived daughters) $^{210}\text{Pb}/^{210}\text{Po}$ contributes most to the exposure (about 75%).

55.5.1.3 Technologically Enhanced Dose Contribution

There are many materials containing radionuclides in which radioactivity is not an essential factor. For example, thorium is used as an additive of welding electrodes and in gas mantles. There are many raw materials containing natural radionuclides and discharges from plants and the use of the waste materials may cause exposure to the public. In phosphate processing, metal ore processing, titanium pigment production, fossil fuels, etc., radionuclides are discharged and expose the public. But the exposure rates may be less than the levels of $1\text{--}10 \mu\text{Sv a}^{-1}$, and can be considered negligible compared to other natural rates.

55.5.1.4 Worldwide Average Exposure from Natural Sources

Finally, averaged worldwide exposure to natural radiation sources are listed in ▶ [Table 55.16](#). There is a wide distribution of exposures from many sources; therefore, typical annual effective doses are also distributed over a wide range, from 1 mSv to 13 mSv and the (population-weighted) average is 2.4 mSv of which 0.39 mSv is due to cosmic rays, 0.48 mSv to external terrestrial radiation, and 1.26 mSv to “radon” and “thoron” inhalation, and 0.29 mSv to the ingestion of ^{40}K and uranium and thorium. As shown in the table, “radon” and its daughters constitute the largest contribution to the total exposure.

55.5.2 Medical Exposure

Medical applications of ionizing radiation are the largest artificial sources of radiation exposure, and population exposures from the diagnostic and therapeutic uses of ionizing radiation

■ **Table 55.16**

Average worldwide exposure to natural radiation sources (UNSCEAR 2000c)

Source	Annual effective dose/mSv	
	Average	Typical range
Cosmic radiation		
Direct ionizing and photon component	0.28	
Neutron component	0.1	
Cosmogenic radionuclides	0.01	
Total cosmic and cosmogenic	0.39	0.3–1.0
External terrestrial radiation

Uranium and thorium series	0.12	
Total ingestion	0.29	0.2–1.0
Total	2.4	1–13

■ **Table 55.17**

Radiation exposure from diagnostic medical X-ray examinations (UNSCEAR 2000h)

Health-care level	Population per physician	Annual number of examinations per 1,000 population	Average annual effective dose to population/mSv	Population in 1996 (million)
I	<1,000	920	1.2	1,508
II	1,000–3,000	150	0.14	3,074
III	3,000–10,000	20	0.02	638
IV	>10,000	<20	<0.02	580
Worldwide average		330	0.4	Total 5,800

are likely to be increasing. In order to obtain a worldwide estimation of medical exposure doses, quantitative information on the frequencies and the dose for diagnostic and therapeutic procedures are required. Since there are significant country-to-country variations in medical radiology, all countries are divided into four levels of health care, based on the number of physicians available to serve the inhabitants of a country (► [Table 55.17](#)). The annual number of examinations per 1,000 people, and the average annual effective doses, are significantly

different on the various health-care levels. Global data were estimated from the data on the number of examinations and their dose per capita and from the populations of countries of different health-care levels.

55.5.2.1 Diagnostic Radiology

Average effective doses from diagnostic examinations with X-ray are shown in [Table 55.18](#). The effective dose of a typical examination of the chest is 0.14–1.1 mSv and other examinations such as lumbar spine, abdomen, and pelvis are 0.3–0.6 mSv. The patient effective dose of an X-ray examination for upper GI (gastrointestinal) tract is 3.6 mSv and that for the lower GI tract is 6.4 mSv, and about 3.7 mSv for urography.

Patient doses per procedure from diagnostic angiographic examinations are 2–10 mSv for coronary, 1–12 mSv for cerebral, 2–48 mSv for abdominal, and 1–22 mSv for peripheral scans ([Table 55.19](#)).

The doses for the procedure during interventional radiology are generally very high, e.g., 7.5–57 mSv for PTCA (percutaneous transluminal coronary angioplasty), 2–40 mSv for TIPS (transjugular intrahepatic portosystemic shunt), 17–25 mSv for radiofrequency ablation, 5.7–20 mSv for cerebral embolization, and 0.3–24 mSv for biliary procedure ([Table 55.20](#)).

The doses to patients from computed tomography (CT) depend on the survey regions, and that for the head is low (1.5–2.5 mSv), that for the abdomen is high (10–17 mSv), and others are 5–10 mSv ([Table 55.21](#)).

■ **Table 55.18**

Average effective doses from diagnostic medical X-ray examinations (UNSCEAR 2000i)

Examination	Average effective dose/mSv
Chest radiography	0.14
Chest photofluoroscopy	0.65
Chest fluorography	1.1
Limb and joints	1.8
Lumbar spine	1.8
Pelvis and hip	0.83
Head	0.07
Abdomen	0.53
Upper GI tract	3.6
Lower GI tract	6.4
Cholecystography	2.3
Urography	3.7
Mammography	0.51
CT	8.8
Angiography	12
PTCA	22

GI (gastrointestinal), CT (computed tomography), PTCA (percutaneous transluminal coronary angioplasty).

■ **Table 55.19****Patient dose per procedure from diagnostic angiographic examination (UNSCEAR 2000j)**

Procedure	Coronary	Coronary	Cerebral	Cerebral	Abdominal
Technique	Cine film	Digital cine	Carotid (DSA)	Digital	Hepatic (DSA)
Fluoroscopy time/min	4.3 (1.5–15)	5.7	3.9 (1.2–11.8)	12.1 (2.9–36)	10.3 (2.3–28.6)
Effective dose/mSv	(2–9)	9.4	4 (1–12)	7.4 (2.1–19.6)	23 (4–48)
Procedure	Abdominal	Peripheral	Peripheral	Peripheral	
Technique	Renal (DSA)	Femoral (DSA)	Femoral	Lower limbs	
Fluoroscopy time/min	12.1 (5.5–21)	3.7 (1.2–19)	2.4 (1.3–8.3)	3.7 (± 3.1)	
Effective dose/mSv	16 (6–34)	4 (1–16)	9	6.2	

Numbers in parentheses mean ranges while the rest averages.

DSA stands for digital subtraction angiography.

■ **Table 55.20****Patient dose per procedure during interventional radiology (UNSCEAR 2000k)**

Procedure	PTCA	PTA	TIPS	Radiofrequency ablation
Fluoroscopy time/min	11.5 (2.4–28)	24 (5–45)	59 (26–115)	53 (± 50)
Localized dose to skin/Gy	0.15 (0.05–0.3)	0.3	0.4	1.3 (± 1.3)
Effective dose/mSv	28.9 (7.5–57)	12.5	8 (2–40)	17–25
Procedure	Valvuloplasty	Embolization	Biliary	Stent
Fluoroscopy time/min	31.8	34.1 (15.2–55.8)	7.1 (0.6–26.3)	17 (± 9)
Localized dose to skin/Gy	–	0.34 (0.19–0.66)	0.11 (0.01–0.37)	2 (max)
Effective dose/mSv	29.3	10.5 (5.7–20)	6.9 (0.3–23.9)	5.8

PTCA: Percutaneous transluminal coronary angioplasty, PTA: Percutaneous transluminal angioplasty

TIPS: Transjugular intrahepatic portosystemic shunt.

Dental radiography is also frequently used. The averaged effective dose for one examination is about 1.1–3.3 μSv , and the frequency is 309 times for 1,000 people for group I. The global average exposure dose per examination of dental radiography is calculated to be 16 μSv . Similar investigations show that the surface absorbed doses for mammography, uterus, and bone densitometry are 0.5–10 mGy, but the effective doses are less than 1 μSv .

Averaged (individual) effective doses and collective effective doses from diagnostic medical X-ray examinations in some counties are listed in [▶ Table 55.22](#).

Germany has the highest effective dose both per examination and per capita. The annual effective doses from diagnostic medical examination of Brazil, China, and Malaysia are lower, and these countries are classified as countries of health-care level II. The number of examinations for the countries of health-care level II has been increased and will reach that of the countries of health-care level I; therefore, the average doses from diagnostic radiology are estimated to be globally increasing.

■ Table 55.21

Average doses to patients from computed tomography (CT) in some countries (UNSCEAR 2000l)

Country	Year	Mean effective dose per procedure/mSv							
		Head	Cervical spine	Chest	Abdomen	Liver	Kidneys	Pelvis	Lumbar spine

55.5.2.2 Diagnostic Administrations of Radiopharmaceuticals

Administration of radionuclide preparations (radiopharmaceuticals) to patients is widely practiced throughout the world. Many of the diagnostic applications of radionuclides are conducted in vitro and in vivo. Since the in vitro experiments do not give rise to the exposure of patients, only diagnostic in vivo examinations are referred to in this section.

The main diagnostic practices with radiopharmaceuticals are the procedures for bone, cardiovascular, lung perfusion, lung ventilation, thyroid scan, thyroid uptake, renal, liver/spleen, and brain examinations. The effective doses per procedure are considerably higher and are 4.5 mSv, 8 mSv, 1.5 mSv, 1 mSv, 3.4 mSv, 15 mSv, 1.9 mSv, 1.7 mSv, and 6 mSv, respectively, and the number of procedures per 1,000 population are 4.5, 2.7, 1.8, 0.34, 4.1, 0.92, 0.89, 2.1, and 1.3, respectively for countries at health-care level I. But patients near to the end of their lives receive many of these exposures, and thus the doses are not distributed evenly among the population. Therefore, these doses should not be used for the assessment of detrimental effects of radiation exposure.

55.5.2.3 Teletherapy and Brachytherapy

Teletherapy has been used for the therapy of various types of tumor. The most frequent ones are (figures in the parentheses show the annual numbers of treatments per 1,000 population in the health-care level I countries): leukemia (0.01), lymphoma (0.06), breast tumor (0.35), lung/thorax tumor (0.36), gynecological tumor (0.12), head/neck tumor (0.06), brain tumor (0.04), skin tumor (0.05), bladder tumor (0.04), prostate tumor (0.18), tumor of the rectum (0.07) benign disease (0.09), and others (0.09). Brachytherapy has been used for the therapy of head/neck tumor (0.01), breast tumor (0.02), gynecological tumor (0.16), prostate tumor (0.004), and others (0.01).

The average doses to patients undergoing radiation teletherapy for countries of health-care level I are 17 Gy for leukemia, 39 Gy for lymphoma, 48–60 Gy for breast tumor, lung/thorax tumor, gynecological tumor, head/neck tumor, brain tumor, skin tumor, bladder tumor, prostate tumor, tumor of rectum, and 6 Gy for benign disease. The average doses to patients on brachytherapy are 44 Gy for head/neck tumor, 16 Gy for breast tumor, 45 Gy for gynecological tumor, and 35 Gy for prostate tumor. These doses are very high, but should not be used to infer deterministic or stochastic risks for the same reason as described in the previous subsection.

55.5.2.4 Therapeutic Administrations of Radiopharmaceuticals

The average annual numbers of therapeutic treatments with radiopharmaceuticals per 1,000 population for countries of health-care level 1 are 0.038 for thyroid malignancy (radionuclide: ^{131}I), 0.15 for hyperthyroidism (radionuclide: ^{131}I), 0.0046 for polycythemia vera (^{32}P), 0.0063 for bone metastases (^{89}Sr), and 0.098 for synovitis (^{90}Y). The average activities administered in the therapeutic treatments are 4,760 MBq of ^{131}I (iodide) for thyroid malignancy, 415 MBq of ^{131}I (iodide) for hyperthyroidism, 170 MBq of ^{32}P (phosphate) for polycythemia vera, 140 MBq of ^{89}Sr chloride for bone metastases, and 250 MBq of ^{90}Y for synovitis.

55.5.2.5 Estimated Doses to the World Population from Medical Uses of Radiation

The doses from various medical uses of radiation have been discussed above and are summarized in ► [Table 55.23](#).

Thus almost all exposures (>90%) of the medical variety are derived from diagnostic radiology. The number of dental X-ray examination is large (520 millions), but because the effective dose per examination is very low (about 16 μSv), the contribution to the total effective dose is small. In contrast, the number of diagnostical nuclear medicine procedures is small, but because the effective dose per examination is high (about 4 mSv), the collective effective dose is about ten times more than that for dental examinations. The absorbed doses involved in radiotherapy and nuclear medicine therapy procedures are very much higher, but their contribution is not used for the assessment of radiological detriment, because a great part of the exposure is received by patients near the end of their lives. Finally, the effective dose per capita for medical use is estimated to be 0.4 mSv, and this value is one sixth of the dose from natural sources of radiation.

55.5.3 Global Fallout and Nuclear Facilities

The major anthropogenic sources that have lead, or could potentially contribute, to the radionuclide contamination of the environment are the following: (1) the testing and production of nuclear weapons; (2) the normal activities of the nuclear power fuel cycle; (3) the radioisotope production and research reactors; and (4) the nuclear accidents.

In this section, the amounts of radionuclides suddenly released from testing of nuclear weapons and from various accidents and that gradually released from normal operational activities of the nuclear cycle and radioisotope production are reviewed and the corresponding dose effects are estimated.

► [Table 55.23](#)

Estimated annual global practices and doses to the world population (UNSCEAR 2000m) from medical use of radiation (1991–1996)

		Number of procedures/ 10^6	Effective dose per capita/mSv
Diagnosis	Medical radiation use	1,910	0.4
	Dental X-ray examination	520	0.002
	Nuclear medicine procedures	32	0.03
Total		2,500	0.4
Therapy	Radiotherapy treatments	5.1	
	Nuclear medicine procedures	0.4	
Total		5.5	

55.5.3.1 Normal Activities

Testing and Production of Nuclear Weapons

Atmospheric tests From the first test in New Mexico on July 16, 1945, to the last atmospheric test at Lop Nor on October 16, 1980, 543 nuclear tests were carried out in the atmosphere, and enormous amounts of radionuclides were released. The radioactive debris is deposited locally (up to 100–200 km from ground zero), regionally (2,000–3,000 km), or released into the troposphere and/or stratosphere resulting in global dispersion (➤ [Table 55.24](#)).

For refractory radionuclides such as ⁹⁵Zr and ¹⁴⁴Ce, 50% are assumed to be deposited locally and a further 25% is deposited regionally, while for volatile radionuclides such as ⁹⁰Sr, ¹³⁷Cs, and ¹³¹I, 50% of the fission yield is assumed to be deposited locally and regionally. The remainder of the debris and all of the debris from airbursts is widely dispersed in the atmosphere.

The radionuclides of mass numbers about 90–140 have high yields in fission¹¹, very large activities were therefore produced of ⁹¹Y, ⁹⁵Zr, ¹³¹I, ¹⁴⁰Ba, and ¹⁴⁴Ce as shown in ➤ [Table 55.25](#). Tritium was produced in large quantities by ternary fission.¹² Although their yields are smaller,

■ Fig. 55.1

Annual deposition of the radionuclides produced in atmospheric nuclear tests (UNSCEAR 2000r)

the radionuclides of long half-lives, ^{90}Sr (28.8 a), ^{137}Cs (30.1 a), and the plutonium isotopes (^{239}Pu : 24,110 a; ^{240}Pu : 6.536 a; ^{241}Pu : 14.4 a) are important in the exposure of people. Since the atmospheric tests were ended in 1980, and the average mean residence time of particles in the stratosphere is about 2 years, almost all fallouts had been deposited in the 1980s as shown in [Fig. 55.1](#).

The sum of the worldwide average annual effective dose for the period of 1945–1999 caused by relevant radionuclides from atmospheric tests is shown in [Table 55.26](#).

At the beginning of the tests, $^{95}\text{Zr}/\text{Nb}$ dominated the external exposure, but due to the short half-life of ^{95}Zr , ^{137}Cs has been the primary source of this irradiation path since the 1960s. ^{131}I and other nuclides with short half-life significantly contributed to the ingestion dose at the time of their fallout, but on the long term ^{90}Sr , ^{137}Cs , and ^{14}C became the most dominant. Since the half-life of ^{14}C is long and circulates in the biosphere, today ^{14}C contributes 93% of the total ingestion and 70% of the total effective dose commitment. Inhalation dose was primarily determined by ^{144}Ce , the transuranium isotopes, and ^{106}Ru , but after 1985 their concentration significantly dropped in the air and today this contribution is not significant.

The annual effective dose from radionuclides due to atmospheric nuclear testing reached a maximum in 1963 of 113 μSv (37.5 μSv for external, 39.8 μSv for ingestion, and 36.0 μSv for inhalation). In 1999, the effective dose dropped to 5.51 μSv (2.9 μSv for external, 2.61 μSv for ingestion, and 0.0 μSv for inhalation) and decays very slowly due to the significant ^{14}C contribution.

Underground testing The underground tests of nuclear weapons were begun in 1951 by the USA and in 1961 by the USSR. Until 1998, 1,876 underground nuclear tests were carried out in seven countries ([Table 55.27](#)).

■ Table 55.26

Sum of the worldwide average annual effective dose for the period of 1945–1999 from radionuclides produced in atmospheric testing (UNSCEAR 2000p)

Radionuclides	Effective dose commitment/ μ Sv			
	External	Ingestion	Inhalation	Total exposure
H-3		23.7		23.7
C-14		144		144
Mn-54	19.2		0.1	19.3
Sr-90		97	9.2	106.2

Pu and Am			37.8	37.8
Total	353	492	149	994

■ Table 55.27

Underground nuclear tests (UNSCEAR 2000q)

Country	Number	Fission energy/Mt ^a	Period
China	22	1	1969–1996
France	160	3	1961–1996
India	6		1974, 1998
Pakistan	6		1998
UK	24	2	1962–1991
USA	908	46	1955–1992
USSR	750	38	1961–1990

^aThe energy is expressed by the weight (mega ton) of TNT gunpowder.

The release of ^{131}I into the atmosphere at the Nevada underground site was estimated to be 5,000 TBq. If other tests release similar amounts of ^{131}I assuming similar magnitudes of explosions, the total release by underground nuclear tests is estimated to be 15,000 TBq of ^{131}I . The estimated released ^{131}I was about 0.004% of the estimated total production of ^{131}I . If the same rate can be applied to other gaseous radionuclides, 50 PBq of ^{133}Xe and 0.1 TBq of ^3H were released by the underground tests.

The exposure dose does not contribute significantly to the total human exposure since the release is very localized and the half-life of ^{131}I is short (8.02 days).

Production of weapon materials The production rates of nuclear weapon materials have never been published; therefore, they are estimated by the amounts of the long-lived nuclides in

high-level radioactive waste in the USA. These data suggest that the USA and Russian Federation stock about 100 tons of plutonium, each.

Tritium is also produced for weapons, and about 55 kg of tritium are stocked in the USA and maybe 110 kg in the world.

Radionuclides released from the production of nuclear weapon materials and from fabrication plants are not widely published. The exposures from nuclear materials production/processing centers (Chelyabinsk, Krasnoyarsk, and Tomsk) in the Russian Federation were published, and the annual effective doses were 0.0054–0.11 mSv.

Nuclear Power Production

Mining and milling Uranium was produced to the extent of 35.7 kilotons globally in 1997. Canada produces one third of this as shown in [Fig. 55.2](#). The uranium mines are unevenly distributed in the world and 90% of uranium is produced in ten countries.

^{222}Rn is the daughter of ^{226}Ra and a descendant of ^{238}U . While producing 1 ton of uranium, ~ 300 GBq of ^{222}Rn is released during mining and ~ 13 GBq during milling. This means that almost all of the radon is released during mining.

In the 100-km range of a model mining activity producing 4,000 t of uranium annually, the average per capita annual effective dose is estimated to be 40 μSv . The normalized collective effective doses per electrical energy generation are estimated to be 0.19 man-Sv(GW y) $^{-1}$ for mining and 7.54 man-Sv(GW y) $^{-1}$ for milling.

■ Fig. 55.2

Annual production of uranium in various countries in 1997 (UNSCEAR 2000s)

Uranium enrichment and fuel fabrication For light-water-moderated and light-water-cooled reactors (LWRs) and for advanced gas-cooled graphite moderated reactors (AGRs), the uranium processed at the mills needs to be enriched in the fissile isotope ^{235}U . Enrichments of 2–5% are required. Before the enrichment, the uranium oxide (U_3O_8) must be converted to uranium tetra-fluoride (UF_4) and then to uranium hexa-fluoride (UF_6).

In fuel fabrication for LWRs (PWRs and BWRs) and AGRs, the enriched UF_6 is chemically converted to UO_2 . The UO_2 powder is sintered, and formed into pellets. The releases of radioactive materials in the processes of the conversion, enrichment, and fuel fabrication plants are generally small and the exposure to the public is also small.

Nuclear reactor operation The reactors used for electrical energy generation are classified for the most part, by their coolant systems and moderators. PWRs and BWRs are light-water-moderated and cooled-pressurized or boiling water reactors, HWRs are heavy water cooled and moderated reactors, GCRs are gas-cooled and graphite-moderated reactors and LWGRs are light water-cooled, graphite-moderated reactors. Fast breeder reactors (FBRs) have no moderator materials and are cooled by a liquid metal, normally sodium metal, and the fission is induced by fast neutrons. FBRs make a minor contribution to the total energy production by nuclear means.¹³

The energy-normalized releases of radionuclides from various types of nuclear reactors are shown in ▶ [Table 55.28](#). The gaseous release is characterized by the type of reactors: noble gases are released largely from GCRs and LWGRs, tritium gas is largely released from HWRs, ^{131}I is released mostly from LWGRs, and particulates are released largely from BWRs. The average of the worldwide total electrical power generated by these various types of reactors for 1995–1997 is also shown in ▶ [Table 55.28](#).

From the average effluents data UNSCEAR determined the collective doses for a model site based on nuclide specific dose-conversion coefficients, which were calculated applying a simple dispersion model, nuclide specific transport parameters, and population density data of 400 km^{-2} for 1–50 km, 20 km^{-2} for 50–2,000 km. The normalized collective effective doses

■ **Table 55.28**

The average of the energy-normalized releases (TBq/GW_y, with the energy expressed in gigawatt-year) of radionuclides from nuclear reactor (UNSCEAR 2000t) for the period of 1995–1997

Total				0.43			

from radionuclides from reactors are shown in ▶ [Table 55.29](#). As shown in the table, noble gases and ¹⁴C mainly contribute to the collective effective doses.

Supposing that all the doses are committed to the population in the 50 km vicinity of a model reactor, the average annual per capita effective dose is 5 μSv for PWR and GCR types, 10 μSv for BWR and HWR types, and 2 μSv, 0.04 μSv for LWGR and FBR types, respectively. Due to the definition and the inappropriate use of the collective dose, these values are somewhat overestimated. This overestimation is well illustrated by the study carried out for European power reactors, where for instance for the 2004 effluents data the annual effective dose for the member of the critical group at 500 m from a PWR or BWR reactor is less than 1 μSv (EUROPEAN COMMISSION 2008).

Fuel reprocessing Fuel reprocessing is carried out to recover uranium and plutonium from spent fuel used in reactors. Most spent fuel from reactors is retained on-site in interim storage, pending decision on ultimate disposal or retrievable storage. Only about 5–10% of fuel is submitted to the reprocessing stage of the nuclear fuel cycle. The plants are operated in France, Japan, and the UK.

The released activities in fuel reprocessing, normalized by the unit of electric energy, are shown in ▶ [Table 55.30](#). In airborne effluents, ⁸⁵Kr is most important, tritium and ¹⁴C are minor, and others are present only as traces. In liquid effluents, tritium is a major component.

Due to the significant decrease of the ¹³⁷Cs activity in liquid effluents, the annual per capita effective dose has decreased from 200–500 μSv in the 1980s to 5–8 μSv in 1997–2004, despite the increase of the amount of reprocessed fuel annually.

Globally dispersed radionuclides Radionuclides that are sufficiently long lived and easily dispersed in the environment can give rise to global doses. The radionuclides of interest are ³H (the half-life: 12.3 a), ¹⁴C (5,730 a), ⁸⁵Kr (10.7 a), and ¹²⁹I (1.6 × 10⁷ a). The estimates of the released radionuclides are shown in ▶ [Table 55.31](#) (UNSCEAR 1993d). The electrical energy generated by nuclear reactors has grown steadily from the start of the industry in 1956 and thus

■ Table 55.30

Normalized release in fuel reprocessing between 1995 and 1997 (UNSCEAR 2000v)

Energy content of reprocessed fuel/GWy	Normalized release, TBq/GWy					
160	Airborne effluents					
	^3H	^{14}C	^{85}Kr	^{129}I	^{131}I	^{137}Cs
	9.6	0.3	6,900	0.006	0.00005	0.0001
	Liquid effluents					
	^3H	^{14}C	^{90}Sr	^{106}Ru	^{129}I	^{137}Cs
	255	0.4	0.8	0.5	0.04	0.2

■ Table 55.31

Globally dispersed activities and corresponding world average effective dose commitments for the period of 1970–1997. The energy produced was 3,860 GWy, the reprocessed fuel was equivalent to 420 GWy

Release radioactivity/PBq				Average annual effective dose commitment/nSv
Radionuclides	Reactor	Reprocessing	Total	
^3H	270	170	440	1
^{14}C	2	1	3	4
^{85}Kr		3,200	3,200	10
^{129}I		0.015	0.015	1
Total				16

the concomitant release of radionuclides has also increased. The noble gas ^{85}Kr , and tritium hydrogen gas are difficult to separate from the exhausting gases. Tritium water is also difficult to separate from the wastewater. Tritium and ^{85}Kr , therefore, are largely released from nuclear facilities, but they are easily dispersed homogeneously in the hydrosphere or atmosphere, then most people in the world are homogeneously exposed to their radioactivity. The world average effective dose commitments from several nuclides are also shown in [Table 55.31](#).

The global collective effective dose estimated for 10,000 years amounts to 50 man-Sv/GWy. The main contribution is from globally dispersed ^{14}C from reactors and reprocessing. The longer-term trends in collective effective doses per unit electrical energy generated show decreases due to reductions in the release of radionuclides from reactors and fuel reprocessing plants.

Solid-waste disposal and transport Solid waste arises at various stages of the nuclear fuel cycle, and is classified as low- and intermediate-level waste (LLW) mainly from reactor operation, and high-level waste (HLW) from fuel reprocessing and from “spent” fuel meant for direct disposal.¹⁴ Low- and intermediate-level wastes are generally disposed of by shallow burial in trenches or concrete-lined structures.

From today’s operating nuclear power plants in 30 countries, over 10,000 metric tons of heavy metal (tHM) are unloaded each year, with annual discharges projected to increase to ~11,500 tHM by 2010. Since less than one third is reprocessed, an additional 8,000 tHM/year, on average, will need to be placed in storage facilities. No geological repository for spent fuel or

HLW has yet been built. The only operating geological repository to date is the Waste Isolation Pilot Plant (WIPP) in the USA. In addition to WIPP, good progress has been made in several countries on repositories for HLW or spent fuel from commercial nuclear power plants.

The radiological impact assessment of the waste disposal sites needs the modeling of the long-term behavior of the waste packages and the migration of released radionuclides near the site. Decommissioning of nuclear facilities gives a huge amount of extra low-level radioactive waste, but the released amounts of radionuclides will be very small.

Radionuclide Production and Research Reactors

Radionuclide production and use Radionuclides are widely used in the fields of industry, medicine, and research. For example, in Japan 5.2 GBq of ^{14}C , 6.1 GBq of ^{125}I , 14 GBq of ^3H , and 34 GBq of ^{131}I are used in hospitals, universities, institutes, and one million people work in this field. The estimates of globally released radionuclides for industry, medicine, and research are 0.13 PBq of ^3H , 0.05 PBq of ^{14}C , 0.02 PBq of ^{85}Kr , 0.7 PBq of ^{123}I , 0.06 PBq of ^{125}I , 0.3 PBq of ^{131}I , and 2.6 PBq of ^{133}Xe . Annual collective doses from these released radionuclides are estimated to be 100 man-Sv. Almost all exposure is derived from ^{14}C . The radionuclides used most widely in medical examinations and in nuclear medicine procedures are ^{131}I and $^{99\text{m}}\text{Tc}$. With the estimated global annual usage of ^{131}I in therapeutic treatments of 600 TBq, a fraction of 5×10^{-4} is released in liquid effluents. The release of $^{99\text{m}}\text{Tc}$ (its half-life is 6.01 h) is reduced by a holdup tank and may be negligible.

Research reactors At the end of 1999, 292 nuclear research reactors had been operated in the world. The annual releases from research reactors are only known from few reactors like that of Obninsk in Russian Federation and are 0.7 PBq of noble gases, 5 GBq of ^{131}I , 0.3 GBq of ^{90}Sr , 0.6 GBq of ^{137}Cs , and 0.1 GBq of plutonium. The annual effective doses to individuals in Obninsk were estimated not to exceed 30 μSv .

The radionuclides released from industry, medicine, and research are limited and localized, and thus the exposure to the public may be negligible.

55.5.3.2 Accidents

Commercial Reactors

Three Mile Island On March 28, 1979, the feed water pumps that supplied the steam generator of Three Mile Island Unit 2 shut down, leading to automatic shutdown of the reactor. Heat from residual radioactivity in the core caused the temperature and pressure of the reactor coolant to rise and a relief valve used to stop the repressurizer, to open. The open valve could not close and since the reactor coolant water was draining, a loss-of-coolant accident was in progress. Large amounts of radionuclides were released in the reactor building basement, but comparatively small amounts of noble gas (mainly ^{133}Xe , 370 PBq) and ^{131}I (550 GBq) were released to the atmosphere and the collective effective dose is estimated to be 40 man-Sv in the surrounding area.

Chernobyl On April 26, 1986, the accident at Chernobyl happened. A water-cooled, pressure tube, graphite-moderated, 1,000 MWe reactor was destroyed. It was the first power reactor accident to result in radiation casualties, the first to result in extensive contamination of the environment, and the first to require the evacuation of nearby residents.

■ **Table 55.32**

Core inventory and estimate of total release of radionuclides from the accident of Chernobyl (IAEA 2006)

Radionuclides	Inventory/EBq	Percent released
^{85}Kr	0.033	100
^{133}Xe	6.5	100
^{131}I	3.2	55
^{137}Cs	0.26	33
^{132}Te	4.2	27
^{134}Cs	0.19	25
^{106}Ru	0.85	8–9
^{90}Sr	0.22	4–5
^{95}Zr	5.85	1–2
^{140}Ba	6.04	4
^{144}Ce	3.92	1
^{239}Pu	0.00096	1
^{242}Cm	0.031	1
^{239}Np	58.1	<1

The reactor had operated since 1983, and thus huge amounts of fission products had been stocked in the core and released corresponding to their chemical characteristics (► [Table 55.32](#)). Gaseous and volatile elements such as noble gases, iodine, and cesium were released in large amounts. In contrast, only 2–3% of nonvolatile elements such as cerium and zirconium were released. Fission products in the core of the reactor were released for about 10 days following the destruction of the core before the sharp drop of the releases at May 6 (► [Fig. 55.3](#)).

The total release of radioactive substances was about 14 EBq (as of April 26, 1986), which included 1.8 EBq of ^{131}I , 0.085 EBq of ^{137}Cs and other cesium radioisotopes, 0.01 EBq of ^{90}Sr , and 0.003 EBq of plutonium radioisotopes. The noble gases contributed about 50% of the total release of radioactivity. About 115,000 residents had to be evacuated from the area of around 30 km of the reactor. The fission products had been transported by the plumes by meteorological dynamics and were deposited all over the world. The first plume moved to the north and arrived in Sweden and Finland on the next day. The second plume moved to the east and on April 29 and 30 arrived in Hungary and Austria. The third plume moved to the south and arrived in Greece on May 2 (► [Fig. 55.4](#)). Furthermore, the radionuclides were transferred with global atmospheric dynamics and arrived on May 4 in China, May 5–6 in Canada and the USA (► [Table 55.33](#)).

An area of more than 200,000 km² in Europe was contaminated with radiocesium (above 0.04 MBq of $^{137}\text{Cs}/\text{m}^2$), of which 71% was in the three most affected countries (Belarus, the Russian Federation, and Ukraine). The deposition was highly heterogeneous; it was strongly influenced by rain when the contaminated air masses passed. Most of the strontium and plutonium radioisotopes were deposited close (less than 100 km) to the reactor, due to their being contained within larger (hot) particles.

■ Fig. 55.3

Daily release rate to the atmosphere of radioactive materials during the Chernobyl accident (excluding noble gases) (UNSCEAR 1988b). The dotted lines show a range of uncertainty of $\pm 50\%$

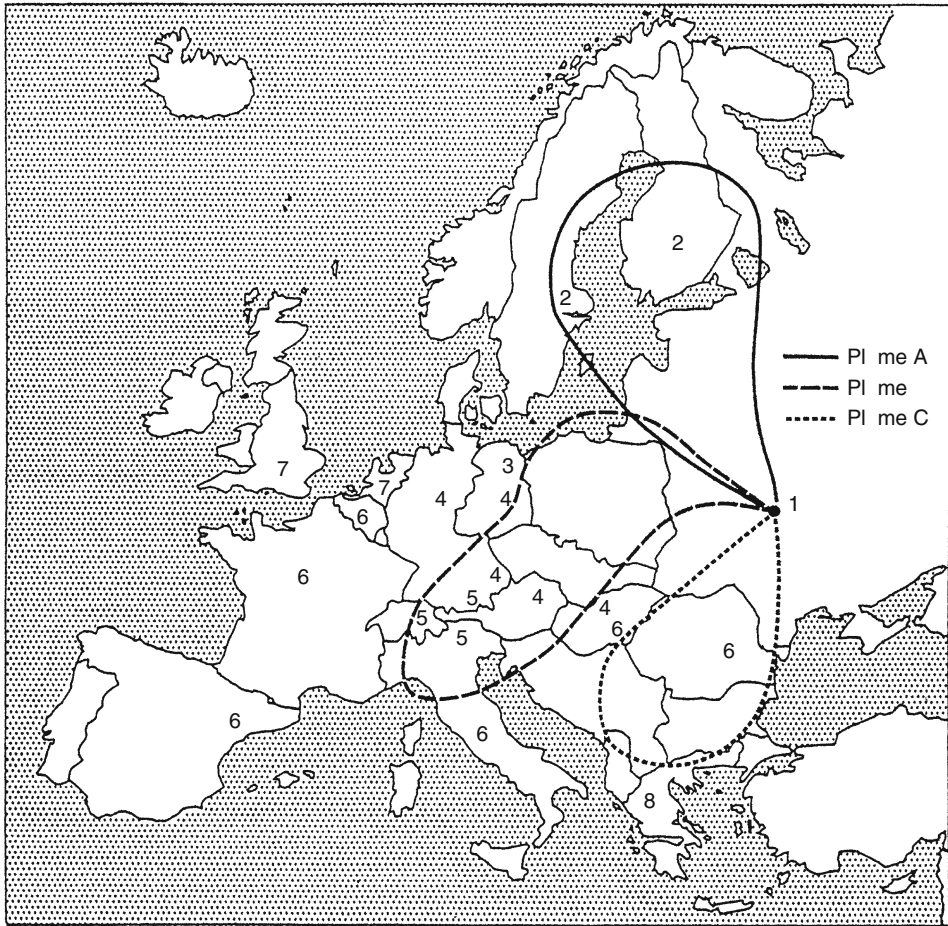

The collective effective dose (not including dose to the thyroid) received by about five million residents living in the areas of Belarus, the Russian Federation, and Ukraine contaminated by the Chernobyl accident (^{137}Cs deposition on soil of $>37 \text{ kBq/m}^2$) was approximately 40,000 man-Sv during the period 1986–1995. The groups of exposed persons within each country received an approximately equal collective dose. The additional amount of collective effective dose projected to be received between 1996 and 2006 is about 9,000 man-Sv. The collective dose to the thyroid was nearly 2×10^6 man-Gy, with nearly half received by persons exposed in Ukraine.

Army Facilities

Kyshtym On September 29, 1957, a 300-m³ tank containing high-level radioactive waste exploded, and about 90% (900 PBq) of the radionuclides in the tank were released and fallen in the area 300 km downwind over the next 11 h. Main released nuclides were $^{144}\text{Ce} + ^{144}\text{Pr}$ (66%), $^{95}\text{Zr} + ^{95}\text{Nb}$ (24.9%), $^{90}\text{Sr} + ^{90}\text{Y}$ (5.4%), $^{106}\text{Ru} + ^{106}\text{Rh}$ (3.7%), ^{137}Cs (0.036%), and trace amounts of ^{89}Sr , ^{147}Pm , ^{156}Eu , and $^{239,240}\text{Pu}$. 1,154 people lived in an area registering 40 MBq m⁻²; 1,500 in an area registering 4 MBq m⁻²; and 10,000 in an area registering 70 kBq m⁻². Within 10 days, 1,154 people escaped from the contaminated area, and in total 10,730 people escaped from that area. The collective dose is estimated to be 2,500 man-Sv in the contaminated area.

■ Fig. 55.4

Descriptive plume behavior and reported initial arrival times of detectable activity in air. Plumes A, B, and C correspond to air mass movements originating from Chernobyl on April 26, April 27–28, and April 29–30, respectively. The numbers 1–8 indicate initial arrival days from April 26 (UNSCEAR 1988c)

Windscale The Windscale (now called Sellafield) Reactor No. 1 was partially consumed by combustion in October 1957, resulting in the release of fission products to the surrounding countryside. The reactor was an air-cooled graphite-moderated natural-uranium reactor employed primarily for plutonium production. The radionuclides ^{131}I (740 TBq), ^{137}Cs (22 TBq), ^{106}Ru (3 TBq), and ^{133}Xe (1.2 PBq) were released. In addition to those fission products, 8.8 TBq of ^{210}Po was also released, because the nuclide was produced by neutron irradiation of bismuth. The released radionuclides moved from Windscale to the south, southeast, and to London, and they contaminated vast grasslands. The collective dose is estimated to be 2,000 man-Sv in the contaminated area.

Transport of Atomic Weapons

Palomares Four hydrogen bombs were released from a crashed airplane on January 17, 1966, and two fell slowly with a parachute and were recovered without damage. But the remaining two bombs crashed to the earth's surface because the parachute did not open, and their normal gunpowder exploded and considerable amounts of ²³⁹Pu and ²⁴⁰Pu were scattered in an area of 2.26 km² of urban areas and uncultivated farmlands. An area of 22,000 m² was contaminated by above 1.2 MBq m⁻² of alpha-emitting nuclides. Contaminated plants and soil (to a depth of 10 cm) were collected and treated as radioactive waste. The collective dose is estimated to be 3 man-Sv in the contaminated area.

Thule An airplane crashed on Thule in Greenland in January 1968 and four hydrogen bombs were exploded by their gunpowder. About 10 TBq of Plutonium was recovered from the snow surface, and about 1 TBq was estimated to be taken into ice. At about 20 km from the crash point, measurable plutonium was found in the summer of the year. The exposure was not estimated because the point is near the Arctic area and people do not live there.

Re-Entry of Satellites

SNAP-9A A navigator satellite was launched on April 21, 1964, but failed to reach orbital speed and reentered the atmosphere at about 45 km over Indian Ocean. The satellite carried an isotopic power unit known as SNAP-9A, which contained about 6,300 GBq of ²³⁸Pu. The ²³⁸Pu was first detected at an altitude of 30 km after 4 months, and was detected following 4 months.

The plutonium decreased exponentially with the half-life of about 14 months. The sizes of the particles ranged from 5 μm to 58 μm . The ^{238}Pu contents of ground level-air were measured and the collective effective dose from the ^{238}Pu exposure in the world is estimated as 2,100 man-Sv.

Cosmos-954 A satellite of the USSR, Cosmos-954, reentered the atmosphere over Northwest Canada on January 24, 1978. The satellite was believed to have contained 20 kg of highly enriched uranium. Released fission products were estimated since the reactor worked for 128 days at 100 kW. 75% of the particulate radionuclides were estimated to be dispersed in the atmosphere and 25% to be deposited on uninhabited regions in Northeast Canada. The vaporized radionuclides, ^{131}I and ^{137}Cs , were dispersed in the atmosphere. The collective effective dose was 20 man-Sv in the world.

Industrial and Medical Sources

Ciudad Juarez, Mexico A medical source of 16.7 TBq of ^{60}Co was discarded by mistake in December 1983 at Ciudad Juarez in Mexico, and the 6,000 pellets of that source contaminated many products of steel, which were sold in Mexico and the USA. About 1,000 people were exposed by this source and the collective effective dose was estimated to be 150 man-Sv.

Mochmedia, Morocco A ^{192}Ir source for the radiography of welding at construction sites was accidentally dropped in a street in September 1984, and a passenger picked it up and went home with it. All eight people of his household were exposed to 8–25 Sv and died, and the collective effective dose was estimated to be 80 man-Sv.

Goiania, Brazil A medical source of 50.9 TBq of ^{137}Cs was disposed of in September 1987 and was dismantled by a trader of scrap metal. Subsequently, 20 exposed people were hospitalized and 4 people died. For the decontamination, 42 houses were decontaminated and the total volume of 3,500 m^3 waste was produced and the collective effective dose was estimated to be 60 man-Sv.

Tokaimura, Japan A criticality accident took place at the Tokaimura nuclear fuel processing plant in Japan on September 30, 1999, because of improper procedures. During the 24-h event, and because of only limited shielding provided by the building, some direct irradiation was measurable outside the plant site. There was only a trace release of gaseous fission products. The collective effective dose was estimated to be 150 man-Sv. Three workers inside the plant were severely exposed (5.4 Gy of neutrons and 8.5 Gy of gamma-rays for Person A, 2.9 Gy of neutrons and 4.5 Gy of gamma-rays for Person B, and 0.81 Gy of neutrons and 1.3 Gy of gamma-rays for Person C). Person A and B eventually died of multiple organ failure after 82 and 210 days following the accident (Hirama et al. 2003).

55.5.4 Occupational Exposure

The definition of occupational exposure is given in ICRP Publication 103 as all radiation exposure of workers as a result of their work (ICRP 1997). The worldwide occupational exposures are reviewed in [Table 55.34](#).

■ Table 55.34

Worldwide occupational exposure (1990–1994), see UNSCEAR (2000v). Totals include other components as well

Practice	Number of monitored workers	Average annual collective effective dose/man-Sv	Average annual collective effective dose per unit energy generated/man-Sv (GWy) ⁻¹	Average effective dose/mSv	
				For monitored workers	Measurably exposed workers

Natural	6,500	11,700		1.8	
Total	11,100	14,000		1.26	

The monitoring practices for radiation workers differ from country to country and the dose recording and reporting practices also vary, e.g., the recording of the dose over the minimum detectable level (MDL), the subtraction of background radiation doses, whether or not internal exposures are included or treated separately.

55.5.4.1 The Nuclear Fuel Cycle

Uranium mining and milling The mining and milling of uranium ores can lead to both internal and external exposures of workers. Internal exposure may arise mainly from the inhalation of radon and its decay products. Higher doses from this source would be expected in the milling of ore and the production of yellowcake. Monitored workers number 69,000 men for mining and 6,000 men for milling and their average annual effective doses are 4.5 mSv and 3.3 mSv, respectively. Their doses are the highest except for the exposure by radon above ground. However, the exposure by radon is very obscure.

Uranium enrichment and conversion Yellowcake, U_3O_8 is converted to UF_6 and enriched in ^{235}U . The enrichment is carried out by the diffusion method or by the centrifugation of UF_6 . The occupational exposures occur during both conversion and enrichment, but average annual effective doses are rather small.

Fuel fabrication Enriched uranium gases are converted again to the metallic form or oxide fuels. The worldwide production of fuel has increased steadily and is 11.3 kt per year with equivalent annual energy figures of 210 GWy from 1990 to 1995. The average annual effective dose is 1.03 mSv.

Reactor operation The exposure doses during reactor operation also depend on the reactor types. The average annual effective doses to monitored workers are 1.34 mSv for PWR, 1.57 mSv for BWR, 1.74 mSv for HWR, and 0.54 mSv for GCR (► [Table 55.35](#)).

Fuel reprocessing Commercial-scale reprocessing of irradiated spent fuel from nuclear power facilities to recover uranium and plutonium is performed only in France and the UK. Some other countries such as Japan, India, and the Netherlands have small facilities. The used fuel elements contain high levels of radioactive materials. But remote operations and heavy shielding insure a low annual effective dose of 1.5 mSv for the workers.

Research in the nuclear fuel cycle It is difficult to estimate the level of occupational exposure to workers from research and development in the commercial nuclear fuel cycle, but evaluated from the data on those from 24 countries, the average annual effective dose is 0.78 mSv.

55.5.4.2 Medical Uses of Radiation

Diagnostic radiology Radiography is the most widely used X-ray imaging technique. Although doses to patients from diagnostic radiography may be high, the exposure of staff is usually low. The dose to a radiographer in the control booth area is typically less than 1 μ Sv for a single film taken with a technique of 80 kVp (the pressurized voltage) and 40 mAs

■ **Table 55.35**

Summary of worldwide exposure from reactor operation (1990–1994), see UNSCEAR (2000y)

Reactor type	PWR	BWR	HWR	LWGR	GCR	Total (Ave.)
Average number of reactors	242	90	31	20	38	421
Average annual energy generated/GWy	149	50	12	9.4	8.4	230
Number of monitored workers/1,000	310	160	20		30	530
Average annual collective effective dose/man-Sv	415	240	35	190	16	900
Collective effective dose per reactor/man-Sv	1.7	2.7	1.1	9.4	0.4	(2.1)
Collective effective dose per energy generated/ man-Sv (GWy) ⁻¹	2.8	4.8	3	20.3	2	(3.9)
Average annual effective dose to monitored workers/mSv	1.3	1.6	1.7		0.5	(1.4)
Annual average dose to measurably exposed workers/mSv	2.5	2.9	4.4			(2.7)

(the current). The annual average individual dose for monitored workers in diagnostic radiology is estimated to be 0.50 mSv for 630,000 workers.

Dental practice In almost every dental office, a diagnostic X-ray machine is available and frequently used. Most dental practitioners do not receive a measurable dose. The annual dose for 370,000 monitored workers is probably very low and is estimated to be 0.06 mSv.

Nuclear medicine Radionuclides used for organ imaging emit penetrating gamma radiation and give rise to an exposure of the nuclear medicine staff and other persons in the vicinity of patients undergoing diagnosis or treatment. For example, the dose rate at a distance of 1 m from a typical diagnostic patient is about $10 \mu\text{Sv h}^{-1}$ after the administration of 0.74 GBq of $^{99\text{m}}\text{Tc}$. Therapeutic administrations, e.g., 3.7 GBq of ^{131}I , give rise to a dose rate about $200 \mu\text{Sv h}^{-1}$ at 1 m from the patient. Then the annual average individual dose of 115,000 workers in this field is 0.79 mSv, which is the highest in the group of medical workers.

Radiotherapy Radiotherapy is an important treatment modality for malignant disease. The annual average effective dose to monitored workers in radiotherapy fell over the four 5-year-periods (from 1975 to 1994) consistently with the values of 2.2 mSv, 1.6 mSv, 0.87 mSv, and 0.55 mSv. Some of this decrease will have been due to improvements in radiological protection arrangements, following the replacement of many ^{226}Ra sources by ^{137}Cs and the widespread use of remote handling after loading the equipment.

55.5.4.3 Industrial Use of Radiation

Industrial irradiation There are 160 gamma-irradiation facilities and over 600 electron-beam facilities in operation in the world. Most facilities are for the sterilization of medical and pharmaceutical products, the preservation of foodstuffs, polymer synthesis and modification, and the eradication of insect infestation. Dose rates in the irradiation chamber would be of the order of 1 Gy s^{-1} . Therefore, there is a need for sophisticated engineered safety systems, and during normal usage the exposure of workers should be very low. The average annual effective dose of 57,200 monitored workers in 15 countries is 0.10 mSv.

Industrial radiography Industrial radiography is carried out in two different ways. In the first case, the source is located in a facility and the items to be radio-graphed are brought to the facility. In the second case, the source is brought to the location where the radiography is required. The most common sealed sources are 1.8–4.4 TBq of ^{192}Ir , 0.3 GBq of ^{60}Co , and 0.3–80 GBq of ^{137}Cs .

In fixed radiography facilities, the shielding and engineered safety systems should ensure low doses, but site radiography is often undertaken in remote, difficult, or even hostile environments. In addition, the supervision tends to be poor. The average annual effective dose for monitored workers is 1.58 mSv and that for the measurably exposed workers is 3.17 mSv, which is considerably higher and may be attributed to high exposure rates to workers of site radiography.

Radionuclide production and distribution Radionuclides are produced for a great variety of industrial and medical purposes. This industry is mature and well established, with multinational companies replacing the often nationally focused entities that prevailed in earlier years. In the manufacture and processing of radionuclides there is the potential for both internal and external exposure, but the internal component is not always apparent. In general, the contribution of internal exposure to the total was reported to be a few percents. The monitored workers' dose rate is rather small, but the average annual effective dose is 1.93 mSv, which is larger than that for radiography.

Others In the fields of luminizing, well logging, and accelerator operating, occupational radiation exposures are observed. Radioactive materials have been used in luminizing, but the shift from radium to tritium reduced the occupational dose significantly. Both gamma and neutron sources are used in well logging. The annual effective dose to monitored workers for 1990–1994 is 0.36 mSv. The distribution ratios of the effective doses indicate that the majority get a low dose, but some receive more significant doses.

55.5.4.4 Natural Sources of Radiation

Aircrew An aircrew is exposed to elevated levels of cosmic radiation, and ICRP Publication 60 (ICRP 1991a) recommended that the exposure of the aircrew in a jet aircraft should be treated as an occupational exposure. The effective dose rate at an altitude of 8 km in temperate latitudes is typically up to about $3 \mu\text{Sv h}^{-1}$, and at 12 km about $6 \mu\text{Sv h}^{-1}$. The effective doses in one flight on short-haul routes for 70–190 min are 3–10 μSv , and those on long-haul routes for 450–760 min are 25–70 μSv . The average annual effective dose is typically 1–2 mSv for those on short-haul flight and 3–5 mSv for those on long-haul flights. The average annual effective doses of aircrews in civil aviation are in the range of 2–4 mSv for 27,300 persons, measured mainly in the UK.

Mining and the processing industries The main source of radiation exposure in most mining operations is radon. The levels of radon in workplaces are exceptionally variable. Mining is an extensive industry, and there are about 4.7 million underground miners worldwide, and about 84% of them are engaged in coal mining. The exposure to radon progeny depends on a number of factors, including the type of mine, the geology, and the working conditions, particularly the ventilation. The average effective dose to coal miners from radon was 0.7 mSv in 1990–1994. A survey of non-coal mines that covers about 1,300 miners indicated an average annual dose of 2.7 mSv.

Exposures to radon progeny may be important in some above ground workplaces. Radon exposures are largely determined by the geology underlying the building, its construction, and the ventilation. These exposures are estimated to contribute to the annual average effective dose of 4.8 mSv, which is the largest dose in occupational exposure. But this is clearly very obscure and country-to-country variable such as geology, building material, configurations, and regulations could have a significant effect.

Totally 4.6 million people are exposed to 0.6 mSv from man-made sources and 6.5 million people are exposed to 1.8 mSv from natural sources.

55.6 Measures in Nuclear Emergency

55.6.1 Averted Dose and Action Levels

55.6.1.1 Principles for Intervention in Emergency

In accidents, there is a possibility for deterministic (non-stochastic) and stochastic health effects. The principles for planning intervention in the case of a radiation emergency are set out in ICRP Publication 60 and 63 (ICRP 1991a, b, respectively). Intervention is the term applied to steps taken, in an accident situation, to restrict the exposure of member of the public and to minimize the consequences of unavoidable exposure. The assessment of the radiological situation and the implementation of the individual protection measures make up an overall protection strategy that is recommended to be justified and optimized. In the process of optimization, reference levels are to be applied and particular attention should be given to the prevention of severe deterministic health effects.

Emergency response is a process that develops in time according to the different phases of the emergency exposure situation:

1. *The early phase* is the period from the time when potential for off-site exposure of the public is recognized, to the time when significant amounts of radioactive material are released, and the first few hours after the commencement of that release.
2. The second stage, *the intermediate phase*, covers that period of time from the first few hours to a few days after the onset of the accident. It starts with the cessation of any release and regaining control of the source of releases.
3. The third stage, *the late or recovery phase* is the one in which decisions are made concerning the return to normal living conditions and it may extend over a prolonged period.

55.6.1.2 The Concept for Intervention

The *projected dose* (PD) is the overall exposure to the population, which is projected to occur as a result of the exposure situation if no protective actions are implemented and should first be estimated for each exposure pathway (ICRP 1991b). The dose that would result when the protection strategy is implemented is called the *residual dose* (RD). The difference dose from each pathway (projected dose minus residual dose) is called the *averted dose* (AD). This is the dose saved by implementing a given protective action and is the concept for the optimization of the protective measures that will make up the overall protection strategy.

55.6.2 Categorization of Radiological Emergencies for Planning Intervention

Radiological emergencies are classified according to exposure pathways. Exposure of the public and workers to radiation following an accident may be either external or internal, or both and may be incurred by various pathways. The pathways of external exposure are derived from the source or the facility, the plume, the radionuclide contamination on surfaces, and radionuclide contamination of skin and clothing. Those of internal exposure are the inhalation of radionuclides in a plume, the inhalation of re-suspended radionuclides, the ingestion of

contaminated food and water, the ingestion of radionuclides from contaminated materials, and the absorption through skin and wounds.

The temporal and spatial aspects of radiological emergencies are also important in planning the appropriate emergency response. The protective actions for averting exposure via various pathways are as follows (ICRP 1991c).

Control of access External irradiation from the source, plume, and/or radionuclides (abbreviated as RI from radioisotope) deposited.¹⁵

- Inhalation or ingestion of RI in the plume and/or re-suspended RI.
- External contamination of the individual.

Shielding External irradiation from the source, plume, and/or RI deposited.

Protective clothing External contamination.

Sheltering External irradiation from the source, plume, and/or RI deposited.

- Inhalation of RI in the plume.
- External contamination of individuals.

Evacuation External irradiation from the source, plume, and RI deposited.

- Inhalation or ingestion of RI in the plume and/or re-suspended RI.
- External contamination of individuals.

Stable iodine administration Inhalation of radioiodine in the plume.

Decontamination of individuals and clothing External contamination.

Intervention in food chain and water supply Ingestion of RI.

- Restriction on food and water, banning consumption, processing of food/water.
- Decreasing RI incorporation into the food chain, alternative fodder, binders, deep plowing and other change in agricultural practice, temporary fixation in ground (e.g., spraying): inhalation of re-suspended RI.

Relocation External irradiation from RI deposited on the ground.

- Inhalation and ingestion of re-suspended RI.

Decontamination of materials and controls on use of contaminated materials Inadvertent ingestion.

Decontamination of ground and other surfaces External irradiation

- Inhalation of re-suspended RI.

55.6.3 Intervention Levels

For intervention measures, it is important that subjective judgments are made within a widely agreed framework. For this reason, national and international organizations have published generic guidance on dose criteria for intervention, particularly for intervention following accidents.

They have produced some recommended generic intervention levels, these levels satisfy the basic principles in that deterministic effects are avoided and the intervention is justified in generic terms that the risks of implementing the interventions are less than the risks of the dose that would be received.

The intervention levels of averted doses recommended by ICRP are those at which intervention is almost always justified. In the early phase, these doses are 50 mSv for sheltering, 500 mSv equivalent dose to thyroid for administration of stable iodine, 500 mSv (1 week) whole body dose or 5,000 mSv equivalent dose to skin for evacuation (ICRP 1991d). For the late phase countermeasures 1,000 mSv for relocation (5–15 mSv per month for prolonged exposure), and 10 mSv (in 1 year) for restriction to a single foodstuff (1,000–10,000 Bq kg⁻¹ for beta/gamma emitters and 10–100 Bq kg⁻¹ for alpha emitters) are recommended.

55.6.4 Protection of Workers for Intervention

The working conditions in relation to the actions required following an accident are divided into three categories (ICRP 1991d).

Category 1 (Urgent action at the site of the accident.) Workers in this category must act to save life, to prevent serious injuries, or to prevent a substantial increase in potential doses to members of the public. They should keep the doses below 1 Sv effective dose or 5 Sv equivalent dose to skin for all actions except life-saving action.

Category 2 (Implementing early protective actions and taking action to protect the public.) This group consists of workers who will incur additional exposure in order to avert doses to the public, such as police, medical personnel, drivers, and crews of vehicles used for evacuation and similar group. Ideally, the aim should be to keep the doses below those permitted in normal conditions.

Category 3 (Recovery operation.) The workers of this category undertake recovery operations. The actions required may include repairs to plant and building, waste disposal, decontamination of the site, and the surrounding area. The workers in this group should be subjected to the normal system of radiological protection for occupational exposure.

55.7 Editors' Notes

1. NAA including RNAA is detailed in ➤ Chap. 30 in Vol. 3 on “Activation Analysis” (p. 2506).
2. See ➤ Chap. 13 in Vol. 2 on “Natural Radioactive Decay Chains” (p. 2506).
3. See ➤ Chap. 12 in Vol. 2 on “The Origin of the Chemical Elements” (p. 2507).
4. See ➤ Chap. 17 in Vol. 2 on “Radioactive Dating Methods” (p. 2507).
5. See ➤ Table 61.3 in Chap. 61 in Vol. 6 on “Radioactive Waste Management” (p. 2507).

6. The concentration factor for aquatic biota is defined by [▶ Eq. \(55.3\) in Sect. 55.4.2.](#) (p. 2508).
7. As regards the other nuclide, ^{127}I , it is the only stable isotope of iodine. On the other hand, the time elapsed since the Earth was formed ($\sim 4.5 \times 10^9$ years) leaves about 280 half-lives for ^{129}I to be erased from the planet. Assuming an initial $^{129}\text{I}/^{127}\text{I}$ ratio of 1, the present ratio would be $\sim 5 \times 10^{-85}$ compared to which the value 10^{-12} is really enormous (p. 2509).
8. ^{129}I together with ^{129}Xe could also make a precise geochronometer as mentioned in [▶ Chap. 17](#) in Vol. 2 on “Radioactive Dating Methods” (p. 2510).
9. Exposure in general and dose-related quantities and units are detailed in [▶ Chap. 47](#) in this Volume on “Dosimetry and Biological Effects of Ionizing Radiation” (p. 2527).
10. For the explanation of the historical names of radon isotopes such as “thoron” (^{220}Rn) and “radon” (^{222}Rn) see the introduction of [▶ Chap. 13](#) in Vol. 2 on “Natural Radioactive Decay Chains” (p. 2531).
11. See [▶ Fig. 4.10 in Chap. 4](#) in Vol. 1 on “Nuclear Fission” (p. 2540).
12. Ternary decay is discussed in detail in [▶ Sect. 4.4.4, Chap. 4](#), Vol. 1 (p. 2540).
13. For more details see [▶ Sect. 57.4 in Chap. 57](#) in Vol. 6 on “Technical Application of Nuclear Fission.” See also [▶ Sect. 58.2 in Chap. 58](#) in Vol. 6 on “Developments and Tendencies in Fission Reactor Concepts” (p. 2544).
14. See also [▶ Chap. 61](#) in Vol. 6 on “Radioactive Waste Management” (p. 2546).
15. In various applications, and particularly in nuclear medicine, the term radioisotope is used in the sense “radionuclide” (p. 2559).

[†]Deceased

56.1 Standards for Detector Calibration

Richard B. Firestone · Gábor L. Molnár

56.1.1 X- and Gamma-Ray Sources

56.1.1.1 Wavelengths and Energies

The latest values of the fundamental constants for *X-ray standards* are grouped in ▶ [Table 56.1](#). The conversion of wavelengths to energies in keV is done by multiplying the reciprocal wavelength with the conversion factor $1.239841857(49) \times 10^{-9}$ keV m (Mohr and Taylor 1999, 2000; CODATA 2003). The database of X-ray wavelengths for elements (Bearden 1967) has recently been updated, adjusted to the new standards, and compared with new calculations using the Dirac–Fock method (Deslattes et al. 2003a). Their values of X-ray energies for neon ($Z = 10$) to fermium ($Z = 100$) are also available on the Internet (Deslattes et al. 2003b).

The most accurate γ -ray energies have been measured with crystal spectrometers and rely on the Si lattice constant (see ▶ [Table 56.1](#)). In their evaluation of *γ -ray energies for calibration standards*, Helmer and van der Leun (2000) used the 1986 values of the fundamental constants. Using their published data it can be estimated that after the adjustments of lattice parameter and conversion factor the energy of the ^{198}Au decay γ -ray, used as the standard, decreases from 411.80205(17) keV to about 411.80176(12) keV, i.e., by only 0.3 eV (0.7 ppm). This change is less than twice the standard uncertainty, hence the recommended energy values in Helmer and van der Leun (2000), relying on this standard, are practically unaffected.

■ Table 56.1

Fundamental constants for X-ray standards (Mohr and Taylor 1999, 2000)

Quantity	Symbol	Value	Unit	Relative std. uncert. u_r
Cu x unit: $\lambda(\text{CuK}\alpha_1)/1\,537.400$	$xu(\text{CuK}\alpha_1)$	$1.00207703(28) \times 10^{-13}$	m	2.8×10^{-7}
Mo x unit: $\lambda(\text{MoK}\alpha_1)/707.831$	$xu(\text{MoK}\alpha_1)$	$1.00209959(53) \times 10^{-13}$	m	5.3×10^{-7}
Ångstrom star: $\lambda(\text{WK}\alpha_1)/0.2090100$	\AA^*	$1.00001501(90) \times 10^{-10}$	m	9.0×10^{-7}
Lattice parameter ^a of Si (in vacuum, 22.5°C)	a	$543.102088(16) \times 10^{-12}$	m	2.9×10^{-8}
{220} lattice spacing of Si: $a/\sqrt{8}$ (in vacuum, 22.5°C)	d_{220}	$192.0155845(56) \times 10^{-12}$	m	2.9×10^{-8}
Molar volume of Si: $M(\text{Si})/\rho(\text{Si}) = N_A a^3/8$ (in vacuum, 22.5°C)	$V_m(\text{Si})$	$12.0588369(14) \times 10^{-6}$	m ³ /mol	1.2×10^{-7}

^a This is the lattice parameter (unit cell edge length) of an ideal single crystal of naturally occurring Si free of impurities and imperfections, and is deduced from lattice spacing measurements on extremely pure and nearly perfect single crystals of Si by correcting for the effects of impurities.

■ Table 56.2

Some radionuclides recommended for calibration of γ -ray detectors

Nuclide	Half-life ^a	Decay mode	Source type	E_{\min}	E_{\max}
²² Na	2.6027 (10) a	β^+	s	511	1,275
²⁴ Na	14.9574 (20) h	β^-	s	1,369	2,754

56.1.1.2 Energy and Intensity Standards

For the calibration of γ -ray detectors, easily produced radionuclides with convenient decay half-life and accurately known *photon energies* and *emission probabilities* or intensities are needed. For many years, the X- and γ -ray standards recommended by the International Atomic Energy Agency (IAEA) have been the most widely accepted choice. As a result of a coordinated research project, the 1991 recommendations (IAEA 1991) are being replaced by a new set of standards data for 64 radionuclides as well as nuclear reactions producing high energy γ -rays (IAEA 2002, 2003). This program has greatly benefited from the parallel effort of the Decay Data Evaluation Project (DDEP) involving about 250 radionuclides (Browne et al. 2001). The data presented here are preliminary values for a subset of nuclides. More details and more nuclides can be found on the DDEP Web site (DDEP 2003), part of which has been published (Bé et al. 1999a, b).

► **Table 56.2** summarizes the main characteristics of the selected *standard radionuclides*. Those labeled with “s” are simple sources emitting one or two γ-rays. Many of them are primary standards with extremely simple decay schemes, for which the relationship between the source activity and the γ-ray emission probability can be derived without any *a priori* knowledge of detection efficiencies. Hence, primary sources with accurately calibrated activity are suitable for absolute *detector efficiency calibrations*. Those sources labeled with “m” are multi-gamma emitters, practical for the calibration of high-resolution detectors, such as Si(Li) and high-purity Ge detectors. The energies and emission probabilities of the strongest X- and γ-rays are presented separately for simple and multi-gamma sources in ► **Tables 56.3** and ► **56.4**, respectively. The data are from the recent evaluation (IAEA 2003; DDEP 2003), unless noted otherwise. For the X-rays the mean energies were obtained by Schönfeld and Rodloff (1999) from the data of Bearden 1967, while the emission probabilities per

disintegration were calculated by Schönfeld and Janssen (2000). Only the strongest $K\alpha_1$ and $K\alpha_2$ lines are listed. In some cases, these lines cannot be resolved. Therefore, their summed intensity at the mean energy is also included, which is the intensity-weighted sum of $E(K\alpha_1)$ and $E(K\alpha_2)$.

56.1.2 Electron and Alpha Sources

For the calibration of charged-particle detectors, emission characteristics of some convenient *conversion electron* and *alpha decay sources* are presented in ► [Tables 56.5](#) and ► [56.6](#), respectively.

The electron data are extracted from the recent evaluation of X- and γ -ray standard sources (IAEA 2003; DDEP 2003). Only the K conversion electrons are given, since those are the most intensive.

For alpha emitters the energy and branching percentage data come from the latest Table of Isotopes (Firestone et al. 1996). The half-lives were obtained from Tuli 2000. More details about the decay characteristics of these nuclides can be found in the Appendix of Vol. 2.

56.2 Fission Product Yields

Richard B. Firestone

► [Table 56.7](#) lists independent *fission product yields* (England and Rider 1994) per 100 fissions for the most important fissionable nuclides. For ²³⁵U thermal, fast neutron (fission spectrum), and high-energy neutron (14 MeV) induced, for ²³⁸U fast neutron induced, for ²³⁹Pu thermal neutron induced, and for ²⁵²Cf spontaneous fission data are provided. Fission yield measurements from the literature and calculated charge distributions were used to produce this recommended set of yields for the fission products. The full data set can be found in the report by England and Rider (1994), which also serves as the primary documentation for the second evaluation of fission yields in the nuclear data library ENDF/B-VI released in 1993.

Table 56.7

57.7 *Editors' Notes* 2660

Abstract: The chapter is devoted to the practical application of the fission process, mainly in nuclear reactors. After a historical discussion covering the natural reactors at Oklo and the first attempts to build artificial reactors, the fundamental principles of chain reactions are discussed. In this context chain reactions with fast and thermal neutrons are covered as well as the process of neutron moderation. Criticality concepts (fission factor η , criticality factor k) are discussed as well as reactor kinetics and the role of delayed neutrons. Examples of specific nuclear reactor types are presented briefly: research reactors (TRIGA and ILL High Flux Reactor), and some reactor types used to drive nuclear power stations (pressurized water reactor [PWR], boiling water reactor [BWR], Reaktor Bolshoi Moshchnosti Kanalny [RBMK], fast breeder reactor [FBR]). The new concept of the accelerator-driven systems (ADS) is presented. The principle of fission weapons is outlined. Finally, the nuclear fuel cycle is briefly covered from mining, chemical isolation of the fuel and preparation of the fuel elements to reprocessing the spent fuel and conditioning for deposit in a final repository.

57.1 Introduction

The impact of nuclear fission on the human way of life is due to the fact that the fission process can be organized in such a way that a self-propagating chain reaction proceeds. This is because the one neutron normally required to induce a fission reaction in a nucleus, like ^{235}U or ^{239}Pu , sets free two to three neutrons that can induce new fission reactions (see [Chap. 4 in Vol. 1](#)). Therefore, in contrast to all other nuclear reactions observed before, macroscopic amounts of matter (up to tons) can undergo nuclear reactions with dramatic consequences. In nuclear reactors (power stations), large amounts of fissile material are burned producing a substantial part of the world's supply of electric energy. Nuclear reactors are used for the mass production of radioisotopes required in medical diagnosis and therapy and in modern technology. Research reactors are used as intense sources of neutrons allowing for neutron diffraction studies that have contributed immensely to the knowledge of the structure of molecules important to chemistry and biology or to the development of new materials. On the other hand, nuclear weapons have changed the military and political equilibrium between nations.

57.2 Historical Aspects

57.2.1 Oklo

A surprising answer to the question as to when the first nuclear reactor was operating was found in the year 1972 by a group of scientists working for the French nuclear weapons program: the first nuclear reactor was operating 2 billion years ago in Africa in a place now called Oklo in the state of Gabon (IAEA 1975; Cowan 1976; Roth 1977).

Different sites have since been found west of Franceville, Gabon, in which the fission reaction occurred. These sites possess rich ore deposits of nearly pure $\text{UO}_2/\text{U}_3\text{O}_8$ that have been formed hydrolytically. Nuclear fission took place in an area containing 500 t of uranium that – at the time – was about 4% in ^{235}U . (Due to the shorter half-life of ^{235}U [7.0×10^8 years] relative to ^{238}U [4.5×10^9 years], the content of ^{235}U in natural uranium has sunk meanwhile to the present value of 0.7%.) The most important of the natural reactors was in operation for at

least 150,000 years and resulted in a production of energy of about 15,000 megawatt-years (MW-years). This would correspond to the output of a modern nuclear power station over a 5-year period.

The discovery of the reactors reminds one of a detective novel. The initial observation was an irregularity in UF_4 , an intermediate product: some samples of UF_4 analyzed on 25 April 1972 showed a weak deficit in ^{235}U (0.7171% differing from the natural value of 0.7207%). (UF_4 is oxidized by F_2 to form UF_6 , a stable compound with a sublimation point of 56°C , which is then used for isotopic enrichment in the diffusion process.) After this first alarm had sounded, evoking the possibility that natural uranium had been thinned by depleted material and, hence, the possibility of fraud or divergence, other samples, a few days later, showed values even less than 0.71%. (Later, in specific samples even values of 0.296% were observed.) The puzzle could however be fairly quickly solved as a large stock of samples of all the batches, from the mined ores to the end products, had been saved. It was soon clear that the low values of ^{235}U were present already in the original ore and the ore could not possibly have been manipulated.

The idea for a possible reason came from the observation that the deficits in ^{235}U (and even deficiencies larger than previously observed) were correlated to the content of the ore in uranium. Such a correlation is to be expected since the criticality depends directly on the amount and concentration of uranium and an ongoing fission process would consume the isotope ^{235}U . In later studies the isotopes produced in fission or their decay products could be detected (IAEA 1975; De Laeter 1988). The composition and amount of fission products allowed for a calculation of the total amount of uranium that underwent fission and, hence, the total amount of energy set free.

As an illustration of the way to disentangle the events that had taken place 2 billion years ago, the measurement of the neodymium isotopes (142–146, 148, and 150) will be presented. It is important to know that neodymium remained in the rocks without migrating. In addition, it is advantageous that the content of natural neodymium in the minerals is small. This content could be determined since ^{142}Nd is practically not formed in nuclear fission. As it results from the systematics of fractional fission yields (see [Chap. 4 in Vol. 1](#)), the (independent, direct) yield of ^{142}Nd is very small. An alternative formation by the β decay of more neutron-rich nuclides of the same mass (i.e., isobars) is not possible because the direct precursor ^{142}Ce is stable. Consequently, the content of the mineral in ^{142}Nd reflects the amount of natural neodymium not produced by fission. Using the known isotopic composition of natural neodymium, the contributions of natural origin of all neodymium isotopes could be subtracted. This is illustrated in [Table 57.1](#) (Columns 1–3).

In addition to correcting the concentrations for Nd of natural origin, corrections have to be made due to neutron capture by Nd isotopes in such a natural reactor. The process is particularly pronounced for ^{143}Nd , which, due to its high neutron capture cross section of $\sigma = 3.25 \times 10^{-22} \text{ cm}^2$, is transformed to ^{144}Nd to a noticeable extent. Correction of column (3) for this effect results in the values given in column (4). A comparison of the values in column (4) with corresponding values obtained from the neutron-induced fission of ^{235}U shown in column (5) shows nearly perfect agreement.

The correction required for the amount of ^{144}Nd (Column 3 and 4) is based on a total neutron dose (fluence) of $1.5 \times 10^{21} \text{ n/cm}^2$ and, hence, gives an estimate for this value.

The total amount of fission reactions that have occurred and the corresponding total amount of energy set free could be calculated from the amount of neodymium from fission (or other fission products) using the known fission yields. It was determined that the energy produced was the value of 15,000 MW-years given above.

■ Table 57.1

Isotopic composition of neodymium of different provenience (at%) (1) Natural Nd; (2) Sample from Oklo; (3) Sample from Oklo after correction for natural Nd; (4) Column (3) corrected for neutron capture; (5) Nd from the fission of ^{235}U

A	(1)	(2)	(3)	(4)	(5)
142	27.11	1.4	0.0	0.0	0.0
143	12.17	22.1	22.6	28.6	28.84
144	23.85	32.0	32.4	26.4	26.50
145	8.30	17.5	18.0	19.0	18.87
146	17.22	15.6	15.6	14.6	14.42
148	5.73	8.0	8.1	8.1	8.26
150	5.62	3.4	3.3	3.3	3.12

The energy set free allows the calculation of the amount of uranium that underwent fission. The deficit in ^{235}U found today (present natural content 0.7207% minus the experimentally determined content) is too small by about a factor of 5. Using the variation of the isotopic ratio of ^{235}U to ^{238}U (that can be calculated from the respective half-lives), one can determine the time when the natural reactors were operating. The result is 2×10^9 years before present. At that time the ^{235}U content in natural uranium amounted to 3.6% – a concentration used in present-day light-water reactors. A few corrections have to be taken into account in these calculations. First, in a natural reactor, like in present-day artificial reactors, some fast neutrons can induce fission also in ^{238}U . In addition, part of the ^{238}U is converted to ^{239}Pu through neutron capture and subsequent β decays. The plutonium can undergo fission itself or – in case of low neutron flux – decay to ^{235}U . Finally, as will be discussed later, in about 17% of the cases the excited nucleus of $^{236}\text{U}^*$ formed by the neutron capture of ^{235}U will not undergo fission but will emit a γ ray and form long-lived ^{236}U ($T_{1/2} = 2.3 \times 10^7$ years). In the time span of the 2×10^9 years since these reactors stopped working this uranium isotope has decayed to ^{232}Th . This thorium isotope was also found at the reactor site.

A question arises with regard to maintaining long-term stable operation of the natural reactors. As it will be pointed out below, a reactor of the given composition can operate only with thermal neutrons, i.e., the neutrons emerging from the fission reaction with an energy around 2 MeV have to be slowed down to thermal energies. In the Oklo reactors water served as a moderator. The amount of water present within the reactor zone determined the reactivity of the reactors. If sufficient water was present, the neutrons were well moderated and the fission rate was high. This led to an increase of the temperature in the zone and to an evaporation of water, hence decreasing the neutron moderation and fission rate. Consequently, the reactor zone cooled down allowing water to enter again. A new cycle then started.

The arguments raised above were also used to estimate the duration of the operation of natural reactors. Using the known heat conductivity of the minerals in the zones one can estimate that the maximum power of the reactors was about 0.1 MW in order to allow sufficient water to be present. For a total energy of 15,000 MW-years this corresponds to a duration of 150,000 years. This value is a lower limit because it cannot be excluded that due to some external influences, like the lack of sufficient water, the reactors were stopped for some periods.

Besides being of academic interest, Oklo is a model for very old deposits of fission products and of ^{239}Pu , and allows for a study of the long-term behavior of radioactive elements in nature. The study reveals that plutonium, in spite of the presence of water, did not show a migration in the loamy sediments. Even a relatively mobile element, like strontium, that is ecologically important due to its long-lived isotope ^{90}Sr (28.5 years) remained essentially within the reactor zone until it had decayed (IAEA 1975; Cowan 1976).

57.2.2 First Attempts to Build Artificial Reactors

Not even a year after the discovery of nuclear fission it became established that in the process neutrons were set free (Anderson et al. 1939; von Halban jun et al. 1939) opening the way to chain reactions and to speculations concerning the production of almost unlimited amounts of energy (Flügge 1939).

Only 3 years later, in 1942, Fermi set up a test version of a nuclear reactor (under the west stands of Stagg Field, University of Chicago). Unfortunately no photograph exists of this reactor. [▶ Figure 57.1](#) shows a sketch of the set up.

Initially, it was planned to build an array of blocks of natural uranium metal surrounded by blocks of graphite. Since the amount of metallic uranium available was not sufficient, at last mainly uranium dioxide was used (total amount: 40 t of uranium and 385 t of graphite). When the critical state was nearly reached, the control rod was pulled out slowly and in portions while the neutron flux was measured continuously. The record of the neutron flux just before reaching criticality is shown in [▶ Fig. 57.2](#).

One observes that as the control rod is removed little by little, an increase in neutron flux takes place that leads to a new equilibrium value. As it will be pointed out quantitatively later,

■ **Fig. 57.1**

An artist's conception of the first chain-reacting assembly built under the west stands of Stagg Field, University of Chicago (Glasstone 1967)

■ Fig. 57.2

Record of neutron intensity obtained with the first chain-reacting system on 2 December 1942 (Glasstone 1967)

the reactor operates in this region as an amplifier (amplifying the neutron flux from a small neutron source kept inside). At the position marked “self-sustaining reaction” an exponential rise of the neutron flux with no indication of leveling off is observed. The reactor is said to have reached criticality (or better to have passed criticality by a minute amount). Without outside interference its power will increase indefinitely.

At this point the chain reaction was interrupted by introducing the control rod in order not to expose the participants to dangerous levels of radiation from this unshielded reactor.

Some attempts to build a nuclear reactor were also made in Germany during World War II in the city of Haigerloch near Tübingen. The concept was based on a combination of heavy water (D_2O) and natural uranium. The location was later transformed into the museum “Atom Museum, Haigerloch” with a display of the initial setup. It also commemorates the “Alsos” project in which US troops in a holdup action had collected scientists and material circumventing the German–French front line.

Today the type of heavy-water-moderated reactor with natural uranium still exists in the form of the CANDU-reactor (CANadian Deuterium Uranium reactor). The graphite-moderated reactor of Fermi has found application mostly in the former Soviet Union (RBMK Series). Of these reactors reactor block No. 4 in Chernobyl has become ill famed for the most severe accident in reactor history (see ▶ Sect. 55.5.3.2 in Chap. 55, Vol. 5). The reactor type that has been generally adopted due to technical and economical reasons is the light-water-moderated reactor based on uranium with an enrichment of 3–4% in ^{235}U . It has been realized in two modifications: the boiling water reactor (BWR) and the pressurized water reactor (PWR). An alternative that is theoretically very tempting but has encountered many difficulties in realization is the fast breeder reactor (FBR).

The principle of reactor operation and the different reactor types will be discussed in the following. Neutrons are the most important agent in driving a reactor. Also neutrons for the scientist are the most important product of a research reactor, because they can be used for various analytical purposes (neutron activation analysis, structural analysis through neutron diffraction, etc.). Therefore, at first, some neutron physics will be presented as of relevance for the existing two main types of reactors (“thermal” and “fast”).

57.3 General Principles of Reactor Design

57.3.1 Thermal and Fast Reactor Types – Neutron Physics in a Reactor

The difference between thermal (e.g., light-water reactors) and fast reactors (fast breeder, nuclear weapons) is in the energy of the neutrons inducing the fission reaction. The reason for the distinction is the reaction cross sections for fission in ^{235}U (^{239}Pu) and for competing (n,γ)-reactions mainly in ^{238}U , the main component of the fuel elements.

For neutron energies from thermal (0.025 eV) up to about 1 eV, the fission cross section of ^{235}U and ^{239}Pu is about 100 times higher than the parasitic (n,γ)-cross section of ^{238}U that consumes neutrons without contributing to the chain reaction. In the energy range from 10 to 10^4 eV on the other hand, the (n,γ)-cross section of ^{238}U is by about a factor of 10 higher than the fission cross section of ^{235}U and ^{239}Pu . At neutron energies above 10^4 eV, and particularly above 10^6 eV, the fission cross section dominates again (Choppin and Rydberg 1980; Mughabghab et al. 1981). The consequence is that a chain reaction – in a mixture of about 3% ^{235}U (or ^{239}Pu) and 97% ^{238}U – is possible at low neutron energies (<1 eV) and at high energies (> 10^5 eV), but at intermediate energies the neutrons required to maintain a chain reaction are absorbed by the reaction of $^{238}\text{U}(\text{n},\gamma)^{239}\text{U}$. Consequently, a reactor must be built in such a way that neutrons, originating from the fission reaction, with an energy of about 2 MeV are moderated down to energies below 1 eV as fast as possible, or alternatively any moderation of the neutrons must be avoided. These two (ideally) disjunct energy ranges are distinctive features of the two main types of reactors, i.e., “thermal” and “fast.” Energy spectra of neutrons in different chain reacting systems are shown in [Fig. 57.3](#).

A typical neutron spectrum in a light-water reactor can be compared to the spectra of neutrons (a) as they originate from the fission reaction, (b) as they are found in a fast reactor, and (c) in a fission weapon. As it is customary, in [Fig. 57.3](#) the relative number of neutrons is multiplied by their energy and the product “flux energy” is plotted as a function of the neutron energy. Hence the line parallel to the “neutron energy” axis and labeled “thermal reactor” represents an exponential decrease of the absolute flux over 8 decades.

In principle, in a reactor, three components of the neutron energy spectrum ([Fig. 57.3](#)) can be distinguished (Erdtmann 1976; Erdtmann and Petri 1986):

1. Completely moderated, “thermal” neutrons (Maxwell distribution in [Fig. 57.3](#))
2. Epithermal neutrons (roughly “thermal reactor” from 0.5 eV to ~0.1 MeV)
3. Fast (unmoderated) neutrons

These three components are found in practically every reactor. Each one of these components has a well-defined energy distribution that will be described next. The contributions of the components vary from reactor to reactor. The distribution designated “Thermal Reactor” in

Fig. 57.3

Neutron spectra of some chain-reacting systems (Choppin and Rydberg 1980). The vertical axis shows the “flux energy,” i.e., the product of neutron flux and neutron energy¹.

Fig. 57.3 represents a fairly “hard” neutron spectrum. Normally, the Maxwell distribution of the fully moderated neutrons dominates the spectrum at low neutron energies.

57.3.1.1 Thermal Neutrons

The spectrum of thermal neutrons is characterized by an equilibrium of the neutrons’ kinetic energy with that of the surrounding moderator. Like for any gas the speed distribution can be described by the “Maxwell equation”:

$$\frac{dn}{du} = \frac{4n}{u_0^3 \sqrt{\pi}} u^2 \exp\left(-\frac{u^2}{u_0^2}\right) \quad (57.1)$$

where n is the number density of neutrons, u is the speed, and u_0 is the most probable speed of neutrons (at $T = 20^\circ\text{C}$ $u_0 = 2,200$ m/s). The most probable velocity of 2,200 m/s corresponds to a neutron kinetic energy of

$$E_n = \frac{m_n u_0^2}{2} = 0.0253 \text{ eV} \quad (57.2)$$

where m_n is the mass of neutron.

57.3.1.2 Epithermal Neutrons (Resonance Region)

The neutron flux above 0.5 eV is characterized by an $1/E$ law. This also appears in Fig. 57.3 showing that the product of neutron flux and energy is constant from 10^{-2} eV up to 10^5 eV (“thermal reactor”). This dependence allows for a convenient definition of a nominal flux of epithermal neutrons ϕ_{epi} and the corresponding reaction cross sections (resonance integrals).

Generally, the “gross” rate constant R of a reaction induced by neutrons of different energies can be calculated by the following integral:

$$R = \int_0^{\infty} \varphi(E) \sigma(E) dE \quad (57.3)$$

where $\sigma(E)$ denotes the cross section of the reaction in question as a function of neutron energy, and $\varphi(E)$ describes the distribution of the neutron flux along the energy axis². For epithermal neutrons in particular one can write

$$R = \phi_{\text{epi}} \int_{0.5 \text{ eV}}^{\infty} \frac{\sigma(E)}{E} dE \equiv \phi_{\text{epi}} I \quad (57.4)$$

where

$$\phi_{\text{epi}} = \varphi(E)E = \text{const.} \quad (57.5)$$

due to the $1/E$ law. The value of the integral I is called the resonance integral. Resonance integrals are properties of nuclides and may be found in tables (Erdtmann 1976; Mughabghab et al. 1981) like the reaction cross sections for thermal neutrons. They may be used for the determination of the flux of epithermal neutrons (ϕ_{epi}) in any reactor or in different locations of the reactor core. Experimentally, R is measured by activating a monitor with known thermal neutron cross section and known resonance integral in the interesting reactor location. The activation is done twice: (1) after wrapping the sample in a sheet of Cd (0.7 mm thick) and (2) without Cd. The cadmium sheet absorbs thermal neutrons but has (nearly) no interaction with epithermal (epi-cadmium) neutrons. Consequently, irradiation (1) gives information on the epithermal flux and irradiation (2) reflects the effect of the sum of epithermal and thermal flux. The thermal neutron flux can be obtained from the difference.

The information on thermal and epithermal neutron flux is important for diagnostic purposes in any reactor. It is particularly important in research reactors that are used for neutron activation analysis.

57.3.1.3 Fast (Unmoderated) Fission Neutrons

The flux of unmoderated neutrons as a function of their energy, $\varphi_f(E)$, where the subscript f stands for fast neutrons, may be described by Watt's equation (Watt 1952) as given in (Erdtmann 1976):

$$\varphi_f(E/\text{MeV}) = \frac{0.484}{\text{cm}^2 \text{ s MeV}} \exp(-E/\text{MeV}) \sinh \sqrt{2E/\text{MeV}}. \quad (57.6)$$

The function is shown in  Fig. 57.3 (“unmoderated fission spectrum”). These fast neutrons, generally, play no role for the usual (n, γ) -reactions because the (n, γ) -cross sections become very small at neutron energies above 100 keV. Instead, in this energy range (n, p) -, (n, α) -, $(n, 2n)$ -, and (n, n') -reactions become important. The latter are threshold reactions, i.e., their cross sections are zero up to a certain neutron energy (threshold energy) and are then a function of the neutron energy.

Again, the reaction rate constant (R_f) may be described as the integral of the product of neutron flux distribution and the cross section as a function of neutron energy:

$$R_f = \int_{E_{th}}^{\infty} \varphi_f(E) \sigma(E) dE \quad (57.7)$$

where E_{th} is the threshold energy. The integration can also be carried out from zero to infinity as the integral amounts to zero below E_{th} .

The cross-section curves $\sigma(E)$ are usually called excitation functions and the curves of the differential products $\varphi(E)\sigma(E)$ are the response functions. In measuring R_f and assuming relation (4.6), one can measure effective cross sections (σ_f) for unmoderated fission neutrons:

$$\sigma_f = \frac{R_f}{\int_0^{\infty} \varphi_f(E) dE} = \frac{\int_0^{\infty} \varphi_f(E) \sigma(E) dE}{\int_0^{\infty} \varphi_f(E) dE}. \quad (57.8)$$

The integral in the denominator is sometimes abbreviated as ϕ_n resulting in the simple relation:

$$\sigma_f = \frac{R_f}{\phi_n}. \quad (57.9)$$

From a measured value of R_f , Eq. (57.9) allows one to calculate the mean reaction cross section for the respective nuclide. Correspondingly, one may determine the integral of the unmoderated neutron flux ϕ_n if the mean reaction cross section is known. Values of σ_f are available in tabulated form (Erdtmann 1976; Mughabghab et al. 1981). The value of ϕ_n varies as a function of the location in the reactor core (irradiation position) but is constant for a well-defined location at a given reactor power.

As pointed out above, the energy distribution of the neutrons in a reactor may be described by the sum of three components belonging to thermal, epithermal, and unmoderated neutrons. The reactor is characterized by the different contributions of these three components.

In a thermal reactor, it is important to slow down the neutrons quickly and effectively avoiding losses due to parasitic (n,γ)-reactions. In the following section, this moderation of neutrons will be discussed.

57.3.2 Neutron Moderation

The neutrons originate from the fission process with an energy of about 2 MeV, and they are moderated predominantly by elastic collisions with the atomic nuclei present in the reactor core. At first the central collision will be discussed. The laws of conservation of momentum and energy are valid:

$$m_n u_n + m_A u_A = m_n u'_n + m_A u'_A, \quad (57.10)$$

$$\frac{m_n u_n^2}{2} + \frac{m_A u_A^2}{2} = \frac{m_n u'^2_n}{2} + \frac{m_A u'^2_A}{2} \quad (57.11)$$

where m_n and m_A denote the mass of the neutron and that of the collision partner with mass number A , respectively, u_n and u_A are the respective velocities, and unprimed and primed velocities refer to velocities before and after collision, respectively.

■ **Table 57.2**

Velocity u'_n of a neutron – after a central collision with an atom of mass number A – relative to its initial velocity u_n , calculated using ► Eq. (57.12)

A	1	2	12	238
$(u'_n/u_n)_c$	0	−0.33	−0.85	−0.992

In the “laboratory system,” the velocity of the target atom (i.e., the collision partner of neutron) before collision can be considered being $u_A = 0$. Since the masses of the neutron and the moderator atom are approximately proportional to their mass numbers 1 and A , respectively, ► Eqs. (57.10) and (► 57.11) can be rearranged to give the relation:

$$\left(\frac{u'_n}{u_n}\right)_c = \frac{1 - A}{1 + A}, \quad (57.12)$$

where the subscript c is to remind that the ratio in parentheses is calculated for central collision.

In the following ► Table 57.2, a few examples are calculated for the velocity of the neutron after a collision relative to the velocity before the collision as a function of the mass of the collision partner (central collision).

A neutron after a (central) collision with a proton (of identical mass) is at rest, i.e., has lost all of its kinetic energy. In collisions with heavier atoms the neutron bounces back (therefore the negative sign) and conserves part of its speed. In a collision with ^{238}U the neutron bounces back with 99.2% of its initial speed, corresponding to 98.4% of its initial kinetic energy.

It is obvious from this simple discussion that water (H_2O) with its two hydrogen atoms (protons) must be (and is, indeed) a very good moderator. For the general case of a noncentral collision, the following equation applies:

$$\frac{u'_n}{u_n} = \frac{\sqrt{1 + A^2 + 2A \cos \theta}}{1 + A} \quad (57.13)$$

where θ is the angle between the incoming neutron and the outgoing collision partner. For the special case of $\theta = 180^\circ$ (central collision) ► Eq. (57.13) is identical to ► Eq. (57.12).

One observes that for both central and noncentral collisions the relative decrease in speed $u'_n/u_n = k$ is independent of the speed (or the energy) of the neutron and only depends on the mass ratio. Correspondingly, for the energy $E'_n/E_n = k^2$ is valid. Frequently the energy loss is characterized by the quantity $\xi_\theta = \ln(E_n/E'_n)$. Again, ξ is independent of E . For the central collision one can write:

$$\xi_c = \ln \left(\frac{1 - A}{1 + A} \right)^2. \quad (57.14)$$

An integration (i.e., averaging) of all collision angles results in the relation (Smith 1965)

$$\xi = 1 + \frac{\alpha}{1 - \alpha} \ln \alpha \quad (57.15)$$

where

$$\alpha = \left(\frac{1 - A}{1 + A} \right)^2. \quad (57.16)$$

Note that for ${}^1\text{H}$ $\alpha = 0$ and therefore [Eq. \(57.15\)](#) yields $\xi = 1$ as one can easily verify using l'Hospitals rule for the limit $\alpha \rightarrow 0$. The average number of collisions required for a fission neutron of about 2 MeV energy to be moderated to thermal energy is given by the equation

$$n = \frac{1}{\xi} \ln \frac{E_n^0}{E_n} \quad (57.17)$$

where E_n^0 and E_n are the mean energies of fission neutrons (~ 2 MeV) and of thermal neutrons (0.025 eV; see [Eq. \[57.2\]](#)), respectively. Typical values of ξ and of n are given in [Table 57.3](#).

The table illustrates the advantage of light elements as moderators. The moderating qualities of a substance depend, however, on other factors too. The “slowing down power” (SDP) of a moderator includes the scattering cross section for neutrons (σ_s) and the number density (N_s) of scattering atoms (in number of atoms per cubic centimeter [cm^3], for instance):

$$\text{SDP} = \xi \sigma_s N_s. \quad (57.18)$$

Generally, the quantities σ_s and SDP depend on the neutron energy and the values given are averages for the region of epithermal energies. Moderators, in addition to the scattering cross section, possess an absorption cross section, σ_a , for (n, γ)-reactions, etc. Obviously, the absorption cross section of a good moderator should be small.

A quantitative description of the moderating properties including neutron absorption is given by the “moderating ratio” (MR):

$$\text{MR} = \xi \frac{\sigma_s}{\sigma_a}. \quad (57.19)$$

If a moderator is composed of different nuclides/elements, then the properties of the nuclides must be averaged. The properties of some compounds used as moderators are given in [Table 57.4](#).

The quality of the moderators as characterized by MR ([Table 57.4](#)) decreases in the order of $\text{D}_2\text{O} > \text{C} > \text{Be} > \text{H}_2\text{O}$. In a commercial reactor many other factors like the price and the phase (liquid/solid) have to be taken into account. In practice H_2O is used in most reactors together with a fuel enriched in ${}^{235}\text{U}$ (3–4%). Reactors operating with natural uranium rely on D_2O as a moderator.

Table 57.3

Values of the average logarithmic energy decrement ξ , as defined by [Eq. \(57.15\)](#), and of n , the average number of collisions required to moderate a neutron from an initial energy of 2 MeV to thermal energy as defined by [Eq. \(57.17\)](#), for various elements of interest in reactor technology

Nuclide	A	ξ_{tot}	n
${}^1\text{H}$	1	1.00	18
${}^2\text{H}$ (D)	2	0.725	25
${}^4\text{He}$	4	0.425	43
${}^{12}\text{C}$	12	0.158	115
${}^{16}\text{O}$	16	0.120	151
${}^{238}\text{U}$	238	0.0084	2,166

■ **Table 57.4**

Moderating properties of different compounds: scattering cross section for epithermal neutrons (σ_s , in barn); absorption cross section for thermal neutrons (σ_a in barn); average logarithmic energy decrement ξ ; slowing down power (SDP) (cm^{-1}) and moderating ratio (MR)

Compound	σ_s	σ_a	ξ	SDP	MR
H ₂ O	49	0.66	0.927	1.52	69
D ₂ O	10.6	0.00092	0.510	0.181	5,880
Be	5.9	0.009	0.209	0.15	137
C	4.7	0.0045	0.158	0.06	165

The time required for moderation differs according to the number of collisions involved. Average values for the thermalization from an initial energy of about 2 MeV are 40 μs for light water, 150 μs for graphite, and 2.1 ms for lead.

For the thermal reactor it is important that the moderation of the neutrons takes place in as short a time as possible in order to avoid the capture of these neutrons in the (n,γ) -resonances along the way.

57.3.3 Buildup Reactions

In the following, neutron capture reactions that lead to a buildup of heavier nuclides (actinides) will be discussed. As has been mentioned before, inside a reactor, in addition to neutron-induced (n,f) -fission reactions, neutron-capture (n,γ) -reactions take place. The products arising primarily from neutron capture in ^{235}U , ^{238}U , and ^{239}Pu (^{236}U , ^{239}U , and ^{240}Pu , respectively) can undergo further reactions like other neutron capture reactions, as well as β decay, α decay, neutron-induced fission, etc. The possible reactions and their cross sections or half-lives are given in [Fig. 57.4](#).

It appears that starting with uranium a number of neutron capture reactions take place. Subsequent reactions of β decay lead to elements with higher atomic number – in [Fig. 57.4](#) up to Cm ($Z = 96$). The buildup of new heavier isotopes is stopped by the fact that some show α decay and others undergo fission. The kinetics of transformation in α decay, β decay, and isomeric transitions characterized by their half-lives follow the well-known exponential law (see [Chap. 7 in Vol. 1](#)):

$$N = N_0 e^{-\lambda t} \quad (57.20)$$

where N_0 and N denote the initial number of atoms and the number of atoms after time t , respectively, λ is the decay constant that is inversely proportional to the half-life $T_{1/2}$ as

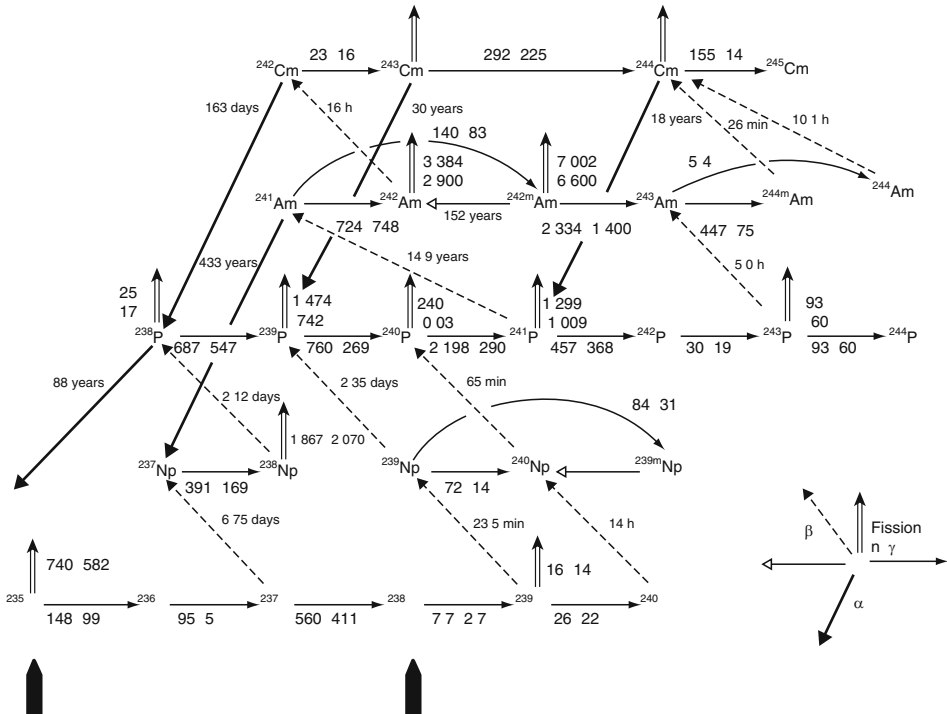

$$\lambda = \frac{\ln 2}{T_{1/2}}. \quad (57.21)$$

For longer decay chains or for a situation of a continuous production of a mother isotope the reader may be referred to the classical system of radioactive growth and decay curves as given in textbooks of radiochemistry. (See also [Eqs. \[38.29\] and \[38.30\] in Chap. 38, Vol. 4.](#))

The situation is similar for neutron-induced fission- and (n,γ) -reactions characterized by cross sections (σ). In a constant neutron flux also an exponential law is realized. The “decay

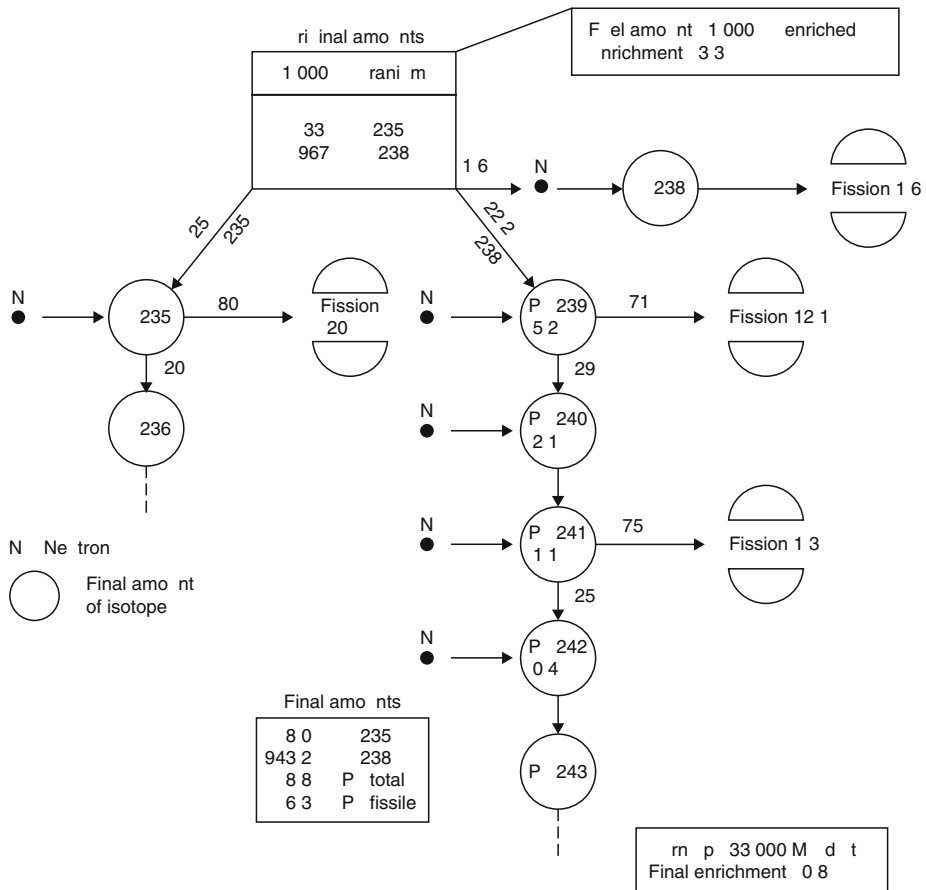

Fig. 57.4

Nuclear reactions and decays occurring by neutron irradiation of uranium. Numbers along the decay paths (α , β , IT) are half-lives (where m is for minute). Numbers along reaction paths ((n, γ) , fission) are cross sections (in barns) for a neutron spectrum of a standard-power light-water reactor, cross sections in parentheses are for thermal neutrons (0.025 eV). (The different arrows are explained by the insert in the lower right corner.) (Choppin and Rydberg 1980)

As it appears from [▶ Fig. 57.4](#), there are numerous other buildup reactions. Among those are the very important formation of ^{239}Pu from ^{238}U by neutron capture and two successive β decays. [▶ Figure 57.4](#) also indicates that a number of the products built up are undergoing fission after neutron capture.

Fig. 57.5
Reaction products in a light-water power reactor after a burn-up of 33,000 MWd/t of fuel (Choppin and Rydberg 1980)

After the burn-up indicated, the amount of ^{235}U that underwent fission is 20 kg. In addition, 1.6 kg of ^{238}U was fissioned by fast neutrons. The amount of 22.2 kg of ^{238}U captured neutrons and decayed to ^{239}Pu . Of this 12.1 kg underwent fission again. Of the remaining 10.1 kg of ^{239}Pu , 5.2 kg remained as such until the end of exposure, the rest of 4.9 kg captured more neutrons forming $^{240,241,242,243}\text{Pu}$. Some ^{241}Pu (1.3 kg) underwent fission. Finally 5 kg of ^{235}U captured a neutron and transformed to ^{236}U without undergoing fission. Therefore, of the 33 kg of ^{235}U present initially, 8 kg remain in the spent fuel and of the 967 kg of ^{238}U , 943.2 kg remain. Instead 8.8 kg of Pu have been formed of which 6.3 kg are fissile ^{239}Pu and ^{241}Pu . In addition, there are 5 kg of ^{236}U and about 35 kg of fission products (formed by the fission of 21.6 kg of uranium and 13.4 kg of plutonium). The total amount of fissionable material remaining in the spent fuel is 14.3 kg (8.0 kg of ^{235}U and 6.3 kg of $^{239,241}\text{Pu}$). This may be recovered by reprocessing.

Therefore, in a typical light-water reactor a considerable amount of new fissionable material is produced. In a breeder reactor more fissionable material is produced from ^{238}U than is consumed in the reactor.

Hence, some of the (n,γ) -reactions that are parasitic in establishing a chain reaction are advantageous from the standpoint of an economic use of uranium.

However, in constructing a reactor, the primary question is at first whether a chain reaction (or a critical assembly) can be established. This question will be discussed in the following section. It can be described by the fission factor (η).

57.3.4 The Fission Factor (η)

A chain reaction is in principle possible if in a substance the number of neutrons set free by fission divided by the number of neutrons required to maintain the fission process is at least equal to 1. This number is designated by η . It is defined by the following equation:

$$\eta = v \frac{\sigma_f}{\sigma_f + \sigma_c} \quad (57.24)$$

where σ_f and σ_c denote the fission cross section, and the capture cross section for (n,γ) -reaction, respectively, and v is the average number of neutrons emitted after fission. Values of σ_f , σ_c , v , and η for the most important fissile nuclides are given in [Table 57.5](#) for thermal and fast neutrons (1 MeV). The highest value of η is obtained for the fission of ^{239}Pu by fast neutrons. A chain reaction with pure ^{238}U is possible neither with thermal neutrons nor with fast ones. For mixtures weighted averages of the cross sections and v values have to be used. Consequently, one obtains

$$\eta = \frac{v_1 f_1 \sigma_{f1} + v_2 f_2 \sigma_{f2}}{(f_1 \sigma_{f1} + f_2 \sigma_{f2}) + (f_1 \sigma_{c1} + f_2 \sigma_{c2})} \quad (57.25)$$

where f_1 and f_2 are the fractions of components 1 and 2, respectively.

Considering, e.g., natural uranium (a mixture of 0.71% of ^{235}U and 99.29% of ^{238}U) and thermal neutrons, the fission factor obtained from [Eq. \(57.25\)](#) is $\eta = 1.33$. Here, a chain reaction is still possible but neutron losses in the moderator and in the construction materials must be kept very small. This requires the use of a very good moderator like D_2O (see above). For a typical light-water reactor fuel (3% in ^{235}U) a value of $\eta = 1.83$ is obtained.

■ Table 57.5

Cross sections for (n,γ)-reactions (σ_c in barn) and neutron-induced fission reactions (σ_f in barn); average total number of neutrons emitted after fission (ν) (Choppin and Rydberg 1980) and fission factor (η) for various fission reactions induced by thermal and fast neutrons (1 MeV)

Neutron	Nuclide	σ_c	σ_f	ν	η
Thermal neutrons	^{233}U	48	531	2.49	2.28
	^{235}U	99	582	2.42	2.07
	^{238}U	2.7	0	0	0
	^{239}Pu	269	742	2.87	2.11
	^{241}Pu	368	1,009	3.00	2.20
Fast neutrons (1 MeV)	^{233}U	0.08	1.95	2.59	2.49
	^{235}U	0.11	1.25	2.58	2.37
	^{238}U	0.17	0.017	2.85	0.26
	^{239}Pu	0.09	1.65	3.02	2.86

Besides neutron capture in the fuel, other parasitic reactions play a role. They will be discussed in the following with respect to the practical case of reactor construction and operation. In this context a criticality factor is defined.

57.3.5 The Criticality Factor – Neutron Multiplication Factor k

As it was shown before, the condition for the establishment of a chain reaction is that at least one of the neutrons originating from fission is inducing a new fission reaction. This condition is expressed by the neutron multiplication factor k (also called criticality factor). k is defined as

$$k = \frac{\text{number of neutrons in generation 2}}{\text{number of neutrons in generation 1}} \quad (57.26)$$

In order to maintain a chain reaction, k has to be at least one. A state of the reactor with $k > 1$ is called supercritical. For every generation of neutrons the reactor power increases by the factor k . The duration of a generation is the average time span between the birth of a neutron and its capture. This time span in a thermal reactor is mainly determined by the time it takes the neutron to be moderated down to thermal energy (usually about 40 μs , see ▶ Sect. 57.3.2) and to diffuse to an absorption site. In a state of exactly $k = 1$ the reactor is called “critical.” The reactor power is constant. A state with $k < 1$ is called subcritical. This topic will be discussed further below (reactor dynamics). The neutron cycle includes a number of steps that have been partly studied already but that will be discussed here in the context of a full neutron cycle.

Assuming that 100 neutrons are captured in the fuel of a reactor with uranium enriched to 3% ^{235}U , $\eta = 1.83$ (see above) and $\nu = 2.42$ (▶ Table 57.5) results in 183 neutrons (second generation) from $(183/2.42) = 76$ fission events (and 24 (n,γ)-capture reactions of ^{235}U and ^{238}U). The 183 neutrons are fast neutrons, which are able to induce fission in ^{238}U producing additional neutrons. This is described by the “fast fission factor” (ϵ). Assuming that $\epsilon = 1.03$, the neutron number increases to $183 \times 1.03 \approx 188$. The neutrons are moderated through

collision with the water molecules. During moderation some neutrons ($\sim 5\%$) diffuse out of the reactor volume and are lost. Thus, the surviving fraction (also called the “leakage factor” of fast neutrons) is $A_f = 0.95$. A number of 179 neutrons are left.

Mainly in the energy range of 1 to 10^4 eV these neutrons undergo (n, γ)-absorption reactions in the moderator, in the construction elements of the reactor and in the fuel (absorption resonances, especially in ^{238}U). This loss can be estimated to amount to 20%. The “resonance escape probability” p therefore amounts to $p = 0.8$, leaving ($179 \times 0.8 \approx$) 143 neutrons. After reaching thermal energy the neutrons diffuse through the reactor core. During this time different effects can take place:

(1) Some neutrons diffuse outside the reactor core and get caught in the construction elements of the reactor. Assuming again a loss of 5%, the surviving fraction (i.e., the “leakage factor”) of thermal neutrons is $A_{th} = 0.95$, i.e., $143 \times 0.95 \approx 136$ neutrons are left. (2) Some thermal neutrons are caught within the reactor core by interaction with the moderator, the construction elements of the reactor, some samples to be activated in irradiation positions, and finally with the control rods and some content of boron in the coolant. The fraction of neutrons that escapes these absorption reactions is called the thermal utilization factor ($f = 0.74$). By moving the control rods this factor can be varied as to maintain a criticality of $k = 1$ and, hence, to leave 100 neutrons for the next cycle. In summary of this discussion the following equation results:

$$k = \eta \varepsilon p f A_f A_{th} \quad (57.27)$$

where η is the fission factor (see [Eq. \[57.24\]](#) or [\[57.25\]](#)), ε is the fast fission factor, p is the resonance escape probability, f is the thermal utilization factor, A_f is the survival of epithermal diffusion loss, and A_{th} is the survival of thermal diffusion loss.

An important point for the safety of reactors is the influence of the core temperature on k , i.e., on the reactivity. Water-moderated reactors can be built to have a negative temperature coefficient: an increase in temperature/power will lead to steam bubbles near the fuel elements and to a decrease in moderation. If the reactor has been designed a little undermoderated, a drop in moderation will bring about a drop in reactivity (k). Such a reactor will be naturally stable against undesired changes in power. One may recall the discussion of the Oklo reactor at the beginning of the chapter.

Other reactors do not have this feature. The Russian developed reactor type RBMK-1000, for instance, is based on neutron moderation in graphite and heat transport by water. Under certain conditions of low power it has a positive temperature reactivity coefficient and this was – among many other reasons – also responsible for the largest accident in reactor history (Chernobyl, 1986).

57.3.6 Reactor Kinetics

The evolution of the generated power after a change in the reactivity is an important point for the control of nuclear reactors. For this purpose, the duration of a neutron generation, i.e., the average lifetime τ of a neutron (from its formation in fission until its capture) is important. Values for these “neutron cycles” in different types of fission assemblies are given in [Table 57.6](#).

■ **Table 57.6**

Average time of neutron cycle in different fission assemblies

Type of assembly	Time of neutron cycle (τ/s)
Thermal reactor	10^{-3} to 10^{-4}
Fast reactor	10^{-6} to 10^{-7}
Nuclear weapons	10^{-8} to 10^{-9}

The time of the neutron cycle in the thermal reactor is mainly determined by the time required to bring the neutrons to thermal energy. This requirement does not exist in the fast reactor and in nuclear weapons. Therefore the cycle times are shorter in these two latter cases.

At every pass of the neutron cycle the number of neutrons (and so the power of the reactor) changes by the factor k . Hence, the change in the absolute number of neutrons per unit of time (dN/dt) is

$$\frac{dN}{dt} = \frac{N(k-1)}{\tau} + K \quad (57.28)$$

where N is the number of neutrons, K is the contribution of a (starter) neutron source that is usually present in any fission assembly ($K = \text{const.}$). For integration ▶ Eq. (57.28) can be rewritten as

$$\int \left(\frac{N(k-1)}{\tau} + K \right)^{-1} dN = \int dt \quad (57.29)$$

Integration of ▶ Eq. (57.29) results in

$$N = \left(N_0 + \frac{K\tau}{k-1} \right) \exp \left[\frac{(k-1)t}{\tau} \right] - \frac{K\tau}{k-1}. \quad (57.30)$$

For the discussion of ▶ Eq. (57.30) three special cases can be distinguished. (1) $k < 1$; the reactor is subcritical, the reactor works as an “amplifier.” (2) $k = 1$; the reactor is critical; the reactor power is constant (the contribution of K is small and can be neglected). (3) $k > 1$; the reactor is supercritical, the reactor power increases exponentially.

57.3.6.1 The Subcritical State

With $k < 1$; $N_0 = 0$, ▶ Eq. (57.30) becomes:

$$N = \frac{K\tau}{1-k} \exp \left[-\frac{(1-k)t}{\tau} \right] + \frac{K\tau}{1-k} \quad (57.31)$$

or

$$N = \frac{K\tau}{1-k} \left\{ 1 - \exp \left[-\frac{(1-k)t}{\tau} \right] \right\}. \quad (57.32)$$

Table 57.7
Amplification of neutron flux by a reactor in a subcritical status at various values of k

K	$N_{\infty}/(K\tau)$
0.1	1.1
0.5	2
0.9	10
0.99	100

The neutron number (reactor power) shows an increase approaching exponentially an equilibrium value of

$$N_{\infty} = \frac{K\tau}{1-k}. \quad (57.33)$$

This “leveling” is exactly what was observed by Fermi when the first artificial reactor was approaching criticality (see [Fig. 57.2](#)). For k between 0 and 1, N_{∞} is larger than $K\tau$. The reactor works as an amplifier. The amplification factor depends on the value of k . This is shown in [Table 57.7](#).

57.3.6.2 The Supercritical State

With $k > 1$ (K can be neglected) [Eq. \(57.30\)](#) becomes:

$$N = N_0 \exp \left[\frac{(k-1)t}{\tau} \right] \quad (57.34)$$

This corresponds to an unlimited exponential increase of N (number of neutrons and reactor power). The behavior is shown in [Fig. 57.6](#) for $k = 1.1$ and may be compared there with the behavior in the subcritical state ($k = 0.5$ and 0.9).

57.3.6.3 The Critical State

The critical state is characterized by a neutron multiplication factor $k = 1$. With this condition [Eq. \(57.30\)](#) becomes $N = N_0$. (The contribution of the constant neutron source K used for starting purposes can be neglected since K is six to seven orders of magnitude smaller than N in an operating reactor.)

The quantity $\tau/(k-1)$ is usually called the reactor period. It is given by the time of the neutron cycle (τ), which is a constant for a given reactor and is determined mainly by the properties of the moderator. It is also determined by the criticality value k that varies, e.g., as a function of the position of the control rods.

A nuclear weapon is a fission assembly with a very short neutron cycle time: $\tau = 10^{-9}$ s. The criticality factor in a fission weapon is near $k = 2$. From these parameters and [Eq. \(57.34\)](#) it can be easily estimated that the fission reaction in a bomb is over in less than 10^{-7} s.

For a thermal reactor ($\tau = 10^{-4}$ s) and for a value of $k = 1.005$ one calculates also a dramatic increase in reactor power in only 1 s of $e^{50} = 5 \times 10^{21}$! The question therefore arises how a reactor can be controlled if its power changes so drastically for a small change in k ?

■ Fig. 57.6

Evolution of the reactor power with time (in units of the time span τ of the neutron cycle) (a) in a subcritical state ($k = 0.5$ and 0.9) and (b) in a supercritical state ($k = 1.1$). The curves are meant to show the time behavior of the reactor power (neutron flux). Quantitatively the curves for $k = 0.5$ and 0.9 are not directly comparable with the curve for $k = 1.1$

The answer is the existence of “delayed neutrons.” A small fraction of the neutrons emitted from the fission process is not set free promptly from the fission products, but is emitted only as a consequence of the β decay of some fission products that feed excited levels in the daughter nucleus with an excitation energy higher than the binding energy of the last neutron. In these cases the excited (daughter) nucleus may give off its excitation energy not in the form of γ rays but by emission of a neutron. These neutrons appear “delayed” with respect to the birth of the fragment in the fission process. They appear actually with the half-life of their β -active precursors. These half-lives range from about 0.1 s up to 55 s (e.g., ^{87}Br decays with a half-life of 55 s [partly] to ^{86}Kr and a neutron). The fraction of these “delayed neutrons” is small. For the thermal neutron-induced fission of ^{235}U it amounts to a fraction of $\beta = 0.0065$ of the total amount of neutrons. (Unfortunately, it has become customary to designate the fraction of delayed neutrons by the letter β . This β should not be confused with β decay!) This small fraction does, however, have consequences for the control of reactors.

As long as the value of k remains smaller than $1 + \beta$ (i.e., < 1.0065 for ^{235}U) the time of the neutron cycle is determined by the time regime of the delayed neutrons. The neutron cycle time therefore lies between 0.1 and 55 s (depending on the value of k within the limits mentioned) rather than being 10^{-4} s. Assuming a value of $\tau = 1$ s, a calculation like the one performed above for $k = 1.005$ leads to a much smaller increase in reactor power per second ($e^{0.005} \approx 1.005$). Under these conditions, an increase of 10% in reactor power takes 19 s. Reactors must always be built in such a way that the construction makes it impossible to reach a criticality of $k > 1 + \beta$ (“prompt criticality”). This is a basic law of reactor construction since Fermi’s first test reactor. In fact, this is how western reactors are designed. In the reactor at Chernobyl, which was destroyed in an explosion, “prompt criticality” was not made physically impossible. It was only forbidden by regulations that were not followed on the day of the accident. As a result, the reactor exploded.

In this context, it is worth remembering the natural reactor at Oklo discussed at the beginning of this article. Apparently the increase in reactivity due to the influx of water was limited to $k < 1.0065$. Otherwise an explosion would have been the consequence.

57.3.7 Critical Size

The formation of neutrons in a reactor is a function of the volume filled by the fuel. The loss of neutrons by diffusion depends on the surface area of this volume. The ratio of volume to surface area depends on the shape. The largest ratio is found for a sphere. Therefore, Fermi chose a spherical configuration for the first test reactor. However, the ratio of volume to surface area is also a function of the size. The larger the sphere, the better (i.e., larger) is the ratio of volume to surface area.

Consequently, there exists a minimum size of a configuration with fissile material to obtain $k = 1$. This size is called the “critical size.” It depends on many factors: the nature of the fissile material, the geometrical arrangement, the presence of a reflector, the presence of a moderator, and the density of the fissile material. A few typical values are given in ▶ Table 57.8 for metallic samples of a spherical shape without moderator and surrounded by a reflector (20 cm of ^{238}U).

A few values of critical masses of aqueous solutions of the sulfates of the nuclides in a spherical configuration, but without reflector, are given in ▶ Table 57.9.

The critical masses serve only as a rough guide. They can be considerably lower if, e.g., the density is increased by extremely high pressures. This is particularly so for metallic actinides in fission bombs.

After this section covering the principles of chain reactions and of reactor operation, the following sections will be dedicated to the concepts of existing reactors. Since nuclear fission weapons are in principle fast reactors, they will also be briefly covered.

■ Table 57.8
Critical masses of different fissile nuclides (pure) in a spherical configuration, metallic state without moderator, surrounded by a reflector (20 cm of ^{238}U)

Nuclide	Critical mass/kg
^{235}U	22.8
^{233}U	7.5
^{239}Pu	5.6

■ Table 57.9
Critical masses of different fissile nuclides in the form of sulfates in aqueous solution, in a spherical configuration, without reflector

Nuclide	Critical mass
^{235}U	820 g in 6.3 l of water
^{233}U	590 g in 3.3 l of water
^{239}Pu	510 g in 4.5 l of water

57.4 Specific Nuclear Reactors and Other Nuclear Devices

In the following, the most important types of reactors will be discussed briefly. In principle, a distinction has to be made between research reactors and reactors of nuclear power stations. The latter ones are built to produce heat for conversion into electric energy. Research reactors are used as intense neutron sources; the energy set free, necessarily, is not used. Actually energy production in a research reactor is normally disturbing rather than helpful. Therefore, research reactors are generally small and compact. More detailed information, comprehensible also for the nonspecialist, may be found in IAEA (2000) for research reactors and in Zech (1988) concerning reactors for nuclear power stations.

In 2000 the number of research reactors operating worldwide was 288. A detailed survey is given in IAEA (2000). (A database for research reactors is maintained by the International Atomic Energy Agency – IAEA – in Vienna and is accessible through the Internet; see IAEA [2003].) It is not possible to discuss all the different types of research reactors here. The following presentation will be limited to two interesting examples.

57.4.1 Research Reactors

Most of the research reactors are “swimming-pool” reactors. The reactor core is immersed in a water basin, which is open on top. The water has the task of moderating the neutrons, cooling the fuel elements, absorbing the radiation from the core and, nevertheless, giving easy access to the reactor core. Because even thick layers of water are transparent, a visual inspection of the reactor core during operation is possible. As an example of a widely used small research reactor a sketch of the TRIGA reactor is given in [Fig. 57.7](#). (TRIGA stands for Training, Research,

Fig. 57.7

TRIGA reactor, sketch of the reactor core with surrounding water tank and cylindrical graphite reflector with rotating irradiation rack. These and other important parts of the core are designated in the sketch (Berwanger 1965)

Industry, General Atomic, indicating three important fields of application and the – former – manufacturer located in San Diego, California, USA.)

In addition to the reactor core, several irradiation facilities are shown: a rotating rack for 40 samples with a tube of access to these irradiation positions, a pneumatic tube, and a central irradiation tube. The neutron flux at a typical nominal power of 100 kW amounts to $4 \times 10^{12} \text{ s}^{-1} \text{ cm}^{-2}$ in the central irradiation tube. The ionization chamber shown allows for a measurement of the neutron flux (the reactor power).

The TRIGA reactor has an interesting feature, namely that it can produce short and very intense bursts of neutrons. This is due to a particular composition of its fuel elements that are made of an alloy of zirconium (91% by mass) with uranium (8% by mass enriched to 20% ^{235}U) and hydrogen (1% by mass corresponding to 50 atom%). Due to the hydrogen content, the fuel elements contribute directly to the moderation of neutrons. A heating of the fuel elements shifts the energy spectrum of the neutrons to higher values. In order to induce a neutron burst, one control rod is removed rapidly from the reactor core. This way, the reactor is made prompt critical. The reactor power rises to 250 MW within milliseconds. Simultaneously, the fuel elements heat up to a temperature of about 300°C and the energy spectrum of the neutrons is shifted into the region of absorption resonances of ^{238}U . Therefore, the reactivity of the reactor drops drastically followed by the reactor power and the neutron flux. Hence, the quick removal of the control rod, mentioned above, results in a short spike of the neutron flux of 100 ms duration with an integrated neutron fluence of $10^{14} \text{ n cm}^{-2}$. This special feature of the TRIGA reactor allows production and study particularly of short-lived nuclides.

Generally the main areas of application of the small research reactors are the following:

- (1) Neutron activation analysis. (See [▶ Chap. 30 in Vol. 3.](#)) Samples are activated inside the reactor. Characteristic radiations given off after (or during) activation are measured. From these measurements one can deduce the elements that are present in the samples and calculate their respective quantities. This analysis is very selective and in many cases shows an extreme sensitivity. Frequently it does not require a chemical sample preparation, thus excluding errors introduced by such procedures. Therefore, neutron activation is frequently used to calibrate or validate other analytical procedures and to detect small traces of elements of specific interest.
- (2) Production of radionuclides as tracers for research, industry, and medicine (see Vol. 4).
- (3) Study of neutron-induced reactions, like (n, γ) -reactions or the fission process itself.

In addition to the many small research reactors, the high-flux reactor of the Institut Laue-Langevin (ILL) in Grenoble and another high-flux reactor (FRM-II) that is under construction in Munich shall be mentioned here. The ILL-Reactor will be discussed briefly. It is devised to produce a maximum neutron flux. For this purpose one has to concentrate a maximum of fission events in a minimum of space. The main problem is to remove the heat due to the fission reactions from such a small volume. The technical solution is to use a single fuel element (for high mechanical stability). This cylindrical fuel element (diameter: 41 cm, length: 1.48 m) resembles a turbine. Inside the outer mantle it contains an inner tube with a diameter of about 27 cm. The fuel consists of 9 kg of highly enriched uranium (93% ^{235}U). A thin layer of the fuel is welded between two slightly curved plates of aluminum (7 cm \times 90 cm, 1.3 mm thick). A total of 280 such plates are inserted into slits between the outer and inner tube of the fuel element and are maintained there in radial geometry.

The reactor has a power of 54 MW. The small size of the reactor core provides an unusually high neutron flux of $10^{15} \text{ s}^{-1} \text{ cm}^{-2}$. The high power density requires very effective cooling. A total amount of $2,010 \text{ m}^3$ of heavy water (D_2O) is pumped through the turbine-like fuel

element described above. The linear speed of the water is 15 m/s. The main control rod can be inserted into the opening of the inner cylinder. The high neutron flux (1,000 times the flux of the TRIGA reactor described above) allows for additional uses of this reactor:

1. Structural analysis of pure organic or biological samples by neutron scattering
2. Detailed analysis of nuclear fission using the mass separator Lohengrin (see [▶ Chap. 4 in Vol. 1](#))
3. Analysis of the properties of cold and hot neutrons, and the decay properties of the neutron
4. Production of radioactive beams for the synthesis of heavy nuclei and for the questions of the nucleosynthesis in stars

Numerous other research reactors with a neutron flux higher than the TRIGA reactor but not as high as the ILL reactor are used on a routine basis for the production of radionuclides such as $^{99}\text{Mo}/^{99\text{m}}\text{Tc}$, ^{131}I , and other radionuclides for medical diagnosis and treatment. Intense γ -ray sources based on ^{60}Co used for external medical radiation treatment and industrial applications are produced in these reactors.

57.4.2 Reactors for Power Stations

In order to illustrate the economic importance of nuclear energy, some statistics shall be cited. The total number of nuclear power stations operating worldwide at the end of 2001 was 439. In addition, 33 power stations were under construction. The (net) output of electricity of nuclear origin at the end of 2001 amounted to 354,639 MWe (Atomwirtschaft 2002; Deutsches Atomforum 2002). (The abbreviation MWe stands for megawatt electrical power. At an efficiency of about 33% in the conversion of thermal into electrical power, 1 MWe corresponds to about 3 MWth of thermal energy.) Assuming an average price of €0.05/kWh, this corresponds to a yearly turnover of €150 billion (or USD).

The vast majority (80%) of the reactors mentioned are light-water-moderated reactors (LWR). The LWR subdivide in 60% PWR and 20% BWR. The remaining 20% of the reactors are divided among CANadian Deuterium Uranium reactor (CANDU), Reaktor Bolshoi Moshchnosti Kanalny (RBMK), large power channel reactor, gas-cooled reactor (GCR), advanced gas-cooled reactor (AGR), and fast breeder reactor (FBR).

In the following, the PWR will be discussed in some detail, followed by a brief discussion of the similar BWR. The RBMK and FBR will be presented as quite different possibilities. Finally, the accelerator-driven system (ADS) will be outlined as an attractive possibility for the future.

57.4.2.1 The Pressurized Water Reactor (PWR)

As it appears from the numbers given above, the pressurized water reactor has become the most frequently used reactor type for electric power stations. A schematic sketch is shown in [▶ Fig. 57.8](#).

The PWR possesses a double cooling circuit. The primary circuit with the main pumps (3) in [▶ Fig. 57.8](#) passes (light) water along the fuel rods. The water takes over the heat evolved.

Fig. 57.8

Schematic sketch of nuclear power station with a pressurized water reactor; (1) reactor, (2) steam generator, (3) main pump for primary cooling circuit, (4) turbines/generator, (5) steam drum, (6) superheater, (7) condenser, (8) feed water pump, (9) preheater, (10) cooling water pump (Zech 1988)

The thermal energy is transferred to a secondary circuit in a heat exchanger (2). The secondary circuit drives the turbines (4) coupled to the generator (4, right).

Generally, two kinds of turbines are used in sequence. A first smaller turbine is driven by high-temperature/high-pressure steam and secondary larger turbines are exposed to steam of lower temperature/pressure. Before entering the secondary turbines, the vapor must be “dried,” i.e., droplets of condensed water must be removed, because their mechanical impact would rapidly destroy the secondary turbines. The drying of the vapor is made by mechanically removing water droplets (5) and subsequent heating (6).

Behind the turbines, the vapor has to be condensed. This is done by a third cooling circuit, which ultimately dumps the thermal energy into a river or to the air by evaporation of water in a cooling tower. An efficient cooling is important for a good efficiency of the power plant.

Thermodynamically the maximum efficiency of a thermal engine is given by

$$\eta = \frac{T_1 - T_2}{T_1} \quad (57.35)$$

where T_1 and T_2 are the temperature of the steam entering the turbine and leaving it, respectively. The condensed water is pumped back to the heat exchanger (2) using pump (8). A heat exchanger is shown in Fig. 57.9 separately. It also contains equipment to remove water droplets from the vapor.

The reactor core contains the fuel elements (Fig. 57.10). A fuel element consists of between 200 and 400 thin tubes of a zirconium alloy (about 1 cm diameter and up to 5 m long) filled with pellets of UO_2 .

■ Fig. 57.9

Heat exchanger of a PWR (height about 20 m) (Zech 1988)

At the top and bottom of every fuel rod, a volume is available to accept (rare) gases produced in fission. The uranium in this type of reactor is enriched to 3–4% ^{235}U . When fission occurs the highly energetic fission fragments are stopped in the fuel, heating up the fuel rods. These give off the thermal energy to the surrounding stream of water. Twenty-four rods in every fuel element remain empty for the introduction of the control rods (made from material with high neutron absorption cross sections like Ag, In, Cd, and B) for regulation of the reactor.

■ Fig. 57.10

Left: Fuel rod (diameter 10 mm) containing UO_2 pellets in a cladding of zircaloy or stainless steel.
Right: Fuel element containing an array of 18×18 fuel rods (Zech 1988)

An additional coarse regulation takes place through the addition of boric acid to the water of the primary cooling circuit. The neutron source(s) introduced for a reliable start of the reactor are also housed in these rods of the fuel elements.

A typical pressure vessel of a pressurized water reactor is shown in ► Fig. 57.11. The height of the pressure vessel for a typical power station of 1,300 MWe generally is 12 m. The thickness of the cylindrical wall amounts to 25 cm. The tank is designed to withstand pressures of 175 bar and a temperature of 350°C. Typical parameters of a PWR are listed in ► Table 57.10.

A nuclear reactor of this size contains an “inventory” of radioactive nuclides that can contaminate large areas – as demonstrated by the reactor accident of Chernobyl in April 1986. Therefore, at least in reactors in Western countries, a number of measures are taken to securely enclose the radioactive inventory. The fission products are surrounded by several barriers:

1. They are enclosed in the matrix of uranium dioxide, a ceramic material resistant to high temperatures and mechanical shock. The uranium dioxide is canned in fuel rods made of stainless steel or “zircaloy,” an alloy consisting mainly of zirconium.
2. The fuel elements are enclosed in a pressure tank (25 cm of steel).

■ Fig. 57.11

Schematic sketch of a pressure vessel of a pressurized water reactor (Zech 1988)

3. The pressure tank is surrounded by walls of concrete (1.5–2 m thick) aimed mainly – under normal operating conditions – at absorbing the radiations from the reactor core.
4. This biological shield normally sits inside a “containment,” a large spherical steel tank (wall thickness 4 cm).
5. This steel tank is surrounded by a dome of concrete (wall thickness 2 m).

In the reactor that exploded in Chernobyl, the barriers (2), (4), and (5) were missing. One problem in the discussion of reactor safety is the fact that a nuclear reactor produces a large amount of heat (3,700 MWth) and about 1% of this thermal energy (=37 MWth) is given off even after a shutdown of the reactor, due to the β decay of the radioactive nuclides.

Consequently, the reactor must be cooled even after shutdown and even in case of an accident. Therefore several independent cooling systems are incorporated. The worst accident that is considered (maximum credible accident “MCA”) is the complete shearing off of the primary circuit line. If this should occur, then a mixture of steam and air would be blown into the containment for a time span of 12 s (blowdown phase). When the pressure falls below 26 bar, water tanks maintained at this pressure automatically would empty into the reactor vessel from both sides (high and low temperature) of the circuit. If this water should evaporate or leak out again, at a pressure of 10 bar, a pump would provide water from other reservoirs. Water leaking out from the primary circuit will have to accumulate on the bottom of the

■ Table 57.10

Typical parameters of a pressurized water reactor (PWR) (GKN-II, Neckarwestheim, Germany)

Quantity	Value	Unit
Thermal power at heat exchanger	3,782	MWth
Electric power	1,300	MWe
Number of fuel elements	193	
Number of fuel rods per fuel element	236 or 300	
Geometrical arrangement of fuel rods in a fuel element	16 × 16 or 18 × 18	
Diameter of fuel rods	0.75 or 9.5	mm
Height of active core	3.9	m
Total mass of uranium	103,000	kg
Mean enrichment in first core	1.9, 2.5, 3.2	mass% ²³⁵ U
Mean enrichment in exchanged rods	3 to 4	mass% ²³⁵ U
Pressure in primary circuit	158	bar
Circulation rate of water	18,800	kg/s
Water temperature at reactor entrance	291	°C
Water temperature at reactor exit	326	°C
Pressure in secondary circuit	65	bar
Steam temperature	280	°C
Circulation rate of steam	2,050	kg/s

containment vessel. Circulating pumps are available there that would pump the water back into the reactor vessel through heat exchangers.

Since this is a handbook of nuclear *chemistry*, a short comment will be made here on chemical tasks in a nuclear power plant. A detailed treatment of the chemical and radiochemical problems encountered in nuclear power stations (PWR and BWR) can be found in the literature (Lin 1996). One important task is the surveillance and control of the cooling circuits, in particular the primary cooling circuit.

As has been mentioned before, the control of the reactor power is partly solved by the addition of boric acid to the primary coolant. A regulation of the reactor by control rods necessarily creates an inhomogeneous neutron field and consequently an inhomogeneous heat evolution in the reactor core. The addition of boric acid to the cooling water results in a very homogeneous load of the reactor core. The dosing of boric acid and its addition to, and removal from, the water is an important chemical task. Boric acid changes the pH of the water that would lead to corrosion if it were not balanced by the addition of basic substances (e.g., LiOH) in the right amount. Radiolysis of water creates elemental oxygen (and hydrogen) in the water of the primary circuit³. To prevent corrosion, extra hydrogen is added to the water. Some longer-lived radioactive corrosion products (like ⁶⁰Co, $T_{1/2} = 5.3$ years) are transported with the primary circuit and may be deposited at undesired locations. This has to be controlled and avoided. Small amounts of tritium diffuse through the cladding of the fuel rods and tritium and fission noble gases penetrate through pinholes. The same is true for some fission iodine,

particularly during power changes (transients) and at shutdown of the reactor. The iodine is found as different species and in various compounds. Decontamination of externally contaminated parts removed from the reactor or decontamination of spills is another task of a radiochemist.

The water of the primary circuit always contains trace amounts of fission products. These may stem from a small outer contamination of the fuel rods by traces of uranium. (The total surface area of the fuel rods exposed to the primary coolant amounts to about 7,000 m², equal to the size of a soccer field.) The fission products may also stem from pinholes in a fuel rod. The measurement of the fission product spectrum and the nuclidic composition allows the radiochemist to decide between the two possibilities. Consequently, the defective fuel rod can be isolated and removed.

Finally, the nonradioactive water used in the secondary circuit and in the third circuit has to be conditioned (removal of calcium bicarbonate and other mineral salts). Waters discharged have to be checked for radioactive and nonradioactive components. Frequently, all the water that has been in contact with radioactive material is released only after distillation!

After this more detailed discussion of the pressurized water reactor, some other types of reactors will also be treated briefly.

57.4.2.2 The Boiling Water Reactor (BWR)

The main difference between the BWR and the PWR is that the former possesses only one cooling circuit. Therefore, the water of the primary cooling circuit is directly driving the turbines. This has the disadvantage that the turbines have to be shielded in order to protect the personnel from the radioactive water. The radioactivity of the steam from the primary circuit is not due to the presence of fission products, because these remain inside the fuel elements, or to (n,γ)-activated corrosion products, because they do not enter into the vapor phase, but to the nuclide ¹⁶N, an emitter of hard γ rays of 6.1 MeV with a half-life of 7.13 s. It is produced inside the reactor core from the oxygen of the cooling water by the following reaction: ¹⁶O (n,p) ¹⁶N. Despite of its short half-life, ¹⁶N reaches the turbines because of the high circulation speed of the water/steam system. Two advantages of the BWR compared with the PWR are that no loss of thermal energy takes place at a heat exchanger and that the absence of a heat exchanger makes a more compact configuration possible and, hence, a smaller containment vessel is needed.

57.4.2.3 The RBMK Reactor

The RBMK reactor has been developed in the former Soviet Union, and has become known in the West mostly because of the Chernobyl accident (GRS 1996). Quite a number of reactors of this type, slightly modified, are still operating in the area of the former Soviet Union. The reactor uses the principle of the BWR. It has, however, neither reactor vessel nor containment. The reactor vessel is replaced by 1,661 pressure tubes. As shown in [Fig. 57.12](#) each pressure tube houses two fuel elements in series. Each fuel element consists of an array of 18 fuel rods. The cooling water enters the pressure tubes from below and exits above as a mixture of water with, on the average, 14.5% steam. The outlet of the 1,661 pressure tubes are united in two

■ Fig. 57.12

Schematic representation of a pressure tube of the RBMK-1000 reactor. The pressure tube contains two fuel elements (above and below). A fuel element consists of a bundle of 18 fuel rods. The pressure tube houses the stream of cooling water. The sketch is not to scale: the diameter of the pressure tube is 88 mm, its length is a total of 22 m, of which 9 m are above the core and 5 m are below and contain no fuel. The pressure tube is surrounded by graphite, which serves as a moderator for the neutrons. The number of such pressure tubes forming the reactor core is 1,661 (GRS 1987; GRS 1996)

pressure tanks where the separation of steam and water takes place. The steam drives the turbines as described for the PWR above. The water is pumped back to the pressure tubes. As opposed to the PWR or BWR in the RBMK reactor, the moderation of the neutrons takes (mostly) place in the graphite elements housing the pressure tubes (► Fig. 57.12). Further details of the reactor are given in ► Table 57.11.

■ Table 57.11

Typical parameters of the RBMK-1000 (Chernobyl version)

Type:	Boiling water/pressure tube reactor
Moderator	Graphite
Cooling agent	H ₂ O
Power, thermal	3,200 MWth
Power, electric	1,000 MWe
Fuel	UO ₂
Total amount of uranium	190 t
Enrichment	2% ²³⁵ U
Height of reactor core	7 m
Diameter of reactor core	11.8 m
Pressure tubes: number	1,661
Pressure tubes: outer diameter	88 mm
Pressure tubes: wall thickness	4 mm
Temperature of moderator	550–700°C
Flow rate of cooling water circulated	37,600 t/h
Water temperature at core entrance	270°C
Water temperature at core exit	284°C
Steam pressure	70 bar
Flow rate of steam circulated	5,780 t/h

This reactor type has some advantages (e.g., no requirement for a pressure tank, which is technologically difficult to manufacture, and the possibility to exchange fuel rods during reactor operation). It has several drawbacks (e.g., a difficulty to control power; under some conditions, a positive temperature coefficient of the reactivity; a decrease in safety due to missing reactor tank and containment). The main problem that led to the accident was however that it was possible for a benevolent but ignorant operating crew to override security measures. Hence, the reactor entered into a state that necessarily led to an explosion. The crew of operators reached this state simply by violating written regulations and by bridging electrical safety switches. In the reactors in Western countries even for a malevolent crew it would not be possible from the layout of the structure to bring a reactor to a similar condition.

57.4.2.4 The Fast Breeder Reactor (FBR)

The idea of a breeder reactor is to dramatically extend the resources available to fission reactors. While the reactors described above “burn” essentially the isotope ²³⁵U, which contributes only 0.7% to the natural uranium, a breeder reactor can convert more ²³⁸U to fissile ²³⁹Pu than it consumes ²³⁵U (or ²³⁹Pu). Therefore, in principle, nearly 100% of the uranium can be used for

energy production rather than 0.7% (^{235}U). This would be more than a factor 100 gained in resources. If it is assumed that the amount of ^{235}U available on earth could provide mankind with energy for about 30 years, the use of such breeder reactors could extend this span to about 3,000 years. In practice, however, the factor gained is smaller than 100.

1. As shown before (see [Fig. 57.5](#)), in a light-water reactor some breeding also occurs and ^{239}Pu contributes to fission so that in practice about 1% of the uranium is used rather than 0.7%.
2. In addition, due to side reactions like the formation of heavier plutonium isotopes 100% of the natural uranium cannot be converted to fissile plutonium isotopes in the breeder technology. However, even the (pessimistic) assumption of a factor of 30 would extend the availability of uranium from 30 to 900 years.

Therefore, the fast breeder technology has been developed in different countries on an experimental or pilot-project scale. It has been shown that the fast breeder reactor (FBR) can be operated safely. However, presently it is not attractive economically because sufficient ^{235}U is available to produce nuclear energy at a lower cost. The FBR is certainly an option for the future when other resources become more scarce.

Breeding more fissile material than is used up in the chain reaction requires a fission factor $\eta \geq 2$ (see [Sect. 57.3.4](#)). One neutron is needed for the chain reaction and the second neutron is required for the reaction $^{238}\text{U} (n, \gamma) ^{239}\text{U}$ (decaying to ^{239}Pu).

The dependence of η for the fission of ^{235}U and ^{239}Pu on the neutron energy is given in [Fig. 57.13](#). It appears that η values clearly higher than 2 are found only for neutron energies of $>3 \times 10^4$ eV for ^{239}Pu and $>10^6$ eV for ^{235}U . Consequently, a breeder reactor based on these nuclides must operate with fast neutrons (FBR).

Hence, a moderator is not only not required but should be carefully avoided. Therefore, in a fast reactor one should not use water (or any compound containing hydrogen) even for

Fig. 57.13

Fission factor η as a function of the neutron energy for the fission of ^{235}U and ^{239}Pu (Zech 1988)

■ Fig. 57.14

Schematic sketch of a nuclear power station based on a liquid-sodium-cooled fast breeder reactor (Zech 1988)

cooling purposes. In the FBRs that have been built so far, metallic sodium has been used as a coolant. A schematic sketch of a nuclear power station based on a FBR is shown in [Fig. 57.14](#).

The sketch in [Fig. 57.14](#) reflects basically the setup of the German SN-300. The French Superphénix is similar with the difference that the main pump is located within the reactor tank. Because of the strong (n, γ) -activation of sodium, the reactor possesses three cooling circuits. The primary circuit containing radioactive ^{24}Na from the reaction $^{23}\text{Na}(n, \gamma)^{24}\text{Na}$ inside the core transfers the thermal energy to a second circuit with nonradioactive sodium. This one transfers the energy to a water/steam circuit that drives the turbines and the generator.

A chemist understands that tons of metallic and highly radioactive sodium at high temperature are a challenge. Therefore special attention has to be paid to the reactor tank. It has a double wall with an alarm system that will go off when sodium leaks out of the inner tank. The tank has no connections to tubes. All tubes enter from above the level of the sodium. Nevertheless most of the technical problems that arose with existing pilot plants were related to sodium.

Some characteristics of the German FBR SNR-300 (Kalkar) which has been built to demonstrate the feasibility of the technique are described in the following section.

The fuel rods (length 2.5 m, diameter 6 mm, stainless steel cladding) in the upper 400 mm contain tablets of UO_2 . In the middle part (950 mm long), which represents the fission zone, they contain tablets of a mixture of UO_2/PuO_2 . The lower part (400 mm) again is filled with UO_2 tablets. The upper and lower parts practically serve as breeding zone only. Some additional characteristics are given in [Table 57.12](#). Further information can be found in Zech (1988).

■ Table 57.12

Some characteristics of the German fast breeder reactor SNR-300 (Kalkar)

Power, thermal	762 MWth
Power, electric	295 MWe
Number of fuel elements	205
Number of fuel rods in fuel element	166
Diameter of fuel rod	6 mm
Active height of core	950 mm
Fuel	PuO ₂ /UO ₂ tablets
Content of fissile Pu in fuel	24% (inner zone fuel elements) 33% (outer zone fuel elements)
Amount of fissile Pu in core	1,150 kg
Number of breeding elements	96
Number of rods in breeding element	61
Composition of breeding material	UO ₂
Circulation rate of Na (1st circuit)	3,552 kg/s
Pressure at entrance/exit of core	9.3/1.3 bar
Temperature at entrance/exit of core	377/546°C
Circulation rate of Na (2nd circuit)	3,264 kg/s
Pressure at entrance/exit	13.6/10.2 bar
Temperature at entrance/exit	335/520°C
Pressure of steam	160 bar
Temperature of steam	495°C

57.4.2.5 The Concept of the Accelerator-Driven System (ADS)

The idea of a reactor driven by an accelerator seems strange at first sight. Why combine a complicated instrument (reactor) with an even more complicated one (accelerator)? Looking more closely a number of advantages appears.

The basic idea is to use a beam of protons (energy: 1–1.6 GeV, beam current: 5–20 mA) impinging on a large target of molten heavy metal (e.g., Pb) as an intense source of neutrons. It costs on the average about 30 MeV of proton energy to produce a free neutron (as a result of a sequence of spallation reactions). Hence, one can calculate that a proton beam of 1 GeV and 10 mA will produce a total number of about 2×10^{20} n/s (corresponding to a neutron flux of about $6 \times 10^{15} \text{ cm}^{-2} \text{ s}^{-1}$ at a distance of 50 cm). These extra neutrons fed into a fissioning system open up a number of possibilities that are otherwise not available due to the scarce neutron balance especially in thermal neutron fission (see ▶ Sect. 57.3.4, values of η). The extra neutrons may be used (1) for (n,γ)-reactions with the purpose to breed new fissioning nuclei or to transform long-lived radioactive isotopes into shorter-lived ones; (2) to operate the reactor in a subcritical state, e.g., with $k = 0.95$ rather than $k = 1$; (3) to selectively destroy by fission

undesired nuclides like some isotopes of plutonium or other transuranium elements that have a potential for weapons and are ecologically problematic.

There are different variants of the basic idea. A survey is given in IAEA (1997). In the following, the concept proposed by Bowmann et al. (1992) will be outlined, which would open up the way to using ^{232}Th as a fertile material that could be transformed into the fissile uranium isotope ^{233}U . The approach is illustrated in ► Fig. 57.15. A beam of highly energetic protons (1.6 GeV) from an accelerator is directed onto a target of Pb.

In the target a very high flux of neutrons of about $10^{16} \text{ cm}^{-2} \text{ s}^{-1}$ is produced. The target is surrounded by a moderator (D_2O at a temperature of $40^\circ\text{C}/70^\circ\text{C}$ inlet/outlet), which contains actinides to be burned in the high neutron flux and fission products to be converted into less long-lived products by neutron capture.

Outside the inner region (D_2O) a subcritical assembly of fissile material in the form of a melt of fluorides (LiF/BeF_2 containing $^{233}\text{UF}_4$ or fluorides of other fissile nuclides at a temperature of $500/700^\circ\text{C}$ inlet/outlet) is circulated producing the thermal energy required to drive the turbines. The operation of the core in a subcritical state ($k = 0.97$) increases the safety of the reactor. As it has been shown before (see ► Sect. 57.3.6), the reactivity window for safe operation of a critical reactor is given by $1 + \beta$ (where β is the fraction of delayed neutrons).

► Fig. 57.15

Schematic sketch of the target assembly and core of an accelerator-driven system (ADS) (Bowmann et al. 1992)

The value of β amounts to 0.0065 for ^{235}U but only to 0.0028 for ^{233}U . In a state with $k = 0.97$ this window is increased to 0.0328, i.e., to more than ten times the value of a corresponding critical state. One may also compare the time behavior of the pilot reactor in Chicago (► Fig. 57.2). After insertion of some reactivity, at $k < 1$ the reactor is self-stabilizing (leveling); at $k > 1$ an indefinite exponential increase in power is observed.

The outermost region (► Fig. 57.15) is again filled with heavy water and contains a solution of salts of ^{232}Th that would undergo the following breeding reaction:

The ^{233}U bred is subsequently put into the fluoride melt in order to undergo fission. The proposed system has a number of additional advantages. (1) It is estimated that about 10% of the electricity produced from the reactor is sufficient to operate the accelerator. (2) The available thorium resources are larger than those of uranium and since thorium would be 100% burned it would provide mankind with energy for centuries. (3) Mining of thorium is easier and ecologically less problematic than mining of uranium. (4) The fission of thorium produces considerably less of the problematic transuranium elements (Np, Pu, Am, etc.).

There are, however, serious problems to be overcome for the realization of the proposal. The main problem of the proposed project is chemical. ^{233}Pa has to be “milked” daily from the breeding area because otherwise it would react to produce ^{234}Pa , which would decay to nonfissile ^{234}U . In addition, fission products would have to be separated in short intervals from the highly radioactive fluoride melt.

Another problem is corrosion due to the hot fluoride melt. Previous experience with the Molten Salt Reactor Experiment (MSRE) at the Oak Ridge National Laboratory (Weinberg 1970) seem to indicate, however, that these problems can be overcome.

The problems mentioned above are certainly the reason why, recently, more modest proposals have been put forth (Bowman 1998).

They concentrate on the removal of neptunium, plutonium, americium, and curium by fission from spent LWR fuel elements. For this purpose, the spent fuel elements would be first converted to fluorides (including their cladding of Zr). This way, uranium could be removed as volatile UF_6 and could be recycled. The remaining ZrF_4 , fluorides of the transuranium elements and nonvolatile fission products could be mixed with NaF. The molten mixture of salts would be passed through an ADR core in such a way (one slow pass) that at the back-end fissile nuclides would have been burned. The output mixture could be deposited without any further chemical treatment. Such a deposit could not be misused for fabrication of weapons and would have no risk of becoming critical again under any external conditions. Such an ADS is proposed for a size of 750 MWth and would produce enough electricity to operate the accelerator and to cover its own cost by selling the remaining power. Recently, some groups have reported studies concerning the chemistry of fluoride melts useful for the project (Ignatiev et al. 2000; Laidler and Bresee 2000; Uhlir 2000; Marecek et al. 2001; Mel'nik et al. 2001; Tanaka et al. 2001; Uhlir et al. 2001). The concept discussed above is based on thermal neutrons moderated by graphite.

Other concepts are based on fast neutrons (Rubbia 1997) and claim to have the advantage that long-lived fission products are also destroyed. Therefore, a geological storage is no longer

needed and could be replaced by a storage of the treated waste in steel canisters for a time span of 300 years. This latter technique resembles the operation of FBRs and, due to the better neutron economy, it could perhaps be realized also without accelerator.

In any case, there are quite a number of options to produce nuclear energy for mankind while existing resources become scarce. Nevertheless it is also certain that these options still require large investments into scientific explorations.

Since weapons based on nuclear fission (“atomic bombs”) are in principle fast homogeneous reactors, the following section is dedicated to the principle of nuclear weapons.

57.4.3 Nuclear Weapons

There are two different kinds of nuclear weapons. Weapons based on the fission process (“atomic bombs”) and weapons based on the nuclear fusion reaction (“hydrogen bombs”). The fusion weapons get most of their energy from a fusion process of light nuclides (like deuterium) to helium. Fusion weapons contain a small fission bomb that serves to heat the fusion matter to a temperature of about 10^8 K required for the start of the fusion process.

A fission bomb is a homogeneous reactor of metallic ^{235}U or ^{239}Pu that can reach a very high reactivity (criticality factor $k = 1.5$ to 2 ; see [Sect. 57.3.5](#)) and possesses a very short neutron cycle time ($\tau = 10^{-8}$ to 10^{-9} s, see [Sect. 57.3.6](#)).

For the values given of k and τ it can be easily estimated using [Eq. \(57.34\)](#) that any amount of fissile material present would be consumed within a time span of 10^{-7} s. In this process the following energy would be set free (using an average value of 170 MeV of [prompt] energy per fission fragment):

$$E_X/J = 1.602 \times 10^{-19} \frac{m_U}{M_U} N_A E_p / \text{eV} \quad (57.36)$$

where E_X/J is the total (prompt) energy set free in joules, m_U is the mass of ^{235}U fissioned, M_U is the molar mass of ^{235}U (~ 235 g/mol), N_A is the Avogadro constant ($6.022 \times 10^{23} \text{ mol}^{-1}$), E_p/eV is the amount of prompt energy set free per fission in eV ($\sim 1.7 \times 10^8$), and the numerical factor is the value of the coefficient converting eV to J.

For 1 kg of ^{235}U ($m_U = 1,000$ g) the result is $E_X = 7 \times 10^{13}$ J. The energy of explosive devices is usually measured in tons of trinitrotoluene (TNT), a conventional explosive. An amount of 1,000 t of TNT corresponds to 4×10^{12} J. Hence, the fission of 1 kg ^{235}U corresponds to slightly less than 20 kt of TNT.

Schematically, the construction of a fission weapon is as follows. Fissile material (pure ^{235}U or ^{239}Pu) in a subcritical arrangement, distributed over a larger volume, is compacted rapidly using conventional explosives. The compacting can take place by approaching two parts in a tube-like arrangement (“canon type”) or several parts in a spherical arrangement (“concentric type”). At the moment of highest density (highest value of k), a neutron source is switched on that starts the fission reaction. The total power set free increases exponentially over a time span of about 10^{-6} s. Due to this exponential time law nearly the whole energy is set free at the very end of the time span. The explosion of the bomb causes a sharp descent of k beyond the maximum, interrupting the chain reaction. Most of the power of about 10^{20} W is set free, while the bomb disintegrates within a time span of 10^{-7} s. An early start of the chain reaction has to be avoided because this would lead to a disintegration of the bomb before its full power has been reached. In any case, two extremely fast processes are competing: the chain reaction

and an explosive disintegration of the supercritical system which then becomes subcritical again. Both processes occur on a timescale of about 10^{-8} s. Hence, the development of a very efficient and well-controllable conventional explosive system is as important as the availability of highly enriched ^{235}U or pure ^{239}Pu . Fortunately, this makes it difficult to build atomic bombs that possess an effective explosive power.

A thermonuclear bomb contains a small fission bomb in the middle serving to ignite the fusion reactions. A thermonuclear bomb produces two peaks of power: a first peak is due to the fission bomb and a second peak is due to the fusion reactions.

The light elements undergoing fusion are deuterium, tritium, and lithium. At temperatures of $T = 10^7$ to 10^8 K, the following reactions take place:

Very large thermonuclear bombs possess an additional outer layer of ^{238}U . It undergoes fission by the fast neutrons originating from the fusion process and this way sets free additional energy.

The so-called neutron bomb that does not have large destructive power but kills by radiation is based on reaction (38). It is obvious from momentum conservation and the relative mass of the neutron and the α particle that the neutron will carry away 80% of the total energy released. The fraction of the energy taken by the α particle – due to the strong interaction of the charged particle with the surroundings (see [Sect. 8.2 in Chap. 8, Vol. 1](#)) – will be converted to heat and hence to mechanical and thermal destruction, whereas 80% of the energy transferred to the neutron, due to the less frequent interaction of neutrons with matter, will contribute to harmful and long-ranged radiation of fast neutrons – except for the case of the presence of water (liquid, or in the form of dense clouds) where neutron bombs are of limited effect ([Sect. 57.3.2](#)). It would certainly be preferable that nuclear weapons are never be used again.

57.5 The Nuclear Fuel Cycle

The discussion of the fuel cycle will be limited here to uranium or plutonium. Other fuel cycles, which may become important due to new alternate reactor concepts like thorium-based accelerator-driven reactors, will not be the subject of the following section.

The fuel cycle starts with the mining of the uranium. It continues with its chemical isolation, possibly an isotopic enrichment of ^{235}U (see [Chap. 51 in Vol. 5](#) on “Isotope Separation”), the manufacture of the fuel elements, and their use in the reactor. If a final storage of spent fuel elements as such, as practiced in some countries, is not preferred, the cycle continues with a dissolution of the fuel elements. The remaining uranium and the newly formed plutonium are separated from the fission products. Plutonium can be reintroduced into the reactor in the form of Mixed OXide (MOX) fuel elements. Uranium has to pass through an enrichment plant in order to increase the content of ^{235}U from about 0.8% in the spent fuel to about 3%. The enriched fraction will be returned to new fuel elements.

■ **Table 57.13**

Survey on resources of uranium (1997). The resources (in units of 1,000 t) are given separately for well-known and less well-known sites (assured resources/additional estimates) and for different estimated prices of mining (\$/per kg of uranium) (NEA 1997)

	Assured resources		Additional estimates	
	<80 \$/kg	<130 \$/kg	<80 \$/kg	<130 \$/kg
Australia	622	93	136	44
Kazakhstan	439	162	196	63
USA	110	251		
Canada	331	0	99	
South Africa	218	52	66	22
Namibia	156	31	91	17
Brazil	162	0	100	
Russia	145		36	
Ukraine	46	38	17	30
Uzbekistan	66	17	39	7
Niger	70	0	1	
Mongolia	62	0	21	
Others	107	112	31	81
Total	2,534	756	833	264

The depleted fraction may be used in a breeder reactor. The separated fission products will have to go to some final deposit.

57.5.1 Manufacture of the Fuel and Fuel Elements

Uranium is found in the Earth's crust in a concentration of $2.7 \times 10^{-4}\%$ and is therefore more copious than, e.g., silver with $0.07 \times 10^{-4}\%$. However, most of the uranium is very uniformly distributed in small concentrations among granites. Rich deposits are seldom. These originate from secondary processes: pegmatites of hydrothermal origin in upper regions of granites and, especially, sediments of $\text{UO}_2/\text{U}_3\text{O}_8$ from the erosion and weathering of granites.

The prospecting of uranium mines is facilitated by the radioactivity of uranium and its daughter products. Uranium deposits are usually judged by their size and by the price it costs to extract a kilogram of uranium. A survey of the worldwide resources of uranium is given in

► [Table 57.13](#).

The yearly consumption of uranium in 1996 was 60,500 t (NEA 1997). It has remained nearly constant since. From this number and the values in ► [Table 57.13](#) (figuring an efficiency of mining of about 90% and a future constant use) one may estimate that the “assured resources” will last for about 50 years (from 1997 on). An expected increase in consumption

would decrease the number accordingly. A transition to the breeding technology would however guarantee a supply for more than 1,000 years.

Mining of uranium takes place in open pits or underground, depending on the location (and origin) of the deposits. For underground mines it is important to have a good ventilation (at least ten times higher than in conventional mining) because the radon isotopes, formed in the decay of uranium, emanate into the mines and create a risk of lung cancer for the workers. Dust of uranium minerals contains radium isotopes that are dangerous bone seekers.

In order to isolate uranium, the mined ore is broken, milled, and extracted by one of two procedures. One of the extraction procedures uses a basic solution of sodium carbonate and sodium bicarbonate. The other one is an acidic procedure using sulfuric acid and sodium chlorate. The latter procedure dominates today and will be briefly discussed here. It has the ecological advantage that radium which ends up in the tailings is left there in the very insoluble form of radium sulfate.

The milled ore is leached for 6–12 h in sulfuric acid. The supernatant is decanted or filtered from the remaining ore. The solution is passed through an anion-exchange column where uranium is fixed and most of the other metals (except iron) pass through. Uranium and iron are eluted subsequently from the column. A solution of calcium hydroxide is added to the solution. This way, iron(III)hydroxide is precipitated and filtered off. Uranium is then precipitated as ammonium diuranate $((\text{NH}_4)_2\text{U}_2\text{O}_7)$ by adding NH_4OH . The yellow precipitate is filtered off (“yellowcake”).

For use in reactors operating with natural uranium, the yellowcake can be converted to UO_2 by heating it under reducing conditions. It may then be incorporated directly into the corresponding fuel elements. For use in reactors working with enriched uranium, the UO_2 has to be converted to UF_6 . For this purpose, UF_4 is first prepared by reacting UO_2 with HF . The UF_4 is then oxidized by elemental fluorine to UF_6 . Other variants of these procedures cannot be discussed here in detail and the interested reader is referred to the literature (e.g., Pickert and Zech 1981).

The compound UF_6 is fairly reactive and hydrolyzes with water. The most important property of UF_6 is its low sublimation point of 56.5°C , which makes it suitable for a separation of the isotopes ^{235}U and ^{238}U in the gas phase.

There are three procedures that are used for the enrichment of ^{235}U (Choppin and Rydberg 1980; Pickert and Zech 1981): (1) gas diffusion process, (2) gas centrifugation process, and (3) nozzle process. All three processes use the fact that UF_6 with the isotope ^{235}U is lighter by three mass units than the compound with ^{238}U .

In the gas diffusion process, UF_6 in gaseous form is pumped along some microporous diaphragms, and the fact that $^{235}\text{UF}_6$ diffuses more rapidly through the diaphragm than $^{238}\text{UF}_6$ is used.

In the gas centrifuge process, light molecules are enriched at the center and heavy ones at the outside of a rotating vessel. The size of a single centrifuge is about 1 m in length and about 40–80 cm in diameter. Rotational speeds are around 1,000 rpm. Details are not published but it is estimated that about ten stages are required to enrich ^{235}U from 0.7% to 3%. For comparison, a diffusion plant would require about 1,200 stages.

In the nozzle-type enrichment method, a fast stream of gas is blown through a nozzle along the wall of a curved surface. The heavier molecules concentrate on the outside of the curved surface and the lighter ones toward the center, where they can be skimmed off. The nozzle-type setup may be looked at as a stationary centrifuge. About 500 stages are required to enrich ^{235}U from 0.7% to 3%. Further details of these processes are found in Choppin and Rydberg (1980)

and Pickert and Zech (1981). Due to the military importance of such enrichment plants, many details are kept secret.

After enrichment, the UF_6 is collected in a reaction tank. There it is converted to ammonium uranyl carbonate ($(\text{NH}_4)_4[\text{UO}_2(\text{CO}_3)_3]$) by adding water, carbon dioxide, and ammonium hydroxide. The ammonium uranyl carbonate precipitates from the aqueous solution, is filtered, and thermally decomposed into UO_3 . The uranium trioxide is reduced to UO_2 using hydrogen gas at 550°C . The UO_2 is pressed into tablets that are sintered at $1,700^\circ\text{C}$ for 3 h forming very hard tablets of ceramic character. They are ground to a tolerance of ± 10 or $\pm 25\ \mu\text{m}$. These tablets are filled into tubes of zircaloy (an alloy with $>90\%$ Zr) up to 5 m long and about 1 cm in diameter. The tubes are flooded with helium and closed by welding. Some head space is left in the fuel rods to allow the expansion of fission product gases (► Fig. 57.10). Finally, the fuel rods are assembled in racks forming the fuel elements to be mounted inside the reactor core. Details differ from reactor to reactor.

57.5.2 Reprocessing of Spent Nuclear Fuel

After the use of the fuel elements in the reactor, there are two options for the treatment: (a) final storage as intact fuel rods and (b) reprocessing. The option (a) is simple and needs no further discussion here. Reprocessing seems, however, preferable from two standpoints: ecologically, it is better to remove the long-lived and dangerous plutonium before the final storage of the waste. In addition, reprocessing is also preferable from the standpoint of making full use of the valuable energy resources of mankind.

In any case, a cooling-down phase of at least 100 days (preferably a few years) is normally observed in a tank adjacent to the reactor core. The fuel rods are then packed into special containers, e.g., “CASTOR.” These containers may undergo an additional waiting time of “intermediate storage” on the premises of the power station. Finally, for case (b) above, they will be transported to the reprocessing plant.

The principle of reprocessing is as follows (“PUREX process”). The process starts with cutting the fuel rods in pieces of about 5 cm length. The fuel (UO_2/PuO_2) is dissolved in half-concentrated nitric acid. Radioactive aerosols and radio-iodine set free in the process are retained in filters (aerosols in mechanical filters, iodine in filters impregnated with silver nitrate). Fission rare gases (mainly ^{85}Kr , $T_{1/2} = 10.5$ years) may be condensed in cold charcoal filters and filled later into steel cylinders.

After filtration of insoluble rest products, the solution containing the remaining fission products, uranyl nitrate, and plutonium nitrate is submitted to an extraction cycle with a solution of 30% of tri-*n*-butyl-phosphate in kerosene. Uranium and plutonium pass to the organic phase and the fission products remain in the aqueous solution. Since a high decontamination factor of 10^{-7} has to be realized for fission products in the U/Pu fraction, the extraction steps are repeated many times using some mixer-settler units or some countercurrent extraction columns (Choppin and Rydberg 1980; Pickert and Zech 1981).

For the separation of uranium and plutonium in the organic phase, the plutonium is reduced (by Fe(II) sulfamate or other reducing agents) to the oxidation state III and is eluted to a new aqueous phase. Finally, uranium is stripped from the organic phase into a solution of dilute nitric acid. Further purification procedures that cannot be detailed here, follow for all the fractions discussed. Ample information is found in the literature (see, e.g., Choppin and Rydberg 1980; Pickert and Zech 1981).

Finally, plutonium in the form of PuO_2 together with UO_2 will be used for the manufacture of new MOX-fuel elements. Uranium with a remaining content of about 0.8% in ^{235}U will return to the enrichment plant. The fission products will go to final storage as described in the next section.

57.5.3 Storage of Nuclear Waste

There are several possibilities for storing the highly radioactive waste from nuclear power stations. Decisions (or no decisions) are made on a national basis and depend on the geological and climatic conditions as well as on the political situation in the different nations. Here only two options will be presented that reflect the broad range of possibilities.

One of the big questions is about the untreated fuel elements mentioned at the beginning of [Sect. 57.5.2](#). The US government has decided for a “once through fuel cycle,” i.e., it has chosen to deposit untreated fuel elements. In addition to political reasons, the decision was made because of the availability of an appropriate repository site: Yucca mountain in the desert of New Mexico. It is isolated from population centers (distance to the nearest large community, Las Vegas: 150 km) and surrounded by a military area and by land owned by the federal government. The repository is planned in a tunnel at a depth of 300 m below ground level. It is located in an arid area 300 m above the ground water level. The mountain consists of welded and non-welded tuff with good isolating properties. A number of (21) fuel elements are planned to be sealed in canisters of stainless steel (Type 316NG) covered with an especially corrosion-resistant alloy (Alloy 22). Tuff has strong adsorbing properties that limit transport of radionuclides even in the unlikely event that (1) the fuel elements would be defective, (2) the steel canister mentioned would be broken, or (3) water would flood the tunnel.

Further information on this project can be found on the Internet (DOE 2003). In early 2003, the site was ready to accept spent fuel elements, but a decision to use it as a final repository had not yet been made. Hence, spent fuel elements and some high-level radioactive waste in the United States are presently stored in 131 different locations in 39 states.

The other option to be discussed, in the following section, is the final storage of high-level waste (HLW) after chemical treatment, i.e., after removal of uranium and plutonium. For this purpose, the solutions of nitrates of the fission products have to be brought to dryness, converted to oxides, mixed with some glass-forming agents (SiO_2 , B_2O_3 , TiO_2 , CaO , and others), and melted at temperatures of 900–1,200°C. At these temperatures, highly resistant borosilicate glasses are formed. The content in fission products amounts to about 20%. The glass may be put into steel containers and solidified there. Alternatively small glass beads can be prepared. Again the glass beads are poured into a steel canister. Liquid lead is added to fill the space between the glass beads. This procedure guarantees a good flux of heat to the outside and adds to the stability of the assembly. The total volume of such highly active waste amounts to 2.5–3 m³ per year per nuclear power station of 1,000 MWe.

In Germany it is planned to take the canisters to the rock-salt deposits of Gorleben (near Lüchow-Dannenberg). These rock-salt formations are unchanged over a period of 100 million years. It can be assumed that such deposits will remain unchanged for at least the next few million years. It is planned to use horizontal corridors (length about 1,000 m) drilled in a depth of about 800 m below ground level. From these corridors, vertical holes (50 m deep and 30 cm in diameter) will be drilled into the salt. These holes will be filled with the waste canisters up to about 10 m below the corridors. The rest will be filled with salt and concrete. One such bore

hole can take the waste that one nuclear power station (1,200 MWe) produces in 1 year. The distance of the bore holes along the corridors will be about 10–20 m. When all the boreholes of a corridor are occupied, the corridor itself will be refilled with salt and other parallel corridors, beside, above, or below will be drilled. The salt has the property to flow under pressure. Any space will fill up again with time.

The actual situation is that the exploration of the repository has been finished. Similar to the situation in the United States, no decision has been made to start depositing waste canisters. Wastes returning from the French reprocessing factory in Cap de La Hague or from the British plant in Sellafield are stored above ground in an interim storage unit.

57.6 Summary

Nuclear fission is a process of high scientific, technical, and military relevance. This is due to the fact that a self-propagating chain reaction can be achieved. Research reactors are an invaluable tool for the scientist. Nuclear power stations provide mankind with energy presently worth 150 billion dollars/euros per year (about 16% of the world's consumption of electric energy). This energy does not contribute to the ecologically relevant production of CO₂. Nuclear energy has, however, the problem that an absolutely safe storage of radioactive waste for extremely long times must be guaranteed. Strategies have been developed that come close to this goal. Recently, additional approaches have been proposed to definitely solve this problem (at least to a large extent) by burning the most dangerous waste products (actinides and, possibly, some long-lived fission products) in ADS. Fission has, however, a negative side. Atomic bombs have taken a terrible toll of human lives in Hiroshima and Nagasaki. Fortunately these weapons have never been used again and it is hoped that a state using such weapons would have to expect consequences from the community of nations that would make their use unattractive and render their possession useless.

57.7 Editors' Notes

1. Owing to the logarithmic energy scale, the equidistant points of the horizontal axis represent units of “lethargy,” i.e., $\ln(E_0/E)$, where E_0 is the initial energy of neutrons. Note, however, that the direction of the lethargy axis is the opposite of the energy axis: the higher the energy, the lower is the lethargy and vice versa (p. 2623).
2. The quantity $\varphi(E)$, representing an un-normalized “density function” of the energy of neutrons – see [Sect. 9.2.1 in Chap. 9, Vol. 1](#), has the dimension of flux density per energy, i.e., $\text{cm}^{-2} \text{s}^{-1} \text{eV}^{-1}$. This is in accord with the unit of R , which turns out to be s^{-1} (p. 2624).
3. See for some details of radiolysis of water as a reactor coolant in [Sect. 23.6.3 of Chap. 23, Vol. 3](#) on “Radiation Chemistry” (p. 2645).

Acknowledgments

The author would like to thank Dr. H. Braun and Dr. K. Eberhardt for several valuable hints. Special thanks are due to Dr. Nancy Hecker-Denschlag and Dr. Peter Black for their help in the English formulation of the text.

Abstract: This chapter describes, in two parts, new-generation nuclear energy systems that are required to be in harmony with nature and to make full use of nuclear resources. The issues of transmutation and containment of radioactive waste will also be addressed. After a short introduction to the first part, ▶ Sect. 58.1.2 will detail the requirements these systems must satisfy on the basic premise of peaceful use of nuclear energy. The expected designs themselves are described in ▶ Sect. 58.1.3. The subsequent sections discuss various types of advanced reactor systems. ▶ Section 58.1.4 deals with the light water reactor (LWR) whose performance is still expected to improve, which would extend its application in the future. The supercritical-water-cooled reactor (SCWR) will also be shortly discussed. ▶ Section 58.1.5 is mainly on the high temperature gas-cooled reactor (HTGR), which offers efficient and multipurpose use of nuclear energy. The gas-cooled fast reactor (GFR) is also included. ▶ Section 58.1.6 focuses on the sodium-cooled fast reactor (SFR) as a promising concept for advanced nuclear reactors, which may help both to achieve expansion of energy sources and environmental protection thus contributing to the sustainable development of mankind. The molten-salt reactor (MSR) is shortly described in ▶ Sect. 58.1.7. The second part of the chapter deals with reactor systems of a new generation, which are now found at the research and development (R&D) stage and in the medium term of 20–30 years can shape up as reliable, economically efficient, and environmentally friendly energy sources. They are viewed as technologies of cardinal importance, capable of resolving the problems of fuel resources, minimizing the quantities of generated radioactive waste and the environmental impacts, and strengthening the regime of nonproliferation of the materials suitable for nuclear weapons production. Particular attention has been given to naturally safe fast reactors with a closed fuel cycle (CFC) – as an advanced and promising reactor system that offers solutions to the above problems. The difference (not confrontation) between the approaches to nuclear power development based on the principles of “inherent safety” and “natural safety” is demonstrated.

58.1 Editors' Introduction

When the project of the second edition was about to be launched by Springer, the Editors of the Handbook had several questions to answer and one of these being how to complete Prof. Denschlag's excellent introduction to the "Technical Application of Nuclear Fission" with the new tendencies and designs of energy production by fission. It has also been realized that some countries were underrepresented among the authors of the first edition compared to their contribution to nuclear science. Fortunately, two experts of nuclear energy production, the Authors of this chapter, have accepted the Editors' invitation to cooperate.

The Editors are well aware that it is rather unusual to write an editorial introduction to one particular chapter; however, in this case it seems to be appropriate and desirable. The reason is that this chapter is at least as much about the future of (nuclear) energy production as about its present (and to some extent its past).

Although there are cases in the history of science when fiction writers like H. G. Wells (in "The World Set Free," written in 1914) predicted scientific and technical breakthroughs (to an accuracy of a few years) such as the discovery of artificial radioactivity or even the first operation of a full-scale nuclear power plant (NPP) (see Wagar 2004). However artistic prophesies that have come true are retrospectively selected and interpreted in a way that is meant to astonish the reader of the present. And if such a prophecy never comes true, it will be forgotten, and no harm is done.

Real scientific writing like this chapter is different. Writing about the past is writing about facts that can be either correct or not. And the scientific community – or even the Editors of this Handbook – can easily judge this. In this respect, there is a resemblance with nonfiction writing like history.

Predictions are a different matter. First of all, they are difficult to make – *especially about future* as Niels Bohr put it in 1957 (who was probably not the first person to use this crack in history). Poor predictions about science will not be easily forgotten either. And this makes it risky for the scientist. If science is connected with an important and controversial industry like in this case, where future depends on politics and public opinion, things become even more difficult. This may cause two equally excellent experts of the same area to have different views (or visions?) about the future, which is also influenced by their characters and personal backgrounds.

For the above reasons, the Editors of the Handbook have decided to split this chapter to two complementary parts with the first one written by Prof. Fuji-ie and the second by Prof. Adamov, and let them express their views as they will. Future will decide whose extrapolation turns out to be more accurate.

58.2 Future: The Extrapolation of Past and Present

The following part has been written by Prof. Y. Fuji-ie.

58.2.1 Introduction

It can be said that civilization is at the turning points to change from that based on chemical reactions to that based on nuclear reactions. The civilization based on chemical reactions started when mankind succeeded in controlling fire in nature and getting heat and light from it, thus making use of the energy produced by chemical reactions. The heat and light enabled mankind to settle down and live from farming as well as cattle breeding in the neighborhood of rivers in the ancient civilization of Orient.

The nature on the Earth has made joint work with sunshine to form the biosphere where a closed system for material flow was possible among plants and animals. However, the industrial revolution about 200 years ago introduced mechanical energy and electricity with steam engines and electric generators. Underground fossil fuel was used without reverse processes of oxidation. It is said global warming due to carbon dioxide urges mankind to find new energy resources other than fossil fuel.

The civilization based on nuclear reactions on the other hand started at the end of the nineteenth century when Röntgen discovered X-rays and analyzed their characteristics. X-rays have been used in various fields of science and technology with success. However, the first application of nuclear energy was made as atomic bombs dropped in Hiroshima and Nagasaki to result in massive deaths of the public and destruction of the cities.

Total abolition of nuclear weapons has not yet been achieved in these decades and there are some countries that have raised suspicions by conducting nuclear testing and obtaining nuclear weapons. Nevertheless, it is good news that nuclear weapons have never been used in wars in these decades exceeding more than half a century.

The aims of nuclear energy development are the following: (1) energy supply to support the civilization, (2) conversion of fertile material to fuel, and (3) creation of knowledge opening the fields and areas for new cutting-edge applications.

Humankind has already succeeded in the first stage of nuclear power development, i.e., electric power generation with fission reactors, especially with light water reactors (LWRs) obtaining excellent safety records. It has taken the latter half of the twentieth century since Dwight D. Eisenhower's speech "Atoms for Peace." However, the issues concerning material conversion and treatment of nuclear waste have been left to this century.

The main efforts in this century therefore must be concentrated to material conversion and management, which mean the realization of nuclear fuel cycle. Practically the following two steps are considered: (1) an LWR fuel cycle that leads to advanced reactors such as the sodium fast reactor (SFR) and (2) an advanced nuclear energy system with related fuel cycle. The second step is more concerned with nuclear material and sensitive to nuclear arms. Therefore, the nuclear menace shall be fully concerned, and individuals as well as organizations in the nuclear community shall make up their minds to develop advanced nuclear energy system exclusively for peaceful use. Advanced nuclear energy system shall be developed for future prosperity of mankind and limited only to peaceful purposes.

The nuclear energy system shall be developed as a "harmonious" system to satisfy the requirements to be discussed in [Sect. 58.1.2](#), fully utilizing the assets of nuclear fission

reactions, i.e., about three neutrons in number and 200 MeV of energy released per reaction. This means not only that nuclear energy should serve just as an energy source but also that issues related to radioactive waste and waste heat should be mitigated to harmonize with the society and the natural environment.

Considering that civilization is supported by science and technology, nuclear science and technology including nuclear energy systems will have to mature into a comprehensive science and technology that supports civilization at the basis. In this century, it is essential to establish the nuclear energy system as harmonious as to be accepted by the society (Fuji-ie 1992, 2005).

In this part, some concepts that are considered promising as advanced nuclear energy systems are described. Reactor type classification in [Sects. 58.1.4](#), [Sect. 58.1.5](#), and [Sect. 58.1.6](#) is basically done by coolant materials. The LWR is selected as an existing reactor system that has succeeded in commercialization and still has a potential to improve its performance and extend the applicable fields ([Sect. 58.1.4](#)). The high temperature gas-cooled reactor (HTGR) is discussed with emphasis on the potential of an efficient and multipurpose use of nuclear energy, including hydrogen production ([Sect. 58.1.5](#)). Focus is placed on the SFR as the promising concept for advanced nuclear energy systems to achieve both expansion of energy sources and environmental protection to contribute to the sustainable development of mankind ([Sect. 58.1.6](#)).

Although the lead-cooled fast reactor (LFR) is not dealt with in this part, it is also a promising advanced FR and will be introduced in the second part by Prof. Adamov. In addition, several topics of international importance, such as nonproliferation, are treated in his part. Other advanced reactors, such as the gas-cooled fast reactor (GFR), the super critical water-cooled reactor (SCWR), and the molten-salt reactor (MSR), are briefly introduced in [Sects. 58.1.4](#), [Sect. 58.1.5](#), and [Sect. 58.1.7](#), respectively.

58.2.2 Requirements on the Advanced Nuclear Energy System

This section considers the requirements for an advanced nuclear energy system as well as for the R&D that will meet these requirements (Fuji-ie 1995).

58.2.2.1 Peaceful Use of Nuclear Energy

The reminiscence of Hiroshima and Nagasaki warns mankind to use nuclear energy exclusively for peaceful purposes. It is worthwhile to note the report of Prof. Dr. Takashi Nagai who contributed the emergency rescue of the atomic bomb victims at Nagasaki in October 1945 (Nagai 2000).

“Everything was finished. Our mother land was defeated. Our university had collapsed and classrooms were reduced to ashes. We, one by one, were wounded and fell. The houses we lived in were burned down, the clothes we wore were blown up, and our families were either dead or injured. What are we going to say? We only wish to never repeat this tragedy with the human race.

We should utilize the principle of the atomic bomb. Go forward in the research of atomic energy contributing to the progress of civilization. A misfortune will then be transformed to good fortune. The world civilization will change with the utilization of atomic energy. If a new and fortunate world can be made, the souls of so many victims will rest in peace.”

The peaceful use of nuclear energy has been accelerated by the statement of the US president, Dwight D. Eisenhower, “Atoms for Peace” in December 8, 1953 (Eisenhower 1953).

“The United States knows that if the fearful trend of atomic military build-up can be reversed, this greatest of destructive forces can be developed into a great boon, for the benefit of all

mankind. The United States knows that peaceful power from atomic energy is no dream of the future. The capability, already proved, is here today. Who can doubt that, if the entire body of the world's scientists and engineers had adequate amounts of fissionable material with which to test and develop their ideas, this capability would rapidly be transformed into universal, efficient and economic usage?... The more important responsibility of this atomic energy agency would be to devise methods whereby this fissionable material would be allocated to serve the peaceful pursuits of mankind. Experts would be mobilized to apply atomic energy to the needs of agriculture, medicine and other peaceful activities. A special purpose would be to provide abundant electrical energy in the power-starved areas of the world."

Recent world interests on nuclear energy are directed also to the peaceful use of nuclear energy through nonproliferation and still forward to abolition of atomic bombs. An example of this movement is the speech of the US President, Barack Obama delivered in Prague on April 5, 2009 (The Huffington Post 2009), who won the Nobel Peace Prize later "for his extraordinary efforts to strengthen international diplomacy and cooperation between peoples" (Nobelprize.org 2009), and another example is the statement by the United Nations (UN Security Council 2009).

Scientifically, research and discussion concerning nonproliferation is directed to change the properties of nuclear fuel with mixing in addition to plutonium transuranium and others to result in small explosion potential for a nuclear weapon (Saito 2005; Kessler 2007). The other direction of nonproliferation is to ask the nations that want to develop nuclear energy to keep safeguards actions guided by the International Atomic Energy Agency (IAEA).

58.2.2.2 Harmonization with Nature

The principle of science and technology in the twenty-first century must shift from a focus on utilization to a priority on harmony with the society and the environment.

For the energy system to harmonize with nature, it should function in a manner similar to the ecological energy system like the biosphere that maintained a balance in the preindustrial era. An important aspect of the biosphere is that it has the potential to maintain a closed circulation of materials through the coexistence of animals and plants. Therefore, it would be meaningful to establish a similar system within the assets of nuclear fission reaction. The biosphere is not closed in energy; it absorbs energy from sunshine and releases the excess back to space. However, it has the potential to be a closed system for the circulation of materials. On the other hand, the fossil energy system cannot maintain the closed circulation of materials because it does not have the capability of dissolving carbon dioxide that the plant has.

While a nuclear energy system inherently generates no carbon dioxide, it does generate radioactive materials. From the scientific point of view, it is necessary to evaluate the feasibility of a nuclear energy system to contain radioactive material in a room, transmute it to nonradioactive or short-lived radioactive material with state-of-the-art science and technology, and release no radioactive waste to the natural environment, i.e., the achievement of full recycle and zero emission should be the expected final goal. With continuous efforts to reach this goal, one can design a nuclear energy system that harmonizes with nature and is accepted by the society.

Then, as quite naturally assumed, questions will arise such as these. Is it possible to have a nuclear energy system that utilizes resources efficiently without producing radioactive waste? Can nuclear energy provide a solution?

To begin with, one should study the possibility of satisfying such a requirement from a scientific standpoint. If it is scientifically possible, then one should consider how and with

what technology it can be done; what is scientifically possible is not necessarily achievable technologically with 100% efficiency. Since technology must always consider efficiency, the energy can never be converted with 100% efficiency and it always involves some energy losses.

Although nuclear fission reaction does not occur between long-lived actinide nuclei and thermal neutrons in LWRs, it does with fast neutrons. Since nuclear fission reduces radioactive waste, it is beneficial in terms of a lowered environmental burden rather than effective utilization of resources. Cross section ratios of fission to capture of actinide nuclides have been compared between the dominant neutron energy range of a fast reactor (FR) and that of an LWR. The results show that the ratios of cross section for minor actinide (MA) nuclides of the FR in particular are one or more orders of magnitude larger than those of the LWR. Therefore, neutrons of the FR can burn more actinide nuclides in the core.

Since the transuraniums are convertible into fissile materials and burnable, the next issue concerning radioactive waste is efficiency in material separation and nuclear reaction, briefly, technological efficiency. This is precisely an issue of technology and method. Even though the current efficiency level is far from satisfactory, further R&D may improve it.

As the other source of radioactivity of FR, R&D should be focused on the long-half-life fission products (FPs). Studies have been just started to transmute long-half-life radioactive fission products or to shorten half-lives. Although further studies are necessary, it seems to be possible to solve this problem. For example, nuclide separation technology may be improved in efficiency with facilities such as lasers as well as particle accelerators.

58.2.2.3 Effective Utilization of Resources and Environmental Preservation

One of the neutrons released by fission reaction is used for the next fission reaction. The other neutrons, i.e., surplus neutrons, are available for producing new nuclear fuel through absorption by fertile materials such as ^{238}U and ^{232}Th , except for those absorbed by other elements or leaking out of the reactor core. In other words, the surplus neutrons can transmute fertile materials to fissile ones.

Higher fuel production, i.e., fuel breeding, is expected if the ratio of produced fuel to consumed one is greater than unity, while fossil fuel relying on chemical reactions does not have this feature. If such a system is built, it is very likely that low-quality uranium and uranium in seawater will become resources, while they have been less useful for the LWR cycle. Thus, the system is expected to ensure stable energy supply for mankind over a long period of time, imposing no practical restriction in resources (🔗 Fig. 58.1).

If the consumption of uranium continues at the current level and is used only for LWRs, the uranium resources for energy sources will be available for less than 100 years. However, if the nuclear fuel cycles are established and fuel breeding is achieved in FRs, then the duration of the use of uranium resources will be extended to several thousand years. In addition, if uranium in seawater becomes usable, the duration of use will exceed more than a million years. To that end, it is important to build nuclear reactors that can breed fuel and to develop nuclear fuel cycles, which can efficiently extract reusable nuclear fuel materials after burning.

Nuclear burning of higher-order plutonium isotopes and minor actinide nuclides, which are difficult to burn in LWRs and therefore turn into waste, in nuclear reactors or particle accelerators, will greatly contribute to reducing the effects of radioactive waste, even if it may bring little benefit as an energy source. It is also beneficial to eliminate the radioactivity of fission products with long half-lives by converting them into stable nuclides.

■ Fig. 58.1

Significance of developing fast reactors (FRs) (OECD/NEA, IAEA 2007; OECD/NEA 2009). The reserve-to-production ratios of petroleum, natural gas, and coal were evaluated by dividing the ascertained recoverable reserves by the amount of production in 2008. The ratios of uranium were evaluated by dividing the reserves by the annual demand in 2006 because uranium is easy to reserve and therefore the amounts of production and demand are not correlative. If the price level rises suddenly because of huge demand, recoverable reserves may increase (This is said to be more likely for natural gas)

Reducing the effects of radioactivity takes considerable time. For instance, if the aim is to reduce the radioactivity of nuclear waste to the same level as that of the natural uranium ores within a millennium, a typical time length for civilization, it is necessary to consider this issue in conjunction with geological storage of waste.

In order to achieve such a goal, it will be necessary not only to focus on the nuclear reactor but also on its nuclear fuel cycle of material management; i.e., to consider the nuclear energy system as a whole.

Developing a nuclear energy system that would keep radioactive materials within the system itself and minimizing the generation of radioactive waste would make it possible to suppress the environmental effects to a socially acceptable level. Since nuclear fuel has high energy density, the amount of necessary material and generated radioactive material corresponding to unit energy production are overwhelmingly smaller than those of fossil fuel. Nuclear energy systems have greater potential benefit for the environment.

58.2.2.4 Safety Assurance

Safety assurance is one of the most important factors in the establishment of both the advanced and current nuclear energy systems in society. The release of radioactive materials into the environment has to be prevented in accidents, as well as in normal operational conditions. For a nuclear energy system aiming at both fuel production and the transmutation of radioactivity, the safety assurance with a focus on high performance of the reactor core is essential. It is therefore important to develop the nuclear energy system that minimizes the risk of severe core damage.

The appropriate combination of inherent safety features and engineered ones should be necessary to prevent the extension of anticipated transients and also postulated accidents within the system. As an example of inherent safety features, one should mention Doppler reactivity that is effective against criticality events, which is a basis to ensure the reactor shut down function. Natural circulation is also an inherent safety feature to enhance the cooling capability of the reactor core. The nuclear energy system should be designed in such a way that severe core damage leading to the release of massive amounts of radioactive materials could be avoided.

It is also essential that these high-level measures for ensuring safety should be easy to understand not only to a limited number of professionals, but also to the general public. While explaining technical matters in non-technical language is a challenge, no matter how high the safety level ensured by the system is, society is unlikely to understand or accept complex descriptions. Therefore, it is important to demonstrate that the system really possesses the inherent and engineered safety features and encourage the public to listen to the professionals. Modern nuclear technology cannot be established with disregard for professional expertise.

58.2.3 Foresight of Expected Form in Future

58.2.3.1 Self-Consistent Nuclear Energy System (SCNES)

A system concept, which (1) seeks to produce an amount of fuel more than or equal to that consumed, (2) contains all the radioactive material produced in the system (spatial containment), and (3) brings it safe for human life within finite lengths of time (temporary containment), would be regarded as a “Self-Consistent Nuclear Energy System (SCNES).” Such a system can be defined as a nuclear energy system that provides mankind with safe and stable energy for long periods of time and exhibits consistency for the management and treatment of radioactive materials produced through energy supply.

The SCNES proposed in 1992 as the scientific concept for the expected nuclear energy system in the future civilization shall simultaneously satisfy at least the following four requirements, as shown in  Fig. 58.2:

- Effective utilization of energy : highly efficient and multipurpose utilization of energy.
- Fuel production: long-term security of resources.
- Transmutation and isolation of radioactivity: containment of radioactive materials in time and space.
- Safety assurance: practical elimination of release of radioactive materials at normal operation and accidental conditions.

The developers of nuclear energy systems have made a steady effort aiming to satisfy the requirements of the SCNES, but they failed to satisfy all the requirements simultaneously. Since it may take a long time to reach the expected goal of the development of the SCNES itself, a step-by-step approach is recommended with the following stages of development:

1. Plutonium burning/producing FR that will be incorporated into the LWR-leading power generation system with its potential for reducing the burden to the environment and sustainable usage of nuclear energy.
2. Actinides cycle FR that can recycle the whole of plutonium as well as other minor actinides.
3. Expected nuclear energy system, i.e., the SCNES, where the elimination of radioactive fission products is pursued.

In this step-by-step approach, it is essential to promote the R&D of the nuclear fuel cycle including reprocessing. Several methods such as advanced aqueous reprocessing and dry reprocessing have potential for the nuclear fuel recycle technologies as a whole. These methods also reduce the environmental burden. The PUREX (Plutonium Uranium Recovery by EXtraction) process focuses on extracting plutonium and has been proven in LWR reprocessing. Dry reprocessing, developed in the USA and Russia has been proven effective for transuranium other than plutonium. Nuclear fuel cycle technologies should also be considered in terms of nuclear nonproliferation, utilization of resources, and reduction of the environmental burden. It is desirable to advance R&D not only for the extraction of specified elements including plutonium with high-purity as is the case with the PUREX process, but also for the elemental separation of transuranium elements with appropriate purity and for the collective separation of them together with minor actinides. In other words, shifting from high-decontamination to low-decontamination is one of the future directions.

58.2.3.2 Fast Reactor and Related Fuel Cycle

It can be said that objective-oriented nuclear reactions such as nuclear fission, absorption, and transmutation occur in a nuclear fission reactor whereas material balance can be kept through separation and mixing of nuclides in a nuclear fuel cycle to satisfy the requirements as discussed in Sect. 58.1.3.3. Here, the important point is that about three neutrons generated from a nuclear fission in the FR core have potential to satisfy the requirements for each stage of the above step-by-step development (Table 58.1). One neutron is indispensable for the nuclear chain reaction for any development stage. More than one neutron among the excess neutrons are needed for fuel production at the stage (1), and further neutrons are required to burn actinides at the stage (2), and transmute radioactive fission products into stable or

■ **Table 58.1**

Neutron balance in fast reactor and thermal neutron reactor (Fuji-ie 1998)

Items	Fast reactor	Thermal neutron reactor ^a	Remarks
Neutrons produced per fission	2.9	2.9	
Neutrons consumed per fission

Scientific feasibility of SCNES	○	×	Produced > Consumed

^a Estimated for an light water reactor (LWR) with mixed oxide (MOX) fuel.

short-lived nuclides at the stage (3). In particular, the feasibility for the stage will depend on how to separate fission products.

Meanwhile, future technological progress may make the recovery of radioactive fission products possible. In order to efficiently transmute radioactive fission products into stable or short-lived nuclides, it is important to use excess fission neutrons effectively. However, neutrons may be in short supply when elements are separated through chemical processes alone, because not only the intended radioactive nuclides but also their stable isotopes absorb neutrons. If radioactive nuclides alone are isolated (isotope separation), many more types of nuclides can be transmuted without excessive neutron absorption (► [Table 58.2](#)). It clearly shows the importance of nuclear fuel cycle in a new nuclear energy system. In such a system, radioactive fission products would be isolated not at the elemental level but at the isotopic level with, e.g., a laser, and also nuclear spallation neutrons would be utilized with particle accelerators to increase the number of neutrons. Some studies to develop technologies of isotope separation and accelerators have been in progress. However, considering the current technical levels, more advanced R&D is necessary to commercialize these technologies.

58.2.3.3 An Expected Nuclear Energy System

Imagine a nuclear energy system in future, a system derived from the successful pursuit of scientific potential on the basis of the discussions thus far. The flow of fuel materials and energy in the expected nuclear energy system would be something like the example shown in ► [Fig. 58.3](#).

Natural uranium employed in the system causes its own nuclear fission in the reactor. On the other hand, the fertile material, ^{238}U , is converted to nuclear fuel material by nuclear transmutation, which is utilized as an energy source as well. In addition, radioactive materials

reprocessing. Thus, most energy is required for uranium enrichment and reprocessing including isotope separation and multi-recycling of long-lived fission products, though the fraction of energy spent for such purposes could be limited to 1% at most (Arie et al. 2007). The fundamentals of adjusting fuel material in a nuclear fuel cycle are separating/mixing materials, elements, and nuclides.

Transuraniums generated by fuel burning include fissile material (e.g., ^{239}Pu and ^{241}Pu) and fertile material (e.g., ^{240}Pu , ^{242}Pu , and minor actinides), separated and recovered in a fuel cycle facility, and then recycled as fuel materials. Basically, transuraniums are assumed to be transmuted into fissile materials in a reactor at some stage and eventually to undergo fission reactions.

Then, fission products could be separated into radioactive and nonradioactive products with the state-of-the-art nuclear technology like lasers and particle accelerators to be called for in the fuel cycle facility. After that, radioactive fission products with short half-lives could be kept within the system until they decay to nonradioactive nuclides, and those fission products with long half-lives could be transmuted into nonradioactive products.

Nuclear R&D should seek ways to technologically achieve this scientific potential with concrete methods.

58.2.3.4 Advanced Nuclear Reactors

It is worthwhile to make a brief review of advanced nuclear reactors including advanced LWRs (ALWRs) and Generation-IV reactors.

During the coming half century, advanced LWRs will not only play an important role as the producers of base-load electricity but their field of application will also be expanded. Thus far, LWRs have been a reliable energy source with exhibiting superior safety performance and high economic efficiency of larger reactors. Their significance as power reactors will not change in the future. In addition to the practical accomplishment of large reactors to date, marine reactors were developed in the past as a power source and they have been used successfully in submarines and icebreakers for some time now. Because of this development, it is expected that these reactors will be developed as a medium-and-small-sized LWR allowing for marine reactors with good controllability. Furthermore, it is expected that nuclear reactors capable of unmanned operation, long plant life, and low output will be developed for various locations including remote areas.

Development of FRs is important in particular because they are expected to deliver high performance in fission reactions.

The Generation IV International Forum (GIF) was chartered in July 2001 to lead the collaborative efforts of the world's leading nuclear technology nations to develop next-generation nuclear energy systems to meet the world's future energy needs. Six types of the reactors are investigated as the GEN-IV system, which has features aiming at performance improvement, new applications of nuclear energy, and/or more sustainable approaches to the management of nuclear materials. Enhanced sustainability is achieved primarily through adoption of a closed fuel cycle (CFC) with reprocessing and recycling of plutonium, uranium, and minor actinides in FRs including the SFR and LFR.

Above all, the SFR has been developed as the most promising FR system in the world so far. The concept of SFR will be presented in [Sect. 58.1.6](#). The LFR will be introduced in the part written by Prof. Adamov.

High temperature systems offer the possibility of efficient process heat applications and eventually hydrogen production. This approach provides significant reduction in waste

disposal and uranium resource requirements (GIF Overview 2009). Especially, the very high temperature gas reactor (VHTR) pursues another direction of R&D, i.e., further utilization of nuclear energy by converting it into not only electrical energy but also, in the future, environmentally friendly forms. Hydrogen energy is a typical example of this form. Converting nuclear energy into hydrogen energy has very high potential for non-carbon dioxide emission systems, but the conversion requires a high-temperature thermal source. As a solution for this conversion, the VHTR, which has been called as a high temperature gas-cooled reactor (HTGR) is under development. This is a good example showing that civilization based on nuclear reactions can integrate technologies based on chemical reactions developed so far.

58.2.4 Light Water Reactor (LWR)

58.2.4.1 Development Results for LWRs

There are two types of LWRs: the pressurized water reactor (PWR) and the boiling water reactor (BWR). The PWR pressurizes the primary coolant, light water, flowing in the reactor vessel at approximately 16 MPa to avoid its boiling, heats it to about 320°C by the heat generated in the core, sends it to the steam generator where the secondary coolant (light water) is boiled, and finally generates electricity by driving the turbine generator with the steam at high temperature and pressure. Although the system of the PWR tends to be slightly complex since it is equipped with a secondary cooling system, it has an advantage in preventing radiation leaks to the outside because the secondary coolant water is basically free of radioactivity. Shippingport 1, a research reactor with 60 MW output in electricity (hereinafter referred to MWe), was very different from the later standardized PWRs with regard to the positions of the inlet and outlet nozzles for the reactor vessel and with regard to the setting of the steam generator. However, after 1965, the PWR power plants started operation one after another, and the technology has been developed to establish today's basic style of the PWR. As the capacity of plants became larger, the standard has shifted from two loops at the 600 MWe class and three loops at the 900 MWe class to four loops at the 1,100–1,300 MWe classes.

On the other hand, the BWR heats the primary cooling water with heat generated in the core and generates steam in the reactor at approximately 7 MPa and 280°C. Then, this steam drives the turbine generator directly to generate electricity. Although the BWR requires careful handling of radioactive steam, because it uses the generated steam directly to generate electricity, it has the advantage of simplifying plant configuration. The first commercial BWR was Dresden 1 in the USA, which started full-power operation in 1967. This reactor was somewhat different from today's BWRs, including a cooling system that adopted a dual cycle method, i.e., a combination of direct and indirect cycles. Later, BWRs had some improvements that included a change to a single cycle method by placing the steam drum in the reactor vessel, the reduction of fuel cost through increased burnup, the downsizing of the containment vessel, and the multiplexing of the emergency core cooling system (ECCS). These improvements have brought today's basic style.

As of January 1, 2009, the number of nuclear power plants around the world is 432, and their total output is 390 GW in electricity. PWRs account for about 60% and BWRs for about 20% of the total. This means LWRs account for around 80% of reactors and serve as the major nuclear power plant worldwide (Japan Atomic Industrial Forum Inc 2009).

If one looks over the world, there are many construction plans for LWRs, and thus the era of LWRs will be continued for the coming 5 decades at least.

58.2.4.2 Large LWRs as Base-Load Power Supply

After LWRs have been established in society as the commercial reactors, more improvements are planned to produce advanced PWRs (APWRs) and advanced BWRs (ABWRs) for higher safety and better economy.

As for APWRs, the USA designed the AP600 with 600 MWe output that adopts a passive containment cooling system. Later, an improved version with better economy, the AP1000, was designed to produce 1,000 MWe output. French and German industries have developed the European Pressurized Reactor (EPR) with 1,600 MWe output. It has adopted passive safety features against severe accidents, easy operation, and economic competitiveness through a plant life of 60 years. An EPR is being built in Finland, with operation scheduled in 2010. The major features in EPR design include preventing the extension of core melting during the severe core damage by enhancing the cooling capability for the molten materials. If the molten material should diffuse to the outside of the reactor vessel, then it would be channeled to an area specially designed to stabilize it and set adjacent to the reactor pit. Beside this area, an in-containment refueling water storage tank (IRWST) is provided to supply cooling water to cool the hot molten material. These features will strengthen the integrity of the reactor vessel in case of severe core damage and thus the safety enhancement can be achieved. In Japan, the advanced PWRs are now under preparation as Tsuruga Power Station Units 3 and 4, with operation scheduled in 2016 and 2017, respectively. They have some improvements including high reliability steam generators, powerful function of engineering safety facilities, and a lower probability of core damage.

On the other hand, the world's first two ABWRs have been constructed and are in operation in Japan. These are Kashiwazaki-Kariwa Units 6 and 7, which started operation in 1996 and 1997, respectively. Later, Hamaoka Unit 5 started operation, in 2005, and Shika Unit 2 started in 2006. The major feature of the ABWR is an internal pump for recirculation placed directly in the bottom of the reactor pressure vessel instead of the conventional method of external recirculation. As a result, large-diameter piping for recirculation is no longer necessary. In addition, the ECCS is composed of three independent systems. These features can always maintain the sufficient coolant level for the reactor core even in case of pipe rupture accidents with the ECCS functions, so that the risk of loss-of-coolant accident (LOCA) can be practically eliminated and thus the safety and reliability are improved. The USA, taking advantage of experience in development and operations of LWRs, has developed the simplified boiling water reactor (SBWR). It is a reactor with 670 MWe output and strengthened passive safety design that includes a core cooling system by natural circulation that does not employ recirculation pumps. Furthermore, a large-scale reactor, the economic simplified boiling water reactor (ESBWR) with 1,590 MWe output has been developed. Currently, the ESBWR is being evaluated for regulatory approval and is scheduled to start operation in 2015.

58.2.4.3 Use of MOX in LWRs

In the LWR, in addition to ^{235}U , ^{238}U undergoes fission reaction naturally with fast neutrons and is transmuted into ^{239}Pu and ^{241}Pu in the core and utilized as fuel. Thus, an idea is considered to reprocess the spent fuel from the LWR, extract plutonium and uranium from it, mix them to fabricate MOX fuel and reuse it as fuel for the LWR.

Plutonium is produced in the reactor core during operation, and the original fuel naturally transmutes into MOX fuel as the operation continues. The form of the MOX fuel is not

particularly different in composition and configuration from past LWR fuels produced in the improvement process. Europe has 20 years of experience of utilizing MOX fuel.

Reprocessing LWR fuel to fabricate MOX fuel for reuse in LWRs is the first step in the nuclear fuel cycle. Ideally, this process can increase the utilization factor of natural uranium by 50% compared with the case of a once-through LWR fuel cycle. Methods of loading MOX fuel in LWRs are being studied. The representative methods include the loading of 1/3 MOX fuel in the core to avoid a significant change in the existing LWR core characteristics, and full loading of MOX fuel over the core following modification based on the ABWR core design. The construction of an ABWR that allows for full loading of MOX fuel over the core started in May 2008, at Ohma, Japan, and is scheduled to start operation in 2014.

The contributions of uranium and plutonium to power generation according to the MOX fuel loading rates are compared in [Fig. 58.4](#). In the case of uranium fuel with an initial enrichment of 3.7% uranium shows a greater contribution than plutonium, 65:35, in terms of the average value during the fuel service period. The ratios are 55:45 and 50:50 in the case of 1/4 and 1/3 MOX fuel in the core, respectively. The plutonium contribution reaches up to 80% when loading MOX fuel over the core. Plutonium use in thermal neutron reactors like LWRs is expected to lead not only to an effective utilization of resources but also to significant achievements toward the establishment of a nuclear fuel cycle based on FRs.

58.2.4.4 Multipurpose Use of Medium-and-Small-Sized Reactors

Conditions on Locating Plants Nearby

When one looks back on the R&D up to the twentieth century, improvements in product quality and reduction of cost were often achieved through economy of scale. The same is true for nuclear power plants. The power output of early reactors, particularly LWRs, was some 300 MWe. The current ABWRs and APWRs can generate around five times as much as the early reactors and have improved reliability and economy. In this way, nuclear power plants as a whole have contributed to higher self-sufficiency in energy supply. However, such development has brought with it huge systems and complex technology, which has made it difficult to gain people's understanding and trust. In addition, it is a natural trend to locate such large systems in remote areas, where the cost of land is less, and people living in urban areas receive greater benefit. This has been recognized socially as "macro benefit and micro non-benefit" and has created obstacles to plant construction. Accordingly, a compromise is sought through plans that call for medium-and-small- sized reactors nearer to cities.

When developing countries first employ nuclear energy as an energy source, large reactors are not necessarily appropriate in most cases from the perspective of power-line installation and consumption balance. Under these conditions, medium-or-smaller-sized plants with even higher reliability and better economy are expected. This completely differs from past planning, which focused on the achievement of reliability and economy through larger plant design. Obviously, totally different thinking is necessary for R&D in this direction.

Simple and Easy-to-Understand Safety Principles

There are two ways of thought in relation to medium-and-small-sized reactors. One is to make full use of high technology to produce a high-performance nuclear energy system. The other is to omit many parts from the system by using various natural laws and operating with a larger time constant at a slow pace. In other words, there are two choices, a high-technology system or

Fig. 58.4
Efficient use of resources by using plutonium for thermal neutron reactors (ratios of uranium and plutonium generating electricity); from (Sugisaki 2002)

a donkey system, i.e., a low-tech system with slow response. The high-tech system is intended to improve reliability and integrity by progressively adopting high-performance equipment in conjunction with the development of technology. However, with this approach only, a medium-and-small-sized reactor may not achieve performance as high as a large one. Therefore, additional measures may be required. For example, efficiency and quality could be achieved at the same time by installing a ready-made or prefabricated system. That is,

systems could be standardized and plants could be fabricated in sections or as an integrated system off-site. When the site is prepared, the sections or the integrated system can then be transported and installed. Such a system could work as well as the order-made system for the current large reactors, which are assembled piece by piece on site by a forest of cranes. Also, new methods for nonproliferation may be worth consideration, such as a cassette system for fuel exchange handling, because nonproliferation should be a key factor regarding the installation of nuclear power plants near cities. One possible direction should be the construction of standardized small-or-medium-sized reactors that have good flexibility near cities.

The low-tech system, i.e., a donkey system, is the opposite. It requires less manpower, although it still needs more than natural reactors. Because of needing little maintenance and having potential for a continuous operation for a decade without fuel replacement, it can be sited in an isolated island or in a remote area. Of course, it would be necessary to design the reactor to be robust to disturbance and less dependent on control system operations. It may be easier to understand it as a typical passive safety system. For example, reactor control against disturbance does not require a rapid response as in the case of control rods but expects reactivity feedbacks, such as the Doppler effect to work. Additionally, natural circulation, which is driven by buoyancy force generated by difference in coolant temperature, should be employed in such reactors rather than pumps.

What is mentioned above is obviously expected for the nuclear energy in the twenty-first century. Some concepts about FRs as well as LWRs have already been suggested, and their design studies have also been carried out. It is expected that these concepts will be developed and used to create the above mentioned nuclear energy systems: the safety systems to be described more simply, the economical nuclear energy systems to be placed near metropolises, and the power supply systems in remote areas far from transmission networks. These ideas are also applicable to other systems such as reprocessing plants; instead of one large plant that can reprocess spent fuel for tens of reactors, the installation of smaller plants is under discussion along with the discussion on advanced fuel cycle concepts.

Marine Reactors

The use of nuclear reactors to drive ships has been promoted particularly among nautical nations. Commercial marine reactors include the Savannah in the USA, the Otto Hahn in Germany, and the Mutsu in Japan. They experienced marine operation but unfortunately the development had been cancelled after several years. Nuclear-powered ships require free access to ports in the world, but unfortunately there were no sufficient number of ports to make the marine reactor's operation feasible. Some countries had accepted to prepare the ports, but doing this would still take time.

As for the features of nuclear-powered vessels, the Mutsu had a displacement of about 10,000 tons. Its reactor produced 35 MW of thermal power to deliver speeds of 18 knots. Meanwhile, the marine reactors were required to withstand incomparably severer load changes than land-based reactors. For example, they were required to be capable of increasing power from base load to full power in 30 s to avoid collision. The Mutsu was able to meet most performance requirements during operation, including experimental voyage.

Although nuclear submarines are not the main theme of this handbook, they can keep running underwater for a long time without emitting carbon dioxide or the need for oxygen for propulsion. Several hundred nuclear submarines have been built for military use in Russia and the USA, and their performance has resulted in proof of the high safety performance of LWRs. Marine reactors had been also applied to icebreakers operated in USSR/Russia over 50 years. Nuclear-powered aircraft carriers are equipped with several nuclear reactors.

58.2.4.5 Supercritical-Water-Cooled Reactor (SCWR)

The SCWR is composed of a high-temperature, high-pressure, water-cooled reactor, which operates above the thermodynamic critical point of water (22.1 MPa, 374°C) to achieve a high thermal efficiency. Since the coolant does not change phase in the SCWR, the balance-of-plant is considerably simplified and directly coupled to the energy conversion equipment.

A design example is a system of 1,700 MWe with an operating pressure of 25 MPa and a reactor outlet temperature of 510°C, which is expected to range up to 550°C (► Fig. 58.5). This feature enables ca. 44% of thermal efficiency, which is about one third higher than current LWRs. Passive safety features are incorporated similar to those of simplified BWRs.

In terms of neutron spectrum and fuel cycle, there are two options of the SCWR: the first is a thermal neutron reactor, and the second is an FR-based closed fuel cycle coupled with full actinide recycle based on advanced aqueous processing. Using fast neutrons will be advantageous for achieving sustainability to be aimed for the Generation IV reactor because of their potential to produce at least as much fissile material as it consumes.

Challenges for the SCWR are a feasible core design, accurate estimation of the heat transfer coefficient, and material development for the fuel and core structure for sufficient

► Fig. 58.5

Supercritical-water-cooled reactor (SWCR) (U.S. DOE Nuclear Energy Research Advisory Committee and the Generation IV International Forum 2002)

corrosion-resistance under the SCWR conditions. The low density of supercritical water will need an additional neutron moderator in the thermal neutron reactor option. For the FR option, potential of a positive void reactivity coefficient and design basis loss-of-coolant accidents should be taken into account in the system design.

58.2.5 High Temperature Gas-Cooled Reactor (HTGR)

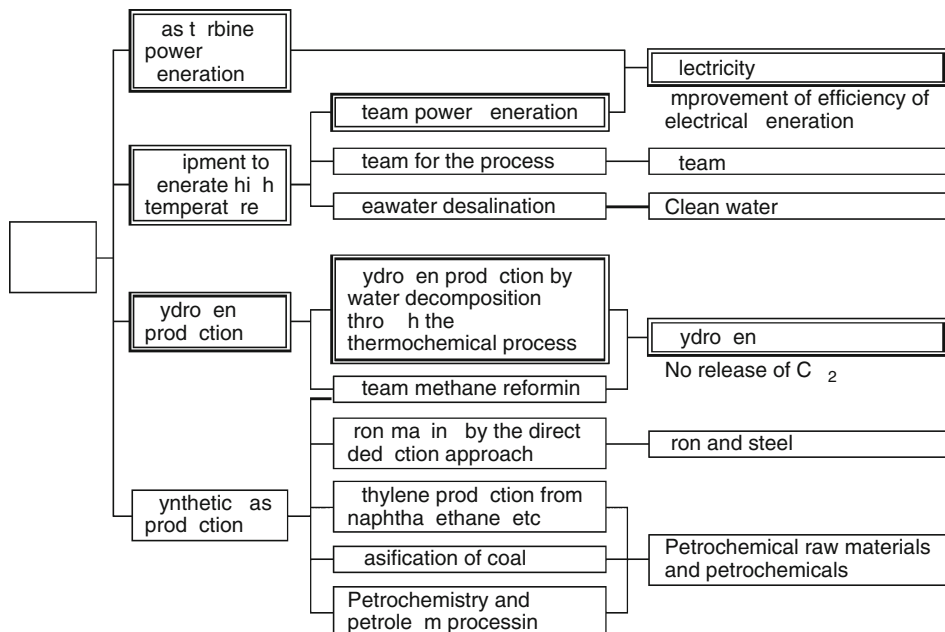

If one could say that the purpose of FRs is to achieve both expansion of energy sources and environmental preservation to contribute to the sustainable development of mankind, the aim of HTGRs is to contribute by offering efficient and multipurpose source of energy, especially chemical energy in form of hydrogen.

If the coolant temperature of a reactor can be raised to more than 700°C, it would not only improve power generation efficiency but also increase the applicability of the reactor as a heat source for purposes such as the generation of hydrogen by thermochemical decomposition of water. If the temperature could be raised to nearly 1,000°C, it would improve thermal efficiency and allow the reactor to be used in chemical and metallurgical industries. [Figure 58.6](#) shows heat utilization assumed in HTGRs. The double-line-boxes in the figure show the particular features of HTGRs.

HTGRs in Japan were originally developed as a substitute for active carbon in blast furnaces used for iron manufacture. This substitution of resources with heat was recognized as a point of compatibility between energy and substance.

Fig. 58.6

Heat utilization of the high temperature gas-cooled reactor (HTGR); from (Fuji-ie 2005)

58.2.5.1 Features of HTGR

A distinctive feature of the HTGRs is its fuel, which differs from the fuel used in LWRs and FRs.  *Figure 58.7* shows a coated particle fuel (approximately 1 mm in diameter), which consists of an oxidative microparticle of uranium or thorium dioxide coated with pyrolytic carbon or silicon carbide. The fuel coating works as a containment vessel. This coated particle exhibits excellent safety characteristics such as the capability to keep radioactive material within itself in up to around 600 MWth module type HTGRs, being a basic element to determine the features of HTGRs. The coated particle is further covered with graphite to moderate neutrons. Therefore, the reactor core becomes larger than that of LWRs; however, the larger size provides the advantage of larger heat capacity.

The typical HTGR fuels are the pebble-bed type, which is a graphite sphere, and the block type fuel; i.e., a graphite block into which coated particles are inserted (Saito et al. 1994). The former is generally suitable for high temperature operation because the fuel spheres circulate slowly in the reactor and each fuel sphere is exposed to high temperature in the reactor for a similar length of time.

As for the coolant, helium, a chemically inactive gas, is used. It is compatible with the structural material and graphite, and it contributes to the reactor's high-temperature features.

58.2.5.2 Hydrogen Production by HTGR

Considering the future utilization of energy, hydrogen production by HTGRs is of particular interest (Ogawa et al. 2009). Distributed energy is typically used in, e.g., batteries and electric cars, and such items do not always require large-sized power reactors, to achieve good economy. This type of advanced nuclear power aims to produce hydrogen by converting the thermal energy generated in nuclear reactors.

High temperature nuclear reactors are advantageous for hydrogen production because they do not use fossil material as energy source, and thus the direct decomposition of water is not accompanied by the release of carbon dioxide. Hydrogen production by HTGRs may be performed by thermochemical cycles like the Iodine–Sulfur (IS) process shown in  *Fig. 58.8*. In the IS process, water reacts with iodine and sulfur dioxide exothermically to produce hydrogen iodide and sulfuric acid, which are then thermally decomposed to produce hydrogen and oxygen, respectively, using high temperature maintained by nuclear energy. The thermal decomposition reactions also produce iodine and sulfur dioxide, which can be used again in the initial reaction, thereby the chemical cycle of water-splitting is completed. The thermochemical cycles offer a means for direct conversion of nuclear heat to chemical energy of hydrogen (Onuki et al. 2009).

There are a couple of questions concerning hydrogen production arising at this point. How much hydrogen production will be necessary, and how much thermal output is expected from HTGRs to produce all the hydrogen needed? Is it economical at all to produce hydrogen with nuclear reactors?

For example, suppose that cars are powered with hydrogen or fuel cells instead of gasoline and that carbon dioxide reduction laws are enacted requiring all vehicles operated in the city to be carbon dioxide free. The current annual consumption of gasoline in Tokyo is equivalent to about 600,000 tons of hydrogen. In order to provide this quantity of hydrogen, about 60 small reactors with a thermal output of 100 MW will be required. Owing to the safety features of

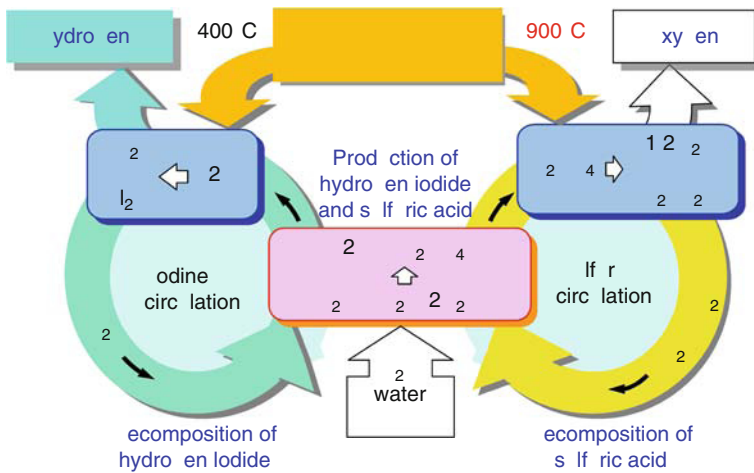

Fig. 58.7

HTGRs and Fuel Forms; from (Japan Atomic Energy Research Institute 1998)

■ Fig. 58.8

Thermochemical water-splitting cycle using iodine and sulfur (Onuki et al. 2009)

HTGRs, it is quite possible to locate them near metropolises in accordance with urban demand. Since the transportation of hydrogen is costly, it would be important to produce hydrogen near points of demand.

58.2.5.3 HTGR as a Power Reactor

As a high-temperature thermal source capable of 950°C, the HTGR offers a more effective way of generating electricity. Because the HTGR can generate steam at higher temperature than the LWR, e.g., the steam turbines will work with significantly higher efficiency.

Another possibility is to develop a direct gas turbine system at high temperature and pressure to increase the efficiency. Since helium has small cross section for neutron capture and is also chemically inactive, no induced radioactivity and no corrosion products can be expected in the coolant. Furthermore, the oxidative microparticle fuel coated with layers such as pyrolytic carbon or silicon carbide is expected to prevent the release of the fission gas into the coolant. Eventually the HTGR is suited to adopt the direct cycle, i.e., the gas turbine cycle, which allows building a more compact electric-power facility than the indirect cycle with a steam turbine system. While the thermal efficiency of electricity generation by steam turbine is about 40%, the gas turbine cycle can increase the efficiency up to ca. 50%.

A set of these compact multiple HTGRs can be referred to as modular type, and an example is the pebble bed modular reactor (PBMR) with the electricity generation of 165 MWe by gas turbine, which can be extended to a medium or large power station by adopting several modules (Koster et al. 2003).

58.2.5.4 Safety of HTGR

The HTGR's "shutdown," "cooling," and "containment" capabilities are as follows. HTGR shutdown using thermal neutrons raises no particular issues except in the case of air or water

ingress. The HTGR also has favorable features for core cooling. The HTGR is robust against high temperature because the fuel particles used are covered with layers of graphite. The sublimation temperature of graphite is as high as 3,500°C, and graphite can keep radioactive materials up to temperatures of about 1,600°C. This temperature is higher than the allowable maximum temperature of the fuel cladding of the LWR and FR, which ranges from approximately 900°C to 1,200°C. Moreover, the graphite in the HTGR has a large thermal capacity, and the power density of the HTGR is several dozen times smaller than that of the LWR. Therefore, a feature of the HTGR is that the temperature rises slowly in response to changes in the reactor output power. Consequently, even if a piping failure causes a helium leak and loss of coolant, the temperature would rise slowly because fuel heat is released through graphite blocks with large heat capacity. This means that engineered safety features such as the ECCS for LWRs, is, therefore, unnecessary. Temperatures in an HTGR during the accident will not exceed the temperature limit against the accidents but be brought under control naturally, representing its high level of safety.

As described, a notable feature of the HTGR using thermal neutrons is that the core is unlikely to melt. On the other hand, graphite oxidation due to the piping failure can be an important safety issue in the HTGR. That is, when a piping failure may occur in the main coolant pipe or in the heat exchanger, the air or steam would flow into the core. Because of its high temperature, the graphite would be damaged by oxidization and generates carbon monoxide. Against the air ingress, the confinement system is provided to restrict the amount into the core, which will mitigate oxidization and suppress the generation density of carbon monoxide to be sufficiently less than the detonation limit. Against the steam ingress, the primary helium system will be kept at higher pressure than the secondary water-steam system or a rapid blowdown system for the water-steam system is provided to mitigate the amount into the core. The gas turbine system is a favorable energy conversion system for the HTGR to eliminate the potential risk of the steam ingress. As a result of air ingress, however, the release of gaseous fission products from the oxidized fuel will be restricted to satisfy the allowable limit, which is equivalent to that for the LWR.

58.2.5.5 Development Status of HTGR

The UK developed coated particle fuel resisting high temperature for HTGRs in 1956. This marked a turning point in the construction of a demonstration reactor in the UK named Dragon. In Germany, an experimental reactor for electricity generation named AVR (Arbeitsgemeinschaft Versuchs Reaktor) has been developed. Its thermal output was 15 MW and it used pebble bed fuel with a diameter of approximately 6 cm. It has successfully operated at a 950°C gas temperature at the core outlet and achieved high availability for around 20 years. Germany has also aggressively performed R&D for a commercial HTGR for electricity generation and cogeneration. In addition, they have studied use of the heat generated by HTGRs to turn coal and lignite, plentiful resources in Germany, into forms such as gas or liquid, which are easy to use and environmentally friendly. Based on experience with the AVR, the thorium high-temperature reactor (THTR) began its operation in 1986. It was a prototype reactor for electricity generation using (Th,U)O₂ fuel with highly enriched ²³⁵U, and its electrical output was 300 MWe. However, it was in operation for only about 3 years because the government had opposed nuclear power, which was a situation similar to that faced by the fast reactor SNR-300.

On the other hand, the USA adopts a block type fuel element in HTGRs. In this fuel element, coated particle fuel and graphite powder are mixed and sintered, then shaped into thin rods, and loaded and sealed into holes in a hexagonal column-shaped graphite block. The experimental

reactor Peach Bottom, designed for electricity generation, started operation in 1967, with power output of 42 MWe. Later, the coated particle fuel was improved, however, operation ceased finally in 1974. In 1981, a demonstration reactor Fort St. Vrain, designed for electricity generation, started operation with a power output of 342 MWe and achieved nearly 40% thermal efficiency. However, repeated small troubles prevented it from maintaining high availability, and the operation ceased in 1989. The USA has also studied the feasibility of large HTGRs with scale merit of economy in mind. Later, however, they shifted to the development of small modular HTGRs such as the gas turbine-modular helium reactor (GT-MHR) (Note: The GT-MHR is an HTGR with improved economy, aiming for high efficiency power generation. In this reactor, high-temperature helium coolant is led to a gas turbine combined with a small power generation unit.). The designs take advantage of the HTGR's coated particle fuel, which resists high temperature. Therefore, even if a piping break causes the loss of core coolant, the heat from the reactor vessel can be dissipated through radiation and will not lead to fuel melting.

The Republic of South Africa aims at the commercialization of a PBMR (thermal power of a little over 200 MW, outlet temperature of approximately 750°C) that employs the technologies of the German pebble-bed type reactor. The national utility ESKOM started development in 1993, and PBMR Ltd. was founded in 1999. The construction schedule of the demonstration plant envisions commissioning in or near 2018.

In China, the 10 MW high temperature gas-cooled test reactor (HTR-10) (thermal power of 10 MW, outlet temperature of 700°C, pebble-bed type) was built with help from Germany. The reactor reached first criticality in 2000 and achieved full power operation in 2003. Presently, the 10 MW high temperature reactor with gas turbine (HTR-10GT) project, aiming at construction of a helium gas turbine power generation system, is underway to study key issues of helium gas turbine technology. In addition, construction of a demonstration plant, high temperature reactor-pebble bed-module (HTR-PM) (electric power of 210 MWe, outlet temperature of 700°C), is underway with completion scheduled for or near 2013.

In Japan, a new reactor project was launched in 1969. Its purpose is to employ HTGRs not only in power generation but also to apply it to steel manufacture and chemical engineering. R&D has been carried out to establish a technological base for HTGRs and to further advance their development. First, the Helium ENGINEERING DEMonstration Loop (HENDEL), a facility for research and testing, had been built for advanced basic study on high temperature technology, and a critical facility VHTRC (very high temperature reactor critical assembly) had been constructed and put into operation. Further, the high temperature engineering test reactor (HTTR) has been constructed, targeting thermal output of 30 MW and an outlet temperature of 950°C (► Fig. 58.9). The reactor achieved full power operation with a helium temperature of 850°C in 2000, and achieved operation at 950°C in 2004. Currently it is operating smoothly, and research and testing are being carried out for other possible applications such as hydrogen production. As for hydrogen production, bench-scale water-splitting was performed by IS process and the chemical reactors such as sulfuric acid decomposer equipped with ceramic heat exchanger have been developed aiming at demonstration of nuclear hydrogen production using HTTRs.

In France, R&D for the ANTARES (AREVA New Technology based on Advanced gas-cooled Reactor for Energy Supply: thermal power of 600 MW, outlet temperature of 850°C, annular core with hexagonal block-type fuel assemblies) is in progress in collaboration with design vendors, utilities, and research institutes. This project is based on the modular high temperature gas-cooled reactor (MHTGR) designed through collaboration with vendors in France, Germany, and the USA, as well as the GT-MHR designed by Russian and US vendors, with the participation of Japanese vendors. The ANTARES aims at an indirect cycle to provide

■ Fig. 58.9

High temperature engineering test reactor (HTTR); from (Japan Atomic Energy Research Institute 1998)

a flexible heat source; either heat supply or cogeneration, with no change in the loop configuration, and is expected to achieve deployment earlier than other technologies that have more development problems to be solved. This R&D started in 2001 and envisions the main results on the problems related to the feasibility being obtained by 2010.

While coated particle fuel has excellent high-temperature durability and is suitable for HTGRs, it is difficult to recycle this type of fuel. That is, mainly due to the fact that this fuel is covered by multilayers of coating material, the fuel cannot be dissolved by nitric acid, which is used to reprocess fuel in LWRs, and it is hard to extract useful nuclear fuel materials from the spent fuel. Therefore, a measure to address this problem has been considered in the development of fuel for HTGRs. The proposal is to enable the complete use of the fuel constituents by remarkably improving burnup. Even in this case, it is difficult to burn higher-order plutonium isotopes and MAs in a thermal reactor, and long-lived radioactive material is contained in the spent fuel. Thus, a concept and methodology have been required, which may lead to commercialize the fuel cycle.

58.2.5.6 High Temperature Gas-Cooled Fast Reactors

For fuel utilization by recycling, a high temperature GFR featuring a helium gas coolant and fast neutrons is being studied. Although R&D is at the basic stage, some types of fuel and cladding

combinations, which do not moderate neutrons as effectively as graphite, are under discussion. For example, the use of particle fuel coated with titanium-group material, which has superior resistance to high temperature, is being considered. Another example is a fuel pin whose cladding tube is made of metallic materials that have a high melting point such as niobium.

A direct gas turbine system working with helium is being considered for GFRs. (Helium, being an inert gas, is advantageous to safety; and the recent technological advances in the gas turbine are expected to progress.)

There is, however, some concern about safety. Since the fuel enrichment is more than 20%, the output density of core fuel tends to be larger than that of thermal neutron reactors like LWRs. In addition, fuel particles without graphite have much less heat capacity, and the high fuel enrichment causes lower Doppler reactivity at the rise of fuel temperature. Because of these factors, it is difficult to ensure a slow temperature rise at an accident, which is possible for HTGR operated with thermal neutrons. Moreover, the countermeasures for core disruptive accidents (CDAs) should be investigated to prevent significant energetics due to concentrating motions of molten fuel and to ensure a long-term stable cooling capability for molten fuels.

The GFR with related fuel cycle is aiming at the sustainable utilization of fuel resources by recycling, as well as multiple utilization and high thermal efficiency, and it may develop new-generation nuclear energy systems that serve as an efficient use of nuclear energy resource and that can harmonize with the environment.

58.2.6 Sodium-Cooled Fast Reactor (SFR)

58.2.6.1 Features of FR

The FR has been emphasized as a leading advanced nuclear reactor following the LWR since the beginning of nuclear energy development. As fast neutrons have high neutronic potential, the FRs are greatly expected to make desired nuclear reactions, which will be capable of expanding the efficient utilization of uranium, transmuting radioactive nuclides into nonradioactive or short-lived ones and managing the quantity and the toxicity of radioactive material within the duration of civilization.

To enable the functions above, the FR system should consist of two parts. One is the reactor where requested reactions should occur and the other is the nuclear fuel cycle where material selections and treatments of materials, elements, and nuclides suitable to feed the reactor core can be made. The necessary functions and the material selection are summarized in the following three Subsections.

Plutonium, instead of ^{235}U , is a main contributor to the nuclear reactions in FRs where mixture of plutonium and uranium is used as fuel. Simple metallic fuel is a candidate to achieve better FR core performance than oxide fuel due to its higher fuel density, which has been employed in the LWR. Carbide and nitride fuels are also considered.

The core configuration without a moderator becomes compact and gives a high power density. The coolant should be less interactive with neutrons, and high thermal conductivity as well as heat transport capability is recommended for an efficient transformation of thermal energy through narrow flow channels. Candidates for the coolant include liquid metals such as sodium and lead, gases such as helium and water including supercritical water.

➤ *Table 58.3* shows comparison of the properties of water, sodium, and helium.

■ Table 58.3

Comparison of the properties of water, sodium, and helium (Iwanami Shoten 1998)

Items		Water	Sodium	Helium
Nuclear	Neutron moderation power	High	Low	Low
Thermal	Melting point °C/Boiling point °C (atmospheric pressure)	0°C/100°C	98°C/880°C	−272°C/ −269°C
	Specific heat (kJ/kg°C)	5.43 ^a	1.30 ^b	5.19 ^c
	Thermal conductivity (W/m°C)	0.57 ^a	66.1 ^b	0.340 ^c
Hydraulics	Density (kg/m ³)	738 ^a	826 ^b	2.38 ^c

^aat 287°C, 7 MPa.^bat 527°C, 1 kPa.^cat 727°C, 5 MPa.

58.2.6.2 Reactor Core of SFR

The reactor core serves to materialize the potential of nuclear reactions and has configuration so as to meet the above-mentioned requirements. The core configuration highly depends on the nuclear fuel cycle such as reprocessing methods and depends on the types of fuel loading; single-region core or multi-region one according to the purposes of the reactor. The main purposes for the core to achieve are to release energy by nuclear fissions, produce new fuel, and transmute radioactive material into short-lived or nonradioactive material. In the development to date, blanket fuel has been provided for fuel production. The core of “Monju,” which is a Japanese prototype FR, is shown in [Fig. 58.10](#) as an example of a sodium-cooled fast reactor core. In Monju, the blanket region is arranged to surround the core fuel region axially and radially so that it can produce fuel material of plutonium. Furthermore, a plan is also investigated to place test fuel to burn minor actinides. Neutron shielding subassemblies are located outside the blanket region. MOX fuel is utilized, which consists of ²³⁹Pu and depleted uranium and has a plutonium enrichment of around 20%. The blanket fuel composed of depleted uranium is arranged on the top, bottom, and circumferential regions of the core, and ²³⁸U in the blanket fuel absorbs neutrons leaking from the core to produce new core fuel.

58.2.6.3 System Configuration of SFR

The system of SFRs is configured to have a process of generating electricity with a high-temperature coolant flowing from the reactor core, i.e., a mechanism by which heat is generated, extracted, and turned into electric power (see [Fig. 57.14 in Chap. 57 of this Volume](#)).

The system configuration varies depending on the method of generating electricity: a steam turbine, a gas turbine, or others. As for sodium cooling, the sodium–water reaction has to be

■ Fig. 58.10

The core of the Japanese prototype fast breeder reactor (PBFR) "Monju"; from (Power Reactor and Nuclear Fuel Development Corporation 1980)

avoided so as not to influence the reactor safety. So far, SFRs have adopted an intermediate sodium system between the primary sodium system and the steam-generating system.

Since the boiling point of sodium at atmospheric pressure is as high as 880°C, the SFR does not require pressurization of the core in principle. The reactor outlet temperature ranges from 510°C to 550°C, which is higher than that of the PWR (~325°C) by 200°C or more. This means that the SFR has great potential for high temperature and conversion efficiency. The thermal efficiency of the SFR can be improved to more than 40% compared to around 35% achieved by the LWR.

58.2.6.4 Safety of SFR

The FR and the LWR have a system that concentrates energy and radioactive material in the core. Therefore, the concepts on safety assurance based on the “defense in depth” principle are also basically the same. However, FR core configuration is not designed to have reactivity maximum configuration and any relocation of core material could increase reactivity (positive reactivity insertion), whereas LWR cores are arranged in the reactivity maximum configuration. Therefore hypothetical core disruptive accidents (HCDAs) are reviewed in the licensing process even though their occurrence probability is negligibly small. As the safety of FRs, the SFR’s safety will be mainly treated here.

Shutdown

Like in LWRs, two independent reactor shutdown systems are installed to protect the reactor core, where safety characteristics of SFRs or LWRs have been taken into account. Concerning the safety characteristics for “shutdown,” the Doppler coefficient of the FR is slightly smaller than that of the LWR. The Doppler coefficient is an important factor from the overpower transient point of view.

When sodium is used as a coolant, the operating pressure is low, and it is unnecessary to assume accidents such as control rod ejection, which may occur in a high pressure operation system like the LWR. In the SFR, an inadvertent control rod withdrawal is anticipated due to the failure of the power control system, which gives no rapid reactivity insertion but a continuous one. Thus, the effect of the control rod withdrawal is not significant, although the Doppler reactivity of the SFR is smaller than that of the LWR. On the other hand, the sodium coolant has the advantages of a large temperature margin for the boiling point and high thermal conductivity.

Based on the above design efforts for the essential safety functions, the occurrence probability of severe accidents can be equivalent to or less than 10^{-6} per reactor years as is similar to the modern LWR. Nevertheless, further efforts to strengthen the passive prevention capability have been devoted in the SFR in addition to the inherent safety features around the 1980s. During this period, passive safety arguments against the anticipated transient without scram (ATWS) have been made in the USA, Europe, and Japan. No detection signals or no driving force is required in the passive mechanism and there are fewer uncertainties to analyze their effectiveness.

In Europe, the thermal expansion (elongation) of the drivelines for the absorber rods was selected as the most promising passive mechanism within the frame of the European Fast Reactor project. This mechanism is reliable with containing less uncertainty due to the axial elongation behaviors of the drivelines of absorber rods. This mechanism would need a rather longer period, and thereby the temperature increase rate should be mitigated by other design measures, e.g., longer halving time for the flow coast down. Nevertheless, the absorber rods will be pushed in by the force created by the thermal expansion and thus suitable to the freestanding core design (Edelmann et al. 1994).

In Japan, the self-actuated shutdown system (SASS) has been developed as a passive safety feature (Takamatsu et al. 2007; Nakanishi et al. 2008) using the phenomena that electromagnetic force of the control rod latch will be lost when alloy temperature exceeds the Curie point. Several kinds of in-sodium transient testing have been carried out together with in-pile experiments in the experimental fast reactor “Joyo.” This mechanism is effective to the robust restraint core, which is designed for seismic requirements.

Cooling

Concerning the cooling of the reactor core, loss-of-coolant accident due to piping breach, which is treated as the major accident in high-pressure systems of LWRs, is no more a significant issue in SFRs, since SFR is a low-pressure system. The ECCS, which is significant also for the safety of LWRs, is not required. Instead, a guard vessel is set outside of the reactor vessel to prevent loss of sodium coolant from the core in SFR.

In the SFR, high potential for natural circulation of sodium coolant due to large buoyancy force can be expected because of large temperature difference of coolant between the inlet and the outlet of the core. In this manner, the SFR has more favorable features for “cooling” than those of the LWR.

Containment

The third essential safety function for safety assurance is “containment” of radioactive materials. Similar to the LWR, the SFR has multiple containment systems, such as pellet, cladding, primary coolant boundary, guard vessel, and containment against the release of fission products. Especially when the guard piping may be adopted both for primary and secondary cooling systems together with guard vessels, these outer boundaries and vessels will play an important role as the first containment. Instead of guard pipes, an inert gas can be filled inside the containment.

58.2.6.5 Safety Studies and the Results

Studies on Reactor Core Safety

The safety issues of nuclear energy systems are discussed sometimes from the viewpoint of the inherent and passive safety characteristics of the system. The essential safety question concerning FRs is how to avoid radioactive material release to the environment during meltdown of the core.

The problem of dealing with the consequences of CDAs – that can be possibly caused by unprotected transient over power (UTOP) and unprotected loss of flow (ULOF) – is an issue in the safety licensing process even though the occurrence probability is negligible. Conservative assumptions predict significant energy release by reactivity insertion due to the compaction of molten fuel. In SFR licensing process, primary coolant boundaries and confinement are required to accommodate the CDA consequences.

One of the advanced measures against CDAs is to avoid energy release. Considering the low occurrence probability, it is not possible to equip a system with active elements whose failure probability is about 10^{-2} per demand. Activation of the safety system should be based on using physical properties like melting point and material relocations by the driving forces such as fission gases and steel vapors. Therefore, a concept of fuel subassembly in which molten fuel discharge from the core is enhanced has been developed to prevent the formation of molten fuel pool and its resultant compaction, and thus energy release due to reactivity insertion can be excluded from the CDA scenario. This safety concept meets the safety requirements for the SCNES.

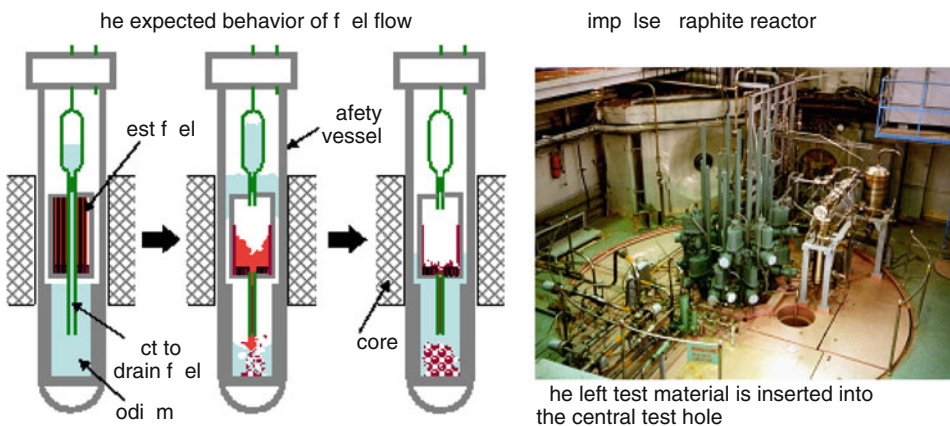

A research program for re-criticality-free core with existent reactor was fixed and tested in an impulse graphite reactor (IGR), in the collaboration between Kazakhstan NNC (National Nuclear Center) and Japan Atomic Energy Agency. It succeeded to obtain positive experimental results (Inagaki et al. 1998; Niwa et al. 2005, 2007; Fuji-ie 1992, 2006) (see Fig. 58.11).

Safety Concern About Chemical Reactivity of Sodium

The disadvantage of using sodium as a coolant is a recurring question of plant design because of its chemical reactivity.

Fig. 58.11

The test to validate a measure to avoid re-criticality during core disruption; from (Fuji-ie 2005). The test has been conducted in international cooperation between National Nuclear Center of the Republic of Kazakhstan and Japan Atomic Energy Agency

There is concern that sodium fire may be caused by sodium leaking out from the piping and vessels. As for a sodium leak, all pipes and vessels in the containment vessel are generally covered with guard pipes and vessels or filled with inert gas. However, sodium leaks from outside the containment vessel could cause sodium combustion and damage the reactor building. Fortunately, sodium outside the containment vessel is only secondary sodium without radioactive contamination.

In fact, the sodium leak that occurred at “Monju” involved the secondary heat transport system, which means that the leaked sodium was not radioactive. Therefore, no radioactive material was released to the environment by the sodium leak and the safety facilities were not affected. Knowledge about sodium fire has been accumulated through operation experiences. So far, there have been about 150 sodium leak events in the UK, France, Germany, and the former Soviet Union. However, no reports have been released of safety facility damage due to the sodium leak or combustion, and the reactors that experienced the sodium leakage were repaired and successfully resumed their operations.

Chemical problems arise when sodium and water react with each other in case of heat transfer tube failure in the steam generator. The secondary sodium exchanges heat with pressurized water in the steam generator, and the high-temperature steam drives the turbines. Therefore, if a failure should occur in the heat transfer tube of the steam generator where the pressurized water flows, then the pressurized water will vigorously react with the sodium in the steam generator and the failure would propagate. The chemical reaction of sodium and water generates hydrogen. As a result, pressure loading is imposed and may damage the intermediate heat exchanger in the reactor cooling system. Further measures have been taken to provide for early detection of water leak caused by the heat transfer tube failure, as well as rapid drain of the pressurized water out of the steam generator to stop the water leak. Experimental research on the propagation of the break caused by the chemical reaction of sodium and water has provided knowledge with which system integrity can be ensured against pressure loading.

In February 1987, in the prototype fast reactor (PFR) in the UK, the heat transfer tube of the steam generator (superheater) was damaged by its fretting caused by flow-induced vibration at the rated operation, and the water leaked out of the tube. Even though the hydrogen detector had been out of order during the operation and no quick depressurization systems were provided for the water/steam system to prevent the propagation of the damage to the surrounding, the burst disks on the sodium water reaction pressure relief system ruptured passively and the reactor was safely shutdown without any impact on the primary cooling system. After that, modifications were made such as automatic connection of the hydrogen detection system triggered by the trip signal, and providing a quick blowdown system for the superheater, and the reactor successfully resumed operation about half a year later.

58.2.6.6 Comparison of SFR types

SFRs are generally categorized into loop and pool types. The features and achievements of loop/pool type FRs are summarized in [Table 58.4](#). Generally, it is found that construction of loop type FRs tends to be more expensive than pool type FRs due to larger mass of components and larger building size for piping system. From the viewpoint of primary sodium accommodation, the pool type FRs seem to have a simpler primary sodium boundary since primary sodium is contained in the reactor vessel. The loop type FRs have advantages concerning reliability and inspection capability. Separated compact components such as the reactor vessel, primary pump, and intermediate heat exchanger, will allow reliable off-site manufacturing and preservice

■ Table 58.4

Comparison between loop type and pool type fast reactors (FRs)

Item	Loop type	Pool type
Safety	No vibration source, such as pumps, in the reactor vessel	Primary sodium is unlikely to leak out because it is contained in the reactor vessel
	Need to take measures on the assumption of sodium leak from the primary piping	Need to take measures against the failure of flow path inside the reactor vessel
Reliability (structural reliability)	Compact-sized reactor vessel is favorable from the seismic viewpoint	Moderate thermal transient due to large heat capacity
	The reactor vessel can be assembled in factory to provide higher reliability	Significant volume of the reactor vessel
	Good accessibility to components	The reactor vessel must be assembled at the reactor site due to its large diameter
		Need for adequate quality assurance concerning the welding of the reactor vessel
		Difficulty in accessing the components installed inside the reactor vessel
		Difficulty in inspection of structures that form the flow path inside the reactor vessel
Potential for improved economy through simplification of the secondary system	Elimination or simplification of the secondary system can be easily achieved by adopting a highly reliable steam generator	
Reactors	EBR-I, Fermi, SEFOR, CRBR, FFTF (USA)	EBR-II (USA)
	DFR (UK)	PFR (UK)
	Rapsodie (France)	Phenix, Superphenix (France)
	KNK-II, SNR-300 (Germany)	BN-600 (Russia)
	BOR-60, BN-350 (Russia)	PFBR (India)
	FBTR (India)	
	CEFR (China)	
	JOYO, Monju (Japan)	

inspection. From the viewpoint of in-service inspection, loop type FRs could inspect and monitor primary sodium boundaries outside the reactor vessel, while pool type FRs have difficulties to inspect and monitor complicate in-vessel structures under sodium.

Such a comparison of reactor types has been performed over a long period, and both types have been really adopted for FRs in various countries. Loop configuration has been well

adapted in all experimental reactors such as Experimental Breeder Reactor-I (EBR-I), South-west Experimental Fast Oxide Reactor (SEFOR), Fast Flux Test Facility (FFTF), Dounreay Fast Reactor (DFR), Rapsodie, Kompakte Natriumgekühlte Kernreaktoranlage-II (KNK-II), BOR-60, BN-350, Fast Breeder Test Reactor (FBTR), Chinese Experimental Fast Reactor (CEFR), and Joyo. And prototype reactors such as Clinch River Breeder Reactor (CRBR), SNR-300 and Monju have adopted the configuration as well. Among these loop type FRs, Monju and Joyo are only available plants that will restart. Regarding prototype and demonstration FRs, a larger number of pool type FRs, including PFR (UK), Phenix and Superphenix (France), BN-600 (Russia), and prototype fast breeder reactor (PFBR) (India), were adopted. In India, a prototype pool type FR of 500 MWe power output is under construction expecting their first criticality in 2010.

58.2.6.7 Development Status of SFR

FR as a Base-Load Power Supply

FR development started in the USA and the former Soviet Union, followed by European countries: France, Germany, and the UK, and Asian countries: India and Japan.

► [Table 58.5](#) shows the current status of FR development in the world. Although not all of them are at the same stage, generally speaking, the technology level has already reached the stage at which commercial reactors can be built. At the beginning of FR development, the USA was the front-runner and led the world. The USA has constructed an experimental fast reactor, EBR-I with 200 kW power output. It is well known as the first reactor in the world to generate electricity, a feat that was accomplished in 1951 (see ► [Fig. 58.12](#)).

The reactor that first succeeded in generating electricity was not the LWR, which has been commercialized, but the FR. Thereafter in the USA, many FRs such as the Enrico *Fermi* Atomic Power Plant, EBR-II and FFTF were constructed and operated. Test data have been accumulated from these reactors through R&D for core fuel, structural materials, neutronic characteristics of core, safety, and so on. CRBR with 380 MWe power output passed the safety review in 1975, and the construction began. However, the nuclear policy changed during President Carter's administration, and the construction was called off.

Then, Europe came to the forefront. The UK constructed and operated PFR, the first prototype FR in Europe, following DFR. Now, the PFR has finished its roles and is in the process of decommissioning. Meanwhile, France constructed and operated a demonstration reactor Superphenix based on the experience of construction and operation of Rapsodie and Phenix, but it is closed.

France in particular has operational experience with a commercial scale fast reactor, Superphenix, with 1,300 MWe power output. In Germany, although a steam-cooled fast reactor had been considered, they have actually developed SFRs, beginning with the experimental reactors, KNK-I and II. Then, a prototype reactor, SNR-300, with 327 MWe power output was constructed. It had the same plant concept as the prototype reactor Monju in Japan. However, the provincial government where SNR was constructed opposed its operation in 1986, and it was dismantled.

In the former Soviet Union, many experimental reactors have been constructed and operated. In Aqtau, Kazakhstan, BN-350 started operation both to generate power and to produce fresh water in 1973 and operated until 2000. In Beloyarsk, Russia, BN-600 with 600 MWe power output started operation in 1981 and continues operation up to now.

■ Fig. 58.12

Experimental Breeder Reactor- I (EBR-I), the FR that succeeded in generating electricity for the first time in the world. Then, four light bulbs were lit (Argonne National Laboratory 2002)

This achieves a reliable operation with average plant availability more than 70% since 1980. The construction of an SFR called BN-800 with 800 MWe output had been suspended for an extended period, but construction has restarted. A study on a lead-cooled FR is being carried out.

In Japan, the experimental fast reactor “Joyo” started operation in 1975 following the criticality test equipment called fast critical assembly (FCA). Joyo has run irradiation tests for domestic fuel material and increased the core thermal output as well. At the beginning of operation, the thermal output of the core was 100 MW. Currently, it employs a third-generation core, called the MK-III, with 140 MW thermal output.

The prototype fast breeder reactor “Monju” was constructed in 1990. The output operation had been carried out and preparations for the full-power operation were being made (► Fig. 58.13). However, it caused sodium leaks from the secondary system on December 8, 1995 and the operation has been suspended. As of 2009, the overall plant and its functions, including long-stopped as well as improved facilities, have been checked, and preparations to restart operation are under way.

Multipurpose Use of Medium-and Small-Sized FRs

A small SFR, commonly referred to as the 4S (Super Safe, Small, and Simple), is under development with the aim of commercialization in the early 2010s (► Fig. 58.14). The reactor is intended to serve as a dispersed supply source of power and heat for local areas with an electric output of 10–50 MWe. This reactor is designed for continuous operation up to 30 years without refueling by steadily driving upward a removable radial reflector surrounding the core. This also has the advantage of nuclear nonproliferation because it is capable of sealed operation with no need to unseal the reactor for maintenance. This can be achieved by a reactor internal structure composed only of passive components, such as an electromagnetic pump with no active parts for in-vessel coolant circulation. There have also been studies on the application of

Fig. 58.13

Prototype fast breeder reactor Monju; from (Fuji-ie 2005)

Bird's-eye view of the 4S plant (Matsuyama et al. 2009; Tsuboi et al. 2009)

nuclear energy to steam supply to extract crude oil from oil sand in Canada. The 4S has been attracting attention as a candidate for this application.

58.2.7 Molten-Salt Reactor (MSR)

This type of reactor uses molten salt as a fuel and a coolant that circulates in the reactor. The neutrons produced by fission reaction in the circulation process are moderated by graphite so that the system features an epithermal to thermal neutron spectrum. The heat generated in the molten salt is transferred to a secondary coolant system through an intermediate heat exchanger, and then through a tertiary heat exchanger to the power conversion system. The excellent heat transport properties of molten salt can contribute to a smaller reactor building and a higher thermal power output.

A representative application of the MSR concept is thorium reactor, and MSRE (Molten-Salt Reactor Experiment) with thermal output of 8 MW was developed by Oak Ridge National Laboratory in the USA and had been operated from 1966 to 1969. In the thorium reactor, the breeding of fissile nuclide, ^{233}U , can be achieved through prevention of parasitic absorption by fission products and ^{233}Pa , a nuclide generated in the process of producing ^{233}U from ^{232}Th . After that, molten-salt breeder reactor (MSBR) with electric output of 1,000 MWe was designed in the 1970s. At that time, there were technological issues to be solved for commercialization, such as necessity of developing material that is durable under the system environment of high temperature molten salt. Other issues were shielding and remote handling against high intensity of gamma rays from the thorium molten salt coolant.

The following example is an MSR plant with a power level of 1,000 MWe, which has been proposed as a reference GEN-IV MSR in GIF aiming at actinide burning with continuous recycling (US DOE and GIF 2002) (see [Fig. 58.15](#)). The reactor can use ^{238}U or ^{232}Th as a fertile fuel dissolved as fluorides in the molten salt. Due to the thermal or epithermal spectrum of the fluoride MSR, ^{232}Th is favorable for achieving the highest conversion performance. It operates above 700°C of coolant outlet temperature, which affords improved thermal efficiency, i.e., 40–50%. The coolant outlet temperature can be improved up to 850°C for the purpose of hydrogen production.

58.3 Future: A More Radical Picture

The following part has been written by Prof. E.O. Adamov.

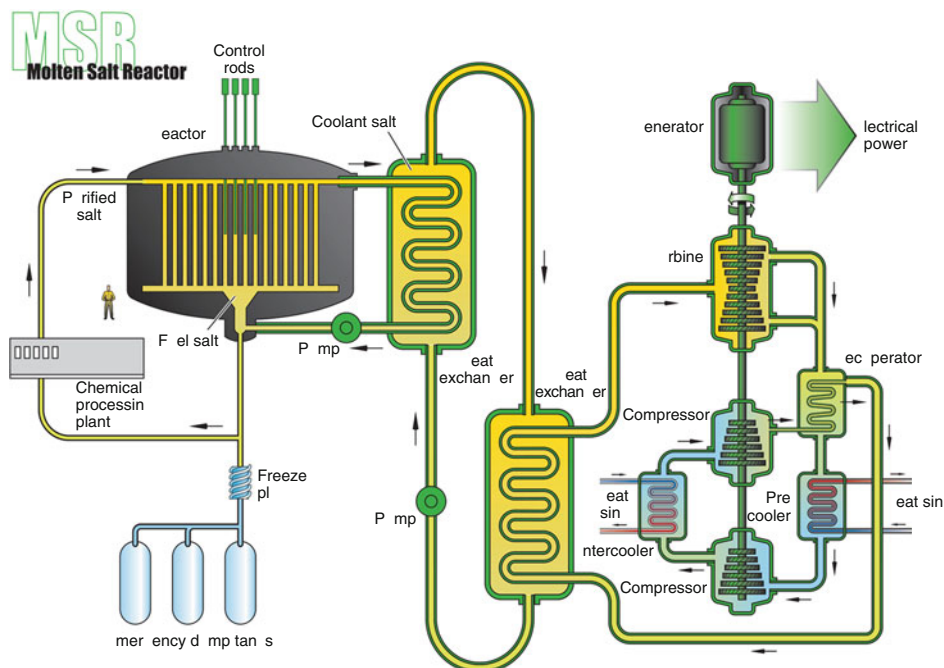

58.3.1 From Advanced Traditional Reactors to New Reactor Concepts

Nuclear power met the close of the twentieth century with accomplishments far more modest than those predicted. According to the projections of 1975, the industry was to build up its total installed capacity to a level of about 1,500 GWe by the end of the century, whereas the actual capacity came merely to 370 GWe (net). The output of the almost 50-year effort in thermo-nuclear fusion never reached the stage of practical use.

The trust in nuclear power safety was shaken by three major accidents at nuclear power plants: Windscale (UK, 1957), Three-Mile Island (USA, 1979), and Chernobyl (USSR, 1986). Public consciousness, which associated nuclear energy with the tragic experience of its military

Fig. 58.15

Molten-salt reactor (MSR) (U.S. DOE Nuclear Energy Research Advisory Committee and the Generation IV International Forum 2002)

application in 1945 against Japan, was more willing to accept myths about the consequences of these rare accidents than scientifically proved information about their actual impacts on life and environment. Nuclear energy uses remained practically confined to electricity production, with the district heating, high-grade heat generation, and transport left entirely to fossil fuels.

The concern about proliferation of nuclear weapons grew dramatically by the end of the century, while the monitoring functions of the IAEA are greatly complicated by the fact that the nuclear fuel enrichment technology is integral to its radiochemical reprocessing both for peaceful and military applications. The environmental requirements gained priority and cast doubt on the adequacy of technologies for treatment of nuclear materials (bituminization, cementation, and vitrification), which retain various levels of radioactivity after irradiation, considering the need for proving their efficiency over periods commensurable with geological epochs.

Wide practical application was found only by vessel-type (PWR, BWR) and pressure-tube (RBMK, CANDU) reactors. The gas-cooled graphite-moderated reactors, which gave rise to nuclear power in Europe (UK, France), are being phased out of operation. Among the wide range of alternative reactor concepts considered, few reactors passed the test of operation at pilot, demonstration, and semicommercial plants, including several fast neutron reactors (BN-350 and BN-600 in the former USSR, Phenix and Superphenix in France, Monju in Japan), as well as high-temperature reactors in Germany (AVR, THTR-300), Japan (HTTR), and the USA (Fort St. Vrain, Peach Bottom-1).

Nuclear power development was slowed down by discovery of new fossil fuel fields (mainly offshore deposits), appearance of new exploitation technologies, and introduction

of energy-saving measures, which decreased the energy demand growth rates, and was hampered by a significant rise in the capital costs of nuclear power plant construction. Further growth of nuclear power with traditional reactor systems will be unavoidably limited by the reserves of natural uranium, of which only 1% is actually used in energy generation by thermal neutron reactors.

Analysis of the realities observed at the turn of the century suggested the inevitability of predominant use of nuclear energy (from both fission and fusion) in resolving the problems of energy supply for sustainable development. Such countries as China and India are already demonstrating the priority of nuclear over other sources of electricity in their current national energy programs. A similar approach was taken in the Strategy of Nuclear Power Development in the Russian Federation, approved by the Russian Government in 2000. The attitude toward nuclear power is changing in the UK, Eastern Europe, and in the European Union as a whole. The US initiative on advanced reactor systems (Generation IV) and the resumed work on the closed fuel cycle, previously banned by law for nonproliferation reasons, are strong evidence of the USA returning to the nuclear option.

After a long period of decline, renewed interest in nuclear power development is observed, which manifests itself so far in resumed efforts to step up construction of nuclear plants, mostly with the well-proven PWRs and BWRs.

However, there is no avoiding the fact that the conditions for a new start of nuclear power are very much different from those of the industry's early days, considering primarily the requirements for safety, environmental quality, and proliferation resistance. Besides, assuming that nuclear energy will be used on a large scale, the industry can no longer afford using uranium reserves as inefficiently as thermal-neutron reactors do. In the USA, analysis of the situation formed after the three mile island nuclear power plant (USA) (TMI) accident led to the concept of "inherent safety" (Weinberg et al. 1985). In Russia, the concept of "natural safety" was developed, which applied both to the reactor design and to the nuclear fuel cycle (Orlov et al. 1992). Japan came up with the concept of "Self-Consistent Nuclear Energy System (SCNES)" (Fuji-ie 1992). It is for this reason that the nuclear community is considering both the earlier and the new reactor designs and fuel cycle concepts, provided they can meet the current requirements better than the existing plants will ever do.

Description of specific concepts will precede an overview of the position that nuclear power came to by the end of the twentieth century.

58.3.2 Fast Reactors with a Closed Fuel Cycle as a Basis of Large-Scale Nuclear Power

Thermal reactors developed for military purposes do not have enough neutrons to resolve the problems of fuel availability and safety on the industrial scale of power production.

Thermal reactors use less than 1% of uranium (^{235}U and a little of ^{238}U converted to Pu), wherefore suitable for this purpose are only the richest ores (currently estimated at ~ 17 Mt) with the metal content of $\sim 10^{-3}$ and up, whose reserves are much smaller than those of coal, oil, and gas. The safety problems of these reactors include reactivity variations with fuel burning, which are vastly larger than the delayed neutron fraction and thus pose the risk of a runaway (Chernobyl), accumulation of radioactive waste, as well as separation of U isotopes and separation of U from Pu during fuel reprocessing, which are potential proliferation hazards.

Fermi must have doubted the potential of thermal reactors for future energy production as he proposed a fast reactor (FR) for this purpose (Fermi 1944) – a reactor with a large excess of neutrons over the amount required for maintaining a chain reaction. Neutron excess (NE) is the key physical resource for dealing with the problems of fuel and, as is apparent now, of safety, given an adequate choice of technological tools:

$$NE = \frac{v_{\text{fis}} - 1 - \alpha + f(v_{\text{fer}} - 1)}{1 + \alpha} \quad (58.1)$$

where v_{fis} , v_{fer} – number of neutrons per fission of a fissile and a fertile nucleus, respectively; α – losses due to radiative absorption by a fissile nucleus; f – contribution from threshold fission of a fertile nucleus.

The breeding ratio (BR) of fissile nuclei (Pu , ^{233}U) from fertile nuclei (^{238}U , ^{232}Th) appears as $BR = NE - A$, with A standing for losses through absorption in structural components and fission products, and through leakage.

With NE in fast reactors reaching 2.3 as against ~ 1 in thermal reactors (1.2 in the ^{232}Th – ^{233}U cycle), it is easy to attain full reproduction ($BR \approx 1$) and even breeding ($BR > 1$) of fissile ^{239}Pu or ^{233}U , with U (Th) used up completely. If such is the case, lean ores are also usable, even if it is hundreds of times more expensive to mine them. Reactivity varies little in an equilibrium operation mode ($BR \approx 1$) where actinides (except for ^{238}U) come to equilibrium rather than accumulate, while separation of Pu from U is ruled out, and so will be U isotope separation in due time.

Use of cheap and inexhaustible U and Th fuel, whose calorific value is 3 million times greater than that of coal, may open a new era in human history. With the average U and Th content in the Earth crust estimated at 4×10^{-6} t and 10^{-5} t, respectively, their reserves of $\sim 10^{14}$ t in the strata down to 2 km are so great that even a thousandth part of them will last for millions of years.

As early as 1951, first nuclear electricity was produced at the experimental fast reactor EBR-I, but both this reactor and the E. Fermi Plant suffered accidents in the 1960s, and in the 1980s the USA stopped the construction of fast reactors and the work on a closed fuel cycle for nonproliferation reasons.

In the USSR, A.I. Leipunsky came to the idea of fast reactors in 1949, and took the lead in development of such machines. In the 1970s, the BN-350 was built, which operated for 25 years, followed by the BN-600, which is still in service.

Power plants with fast reactors were also constructed in France and the UK but saw no further development in either country mostly for the reason that those reactors proved to cost much more than their thermal counterparts. The closed fuel cycle (CFC) of nuclear power plants with fast reactors was never brought into practice. So, nuclear power based on fast reactors failed to evolve into a common business in the market of energy and investments. As regards fuel, including the problems of radioactive waste and nonproliferation, even with thermal reactors nuclear power is still unable to take over any significant part of global energy production. Its share of $\sim 7\%$ in terms of fuel (16% of electricity) has little effect on the growing consumption of fossil fuel and CO_2 emissions on the planet.

The idea of developing nuclear power based on fast reactors met with no success in the twentieth century. The industry, which started with thermal reactors of military origin in the 1950s, declined into stagnation, despite a steep rise in fossil fuel prices, as early as the 1970s in the USA and in the 1980s, after the Chernobyl accident, in Russia and Europe.

The third oil crisis in the past 30 years reawakened interest in building power plants with thermal reactors in a number of countries. Nuclear power has long grown from a sphere of science into that of engineering and industry, pragmatically focusing today on building nuclear plants with thermal reactors, their improvement, and marketing. For this reason, it appears necessary to recur to the original concept of nuclear power based on fast reactors, to analyze the reasons for the failure of the earlier efforts, and to correct the mistakes made.

Pragmatism prevailed over all other considerations in nuclear power engineering during the decades of the industry's efforts to survive. The first attempt to revise in a radical way the traditional nuclear engineering approaches after the Three-Mile-Island accident was made by a well-known American physicist A. Weinberg in his book "The Second Nuclear Era. A new start for nuclear power" (Weinberg et al. 1985). His principles of "inherent safety" were rather oddly taken by the engineering community: all the operating nuclear power plants (NPPs) were claimed to comply with such principles. Having found its way into the Nuclear Regulatory Commission (NRC) regulations, the requirement of "inherent safety" led to further increase of capital costs associated with provision of additional safety barriers in new US reactor designs. After the Chernobyl accident, Russian physicists led by V. Orlov developed the "natural safety" approach, which has much in common with Weinberg's principles. Both concepts require that high safety should not be sought by designing more and more complicated engineered features or by increasing their number but should rely on the fullest possible use of the laws of nature (hence the new concept is referred to as "natural safety"). On the other hand, there is a significant difference between the two approaches, which makes it impossible to reconcile the old engineering solutions with the new concept. As applied to nuclear reactors, *this concept does away with classification of accidents into design-basis and beyond-design-basis events and may not be extended to a design (or an operating plant) where an accident requiring local public evacuation is possible*. As regards the fuel cycle, the *concept of natural safety calls for radiation-equivalent management of nuclear materials, for elimination of the technologies posing the greatest proliferation hazards (isotope separation and enrichment, reprocessing of irradiated fuel with extraction of weapons-grade plutonium), and provides for substantial reduction of nuclear material transportation*, especially long-distance hauls. It is worth noting that there is much in common between the concept of "natural safety" (Russian approach, Orlov et al. 1992) and the idea of "harmonization with nature," which is central to the Japanese concept of "Self-Consistent Nuclear Energy System, SCNES" (Fuji-je 1992, 2005).

Fermi created the first thermal reactor, but it was not this reactor type that he proposed for power production (this was done later by "pragmatists"). His idea was a fast reactor with high NE and $BR > 1$, which would open the way for a new power industry consisting of inexpensive nuclear plants using cheap and inexhaustible fuel. The first nuclear power plants were but little more expensive than conventional ones, but their cost grew fourfold in the 1970s due to the safety requirements introduced by the NRC, and the US companies stopped building new nuclear plants. Later, the TMI and Chernobyl accidents happened and the general public, who had been apprehensive of nuclear energy since the first use of nuclear weapons, was turned strongly against nuclear power.

Having certain doubts about nuclear power (with its huge radioactivity and production of "nuclear explosives") and seeing no good way to ensure safety, Fermi suggested that Argonne National Laboratory (ANL) should develop the fast reactor concept so that the first reactors of this type would be started on Pu from natural uranium-fueled thermal reactors, with the ones to follow them relying on the surplus Pu (given $BR > 1$) for their first cores. He did think about

enriched uranium, too, but his conclusion – with the Oak Ridge facility yet to be built – was that nuclear power would be better off without energy-intensive U isotope separation (i.e., diffusion method used at that time in the USA).

It was not until the 1980s that the main reason for the failure of the earlier effort to create fast reactor plants became clear. It lies in the very concept of a fast breeder reactor with $BR > 1$ and using plutonium from irradiated fuel of thermal reactors for the first cores. In fact, the uranium consumption and the separation work required for starting up fast reactors on enriched uranium are much smaller than in the case of using plutonium from thermal reactors for the same purpose. Hence, it is possible to give up high rates of Pu breeding, while the “excessive” neutrons may be used for and the design effort aimed at bringing out and employing the natural safety qualities of fast reactors, including waste management and proliferation resistance, with the cost of nuclear plants reduced.

To correct the mistakes made in the past and to move toward large-scale nuclear power with fast reactors as its basic component it is essential to give up the fast breeder reactor in favor of a “naturally safe” fast reactor of pool-type configuration, with high-density fuel of equilibrium composition ($BR \approx 1$), moderate power density, and heat removal by noncombustible high-boiling coolant, providing transmutation of minor actinides, and having an on-site closed fuel cycle.

Within the next 2 decades, when mostly thermal reactors will be built in the world, it is necessary to develop and bring in new fast reactors of natural safety with a closed fuel cycle, which can pave the way for large-scale nuclear power in the twenty-first century.

58.3.2.1 Fast Reactor of Natural Safety

Having created the first thermal reactor, Fermi came up with the idea of a fast reactor with a large neutron excess and $BR > 1$, which held the promise of large-scale energy production at inexpensive nuclear plants using inexhaustible fuel.

In elaborating this idea of Fermi's, specialists of the ANL (USA) chose metallic fuel and lightweight sodium as coolant (Na–K in the EBR-I reactor). In the USSR, Leipunsky considered Pb–Bi and gas but decided on Na (Pb–Bi found its first application in reactors of nuclear submarines in the 1950s.) As regards fuel, he gave preference to heat-resistant ceramics.

Starting with the BR-5 reactor (PuO₂ fuel, Na-coolant, 1959, USSR), fast reactors have run on oxide fuel, proven already in thermal-neutron machines (Shippingport NPP, USA, 1957). But high-density, heat-conducting ceramics were much better for such reactors from the viewpoint of attaining, among other things, the in-core Pu breeding ratio of ~ 1 (with fuel operation in equilibrium), which is why, beginning in 1965, the BR-5(10) used U monocarbide and, later (in 1983), mononitride fuel. The subsequent BN-350 and BN-600 reactors relied on enriched UO₂, as construction of a plant for fabrication of mixed U–Pu fuel, including its nitride and metallic varieties, had been stopped.

Plutonium extraction by organic agents from aqueous solutions of irradiated U was first practiced for weapons production and was later applied for reprocessing of NPP fuel. It was clear, though, that the aqueous process, requiring long fuel cooling, would add vastly to the duration of the closed fuel cycle and to the consumption of Pu in starting up a fast reactor; it reduces drastically the breeding rates and leads to safety problems in transportation of fissile and radioactive materials to the remote reprocessing facility. Therefore, in the 1960s, efforts were undertaken in the USA (Idaho) and in Russia (NIAR, Dimitrovgrad) to study “dry”

reprocessing of fast reactor fuel on the nuclear plant sites. Such processes never came into industrial practice as the fast reactor development program was terminated.

By the 1980s, Russia had nuclear submarines with reactors cooled by Pb–Bi eutectic and work was in progress to develop a concept of naturally safe fast reactors that could have the features studied since the 1950s–1960s but not applied in the early fast reactors, such as,

- Nitride fuel with $BR \approx 1$, no uranium blanket, small reactivity variations with fuel burning (optimal $BR \approx 1.05$), fuel composition designed to require no U, and Pu separation in reprocessing (merely addition of ^{238}U)
- “Dry” electrochemical reprocessing of irradiated fuel on the NPP site after relatively short cooling, a factor of ~ 3 smaller consumption of Pu (or enriched U) for reactor startup, and radical reduction of fresh and irradiated fuel transportation
- Moderate power density, Pb coolant instead of combustible Na with its small boiling margin, a widely spaced fuel lattice instead of the close-packed one chosen for the moderating Na, Pb temperature gain reduction, and increase in its temperature at the core inlet upward of 400°C with a margin to Pb melting, no fuel assembly shrouds (as in PWR with a widely spaced lattice)
- Austenitic steels replaced by the ferritic–martensitic steels practically proven in nuclear submarines, low-swelling, and resistant to lead action

This made it possible for Russia to initiate development (Adamov and Orlov 1992) of a fast reactor named lead-cooled fast reactor of natural safety (BREST), i.e., a pilot 300 MWe reactor (for trying out, e.g., equilibrium operation) and the first-of-the-kind 1,200 MWe power unit, with the R&D effort to support it, aimed at demonstration of the new fast reactor and its closed fuel cycle within the normal period of ~ 20 years.

Deterministic exclusion (assured negligible probability) of the most dangerous accidents involving prompt criticality excursion, loss of cooling, fires and explosions with catastrophic radioactive releases, upsetting of the natural radioactivity level in radioactive waste disposal, together with exclusion of U and Pu separation in reprocessing and – later, gradually – of U isotope separation – all add up to make the safety of nuclear power convincing and to simplify the “defense in depth” (against residual risks).

Changeover from chemical to physical treatment to remove fission products from fuel (based on mass difference and using plasma) will render illicit Pu extraction impossible, which will make this technology eligible for transfer to the countries that seek to develop their own nuclear power for self-sufficiency in energy supply. This will allow attaining the long-declared objective of the “universal and total ban and elimination of nuclear weapons.” It is at this point that the world community will be entitled and able to stop any secret Pu extraction from irradiated fuel in places other than those legally established. If they see prospects for independent development of their national nuclear power based on fast reactors, certain countries may accept for the time being the services of nuclear states or of international centers for uranium enrichment, reprocessing of thermal-reactor fuel, and fabrication of the first cores of fast reactors.

Technical and political palliatives do restrain but have failed to prevent the propagation of nuclear weapons. If consistently implemented for nuclear reactors and, especially, for the fuel cycle, the concept of natural safety can technologically strengthen the non-proliferation regime under the conditions of a large-scale nuclear power industry in the twenty-first century (Adamov et al. 1995).

58.3.2.2 Choice of Coolant and Fuel for Fast Reactors in Large-Scale Nuclear Power

Selection of Coolant

Analysis of the characteristics of liquid-metal coolants, such as sodium (Na), lead (Pb) and lead-bismuth eutectic (Pb-Bi), makes it possible to decide on the coolant for the new fast reactor considered as a basic component of large-scale nuclear power, which will be capable of taking over the greater part of the electricity generation increase and, possibly, of providing for other energy-intensive processes.

In safety terms, the noncombustible, high-boiling ($T_{\text{boil}} \approx 1,750^{\circ}\text{C}$) and only slightly activated Pb has obvious advantages over the flammable, low-boiling ($T_{\text{boil}} \approx 890^{\circ}\text{C}$), and easily activated Na. The lower melting temperature of Na, and of Pb-Bi as a matter of fact, offers no preference over Pb as both these coolants necessitate external heating prior to the initial startup of the reactor. It will take relatively short operation at full power to have the decay heat high enough to keep both sodium and lead liquid when the reactor is shut down. Neither expensive engineered features are required for sealing the Pb coolant circuit, as distinct from sodium-cooled reactors (SFRs), nor are safeguard vessels, nor additional (intermediate) circuits, nor fast-acting cutoff devices, which are used for mitigating the consequences of Na leaks and of its contacts with air and water leading to fires and radioactive releases. Moreover, the above advantages promise a higher economic efficiency of the lead-cooled fast reactor (LFR).

Neutron moderation in Pb, with its high atomic weight, is much less than in lightweight Na, while absorption is equally low. Therefore, in contrast to Na, a larger Pb fraction in the core owing to greater fuel lattice pitch will cause practically neither softening of the neutron spectrum nor decrease of the core breeding ratio (CBR), i.e., the ratio between Pu generation in capture of fertile ^{238}U neutrons, and its fission rate. Given $\text{CBR} \approx 1$, Pu breeding fully makes up for its burnup in the core, which is important in regard to both safety (small reactivity margin) and self-supply of fuel. Small reactivity variations with fuel burning in the LFR as compared to other reactors, with $\text{CBR} < 1$, allow a considerable increase in the time of reactor operation without refueling or rearrangement of fuel assemblies (FA). In this case, the fuel lifetime is limited not so much by the reactivity margin as by the service life of fuel rods and assemblies and other structural components of the LFR, which depends on the irradiation, corrosion, and other processes affecting their integrity and performance.

With a wider-spaced fuel lattice in the LFR it is possible to increase the coolant flow area and to reduce its velocity. As a result, the hydraulic resistance and the pumping power requirements in the LFR are a factor of 3–5 smaller than in the SFR. The lead coolant temperature gain reduced down to $100\text{--}120^{\circ}\text{C}$ allows raising its temperature at the core inlet to $400\text{--}420^{\circ}\text{C}$ and providing a sufficient margin to its crystallization point ($T_{\text{cryst}} = 327^{\circ}\text{C}$). Even so, the fuel cladding temperature in the “hot spot” will not exceed 650°C , whereas in the sodium-cooled reactors it is higher than 700°C .

A decrease in the Na density and a drop of its level in the core cause reactivity and power growth, and Na boiling may lead to a quick criticality excursion with possible fuel failure and release of radioactivity. In the case of lead, such an accident is impossible due to the high temperature of Pb boiling, which exceeds the temperature of core failure. Besides, when the core is surrounded by a lead reflector, whose level depends on that in the core, its leaks and the core uncovering result in increase of neutron leakage, input of negative reactivity, and shutdown of the reactor (Adamov et al. 1997).

As compared with Pb, Na has better mass heat capacity and heat conduction, permitting removal of heat fluxes at high unit power of the reactor, which is essential for high rates of fuel burning and Pu production. These advantages dictated the priority of the sodium-cooled fast reactor in the 1950s, when ambitious plans were made for nuclear power development – in the absence of Pu and with insufficiently explored uranium reserves – and a short Pu doubling time was regarded as the most important characteristic of fast reactors providing for the growth of nuclear generating capacities. Today, however, considering the great Pu quantities (2,300–2,500 t) accumulated in the “spent” (or, more correctly, irradiated) fuel of thermal reactors, this purpose is no longer on the agenda. Besides, in order to reduce positive density and void effects of reactivity in a high-power sodium-cooled fast reactor, the designers had to resort to considerable flattening of the core, where it is difficult to provide $\text{CBR} \approx 1$. As a result, for self-supply of Pu alone, a perceptible part of it was to be produced in a uranium blanket, with its resulting quality making it fit for nuclear weapons – in contradiction to the nonproliferation requirement.

Failure of the sodium coolant circuit and its long exposure to the atmosphere lead to a fire and, consequently, to a 24-h release of $\sim 10^5$ Ci accounted for by ^{24}Na alone. Further Na burning will cause cooling interruption and fuel melting with release of $\sim 10^7$ – 10^8 Ci, depending on the reactor power level and the time of fuel irradiation. Such an accident is classed as Level 7 of the International nuclear event scale (INES) and involves inevitable evacuation of the local residents with prolonged isolation of the territory (ISTC 2001; Orlov et al. 2003).

Although the SFR operation record and the design experience show such reactors to meet the current safety requirements, there is still a risk of an accident with Na burning or boiling and with large radioactive releases. Moreover, the probability of such an accident and the safety costs will grow with the increase in the scale of the nuclear power industry based on these reactors.

The main problems with Pb today are the needs for improving the coolant technology and testing the chosen structural steels for corrosion resistance in lead at its operating temperatures, which has been largely done already on test facilities with a positive outcome both for the core and for the coolant circuit materials. As in the case of Pb–Bi eutectic used in reactors of nuclear submarines, corrosion resistance is sustained by control of oxygen concentration, kept within a fairly narrow range. At the same time, it is important to note that though considerable upward or downward departures from the nominal oxygen regime are possible during operation for hundreds of hours, they will not result in dangerous corrosion intensification. Nevertheless, the problem of maintaining the required oxygen concentration throughout the lead circuit and the problem of damage to oxide films under thermal and radiation impacts, call for further tests under conditions brought as close as possible to the operating ones.

An advantage of the Pb–Bi eutectic over Pb is its lower crystallization temperature of 125°C , which allows operation in a lower temperature range, where the corrosion problems of structural materials may be fairly easily solved (and, in fact, have been solved already). The Pb–Bi eutectic was considered as a coolant option for fast reactors back in the 1950s, but preference was given to Na, mainly for the reason of its better thermal properties. Pb–Bi was used for cooling ships’ reactors, and Russia – as the only country to have operated such facilities – has unique technologies for working with this coolant.

The problems of structural material corrosion and slagging in Pb–Bi were resolved by choosing an appropriate oxygen regime, as well as by monitoring and maintaining the coolant quality. The main objective today is to demonstrate the possibility of increasing the operating coolant temperatures for the selected structural materials, which is necessary for the future reactors.

The current high price of Bi and its very limited prospected resources are prohibitive for building large-scale nuclear power on reactors with Pb–Bi coolant. The total capacity of a nuclear power industry using mostly such reactors and relying on the explored, estimated, and economically acceptable global reserves of Bi would not be more than 50–70 GWe. For operation of Pb–Bi-cooled reactors, it is necessary to solve the problem of α -active ^{210}Po in their maintenance and repairs. Moreover, ^{210}Po brings about the risk of large radioactive releases in the event of the circuit failure due to, e.g., an act of sabotage. If the reactor vessel head were opened while Pb–Bi is still in the liquid form, the 24-h release of ^{210}Po would come to $\sim 6 \times 10^4$ Ci, which, considering the radiation (biological) hazard of ^{210}Po , is commensurable with the radiological consequences of an accident involving Na burning (Tupper et al. 1991; Orlov et al. 2003).

Considering that the lead-cooled fast reactor will show its chief merits at the power level of at least 300 MWe, Pb–Bi is being considered for cooling self-contained transportable small modular reactor facilities designed to serve as power sources in remote and hard-to-reach regions. The reactor core protection preventing access to fuel, the CBR of ~ 1 , which allows refueling-free operation with a small reactivity margin for as long as ~ 20 – 30 years, the thermal parameters making Pb–Bi fit for natural circulation, all are significant advantages from the viewpoint of proliferation resistance and safety. Besides, cooling by natural circulation of Pb–Bi offers a good possibility of simplifying the coolant circuit design, which may facilitate building such reactors in developing countries.

The natural occurrence of Pb is ~ 200 times as great as that of Bi, its explored recoverable reserves and global production ($\sim 2 \times 10^8$ t and $\sim 3 \times 10^6$ t per year, respectively) are $\sim 1,000$ times larger, while the price is a factor of 3–7 lower. Besides, the specific radioactivity of Pb–Bi coolant caused by its activation, though largely providing the radiation safety of the reactor, is $\sim 1,000$ times as high as that of Pb coolant, and the corrosivity of Pb–Bi is also higher in the operating temperature range of (~ 400 – 600°C) of lead.

Thus, comparison between Na, Pb, and Pb–Bi as candidate liquid–metal coolants shows Pb to be the best option for the fast reactors that are considered as a possible basic component of the future large-scale nuclear power industry.

Selection of Fuel

After successful use of PuO_2 in the first core of the BR-5 reactor in Russia, oxide fuel found application in the fast power reactors (BN-350, BN-600). However, it was clear in the late 1950s already that fuel of higher density and heat conduction has a number of advantages in a fast reactor. These advantages include smaller critical inventory and higher CBR; lower operating temperatures of the fuel and its larger melting margin; smaller release of fission gas from fuel, its smaller pressure on the fuel cladding; higher reliability of fuel rods; and, finally, smaller amounts of thermal energy accumulated in fuel, which may be released in an accident with loss-of-coolant circulation and result in its boiling with possible vapor explosion. For this reason, beginning in the 1960s, carbide and nitride fuels were studied, using them as the main fuel in several charges of the BR-5 reactor and later of the BR-10 reactor.

In the USA, even the first fast reactors, EBR-1 and EBR-2, ran on metallic fuel, i.e., U–Pu–Zr alloy and, with the experience gained, it was intended to use this fuel in the IFR – a fast power reactor with a closed fuel cycle (Wade and Chang 1988).

Admittedly, the experience of using the advanced fuels in fast reactors is by far less substantial than that obtained in operation of oxide fuel. Nevertheless, for all the importance of the previous experience and the maturity of the technology, choice of fuel for the innovative fast reactor of the future large nuclear power will be dictated by the requirements of high safety and economic efficiency.

If oxide fuel is used, its low density will make it possible to attain $\text{CBR} \approx 1$ only with relatively high power and large dimensions of the reactor core, or with very low power densities. Low heat conduction of oxides leads to high operating temperatures, small fuel melting margins, poor confinement of gaseous and volatile fission products in the fuel matrix, and high power effect of reactivity ($\Delta\rho_N \gg \beta_{\text{eff}}$); it also requires fuel rods of a small diameter, which adds to their fabrication costs.

The disadvantages of metallic fuel are its considerable swelling in burning, which calls for high alloying and porosity, and the existence of phase transitions at temperatures as low as those approaching the operating temperatures of lead. Phase transitions of metallic fuel and, especially, its interaction with steel claddings with formation of easily melted eutectic (510°C for Pu, 710°C for U, and 750°C for U + 15%Pu + 10%Zr), are responsible for small margins to fuel failure in accidents with temperature growth. Lead reacts with metallic fuel to form U and Pu plumbates.

With the priority given to reliable fuel operation in the reactor, to confinement of radioactive products, and to prevention of fuel failure in accidents, two types of fuel, i.e., carbides and nitrides, were considered for the concept of lead-cooled fast reactors. Both types have high density and heat conduction, they are both resistant to thermal decomposition, show little swelling at moderate operating temperatures and good confinement of fission gas. This – given a gas plenum in fuel rods for collection of fission products and a small heat-conducting gap between fuel and cladding – makes it possible to reduce significantly stresses in the claddings and the risk of their failure. The properties of high-density and heat-conducting fuel combined with those of lead coolant ensure full Pu reproduction in the core and a small magnitude of the power effect of reactivity, which allows operation with the total reactivity margin as small as $\sim 1 \beta_{\text{eff}}$, excluding accidents with prompt criticality excursion in case of inadvertent input of positive reactivity caused, e.g., by spontaneous withdrawal of Control and protection system (CPS) rods (ISTC 2001).

The choice of mononitride fuel for fast reactors was dictated by its certain, if small, advantages over carbides from the viewpoint of density, swelling, and confinement of fission gas. An important factor in the final decision made in favor of mononitrides was the higher pyrophorosity of monocarbide, which causes problems in fuel fabrication and handling of irradiated fuel with failed claddings (Rogozkin et al. 2003).

It should be noted, though, that mononitride fuel shows considerable parasitic absorption of neutrons in the $^{14}\text{N}(\text{n,p})^{14}\text{C}$ reaction, which results in an impaired neutron balance and in formation of environmentally hazardous ^{14}C . However, it is possible to overcome this drawback by using nitrogen enriched with ^{15}N in the future, as well as by catching carbon and fixing it in stable chemical compounds during fuel reprocessing. A later changeover to mononitride with enriched nitrogen having low neutron absorption and moderation, allows counting on a perceptible economic gain owing to a reduced mass of fuel inventory despite the high cost of ^{15}N (ISTC 2001).

58.3.2.3 Lead-Cooled Fast Reactor with an On-Site Fuel Cycle

The concept of an innovative fast reactor with lead coolant and nitride fuel, under development at present, implies that beyond-design-basis accidents should be excluded through consistent implementation of the principles of natural safety, i.e., by using the natural properties of a fast reactor, of its high-boiling coolant chemically passive in contact with air and water, and of the high-density, heat-conducting fuel, which allow operation of the reactor with a small reactivity margin commensurable with $1 \beta_{\text{eff}}$. Losses of coolant are prevented by the pool-type reactor design and its boiling, by passive removal of decay heat.

This concept is essentially different from the concepts of the reactors currently in operation and under development in its radically new approach to safety. Instead of addition of expensive engineered features and systems, safety relies mostly on fundamental natural behavior patterns and processes, feedbacks, physical and chemical properties inherent in a fast reactor, its fuel, coolant, and other components. Also important in this respect are the design solutions that allow using to the utmost the natural safety properties.

However, there is no identifying natural safety with absolute safety, which means that all possible accidents are ruled out. Natural safety implies exclusion of accidents with large radioactive releases requiring evacuation of the local people. Technical accidents involving failure or breakdown of systems and components may still happen but their radiological consequences, if any, will never be dangerous. They can lead, though, to a prolonged shutdown but are, in any case, limited to losses no greater than the cost of the plant. Such accidents are events of economic significance, and protection against them should be provided – as for other dangerous facilities – by defense in depth, while the ensuing economic losses may be taken care of by appropriate allocations for insurance.

It will not be a great exaggeration to say that the high cost of present-day NPPs is largely a price paid for their safety, and the safety requirements will inevitably get bigger because the probability of accidents will rise with growth of the nuclear power scale. With the principle of natural safety put into effect, it will be possible to reconcile the usually conflicting requirements for NPP safety and economic efficiency. The level of insurance costs for facilities of natural safety will be by far lower than that for, e.g., contemporary NPPs, where allowance is made for the losses associated with possible public evacuation, damage to human health, and isolation of contaminated land areas (ISTC 2001; Adamov and Orlov 1997).

For the properties of natural safety to be fully and consistently implemented, it is not only nitride fuel and lead coolant but also certain other options that should be translated into the reactor design, such as:

- Fuel inventory that should be made up so as to provide a small (comparable to $1 \beta_{\text{eff}}$) total reactivity margin due to compensation of burnup of fissile nuclides by their full reproduction (the optimal CBR being roughly equal to 1.05) and owing to the small power effect of reactivity.
- Widely spaced fuel lattice with a large coolant flow area – for reducing its velocity to 2 m/s and the hydraulic losses, to 0.10–0.15 MPa, as well as for increasing the amount of heat removed by natural circulation.
- Highly heat-conducting fuel rods – for reducing the maximum operating fuel temperature to $T < 1,000^\circ\text{C}$, which provides a small (less than 7%) fission gas release from fuel and its low pressure on claddings, as well as a relatively small amount of thermal energy in fuel.

- Fuel claddings made of ferritic–martensitic chromium steel which will show radiation and corrosion resistance in liquid lead.
- Absence of uranium blankets, replaced by lead reflector with a better albedo, which improves the power distribution, provides for negative void and density effects of reactivity, and rules out production of weapons-grade plutonium.
- Coolant flow rate feedback to power, provided passively by lead columns in special channels adjacent to the core, where the lead level varies with the flow rate, hence changing neutron leakage.
- Reactor shutdown in the event of loss of forced circulation or abnormally high coolant temperature at the core outlet, produced by insertion of absorber rods of passive threshold action.
- Passive and unlimited in time removal of residual heat directly from the lead circuit by natural circulation of air through air-cooled heat exchangers, with the heated air vented to the atmosphere.
- Lead coolant circuit of high heat capacity, capable of accumulating heat during accidents and transients without a perceptible increase in the temperature of the core and safety-related circuit components.
- Coolant circulation pattern, which prevents steam (in case of steam generator leakage) and gas bubbles from getting into the core and ensures inertial coolant flow in the event of pumps' trip.

The characteristics of a lead-cooled fast reactor and of its closed fuel cycle (CFC) allow operation with fuel of equilibrium composition. This mode of operation features full reproduction of fissile nuclides in the core ($\text{CBR} \approx 1$), irradiated fuel reprocessing in the closed fuel cycle, refabrication of fuel and its return to the reactor, with the reprocessing limited to removal of fission products without separating Pu and minor actinides (MA) from the mix (U–Pu–MA). Plutonium and minor actinides have practically the same mass and isotopic composition in the loaded (fresh) and unloaded (irradiated) fuel. In the long run, it is only ^{238}U that burns out, whose loss is made up for by depleted U during fuel fabrication. Ideally, operation in the equilibrium fuel mode implies roughly equal reactivity margins at the beginning and at the end of the refueling interval, referred to as the cycle, with allowance made for all the processes – fuel burning and swelling, cladding corrosion, deformation of fuel rods and fuel assemblies, etc. – that accompany the reactor operation.

The fuel type considered for the first core of the fast reactor is nitride of depleted U mixed with Pu and MA, whose composition corresponds to that of PWR's irradiated fuel after its reprocessing and subsequent cooling for ~ 20 years.

The reactor is planned to operate in cycles, which are equal to the time between periodical fuel replacements. At the end of the first and second cycles, additional fuel with the composition similar to that of the first core will be loaded into the reactor. The fuel assemblies retrieved from the core at the end of each irradiation cycle are placed in the in-pile storage, where they will be cooled for the duration of the next cycle, to be then sent to the CFC facilities for reprocessing. The time of irradiated fuel reprocessing and of new fuel fabrication is also equal to the cycle duration. Thus, as early as the beginning of the fourth cycle, the core will receive fuel assemblies containing its own reprocessed fuel, which was unloaded after its irradiation during the first cycle. If the cycle duration is assumed to be 1 year and the fuel lifetime, 5 years, by the beginning of the eighth cycle (after ~ 7 years) the reactor will be loaded only with its own irradiated and reprocessed fuel and will start operating in an equilibrium fuel mode.

An example of an innovative lead-cooled fast reactor of natural safety is the pilot 300 MWe reactor BREST-OD-300, which is being developed in Russia (ISTC 2001; Adamov et al. 1997).

Use of the chemically inert and high-boiling lead coolant allows giving up the three-circuit arrangement of heat removal in favor of a two-circuit system.

The reactor facility of pool design, which incorporates the core with reflectors and control rods, the lead coolant circulation circuit with steam generators, pumps, equipment of the fuel reloading system, as well as safety and auxiliary systems, is arranged in a steel-lined thermally insulated concrete vault (► Fig. 58.16). The concrete temperature is maintained within the permissible limits by natural circulation of air.

Lead circulation in the core and steam generators is provided by a difference in the “cold” and “hot” coolant levels produced by the pumps rather than by the pressure set up by them. There will be no variation of the lead flow in the steam generators if one or several pumps should stop, and

■ Fig. 58.16

BREST-OD-300 reactor: 1 – reactor core; 2 – steam generator; 3 – pump; 4 – reloading machine; 5 – reactor vault; 6 – cooling system

inertial flow will be provided in the event of a quick pump trip owing to leveling of the coolant surfaces. To mitigate the consequences of possible breaks in the steam generator tubes, the primary circuit is designed to have an integral loop configuration, with the steam generators and the main circulation pumps placed outside the reactor vessel. Such a configuration together with the arrangement of lead circulation and steam venting from the reactor vault via hydraulic locks into the confinement system and then on through filters to the atmosphere, prevents any dangerous ingress of steam into the core and overpressure of the reactor vault.

The low pressure in the concrete vault of the reactor and the relatively high temperature of lead freezing, which contributes to self-healing of possible cracks in the concrete, rule out the possibility of large lead leakage, loss of cooling, and fuel melting.

Fuel assemblies (FA) and reflector blocks are reloaded with the aid of rotary plugs, using the in-pile reloading machine and a set of mechanisms for out-of-pile handling.

The reactor core is built of fuel assemblies with the same fuel composition and fuel rod pitch. Radial equalization of the FA power and the coolant temperature gains relies on profiling of the fuel inventory and lead flow, with the former provided by using fuel rods of a smaller diameter in the central assemblies and those of a larger diameter in the peripheral ones. The equalized distributions are kept stable owing to the same fuel composition in all assemblies, subject to the condition of $\text{CBR} \approx 1$.

Considering the small reactivity margin, some control elements are arranged around the core, which operate by changing neutron leakage. In the same space lead-filled channels are located, which passively provide feedbacks from the coolant flow in the core to the reactivity and reactor power.

The central tubes of fuel assemblies located in the middle of the core accommodate hydraulically driven absorber rods made of WB_2 sinking in lead. These rods serve the purpose of reactivity compensation and also perform the function of the reactor safety system, which operates passively in the event of coolant flow interruption or increase of its temperature at the core outlet.

The natural properties of lead coolant and mononitride fuel and the neutronic characteristics of the fast reactor combined with the design of the core and cooling circuits raise the BREST reactor to a radically different level of safety and provide for its stable behavior without involving active safety features in the severe accidents unmanageable in any one of the existing reactors, such as:

- Spontaneous withdrawal of control rods.
- Trip of all pumps in the primary (lead) circuit.
- Trip of all pumps in the secondary circuit.
- Reactor vessel failure.
- Breaks of the secondary circuit pipelines.
- Total loss of power, with cooling required for unlimited time, etc.

Even in the most severe accident with coolant circuit failure and direct contact of lead with the atmosphere, the ensuing toxic and radioactive releases would correspond merely to Level 5 on the international scale of events at NPPs (INES), which is an accident dangerous for the environment but not requiring evacuation of the local population (ISTC 2001; Orlov et al. 2003).

With the fast reactor operating in a closed fuel cycle, the fuel quantity running through the cycle is largely determined by the duration of the external (to the reactor) part of the CFC. Therefore, in order to reduce the time and costs required for cooling of irradiated fuel and for

transportation of irradiated and reprocessed fuel, as well as for providing trouble-free operation, radiation safety and proliferation resistance, the external part of the BREST-OD-300 fuel cycle should be arranged on the power plant site (► Fig. 58.17). Besides the reactor facility, the turbine hall and all the NPP structures, the site is expected to accommodate the facilities for fuel reprocessing and for fabrication of replacement fuel assemblies. On the site, there may also be a facility for long-term (150–200 years) monitored cooling of radioactive waste so that it can be subsequently buried without upsetting the radiation balance of the Earth.

In the future, electricity production at large NPPs is likely to remain the main application of nuclear energy. This factor and the reduction of unit costs with increase in the power and number of nuclear units were the reasons for conceptual study of a 1,200 MWe lead-cooled fast reactor as a candidate basic component of a large-scale nuclear power mix. The BREST-OD-300 being developed as a prototype of the BREST-1200 reactor, their design and engineering features are largely similar, as may be seen from the data of ► Table 58.6 (ISTC 2001; Adamov et al. 1997).

58.3.2.4 Fuel Cycle of Fast Reactors

Introduction of fast reactors with a closed nuclear fuel cycle into the nuclear power industry can radically change the current approaches to fuel supply and management of long-lived radwaste.

A fast reactor produces more nuclear fuel than it burns during operation, due to irradiation of the fertile ^{238}U isotope. All the depleted uranium that now has no use in the nuclear power

industry may be processed to serve as reactor fuel; if so, the fuel resources available to nuclear power will increase 100 times (whereas less than 1% of the mined natural uranium is actually used today).

In production of fuel for a fast reactor, uranium – natural or depleted – is only needed to make up for the fission products separated during reprocessing of irradiated nuclear fuel (INF), which accounts for about 10% of the “fresh” fuel mass. For a thermal reactor, natural uranium is enriched to a required level, with roughly 10% of the mined uranium going into fuel, while its remaining 90% ends up in the tails of enrichment processes and is not involved in energy generation.

Thus, the consumption of natural or depleted uranium in producing fuel for a fast reactor is roughly a factor of 100 less than for a thermal reactor, and therefore much less expensive natural uranium may be used for making up fast reactors. It should be also taken into account that the existing quantities of depleted uranium are large enough already to serve as makeup fuel for a mix of fast reactors for several hundreds of years, so that natural uranium mining for the makeup purposes may be at least suspended.

The long-term radiation hazard of irradiated nuclear fuel is accounted for mostly by actinides. Given INF cooling for 60–60,000 years, the governing part is played by plutonium and americium, while longer cooling would bring neptunium to the fore, with a relatively small contribution from curium. To reduce the long-term radiation hazard of actinides, it is proposed to subject them to transmutation (to “burn” them in fuel).

A fast reactor can burn Np, Am, and Cm without any additional fuel consumption, including not only those produced in its own fuel but also in the fuel of thermal reactors. The final objective of transmutation is to convert long-lived actinides into fission products, as fission-free irradiation turns some actinides into others, and long-lived actinides will not disappear. Unless fission occurs, irradiation, e.g., of ^{237}Np ($T_{1/2} = 2.14 \times 10^6$ years) results finally in formation of the $^{234}\text{U} - ^{238}\text{U}$ isotopes, among which ^{234}U is the shortest-lived one ($T_{1/2} = 2.46 \times 10^5$ years), which means that long-lived activity will not be significantly decreased. Conversion of actinides into fission products can effectively reduce long-lived radioactivity.

Transmutation of long-lived nuclides (actinides and fission products) in the fuel cycle of fast reactors should proceed, at least, until the biologically equivalent activity of the waste to be buried declines to that of the natural uranium consumed (this condition is referred to as equivalence in terms of radiation and biological hazards). Notably, such equivalence may be attained both by the time of burial and within a historically short and reliably predicted period of, e.g., 200–1,000 years. This approach allows reasonably minimizing the mass and hazard of long-lived waste, while the specific conditions of waste disposal should meet the national regulatory requirements.

In the currently used open fuel cycle, with irradiated fuel recognized as mere waste, radiation equivalence is achievable only after 100,000–500,000 years of its cooling.

Based on the earlier studies (Adamov and Orlov 1992; Adamov et al. 1992, 1996, 1997), it was shown that radiation equivalence is feasible if radioactive waste is stored for 100–1,000 years, provided the nuclear power industry introduces a fuel cycle with transmutation, which will have the following key features:

- Reprocessing of the whole INF quantity from thermal reactors with specified partitioning for transfer of Pu, Np, Am, Cm, and other long-lived fission products into the fuel cycle of fast reactors.
- Operation of fast reactors in a closed fuel cycle to burn the bulk of actinides and to transmute long-lived fission products in the course of their operation.
- Thorough treatment of the radioactive waste subject to disposal to remove Pu, Am, and some other long-lived nuclides.
- Interim storage of highly active waste before its final disposal.

In setting up a fuel cycle with transmutation and seeking proper environmental protection, it is appropriate to modify the uranium mining process so that the associate highly radioactive radium and thorium could be co-extracted together with natural uranium for subsequent transmutation in fast reactors.

Possibilities for implementation of this fuel cycle concept may be illustrated by two scenarios:

Scenario 1 – Only thermal reactors are developed and built.

Scenario 2 – Using the reprocessed fuel of thermal reactors, a system of fast reactors develops, with all Pu, Np, Am, and Cm from INF of the former transferred into the fuel cycle of the latter. By the end of the twenty-first century, the energy output of the system of fast reactors is two times that of the thermal reactor mix.

Scenarios 1 and 2 assume availability of all the above components of the fuel cycle with transmutation, including cooling of radioactive waste before burial.

As new fast reactors are built and started on Pu, Np, Am, Cm from INF of thermal reactors, the previously accumulated irradiated fuel peters out. Transmutation of Pu, Np, Am, and Cm from INF of fast reactors and replacement of INF (disposed of in the open cycle of thermal

reactors) by the radioactive waste from regeneration of thermal and fast reactor fuel have a significant positive effect on the potential biological hazard (PBH) of long-lived waste produced by the nuclear power industry (Fig. 58.18).

It was assumed in the calculations that reprocessing of thermal and fast reactor fuel would give rise to waste with the following percentage of certain elements relative to the reprocessed fuel mass: Sr, Tc, I, and Cs each accounting for 0.1%; U and Cm, for 0.1%; Pu and Am, for 0.01%, and the rest coming to almost 100%.

Whereas the potential biological hazard (PBH) of thermal reactors' irradiated fuel declines to that of the natural uranium consumed by them (radiation equivalence) after about 10^5 years of cooling, it takes only 50 years for the PBH of the waste generated in INF reprocessing to reach a radiation-equivalent level. The proportion of elements going to waste during reprocessing is an effective control parameter for attaining radiation equivalence; it will decrease with the time of fast reactor operation.

Analysis of the radiation balance in a closed cycle of nuclear power plants suggests strategic decisions for management of the long-lived waste components. However, this is but the first step in developing a scientific groundwork for environmentally acceptable nuclear power. The next step is to prove the long-term environmental safety of the sites chosen for final disposal of radioactive waste, attainable by preserving the local radiation balance and by providing a likeness to natural conditions (Lopatkin et al. 2003). This requirement could be best met on the uranium mining sites. However, provision of a local balance need not be treated as an imperative requirement. Waste may be also disposed of in repositories specially built in deep rocks, which would offer better confinement of radioactive elements as compared with natural uranium fields.

The main current approach to proving the environmental safety of waste burial sites relies on numerous barriers to keep in high specific radioactivity. Safety is not easily, if at all, demonstrable where the time required for cooling of INF from thermal reactors reaches 10^4 – 10^6 years.

■ Fig. 58.18

Ratio between the potential biological hazard (PBH) (through ingestion) of the natural uranium accumulated in the irradiated fuel of thermal reactors by the year 2100 (*Scenario 1*) and that of radioactive waste (*Scenario 2*)

Allowance for the migration conditions, i.e., for temporary retention of a radionuclide on the way from its burial place to the biosphere, permits easing the requirements for the radiation balance attainment, which in this case may be more appropriately referred to as the radiation balance between waste components and natural uranium with allowance for migration. Consideration of all these circumstances shows that a perceptible radiation imbalance between waste and feed materials is tolerable at the time of waste disposition in a deep repository. It will change to a balance within the time required for the waste components to cover the distance from the deep repository to the biosphere. Clearly, the repository depth and the rock structure at the burial site are the parameters that, if appropriately chosen, can facilitate attainment of the required balance and reduce the time required for it. In terms of radiation equivalence with allowance for migration in waste disposal, the traditional approach to the burial safety involves a highly conservative judgment, which assumes that all the barriers in the path of radioactive nuclides have failed and these elements will migrate to the biosphere with groundwater.

58.3.2.5 Technological Consolidation of the Nonproliferation Regime

The Nonproliferation Treaty and the international safeguards to support it failed, unfortunately, to stop new countries from getting possession of nuclear weapons. The effectiveness of political measures would be largely enhanced, if the processes of potential danger from the viewpoint of nuclear proliferation were phased out with development of the new nuclear technology. Such processes include the following:

- Separation of U isotopes (enrichment).
- Production of weapons-grade Pu in uranium blankets.
- Extraction of Pu and/or ^{233}U from irradiated fuel.
- Long-term storage of INF.
- Storage of extracted Pu.
- Transportation of weapons-grade and irradiated nuclear materials over large distances.

A nuclear power industry built with the currently available technologies in a nonnuclear country to the level of 5–10 GWe and following a long-term development program, may sooner or later encourage such nations to create facilities for isotope separation and extraction of Pu (or ^{233}U) as well as other, associated facilities of the fuel cycle. The international nuclear fuel cycle centers, proposed by the presidents of Russia and the USA some time ago, could prevent the worldwide sprawl of such technologies. But it is a far from easy business to harmonize the day-to-day relations between a large national nuclear energy complex and a foreign supplier of fuel cycle services, especially if the national energy security is at stake. Establishment of such centers within international jurisdiction would provide, perhaps, an optimal answer to this problem.

The most important objective of the new nuclear technology under development is to make the peaceful nuclear power free from the need for the elements that are dangerous from the viewpoint of proliferation of nuclear weapons. If this is achieved, annual circulation of large nuclear fuel masses will no longer be a proliferation hazard, and the attention of international monitoring agencies may be then focused on preventing creation of illegal facilities for uranium enrichment and for extraction of Pu and ^{233}U .

This objective may be accomplished by developing nuclear power with fast reactors as its basic component, which will feature full fuel reproduction in the core without breeding

blankets. Fast reactors operating in a closed uranium–plutonium fuel cycle, will have no need of uranium enrichment, and this process may be phased out in due course. The first cores of fast reactors will be fabricated by clearing the plutonium storage places and the irradiated fuel pools of the present-day NPPs. The initial Pu separation and the fabrication of first cores for fast reactors, using plutonium or enriched uranium, should take place at the facilities of the Nuclear Club countries or at international nuclear technology centers.

The nonproliferation regime may be technologically supported in the fuel cycle of a fast reactor with full fuel reproduction in the core owing to the following:

- Presence of transmutable actinides and fission products in fuel (about 1% after treatment) facilitates its protection against theft in all the links of the fuel cycle.
- Full Pu reproduction in the core ($\text{CBR} \approx 1$) requires no U blankets, which excludes in-pile weapons-grade Pu production and the need for its separation.
- Similar composition of the fuel unloaded from and loaded into the reactor core, requires no separation or addition of plutonium, with possible correction the fuel composition by adding ^{238}U to make up for its burnout.
- The fuel cycle complex is arranged on the NPP site, which excludes diversion of nuclear materials outside, eliminates the need for long-distance transportation and handover, and reduces the risk of accidents and thefts.
- The reactor design should rule out any possibility of loading target materials for production of weapons-grade fissile elements.

In fast reactors, the uranium–plutonium fuel of equilibrium composition is unfit for production of nuclear weapons. Its breeding properties are worse than those of uranium 20% enriched in ^{235}U (the IAEA limit). Absence of plutonium and uranium separation in all stages of the fuel cycle guarantees proliferation resistance.

The ^{238}U isotope burns out in the closed fuel cycle of a fast reactor, while plutonium is an integral and inseparable part of fuel (a “catalyst” for burning) and stays at all times incorporated in highly active materials. The international fuel cycle centers are expected to provide services to nuclear power complexes with fast reactors of the proposed type by producing only the first-core fuel and the makeup fuel, required for bringing NPPs into service, till the fuel cycle is closed. For the rest of the time, the plants will rely for their operation on the fuel they will breed, and will be independent from the foreign fuel suppliers.

58.3.3 Generation IV Nuclear Energy Systems

The ten countries (Argentina, Brazil, Canada, France, Japan, the Republic of Korea, the Republic of South Africa, Switzerland, the UK, and the USA) have joined together to form the Generation IV International Forum (GIF) to develop future-generation nuclear energy systems that can be licensed, constructed, and operated in a manner that will provide competitively priced and reliable energy products while satisfactorily addressing nuclear safety, waste, proliferation, and public perception concerns. Subsequently, the GIF Charter was signed by Euratom in 2003, and the People’s Republic of China and the Russian Federation, both in 2006.

The objective for Generation IV nuclear energy systems is to have them available for international deployment about the year 2030, when many of the world’s currently operating nuclear power plants will be at or near the end of their operating licenses.

Basic goals for Generation IV are defined in the four broad areas of sustainability, economics, safety and reliability, and proliferation resistance and physical protection:

- *Sustainability* (effective fuel utilization, development of new energy products that can expand nuclear energy's benefits beyond electrical generation, improved waste management, and demonstration of its safe long-term storage, minimal environmental impacts).
- *Economics* (competitive life cycle and energy production costs, low financial risks comparable to other energy projects, practical applications other than power production – hydrogen, process heat, district heating, potable water).
- *Safety and reliability* (safe and reliable operation, improved accident management and minimization of consequences, investment protection, and reduced need for off-site emergency response).
- *Proliferation resistance and physical protection* (effective proliferation resistance of nuclear energy systems through improved design features and other measures, increasing physical protection against terrorism by increasing the robustness of new facilities).

From more than 100 various proposals, six promising reactor systems were selected by GIF experts for further R&D within the framework of Generation IV (DOE 2002):

- Gas-cooled fast reactor (GFR) system
- Lead-cooled fast reactor (LFR) system
- Molten-salt reactor (MSR) system
- Sodium-cooled fast reactor (SFR) system
- Supercritical-water-cooled reactor (SCWR) system
- Very-high-temperature reactor (VHTR) system

The solutions in physics and design of SFR and VHTR (HTGR) were discussed in the first part of the chapter. The second part of the chapter deals with the innovative approaches to development of naturally safe fast reactors with a closed fuel cycle, including LFR, which is treated as the main line in establishment of large-scale nuclear power. The other three reactor systems selected for the Generation IV Project are briefly discussed below.

58.3.3.1 Gas-Cooled Fast Reactor System

The gas-cooled fast reactor (GFR) system features a fast-spectrum helium-cooled reactor (➤ Fig. 58.19) and closed fuel cycle. Like thermal-spectrum helium-cooled reactors such as the GT-MHR and the PBMR, the high outlet temperature of the helium coolant makes it possible to deliver electricity, hydrogen, or process heat with high conversion efficiency. The GFR uses a direct-cycle helium turbine for electricity and can use process heat for thermochemical production of hydrogen. Through the combination of a fast-neutron spectrum and full recycle of actinides, GFRs minimize the production of long-lived radioactive waste isotopes. The GFR's fast spectrum also makes it possible to utilize available fissile and fertile materials (including depleted uranium from enrichment plants) two orders of magnitude more efficiently than thermal spectrum gas reactors with once-through fuel cycles. The GFR reference assumes an integrated, on-site spent fuel treatment, and refabrication plant.

A summary of design parameters for the GFR system is given in the ➤ Table 58.7.

The GFR system is top ranked in sustainability because of its closed fuel cycle and excellent performance in actinide management. It is rated good in safety, economics, and in proliferation resistance and physical protection. It is primarily envisioned for missions in electricity

■ Fig. 58.19

Gas-cooled fast reactor (GFR)

production and actinide management, although it may be able to also support hydrogen production. Given its R&D needs for fuel and recycling technology development, the GFR is estimated to be deployable by 2025.

58.3.3.2 Molten-Salt Reactor System

The molten-salt reactor (MSR) system features an epithermal to thermal neutron spectrum and a closed fuel cycle tailored to the efficient utilization of plutonium and minor actinides. A full actinide recycle fuel cycle is envisioned. In the MSR system, the fuel is a circulating liquid mixture of sodium, zirconium, and uranium fluorides. The molten salt fuel flows through graphite core channels, producing a thermal spectrum. The heat generated in the molten salt is transferred to a secondary coolant system through an intermediate heat exchanger, and then through another heat exchanger to the power conversion system (● Fig. 58.20). Actinides and

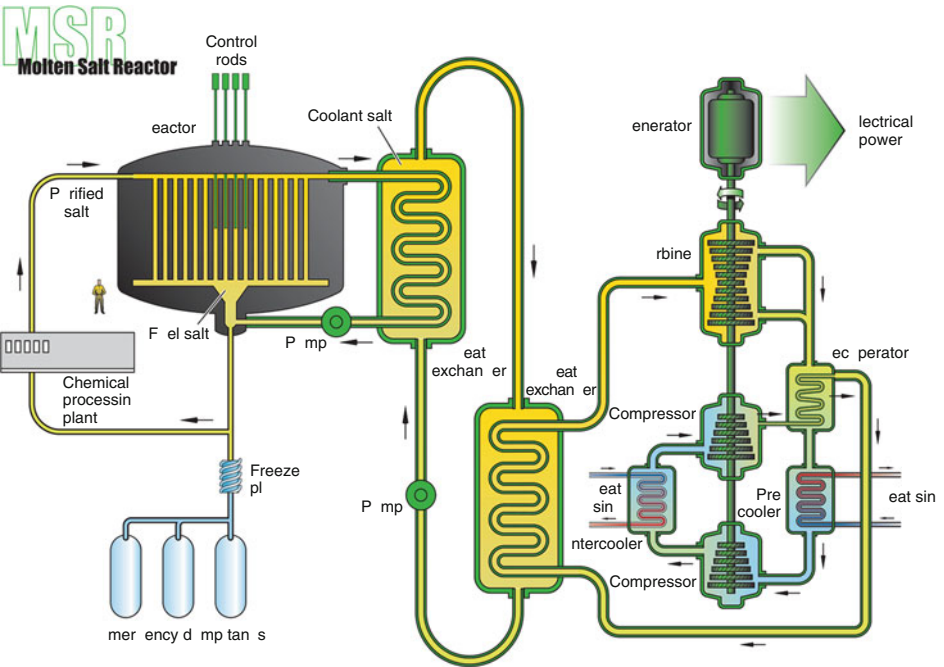

Table 58.7

Design parameters for the gas-cooled fast reactor (GFR) system

Reactor parameters	Reference value
Reactor power	600 MWth
Net plant efficiency (direct cycle helium)	48%
Coolant inlet/outlet temperature and pressure	490°C/850°C at 90 bar
Average power density	100 MWth/m ³
Reference fuel compound	UPuC/SiC (70/30%) with about 20% Pu content
Volume fraction, Fuel/Gas/SiC	50/40/10%
Conversion ratio	Self-sufficient
Burnup	5% FIMA (fissions per initial metal atoms)
Damage	60 dpa

Fig. 58.20

Molten-salt reactor

most fission products form fluorides in the liquid coolant. The homogenous liquid fuel allows addition of actinide feeds with variable composition by varying the rate of feed addition. There is no need for fuel fabrication. The reference plant has a power level of 1,000 MWe. The system operates at low pressure (<0.5 MPa) and has a coolant outlet temperature above 700°C, affording improved thermal efficiency.

Table 58.8

Design parameters for the molten-salt reactor (MSR)

Reactor parameters	Reference value
Net power	1,000 MWe
Power density	22 MWth/m ³
Net thermal efficiency	44–50%
Fuel-salt	
Inlet temperature	565°C
Outlet temperature	700°C (850°C for hydrogen production)
Vapor pressure	<0.1 psi (pound-force per square inch)
Moderator	Graphite
Power cycle	Multi-reheat recuperative helium Brayton cycle
Neutron spectrum burner	Thermal actinide

Fig. 58.21

Supercritical-water-cooled reactor (SWCR)

The MSR system is top ranked in sustainability because of its closed fuel cycle and excellent performance in waste burn-down. It is rated good in safety, and in proliferation resistance and physical protection, and it is rated neutral in economics because of its large number of subsystems. It is primarily envisioned for missions in electricity production and waste burn-down. Given its R&D needs for system development, the MSR is estimated to be deployable by 2025.

A summary of the reference design parameters for the MSR is given in the ► [Table 58.8](#).

58.3.3.3 Supercritical-Water-Cooled Reactor System

The supercritical-water-cooled reactor (SCWR) (► [Fig. 58.21](#)) system features two fuel cycle options: the first is an open cycle with a thermal neutron spectrum reactor; the second is a closed cycle with a fast-neutron spectrum reactor and full actinide recycle. Both options use a high-temperature, high-pressure, water-cooled reactor that operates above the thermodynamic critical point of water (22.1 MPa, 374°C) to achieve a thermal efficiency approaching 44%. The fuel cycle for the thermal option is a once-through uranium cycle. The fast-spectrum option uses central fuel cycle facilities based on advanced aqueous processing for actinide recycle. The fast-spectrum option depends upon the materials' R&D success to support a fast-spectrum reactor.

In either option, the reference plant has a 1,700-MWe power level, an operating pressure of 25 MPa, and a reactor outlet temperature of 550°C. Passive safety features similar to those of the simplified boiling water reactor are incorporated. Owing to the low density of supercritical water, additional moderator is added to thermalize the core in the thermal option. Note that the balance-of-plant is considerably simplified because the coolant does not change phase in the reactor.

■ **Table 58.9**

Designs parameters for the supercritical-water-cooled reactor (SCWR) system

Reactor parameters	Reference value
Plant capital cost	\$900/KW
Unit power and neutron spectrum	1,700 MWe
Net efficiency	44 %
Coolant inlet and outlet temperatures and pressure	280°C/510°C/25 MPa
Average power density	100 MWth/m ³
Reference fuel	UO ₂ with austenitic or ferritic–martensitic stainless steel, or Ni-alloy cladding
Fuel structural materials, cladding structural materials	Advanced high-strength metal alloys are needed
Burnup	~45 GWD/MTHM (gigawatt-day/metric tons of heavy metal)
Damage	10–30 dpa (displacements per atom)
Safety approach	Similar to advanced light water reactors (ALWRs)

A summary of design parameters for the SCWR system is given in the ► [Table 58.9](#).

The SCWR system is highly ranked in economics because of the high thermal efficiency and plant simplification. If the fast-spectrum option can be developed, the SCWR system will also be highly ranked in sustainability. The SCWR is rated good in safety, proliferation resistance, and physical protection. The SCWR system is primarily envisioned for missions in electricity production, with an option for actinide management. Given its R&D needs in materials compatibility, the SCWR system is estimated to be deployable by 2025.

Acknowledgments

Prof. Y. Fuji-ie is grateful to Mr. Shoji Kotake and Mr. Nariaki Uto for their support through his contributing part of the chapter especially for the section on sodium-cooled fast reactor. The author is grateful also to Dr. Kazuo Arie, Dr. Masurou Ogawa, Dr. Kazuhiko Kunitomi and Dr. Kaoru Onuki for their contribution on HTGRs including valuable discussion on advanced nuclear energy system.

Prof. E. Adamov would like to thank Prof. V. Orlov and Drs. V. Smirnov, A. Lopatkin, and A. Dzhalavayan for their significant contribution to this chapter.

The chapter could not be completed without their contributions.

Abstract: This chapter contains the information about nuclear power sources for space systems. Reactor nuclear sources are considered that use the energy of heavy nuclei fission generated by controlled chain fission reaction, as well as the isotope ones producing heat due to the energy of nuclei radioactive decay. Power of reactor nuclear sources is determined by the rate of heavy nuclei fission that may be controlled within a wide range from the zero up to the nominal one. Thermal power of isotope sources cannot be controlled. It is determined by the type and quantity of isotopes and decreases in time due to their radioactive decay. Both, in the reactor sources and in the isotope ones, nuclear power is converted into the thermal one that may be consumed for the coolant heating to produce thrust (Nuclear Power Propulsion System, NPPS) or may be converted into electricity (Nuclear Power Source, NPS) dynamically (a turbine generator) or statically (thermoelectric or thermionic converters). Electric power is supplied to the airborne equipment or is used to produce thrust in electric (ionic, plasma) low-thrust engines. A brief description is presented of the different nuclear systems with reactor and isotopic power sources implemented in Russia and the USA. The information is also given about isotopic sources for the ground-based application, mainly for navigation systems.

59.1 Introduction

The opportunity to employ nuclear power (power released by fissioning heavy nuclei and power released in radioactive decay) in space systems became evident as early as in the middle of the twentieth century. After the creation of atomic weapon both in the USA and in the USSR, practical studies of possible lines and patterns of atomic power sources for different space missions were initiated (Snyder 1961).

It is known that the advantages of nuclear power manifest themselves where continuous operation and comparatively high power are needed. In space applications, it is a great advantage that a small amount of nuclear fuel produces a large amount of energy. Solar power systems provide for a continuous lifetime, but large surfaces of solar cell panels are needed to increase power output, which is a limiting factor.

Nuclear power sources (NPSs) are classified first of all according to the type of the nuclear conversion taking place in them:

- In reactor power sources, energy is released by heavy nuclei fissioning in controlled chain reactions.
- In isotope power sources (actually: radionuclide sources), energy of radioactive decay of nuclei is used. The radionuclides themselves are products of fission or activation due to irradiation by neutrons.

Energy released in reactor sources is higher by orders of magnitude. The energy output depends on the reactor power and can be controlled.

Energy release in isotope sources depends on the type and quantity of the radionuclide used. The rate of decay cannot be controlled. Only the quantity of energy directed to the conversion system can be changed.

59.2 Reactor Power Sources

Reactor power sources are subdivided into two types:

- Onboard power sources. Electric power generated by them powers the instrumentation in space vehicles; it serves system survival and the operation of electric jet engines of low propulsion.
- Nuclear reactor engines. Fission energy is used for the heating of propellant to produce a jet thrust.

Hybrid patterns such as power propulsion systems are also feasible.

59.2.1 Onboard Reactor Power Sources

The advantages of these systems are as follows:

- Compact size.
- Independence of the distance to the Sun and of the vehicle orientation to the Sun.
- Maneuverability, the opportunity to operate at different power levels including increased power.
- Tolerance to cosmic radiation exposure.

At the current status of solar power sources, the advantages in mass-dimensions characteristics of those manifest themselves at the level of their electric power of several tens of kilowatts (for unmanned space vehicles).

The nuclear power unit (NPU) and the automatic control system (which is protected by radiation shielding and located in the instrumentation module at some distance from NPU) are the basic components of nuclear power systems.

The basic components of the nuclear power unit are as follows: the reactor, the system of power conversion, the system of power transfer (the coolant loop), the system of heat removal into the environment, and the unit of radiation protection.

Both dynamic (machinery) and static (non-machinery) conversion systems, that is, thermoelectric and thermionic ones, are considered as systems for the power conversion (production).

As static systems are more common in practice, the information about those will be given in the following sections.

59.2.1.1 Thermoelectric Nuclear Power Systems

The distinguishing feature of space power systems is that they operate at high temperatures because excess heat can only be removed into the environment by radiation. As the radiator surface (and weight) is limited, the temperature level of the whole system gets high. Therefore, high-temperature semi-conductors, silicon and germanium, are the elements of the thermoelectric converter.

Heat generated in the reactor is supplied to the hot ends of the elements; excess heat is removed to the radiator and rejected into the environment.

According to the methods of heat supply and removal, there are different configurations that have been implemented by developers in different countries (USSR and the USA):

- The configuration with the reactor, converter, and radiator arranged within one unit with heat transfer by heat conduction and radiation (without a coolant) is characteristic of the reactor-converter “Romashka,” USSR (Millionshchikov et al. 1964).
- In NPS SNAP-10A (USA), the converter has been combined with the radiator. Heat has been transferred from the reactor by a liquid-metal coolant (Johnson et al. 1966).
- In NPS “Buck” (USSR), the converter was an individual unit. Heat was removed from the reactor to the radiator also by a liquid-metal coolant – Na-K eutectics (Gryaznov 1999).

Each configuration has definite advantages and disadvantages. For instance, the system “Buck,” which was successfully employed in space, had a high-power output.

Thermoelectric Reactor-Converter “Romashka”

“Romashka,” as a terrestrial model, was the first NPS with a thermoelectric converter turning nuclear reactor heat into electric power. It was brought to electric power in August 1964 at the terrestrial facility of Kurchatov Institute and operated successfully about 15,000 h producing 6,100 kWh of electric power. Its basic characteristics are summarized in [Table 59.1](#) (Gverdtseteli et al. 1969; Kukharkin et al. 2008).

The basic NPS unit is a high-temperature fast-nuclear reactor (NR) ([Fig. 59.1](#)) in which heat generated in the core is transferred by conduction and radiation to the converter adjacent

Table 59.1

The “Romashka” NPS basic characteristics

Core diameter/height	241/351 mm
Radial reflector outer diameter/height	483/553 mm
Reactor load mass by ^{235}U	49 kg
Total mass (without drives and control rods)	635 kg
Effective thermal power (without taking into account the end wall spread of heat)	28.2 kW
Electrical output (at start-of-life)	460–475 W
A coefficient of electrical power reduction over a lifetime of 15,000 h	0.8
Operating voltage	21 V
Maximum temperature of the	
Core center	2,173 K
Radial reflector outer surface	1,233 K
Hot ends of thermopiles	1,088 K
Cold ends of thermopiles	858 K
Mounting of radiating fins	823 K
Neutron flux in the core center	$9.2 \times 10^{12} \text{ n/cm}^2 \text{ s}$
Neutron leakage from the reactor	$3 \times 10^{12} \text{ n/cm}^2 \text{ s}$

■ Fig. 59.1

Reactor “Romashka” and fuel element

to the outer surface of a radial reflector. The reactor core comprises a stack of 11 fuel elements (FEs); the segmented FEs consists of discs of uranium bicarbide with 90% enriched uranium. This is located within a graphite package, so built that a significant part of heat from the core goes through the package body, thus reducing the temperature drop in uranium bicarbide.

A cylindrical radial beryllium reflector encloses the reactor. A graphite bushing is located between the core and reflector coated with silicon carbide and beryllium oxide providing the compatibility of materials at high ($\sim 1,473$ K) operating temperatures. Graphite plates also coated with beryllium oxide preventing the interaction of beryllium with the converter keyboard and reducing beryllium evaporation are located at the reflector 24-hedral outer surface.

The reactor end reflectors are also made of beryllium. The high-temperature heat insulation made of foam graphite and graphitized fabric is mounted on the reactor end walls to

reduce heat transfer. The reactor design and employed materials provide its long-term operation at high temperatures (up to 2,173 K in the center of the core and between 1,273 and 1,373 K on the reflector outer surfaces) that ensures the optimum operational conditions for the high temperature silicon–germanium converter.

The converter consists of 1,536 pairs of thermopiles made of silicon–germanium alloy (Si: 85% by mass, Ge: 15% by mass) with n- and p-conductivity. Each module of 16 thermopiles is mounted on the inner surface of the hermetically sealed steel vessel. To provide for a good contact on the reactor heating, each module is pressed on the reflector by gas bellows elements. On the hot side, the keyboard consists of molybdenum plates, on the cold one – of copper bridges. To prevent an electric contact (shorting), insulating plates of beryllium oxide are used on the hot and cold sides. The excess heat is removed from the reactor-converter by shaped enamel-coated copper fins with an emissivity of at least 0.9 (► Fig. 59.2).

The reactor control system consists of four rods located in the radial reflector and in the lower movable end reflector. Two rods are used for automatic and manual control, whereas the other two, together with the movable reflector, are used for the protection in case of emergency. The negative temperature coefficient of the reactor reactivity allows operating for a long time without the interference of the control system. Only some deterioration of electric power necessitated increasing of thermal power up to a new level.

The “Romashka” system testing confirmed the opportunity of a durable lifetime for thermoelectric elements under the conditions of neutron and gamma radiation exposure. Electrical power reduction over the lifetime of 15,000 h was determined by 1.5 times increase of the converter internal resistance (mainly, of the contact one) with 1.17 times increase of the thermoelectromotive force. Studies showed that the temperature annealing without irradiation resulted in significant restoration of properties.

Nuclear Power System SNAP-10A (USA)

SNAP-10A was the first power system in the World with a nuclear reactor launched in space. It was put into a near-earth 1,300 km orbit on April 3, 1965. The flight lasted 43 days and then the NPS was shut down by a radio command from Earth because of malfunctions in the electric circuits of the spacecraft (Johnson et al. 1966; Wetch 1990).

➤ Figure 59.3 shows the SNAP-10A NPS schematics. ➤ Figure 59.4 presents the system's general view.

A thermoelectric generator (TEG, for its performances see ➤ Table 59.2) and radiator are arranged in one unit.

Heat is supplied from the reactor with TEG by the eutectic sodium and potassium alloy, which is circulated by a conduction electromagnetic pump having a self-contained Pb-Te thermogenerator. The main TEG consists of 120 modules. The coolant heated in the reactor comes through the module pipeline heating hot ends of thermoelements. Thermoelements are connected in sequence by copper bridges along the hot side and by aluminum plate-type radiators along the cold one. The converter-radiator mounting assemblies are welded to the space frame surface that represents the system's basic load-bearing element.

The nuclear reactor and shield are mounted on the upper bearing ring of the load-bearing unit.

The shield represents a steel container filled with cold-pressed lithium hydride. The thermoelectric generator and other units of the system are located behind the shield. The SNAP-10A NPS maximum diameter is 1.5 m, height is 3.65 m, and mass is 450 kg.

The core consists of 37 fuel rods of 3.18 cm diameter combining the functions of neutron-induced fission and moderation. Fuel rods are made of a homogeneous mixture of enriched uranium and zirconium hydride. They are tightly packed into a cylinder vessel of 22.7 cm diameter and 40 cm height. A beryllium reflector and tiltable semi-cylindrical controls being the part of the reflector are located at the vessel outer side.

Loading of ^{235}U is 4.3 kg, the reactor mass is 125 kg.

■ Fig. 59.3

Reactor SNAP-10A conversion scheme

■ Fig. 59.4

Space nuclear thermoelectric plant SNAP-10A

For safety purposes, the reflector can be ejected on radio command from the Earth in case of an abnormal operation or automatically on the entry into dense layers of the atmosphere.

Space Thermoelectric System “Buk”

The “Buk” space thermoelectric system was created in the USSR at the end of the 1960s. Between 1970 and 1988, there were more than 30 launches of these systems on “Kosmos” launch vehicles (Gryaznov 1999, Mashinostroyenie Entsiklopediya). The system was operated at low orbits about 300 km high.

■ **Table 59.2**

TEG performances

Inlet coolant temperature	803 K
Reactor thermal power	34 kW(t)
Radiator average temperature	588 K
Average temperature drop in thermoelectric material	170 K
Q-factor of thermoelements	$0.58 \times 10^3/\text{K}$
Number of thermoelements	1,440
Operating voltage	28.5 V
Electric power (at the lifetime beginning)	540 W
Conversion total efficiency	0.016
Mass of the TEG 120 modules	68 kg
Radiator total area	5.8 m^2

■ **Fig. 59.5**

Space nuclear thermoelectric plant “Buk”

➤ **Figure 59.5** presents the “Buk” system’s general view. The “Buk” NPS consists of the nuclear reactor, the shield, the radiator with the TEG inside located in series along the nuclear reactor axis.

A small fast reactor is used as a power source, the core of which contains more than 30 fuel rods. The fuel is a highly enriched uranium-molybdenum alloy. Longitudinally movable control rods are placed in the beryllium side reflector.

A two-loop heat removal system uses a eutectic alloy of sodium and potassium as coolant. The first loop coolant, heated up to about 1,000 K, is supplied into the TEG located in a cylindrical casing. The second loop coolant removes the excess heat to the radiator.

The TEG has two independent sections: the main one for the spacecraft users and the auxiliary one for the power-to-conduction type electromagnetic pumps used for both coolant loops. There are two cascade thermoelectric converters in the TEG.

The reactor thermal power is about 100 kW(th), the maximum electric power is about 3 kW. The “Buk” NPS lifetime was extended in operation to several thousands of hours by which time the efficiency was reduced down to 0.9 of its start-of-life value.

The operation in low orbits required two safety systems.

The basic safety system is intended for moving the nuclear spacecraft into a long-term disposal orbit at a height of more than 850 km. The lifetime of the system moved to this orbit is quite enough for the nuclear reactor fission products to decay to the level of natural radioactivity.

The second back-up system provides for the aerodynamic dispersion of a fuel composition with fission products into the upper layers of the Earth atmosphere into particles the sizes of which are sufficiently small to pose no excess radiological hazard to the population and environment.

Problems of Power Increase

A low-efficiency coefficient is a disadvantage of nuclear power systems with TEGs. In case of need to increase power up to several tens of kilowatts, it is necessary to increase the temperature drop in the generator. The temperature increase is limited by the liquid-metal loop capabilities. In this case, lithium technologies are to be employed. The temperature decrease on cold junctions results in a sharp enlargement of the radiator surface. This explains the fact that the development of the SP-100 NPS in the USA has been unfinished.

With the current state-of-the-art of solar generators, thermogenerators with electric power of less than 30 kW become noncompetitive.

The foresight of these trends led to the necessity to develop nuclear power systems with a thermionic converter.

59.2.1.2 Thermionic Nuclear Power Systems

The merits of thermionic converters lie in the fact that they operate at higher temperatures, have smaller dimensions and higher efficiency. They may be located inside the reactor core as their cathodes may serve as claddings of fuel elements making a thermionic fuel element (TFE). In this case, the high-temperature coolant loop is eliminated. These designs were developed in the USSR.

There are other possible layouts too, such as the NPS with the outrigger generator, heat to which is supplied by a high-temperature lithium coolant, and other advanced patterns with heat supply by heat pipes (HP) providing a minor temperature drop. These patterns, along with built-in TFEs developed in the USSR, were investigated in the USA.

Built-in TFEs may be divided into two types: single-cell and multi-cell ones. In a single-cell TFE, the thermionic cell is of the same length as the core or TFE. In a multi-cell TFE, several thermionic cells are located along the TFE length. In the USSR, both layouts of 5–10 kW electric power were developed (and created) on a competitive basis. They used thermal neutron reactors with a zirconium hydride moderator.

Simultaneously, studies were performed to justify the opportunity to create a more powerful (~500 kW) system in which a fast reactor was considered as a power source.

Space Nuclear Power System “Topaz” with Multi-Cell TFEs

The system development started in the 1960s. In 1970–1973, first time in the world, three prototypes of thermionic reactor-converters with multi-cell TFEs underwent terrestrial electrical testing. Then, after the testing of the fourth prototype employing TFEs with single-crystal molybdenum emitters coated with single-crystal tungsten, the creation of the “Topaz” NPS for

■ Fig. 59.6

Space nuclear thermionic plant “Topaz”

the experimental space vehicle (SV) started (Mashinostroyeniye Entsiklopediya, Kuznetsov et al. 1974; Gryaznov et al. 1989). ➤ Figure 59.6 presents the “Topaz” NPS layout.

The unit for cesium vapor supply, of the control system drivers, the reactor-converter, the reactor shielding, and the radiator are located in series along the system axis.

The automatic control system (ACS) is located in the instrumentation module and connected to the NPS systems by electrical service lines.

The core consists of several tens of TFEs and four zirconium hydride moderator discs. Fission gas is vented from multi-cell TFEs to the interelectrode gap (IEG). TFEs are electrically connected so that they form the operating section and the pump section. TFEs are electrically connected at both ends in cesium vapor. The operation section terminal electrical output is about 6 kW.

Rotating beryllium drums with boron carbide cover plates located in the side reflector provide the control. Each group of controls has its own drive.

The system of cesium vapor generation and supply providing its venting through the TFE interelectrode gap is employed.

The lithium hydride single-component radiation shielding is placed in the hermetically sealed steel cask.

The radiator has a load-carrying capacity and serves as a structural component. It is designed as a system of D-shaped tubes welded into the ring-type collectors and supported by the load-bearing elements. The tubes' plate surface is soldered to the radiator steel ferrule having a high emissivity coating. The sodium–potassium coolant cooling TFEs anodes transfers heat to the steel ferrule. The radiator emissivity ensures rejection in space of at least 170 kW (th) at the coolant temperature at the radiator inlet up to 880 K.

The NPS “Topaz” is 4.7 m long of 1.3 m maximum diameter and ~1,200 kg mass.

Starting from 1979, three nuclear-power tests of the NPS with the ACS were performed during terrestrial running tests. The last test lasted for about 7,000 h. During the tests, a conversion efficiency degradation by ~ 20% was found, which was attributed mainly to hydrogen outflowing from the moderator units and penetrating into the IEG. Hydrogen presence resulted in the plasma losses and extraneous heat removal into the IEG.

Two “Topaz” NPSs were tested in flight in 1987–1988 with the spacecrafts “Cosmos-1818” and “Cosmos-1867.” Spacecrafts were placed in a circular operational orbit at a height in excess of 800 km. NPSs were operated for 5 months and about 1 year, respectively. The initial values of the systems' parameters after bringing to a nominal power were close to those obtained in the terrestrial tests. However, by the end of tests, the efficiency degraded by 25%.

Space Nuclear Power System “Yenisey” with Single-Cell TFEs

Development of the “Yenisey” NPS (“Topaz-2”) was initiated at the end of the 1960s. As it can be seen from ▶ Fig. 59.7, its layout is close to that of the “Topaz” NPS. The system is 3.9 m long of 1.4 m diameter and 1,000 kg mass. Its distinctive feature is the employment of single-cell TFEs that allowed to simplify the perfection of units and the NPS as a whole and to establish better hygienic conditions for the thermionic converter operation (Ponomarev-Syepnoi et al. 1993; Kukharkin et al. 1999; Nikitin et al. 2000; Kukharkin et al. 2008).

A single-crystal molybdenum alloy coated with single-crystal tungsten (enriched in tungsten-184 isotope as it has the lowest cross section for neutron capture of all the W isotopes) was

■ Fig. 59.7

Space nuclear thermionic plant “Yenisey”

used as the emitter material. The collector was made of the polycrystalline molybdenum alloy. The emitter units have central orifices. Pellets of uranium dioxide of 96% enrichment in U-235 may be loaded through the orifice at any stage of the system preparation. Tungsten electrical heaters may be inserted instead of nuclear fuel to perform the system-running tests without nuclear heating and to check the system output parameters at the stage of system manufacturing. These orifices allow removing fission gas into space that facilitates the cathode integrity.

There are 37 TFEs in the reactor core (► Fig. 59.8). Three of those supply electric current to the pump section. The remaining 34 TFEs supply electric current to the operating section. The electrical connection is at the reactor, both ends in a helium chamber. The electrical power on the operating section terminals ranges from 4.5 kW up to 5.5 kW at the voltage of about 30 V.

The ACS controls the system. Nine of 12 control drums located in the reflector are controlling members and are actuated by one automatic control (AC) drive located behind the radiation shielding.

Three controls of the emergency protection system are actuated by their own drives operating only on bringing the reactor to power.

The original system for generation and wick feed of cesium vapors is employed. Cesium vapor is rejected into space through the controlled throttle. Depending on cesium flow rate, the necessary pressure is settled in the volume of interelectrode gaps. Cesium is heated by the liquid metal loop.

The radiator consists of round finned tubes forming a conical surface joined to the frame. The outer surface of fins has a special coating increasing the emissivity.

The hydrogen retention system, based on the protection of the moderator units and the reactor inner cavities by special coatings with special gas supplied into these cavities to replenish and recover the coatings became an important distinction of the “Yenisey” NPS. This system allowed extending the system lifetime significantly.

The “Yenisey” NPS underwent a whole cycle of the terrestrial running tests including off-line tests of units and systems and mechanical, vibration, thermal physic, electrical, and power tests of models and prototypes. In the course of running tests, the opportunity was taken to

■ Fig. 59.8

replace nuclear fuel in single-cell TFEs by electric heaters that allowed simulating all basic operational modes of the NPS without nuclear fuel.

Between 1975 and 1986, six terrestrial nuclear power tests that lasted from 3,000 up to 14,000 h confirmed the rated performances. On the basis of these tests and on a series of off-line tests of TFEs, the system predicted lifetime was not less than 3 years.

The main difficulties occurring in the course of durable terrestrial running tests were associated with the maintaining of operational ability of facilities' systems providing the conditions close to the flight ones.

The “Yenisey” NPS did not undergo flight tests.

Russian-American Cooperation

Tests and further development of the NPS with single-cell TFEs were continued in 1991–1996 under the agreement between the SPI/ISP (USA) and Russian developers approved by the Governments of both countries. Two models of the “Yenisey” NPS (named in the USA as “Topaz-2”) were tested in the new-built facilities with electric heating at University of New-Mexico and in Albuquerque. Specialists from Russia, USA, Great Britain, and France took part in these tests. The results of tests confirmed the required parameters (Nickitin et al. 1992; Topaz 1995; Andreev et al. 1995; Wetch et al. 1997).

Successful tests gave grounds to the American specialists to start development of the experimental space system NEPSTP with the “Topaz-2” NPS and electrical jet-propulsion engines of different types to transfer a space vehicle from a radiation-safe orbit to the geostationary one ($H = 36,000$ km) (► Fig. 59.9), and to start development of the SPACE-R thermionic NPS of 40 kW electrical power using the “Topaz-2” technology.

Though the “Topaz” program was not fulfilled in a full scope, it was an example of cooperation between Russia and the USA and promoted the achievements in new technology knowledge.

Works on the TFEs perfection and increase of their power are being continued in Russia.

59.2.2 Nuclear Power Propulsions

This section considers nuclear power propulsions (NPPs) in which the propellant heated up to a high temperature expels through the nozzle creating a jet thrust. They are intended for a delivery of space vehicles to the near-earth high orbits, to the Moon and to the solar system planets. As compared to chemical jet engines, the NPP specific impulse is more than two times higher. Among other propellants, hydrogen is preferred that is stored in liquid state on the SV board. Though the ratio of thrust to the engine mass of the NPP is less than that of the oxyhydrogen liquid engine, the mass of delivered payload is two times higher due to the exceeding specific impulse and relatively low propellant consumption.

Different reactor layouts were studied for the employment in the NPP. According to the set of developed technologies and obtained study results, NPPs with a solid-core reactor are best prepared for the practical application. Though, along with those, the NPPs with a gas-core reactor were studied theoretically and experimentally in the USSR and in the USA.

59.2.2.1 Programs of the NPP Development in the USSR and the USA and the Achieved Results

The NPP development started in the USA and USSR almost simultaneously in the mid-1950s, but the American researchers managed to demonstrate the feasibility of their ideas somewhat earlier (Dyakov et al. 1985; Demyanko et al. 1993; Deniskin et al. 1993; Bennet et al. 1994; Ponomarev-Stepnoy et al. 1999).

During 1955–1973, under the national program ROVER/NERVA 20 NPP reactors (of the KIVI, NRX, Phoebus, Pewee, XE series) of 100–5,000 MW rated power to produce thrust of 2×10^6 – 1.1×10^7 N were developed in the USA and tested at the nuclear site Nevada. The program of running tests was focused on the integrated testing of the whole system.

The concept of the American NPP reactor was based on the homogeneous graphite core stacked up of hexagonal fuel elements with a turnkey size 19 mm having 19 orifices for hydrogen flowing through. Microparticles of uranium bicarbide dispersed in a graphite matrix served as the fuel. The average temperature for hydrogen heating up to 2,280–2,550 K and the thrust specific impulse of 8100–8500 m/s were achieved in tests.

Another line of the NPP development was chosen in the USSR. The program was based on the creation of the technology, production, and testing basis for the element-by-element individual running tests of the engine basic units and systems and for their finishing in tests of the reactor models and engine as a whole. All this allowed reducing expenses significantly.

An impulse graphite reactor IGR (➤ Fig. 59.10) with a central channel to test fuel assemblies at the NPP transient operation modes and a research reactor IVG-1 (➤ Fig. 59.11) to test full-scale fuel assemblies (FA) of nuclear rocket engines of 3×10^5 – 4×10^6 N and higher thrust were built at the Semipalatinsk nuclear test site. Further, an experimental NPP model of a low thrust was mounted at the same site.

The concept of Russian NPP reactors was based on a heterogeneous structure consisting of fuel assemblies located in the moderator units. High-temperature compositions of uranium carbide and refractory metals (UC-ZrC-NbC, UC-ZrC) were employed as FAs materials allowing to achieve the level of hydrogen heating up to 2,900–3,100 K and to increase the thrust specific impulse up to 9,000–9,500 m/s. The heterogeneous structure allowed to perform

running tests of the reactor's most crucial component (FA) individually. The components were tested in the IGR and IVG-1 reactors.

The IVG-1 test facility was commissioned in 1975. By 1990, about 150 FAs of more than ten modifications including a set of FAs for the IRGIT prototype reactor for the low-thrust NPP were tested at that facility. In the course of these tests, the following parameters were achieved:

Temperature of hydrogen heating in a FA	2,600–3,100 K
• A single FA lifetime	4,000 s
• Number of times of a single FA bringing to power	12
• Rate of a FA heating-cooling	150 K/s
Density of power rate in fuel elements	35 kW/cm ³

No losses of FAs operational abilities were established in the tests.

► [Table 59.3](#) presents the NPP comparative performances achieved in the USSR and USA.

59.2.2.2 The Russian Concept of the Model NPP Designs

Characteristic features are a heterogeneous core and a modular structure that allow simplifying the reactor and NPS running tests.

The reactor is a channel-tank type unit in which a core, a side reflector with rotating control drums and internal protection are located. A nozzle chamber is located below the reactor.

The core comprises fuel assemblies, the moderator, and complementary nuclear safety rods (on delivery to the supporting orbit). FA consists of a bundle (► [Fig. 59.12](#)) of densely packed carbide-graphite elements and of twisted carbide FEs of different compositions based on uranium enriched up to 90%. This design allows reducing the nonuniformity of power deposition and the coolant temperature at the FA outlet.

Yttrium hydride or zirconium hydride may be used as a moderator. Boron carbide or alloys of rare earth elements (Eu, Gd, Hf) serve as absorbing elements in control drums. The beryllium reflector is sectional (at high temperatures, beryllium oxide may be also employed).

■ [Table 59.3](#)

NPP performances achieved in the USSR and the USA

Performances	USSR	USA
Power, MW	230 (IVG1)	4,100 (Phoebus 2A)
Propulsion, MN	~0.15 (IVG1)	≈0.93 (Phoebus 2A)
Hydrogen flow rate, kg/s	16 (IVG1)	120 (Phoebus 2A)
Specific propulsion pulse, m/s	~9,500 (IVG1)	≈8,480 (Pewee)
Coolant outlet average temperature, K	3,100 (IVG1)	2,550 (Pewee)
Average power density in the core, kW/cm ³	15 (IVG1)	2.3 (Pewee)
Maximum density of power rate in fuel, kW/cm ³	35 (IVG1)	5.2 (Pewee)
Lifetime at the nominal power, s	4,000 (IVG1)	6,540 (NF1)
Maximum number of start-ups	21 (IVG1)	28 (XE)

■ Fig. 59.12
Bundle of fuel elements

Materials for the reactor load-bearing elements are chosen with regard to the specified operation conditions (pressure, consistency with hydrogen, irradiation conditions). Both nitrogen-doped chromium-nickel steels and alloys of the Fe-Cr-Ni system containing Mo, Nb, Al, and Ti may be employed. The compositions $\text{ZrH}_{1.85} + \text{LiH}$, $\text{ZrH}_{1.85} + \text{B} + \text{LiH}$, $^{238}\text{U} + \text{LiH}$ are the candidates for the radiation shielding. The shielding forms a shadow cone with $10^\circ\text{--}30^\circ$ angle.

As applied to space missions (a CV delivery to the geostationary orbit, cargo delivery to the Moon, Mars), different NPPs with the thrust between 5 kN and 10^4 kN, total time of the engine operation 1–6 h at 10–20 start-ups were put under consideration. Due to the difficulty to perform running tests of powerful engines, the opportunity to employ a bunch of engines for spacecrafts was considered.

The NPP design performances for the Moon and Mars exploration are as follows:

Reactor type	Intermediate
• Propellant	Hydrogen
• Thrust-specific impulse	9,400–9,550 m/s
• Thrust of the NPP single module	6.8×10^4 N
• The NPP module reactor thermal power	340 MW(t)
• Propellant flow rate	7.1 kg/s
• Propellant temperature in the nozzle chamber	2,900–3,100 K
• Propellant pressure in the nozzle chamber	6 MPa
• Fuel	Solid solutions of UC-ZrC-C, UC-ZrC, UC-ZrC-NbC

• Uranium enrichment	90%
• ^{235}U loading	20.1 kg
• Moderator	$\text{ZrH}_{1.85}$
• Neutron flux in the core	$1.2 \times 10^{19} \text{ cm}^2/\text{s}$
• Efficiency of controls:	
Control drums	5.6%
Nuclear safety rods	9.8%
Thrust to the NPP mass ratio (without hydrogen tanks)	24–31 N/kg

59.2.3 Nuclear Power Propulsion Systems (NPPS)

Nuclear power propulsion systems (NPPS) in contrast to onboard sources and NPPs discussed in [Sects. 59.2.1](#) and [59.2.2](#), respectively, may perform both functions: generate electric energy for the spacecraft's onboard needs and/or heat the propellant producing thrust (Pupko et al. 1991; Kolganov et al. 1993; Ponomarev-Stepnoi and Usov 1995; Ponomarev-Stepnoi et al. 1995, 1996, 2003, 2005).

They may be developed on the basis of both the NPP and the onboard nuclear power system technologies. The NPPS reactor is operated in two modes: either continuous power or short propulsion. Power levels at those modes differ by 3–4 orders of magnitude.

In the NPPS based on the NPP technology, the reactor is successfully combined with a dynamic power conversion system operating in a closed gas turbine Brayton cycle (helium and xenon) or in a potassium steam turbine Rankine cycle.

[Figure 59.13](#) illustrates the layout of the NPPS with a dynamic converter operating in the Brayton cycle. This layout is considered to be the prospective one for the manned Martian mission. Its performances for the power mode are as follows:

Reactor thermal power	90 kW
• Coolant	98.3% Xe + 1.7% He
• Coolant flow rate	1.13 kg/s
• Coolant temperature at the reactor inlet/outlet	1,190/1,500 K
• Maximum pressure in the power conversion loop	1.0 MPa
• Electric power	25 kW
Brayton cycle efficiency	28.6%

The system performances for the propulsion mode correspond to those of the NPP operating with hydrogen.

The planned lifetime in the mode of electric power production employing intermediate reactors is 3 years. On extending the lifetime up to 10 years, fast reactors are the best choice.

The NPPS based on the NPP technology are effective at high-altitude near-earth orbits as electric power sources. With the NPPS thrust of about 500 kN, time of delivery to the geostationary orbit will be 6–10 h.

■ Fig. 59.13

Nuclear power propulsion system (NPPS): 1, Recuperator; 2, Fuel assembly; 3, Control drum (CD); 4, Nuclear safety rod (NSR); 5, CD Drive; 6, Radiator; 7, Turbogenerator; 8, NSR Drive; 9, Hydrogen Tank; 10, Turbo-pump; 11, Hydrogen recuperator; 12, Shielding; 13, Reflector; 14, Nozzle

The NPPs based on thermionic reactor converters may also become the basis for nuclear power propulsion systems. There are two possible development lines:

- Power increase and employment of electrical jet engines to produce thrust.
- Development of bimodal reactors.

The NEPSTP project carried out in the USA by the APL incorporating Russian space NPS “Yenisey” and different electrical jet engines either American or Russian ones may serve as an illustration of the first development line. The long duration (about half a year) of a payload delivery to the geostationary orbit is a disadvantage of this system, though its readiness is of the highest degree.

The system based on the bimodal reactor in which electric power is generated in a thermionic converter and thrust is produced by hydrogen expelled through the core (TFE) will allow significantly shorter time of delivery to high-altitude orbits.

Thus, the employment of the NPPS based on the NPS with dynamic power conversion system is preferable for missions of fast delivery (especially, in case of manned interplanetary flights), but for the cargo carrying, the NPPS based on the NPS with the electric jet propulsion system is preferred.

59.3 Radioisotope (Radionuclide) Power Sources

Power released in these sources is associated with radioactive decay of different radionuclides generated either on fission in nuclear reactors or on neutron irradiation of stable isotopes (Corliss and Harvey 1964).

In this case, it is impossible to control power-deposition processes. Power starts to be generated as soon as the radionuclide is produced. It decreases exponentially and is determined by the amount and the decay constant of the radionuclide. Thus, safety issues concerning these sources are crucial not only in the course of their operation but also at the stages of their production, of power-source assembling, storage, pre-starting procedures, and after decommissioning.

This section considers the radioisotope sources of electricity though they may be employed in space systems for the thrust production similar to the reactor sources. It is obvious that power of these sources is significantly lower than that of the reactor NPS.

Radioisotope sources of electric power are divided into two types according to the principle of electricity production: sources not employing a thermal cycle and sources employing that. The first ones are ordinarily termed as nuclear batteries.

Nuclear batteries are well suited to terrestrial applications; however, they are less applicable in space. They are divided into three categories:

- Single-stage batteries with a direct charge accumulation, that is, batteries with a direct conversion of radioactive decay energy into electricity.
- Two-stage batteries in which decay energy goes into the generation of a charge-free carrier (batteries with the p-n junction, Volta effect, secondary electron emission).
- Three-stage batteries in which decay energy goes into the production of photoradiation converted into electricity (photovoltaic arrays).

Let us consider sources employing a thermal cycle in more detail.

59.3.1 Radioisotope Thermoelectric Generators (RTGs)

These generators (which should be properly called radionuclide thermoelectric generators – a term rarely used) convert almost all energy of charged particles (α , β) and gamma-quanta into heat on their deceleration in the radioactive material and in the cladding of the capsule containing this material (Radioizotopnye istochniki elektricheskoy energii 1978; Turi et al. 1991).

This capsule with the radioactive material is called a radiation heat source (RHS). Heat may be produced in dynamic or static cycles using the temperature difference between RHS and environment. Similar to the reactor sources, static conversion systems, particularly thermoelectric ones, were widely used both in the USSR and in the USA. Systems on their basis have been named as radioisotope thermoelectric generators (RTG).

The RTG basic units include the radiation heat source (RHS), thermoelectric unit (TEU), radiation shielding (RS), and radiator. (Space systems need radiators also to cool them.) RTGs' merits are determined by the following unique properties: spontaneous release of thermal power, its direct conversion into electricity, a simple design, high-energy output, a long lifetime, the opportunity of employment practically in all scopes of activities: under water, at the surface of the Earth and planets, and in space.

In the USA, RTGs were mostly used in space systems. In the USSR, they were widely employed in navigation.

59.3.1.1 The Choice of Radionuclides and the Methods of RTG Manufacturing

A wide range of radioactive nuclides (► [Table 59.4](#)) may be employed for RTGs as power sources. According to the fabrication method, they may be divided into four groups (Radioizotopnye istochniki elektricheskoy energii 1978, Mashinostroyenie Entsiklopediya):

- ^{90}Sr , ^{147}Pm , ^{144}Ce , and ^{137}Gs are produced from nuclear wastes (fission products).
- ^{60}Co , ^{170}Tm , ^{192}Ir , and ^{210}Po are generated in nuclear reactors on the neutron irradiation of targets made of stable ^{59}Co , ^{169}Tm , ^{191}Ir , and ^{209}Bi .
- ^{227}Ac and ^{232}U are produced by the neutron irradiation of uranium-cycle by-products such as ^{226}Ra , ^{230}Th , and ^{231}Pa .
- ^{238}Pu , ^{242}Cm , and ^{244}Cm are generated in the course of the irradiation of plutonium-cycle by-products ^{237}Np , ^{241}Am , and ^{243}Am .

Nuclear wastes are the most readily available and cheapest raw materials for the production of radioactive nuclides in large amounts. The nuclides ^{210}Po and ^{60}Co of the second group are the most advanced ones both in their production method and in their properties. The production

■ **Table 59.4**

Radionuclides with a half-life between 100 days and 100 years

Nuclide	$T_{1/2}$	Specific activity ^a Ci/g	Nuclide	$T_{1/2}$	Specific activity ^a Ci/g
^3H	12.26 years	9,700	^{171}Tm	1.9 years	1,100
^{22}Na	2.58 years	6,320	^{192}Ir	74.4 days	9,170
^{45}Ca	164 days	17,750	^{194}Os	1.9 years	980
^{60}Co	5.27 years	1,140	^{204}Tl	3.56 years	490

^{147}Pm	2.62 years	930	^{249}Ci	360 days	1,460
^{155}Eu	1.7 years	1,360	^{250}Cf	10.9 years	130
^{170}Tm	128.5 days	6,000	^{252}Cf	2.9 years	650

^aSpecific activity of the real radioisotope fuel is determined by the content (%) of the respective nuclide

of radionuclides of the third and fourth groups is associated with a series of technological difficulties both in the production of initial materials and in their processing after the irradiation. ^{238}Pu and ^{244}Cm are the best candidates for the creation of the durable lifetime sources of electricity.

59.3.1.2 Purpose. Classification. Basic Requirements and RTG Performances

According to the application environment, RTGs are grouped into terrestrial, marine, and space ones (Mashinostroyeniye Entsiklopediya, Corliss and Harvey 1964; Radioizotopnye istochniki elektricheskoy energii 1978).

Terrestrial RTGs are usually placed at the distant and hard-to-reach areas to supply electric power to scientific equipment or beacons of different purposes. They are distinguished by simplicity of fabrication and maintenance. These generators employ, as a rule, cheap fuel with a long half-life (^{90}Sr or mixed fission products). ▶ Table 59.5 presents the basic performances of these RTGs fueled by ^{90}Sr .

Marine RTGs are used as the sources of electricity for subsea buoys and lighthouses. ▶ Table 59.6 comprises the performances of these systems.

Space RTGs are employed as the power supply for the equipment and instrumentation of space vehicles operating in near-Earth orbits, on the Moon, Mars and other planets, and their satellites.

In the USSR, RTGs operated in artificial satellites (AS) of the “Kosmos-84” series. In the USA, 38 RTGs of different design and power were launched in space between 1961 and 1977. Later, a unified GPHS RTG with ^{238}Pu fuel pellets and thermal power of 300 W was developed

that supplied electric power for space vehicles (SV) in flights to Jupiter, Saturn, and other planets. ➤ [Table 59.7](#) contains the basic performances of space RTGs.

The basic common requirements imposed on RTGs of different purposes are as follows: a high efficiency and electric power density, long lifetime, reliability, and sufficiently high operating temperatures of the conversion system. Strong gamma-radiation requiring heavy

shielding must be eliminated. The following special requirements are imposed on space-based RTGs: the mass and dimensions must be minimized; the radiator temperature must be optimized to provide the removal of excess heat into the environment.

59.3.1.3 Examples of RTG Designs for Terrestrial and Space Applications

In the course of the RTGs' development, the general concept took into account their purpose. The following units and materials were developed and fabricated for the terrestrial RTGs (Mashinostroyeniye Entsiklopediya, Radioizotopnye istochniki elektricheskoy energii 1978; Turi et al. 1991; Schock et al. 1999):

- A parametric series of unified RHS designs based on strontium titanate of 20–100 W thermal power, 0.8 W/cm^3 volumetric heat generation, $800\text{--}900^\circ\text{C}$ operating temperature, and 11.5 year lifetime.
- Medium-temperature two-stage thermal-electric batteries (TEBs) of 8–9% efficiency, $400\text{--}500^\circ\text{C}$ operating temperature, electric power of 2–159 W, and 10 year lifetime.
- High-temperature refractory alloy based on depleted uranium (U+Mo) for gamma-shielding. The operating temperature is $700\text{--}800^\circ\text{C}$, lifetime is 10 years, density $\geq 17 \text{ g/cm}^3$.
- Fibrous thermal-insulating material with the operating temperature 800°C , coefficient of heat conduction 0.04 W/m/K , lifetime 15 years, density $0.30\text{--}0.35 \text{ g/cm}^3$.

The RTGs of the “Gong,” “Gorn,” “Heli,” and “Gloria” types (Fig. 59.14) were developed on the basis of these units.

These RTGs employ multibank plate TEBs enclosed in hermetically sealed casings located at the RHS upper and/or lower end with the combined radiation shielding and prestressed

■ Fig. 59.14

RIG “Gloria 40”: 1, Cooling system; 2, Thermogenerator; 3, Insulation; 4, RHS

thermal insulation. The available heat factor is 85–92%, efficiency is 7–8%, lifetime amounts to 10–15 years, electric power ranges between 10 and 15 W, voltage is 7, 14, 28 V, specific power is 0.08–0.2 W/kg.

The low-power RTGs fueled with ^{238}Pu were mainly developed in the USSR for medical purposes.

The RTGs for space applications were developed largely in the USA. Unified generators and their units (modules) were also created there.

Their design can be illustrated by the American GPHS-RTG thermoelectric generator (► Fig. 59.15) employing ~ 20 heat-source modules (► Fig. 59.16). The RTG of this design may supply electricity to space vehicles exploring the solar space under almost all programs.

■ Fig. 59.15

■ Fig. 59.16

Radioisotopic thermoelectric generator GPHS-RTG: 1, Coolant tubes; 2, Radiator edge; 3, RHS modules; 4, Thermoelectric element; 5, Insulation

According to their simple and reliable design, mass-dimension characteristics, and lifetime, space RTGs with electric power ranging from fractions up to hundreds of watts are the best power sources for space vehicles. The GPHS-RTG, the USA basic space RTG, based on ^{238}Pu with electric power $W = 300\text{ W}$ has a specific electric power $W_{\text{sp}} = 7\text{ W/kg}$. The RTG lifetime for the flights into deep space comprises 8–10 years.

Abstract: This chapter gives the conditions for achieving power production using nuclear fusion reactions. The two basic schemes for plasma confinement, inertial and magnetic, are briefly considered and the present technical solutions are outlined. The physical and chemical processes taking place between the hot plasma and the containing vessel wall are discussed in more detail. At the end of the chapter, the present status of research and the planned future development plans are summarized.

60.1 The Necessary Conditions for Fusion Energy Production

Inevitably, the final goal of nuclear fusion research is to create such conditions that $P_{\text{out}} > P_{\text{in}}$, that is, the power P_{in} necessary to run a fusion-based power station, must be smaller than the power output P_{out} of the station. From a global perspective, this inequality is *the* necessary condition for efficient fusion energy production. However, it is clear that in the everyday work, this inequality is too general and so practically meaningless. More practical necessary conditions are needed (see later on), which can serve as reachable targets during the developments.

In [Chap. 6 of Vol. 1](#), it was shown that sustained fusion reactions can only take place in a high-temperature thermal medium called plasma. It was also shown – and here it shall be repeated for convenience – that the most important nuclear reactions are at the present stage of research. Note that below (as throughout this chapter), element symbols refer to bare nuclei without the electron shell – a special notation common in the field of fusion.

As also shown in [Fig. 6.3](#) in Chap. 6 of Vol. 1, of the above mentioned chapter, the $\text{D}(\text{t}, \text{n}){}^4\text{He}$ reaction (DT reaction in short) is distinguished by the lowest plasma temperature needed and by the highest fusion probability. Consequently, this reaction is the most promising one, and therefore it will be dealt with almost exclusively throughout the rest of this chapter.

To derive the necessary conditions for fusion energy production, one needs to list and calculate all the sinks and sources of power both in the DT reaction and in the power station as a whole.

60.1.1 Sources and Sinks of Power

The energy generated in the course of a DT reaction is released in the form of the kinetic energies of the created particles. In the DT reaction, two particles are generated: an alpha particle and a neutron. Bearing no electrostatic charge, the neutrons rarely collide with plasma particles and, therefore, transfer only a negligible fraction of their kinetic energy to the plasma medium before leaving it. The alpha particle on the other hand, depending on the plasma parameters (density, size, etc.), can deposit a considerable fraction – in an optimum situation up to 100% – of its energy to the plasma.

Therefore, from a fusion reactor point of view, the utilization of the energy of alpha particles is different from that of the neutrons. The alpha particles' energy can and must be used for plasma heating (alpha heating), whereas the neutrons' energy must be absorbed

outside the plasma and converted to some useful form of energy (e.g., by heating steam generators and driving turbines with the steam in order to generate electricity). In the DD reactions, the situation is similar, but in the case of the D-He reaction all resulting particles are charged, therefore more energy is kept in the plasma.

At present, the problems, both technical and physical, connected with the maintenance of a proper energy balance of the plasma, are far more difficult to solve than the absorption of neutrons in a mantle that surrounds the plasma. Before continuing the topic of utilization of neutrons, the power balance for the plasma will be treated below.

A simple expression for the requirements for positive energy balance shall be derived below by assuming homogenous plasma with volume V . The volumetric rate (number per volume per time) of fusion reactions is

$$f = n_D n_T \langle \sigma v \rangle = \frac{1}{4} n_e^2 \langle \sigma v \rangle. \quad (60.1)$$

Here it was assumed that there are no ions other than the fuel ions present (i.e., no impurities and no helium ash), and that D and T are present in the optimal 50–50% mixture. n_D , n_T , and n_e are the deuterium, tritium, and electron densities, respectively, and $\langle \sigma v \rangle$ is the Maxwellian-averaged fusion reaction rate at the temperature T as given in [▶ Chap. 6 of Vol. 1](#).

The volumetric rate of alpha heating is f times E_α , the energy of the alpha particle (neutrons escape). Assuming alpha particle energy deposition with 100% efficiency:

$$P_\alpha = \frac{1}{4} n_e^2 \langle \sigma v \rangle \cdot E_\alpha. \quad (60.2)$$

The losses of power from the plasma can be very diverse: radiation losses (line radiation and bremsstrahlung) and losses associated with plasma particles lost to walls of the plasma container due to the imperfect confinement. To characterize the integral effect of all possible power losses, a quantity τ_E , called *energy confinement time* is introduced as

$$\tau_E = \frac{W}{P_{\text{loss}}}. \quad (60.3)$$

Here W is the total energy content of the plasma and the energy confinement time measures the rate at which a system loses energy to the environment. Supposing equal electron and ion temperatures T and a 50–50% D-T mixture, the total energy content of a hypothetical homogeneous plasma with volume V can be given as $W = 3n_e k_B T V$.

A self-sustaining fusion plasma requires $P_{\text{loss}} < P_\alpha$, that is,

$$\frac{3n_e k_B T}{\tau_E} V < \frac{1}{4} n_e^2 \langle \sigma v \rangle \cdot E_\alpha V. \quad (60.4)$$

Or, after rearrangement

$$L \equiv \frac{12 k_B T}{E_\alpha \langle \sigma v \rangle} < n_e \tau_E. \quad (60.5)$$

The L -function, named after J.D. Lawson, has an absolute minimum as a function of temperature ([▶ Fig. 60.1](#)).

The minimum of the L -function occurs at temperature about 25 keV (approximately 250 million K) and has a value of approximately $1.5 \times 10^{20} \text{ s/m}^3$. Substituting this value into [▶ Eq. \(60.5\)](#), one gets the so-called Lawson criterion (Lawson 1957)

■ Fig. 60.1

The D-T L-function has a minimum around 25 keV plasma temperature

$$n_e \tau_E > 1.5 \times 10^{20} \text{ s m}^{-3}. \quad (60.6)$$

In the above treatment, it was assumed that alpha heating compensates all the losses from the plasma. This condition is called *ignition*. One can set similar Lawson condition for various $Q = P_f/P_{\text{loss}}$ values. Abundantly used is the case when the total (alpha + neutron) fusion power reaches the losses, that is $Q = 1$. This condition is called *breakeven*. In a given experiment, the value of the product $n_e \tau_E$ and its deviation from the minimum requirement is a measure of fusion performance. From the above derivation, it is clear that the actual value of the number before the factor 10^{20} s m^{-3} in the Lawson criterion depends on the plasma temperature. In the early decades of controlled fusion research, the fusion performance of the plasmas was so far from the Lawson criterion that its use was satisfactory. In the recent years, however, the use of another quantity called *fusion triple product* $T_i n_e \tau_E$ became more popular, because it also contains the ion temperature T_i and describes the Lawson criterion off the optimal temperature as well:

$$T_i n_e \tau_E > 2.5 \times 10^{21} \text{ keV s m}^{-3}. \quad (60.7)$$

This expression is valid sufficiently close to the minimum of the L -function where $\langle \sigma v \rangle$ can be approximated with a quadratic function.

Looking at the Lawson criterion, one can immediately see that there are two basic ways to satisfy it:

1. Creating a sufficiently high plasma density and confining the plasma for a rather short time, or
2. Maintaining a rather low plasma density and achieving a suitably long confinement.

Although not necessarily only these two options exist, nowadays the main stream of research concentrates on these two solutions. In case (1), the confining “force” is simply the inertia of the plasma against expansion. This method is called *inertial confinement fusion* (ICF), which speaks of confinement times of the order of nanoseconds and plasma densities on the order of 10^{31} m^{-3} . In the case of method (2), the confinement is reached with magnetic fields

(*magnetic confinement fusion*, MCF) as charged particles (D and T) gyrate around the magnetic field lines, and no perpendicular motion is present in zero order. Here, typical number densities are around 10^{20} – 10^{21} m⁻³ and energy confinement times of the order of 1 s.

Before going any further and discussing the two main confinement schemes, the problem of utilization of fusion-born neutrons needs to be considered briefly.

The DT reaction involves one deuterium and one tritium ion. Deuterium is abundantly present in water: every 6,500th hydrogen atom is deuterium. On the other hand, Tritium – because of its radioactive half-life of 12.32 years – is negligibly present in nature, and so must be produced artificially. And here the neutrons come into play. Lithium occurs in notable percentages everywhere in the mantle of Earth, and the following two nuclear reactions can very conveniently be used to breed tritium:

Both reactions produce tritium although the first reaction generates energy while the second one consumes it. In addition, natural lithium comprises 7.4% ⁶Li and 92.6% ⁷Li. Even though there is a much larger fraction of ⁷Li, nuclear data show that the ⁶Li reaction is much easier to initiate and as a result, it is this reaction that dominates in the breeding process.

With respect to the ⁶Li reaction, if there were no loss of neutrons, then each neutron produced during DT fusion and consumed in this reaction would produce one new tritium. In a practical reactor, however, there are always some unavoidable neutron losses. Thus, some form of neutron multiplication is required. Also needed is a method of slowing down the high-energy fusion neutrons since the ⁶Li reaction is most easily initiated with thermal, low-energy neutrons.

The breeding of tritium is envisaged in a mantle (called breeding blanket) that surrounds the chamber where the fusion plasma is confined.

In the following sections, the inertial and magnetic confinements shall be examined separately.

60.2 Inertial Confinement Fusion

As shown in the previous section, the inertial confinement scheme involves creation of very high densities for very short times. A small piece of solid or liquid material (a *fuel pellet*) is compressed by intense beams of energy (called *driver*) to the desired densities, and the confinement is simply achieved by the finite free expansion time of the compressed pellet.

Interest in the peaceful uses of inertial confinement fusion emerged later than that in magnetic confinement fusion, because until powerful laser or ion beams were developed and became available to civil researchers in the late 1960s, only an A-bomb's explosion could serve as a driver.

The sequence of events in inertial confinement can briefly be described as follows. A small pellet of radius less than ~5 mm and containing the fuel mixture (DT, in this case) is symmetrically struck from several directions by intense pulses of energy from either a laser or an ion beam. Absorption of this energy below the pellet's surface leads to local ionization and plasma formation. The consequence of these processes is an outward-directed mass transfer by ablation and – by a rocket type reaction – an inward-directed pressure wave leading to the compression and heating of the target. With the temperature and fuel density sufficiently

high, the fusion reactions will start and the pellet disassembles in a micro-explosion. The pellet can be further heated by the alpha particles originating from the DT reaction provided the density is high enough so as they can be slowed down inside the pellet. (Slowing down of fusion neutrons would need unreasonably high densities.) The disassembly typically takes place in a time interval of less than 10^{-8} s, corresponding to the propagation of a pressure wave across the pellet with sonic speed.

For inertial confinement fusion, a criterion equivalent in meaning to the Lawson criterion but different in form is applicable, which considers time integrated quantities during the whole fusion burn process rather than the steady-state conditions in the original Lawson criterion. For the simple calculations below, uniform compression of a pellet is considered. Suppose that ignition and fusion burn conditions are attained when the pellet containing N_0 atoms has a radius of R_0 .

From this time on, the pellet freely expands with the sound speed, which is $c_s = \sqrt{k_B T_e / m_i}$. To get the corresponding Lawson criterion, it shall be assumed that the pellet consists of a 50–50% deuterium-tritium mixture and the $\langle \sigma v \rangle$ fusion rate is constant during the expansion; as a first approximation, the consumption of fuel during the explosion shall not be taken into account. The number of reactions in the whole pellet during time dt is $N_f = N_D n_T \langle \sigma v \rangle dt$. The *burn fraction* f (i.e., the ratio of the burnt fuel to its initial quantity) during the expansion time is

$$f = \frac{1}{N_D} \int_0^\infty N_f dt = \langle \sigma v \rangle \int_0^\infty \frac{N_0/2}{(4\pi/3)(R_0 + c_s t)^3} dt = \frac{\langle \sigma v \rangle}{4c_s} n_0 R_0, \quad (60.8)$$

where n_0 is the initial number density of hydrogen atoms (deuterium and tritium) at $t = 0$. At around 20–25 keV temperature the ratio $\langle \sigma v \rangle / c_s$ is approximately constant, so the burn fraction is proportional to $n_0 R_0$ or, in other words, to $\rho_0 R_0$. The larger the pellet and the higher its initial density, the larger is the attainable burn fraction. Taking into account the consumption of fuel during expansion, the burn fraction is limited to around 30%, which gives the Lawson criterion for ICF in the form (Gil 1981):

$$\rho R > 0.3 \text{ g/cm}^2. \quad (60.9)$$

In principle, this criterion can be satisfied with $R = 1$ cm and $\rho = 0.3 \text{ g/cm}^3$. However, in this case, the generated fusion energy is uncontrollably high: equivalent to some few tens of megatons of TNT. Therefore, if the energy released from the implosion of one fuel pellet is limited to about 100 MJ from practical considerations, the necessary density is 300 g/cm^3 , which is very difficult to achieve, given the DT liquid density is only 0.2 g/cm^3 . This calls for a 10-times linear compression of the initial fuel.

Beside the burn fraction, another important parameter of inertial fusion experiments is the *target gain*. Assuming that the fusion reactions are initiated in a homogeneous target compressed to the necessary density and fusion temperature in the 10 keV range, the energy gain from the process is the ratio of the 17.6 MeV energy released in the reaction to the $2 \times 10 \text{ keV}$ energy of the DT fuel, giving about 1,000. Given the present efficiency of lasers - which is of the order of a few percent-, the losses in target drive, and the conversion efficiency to electricity, this number is not very high. A more efficient operation mode is when only the center of the target is heated and ignited, for example, by shock waves. In this case, a burning front can be driven by the fusion-generated alpha particles and the target gain can be higher.

The years of experience with inertial confinement have shown the importance of several processes and phenomena:

- It is essential that during compression, the illumination of the target by the driver be extremely homogeneous and symmetrical. If the illumination by *direct drive* is not satisfactory, conversion of the direct radiation into a secondary radiation might be a solution (*indirect drive*, see below).
- The inner core should reach a high density very quickly before thermal conductivity or shock wave preheats the central region to cause an internal pressure build-up that opposes the compression.
- The absorption characteristics of short-wavelength laser radiation are better than those of long-wavelength radiation. This calls for the development of effective, short-wavelength laser radiation sources.
- Laser-based drivers transfer their energy predominantly to electrons, and these energetic electrons can preheat the fuel pellet, which is again an undesirable process.
- Accelerators transfer the energy with better efficiency to the ions and can therefore be significantly more efficient than lasers. This provides some appeal for the use of light or heavy ion accelerators for driver purposes, although focusing of charged particle beams is an issue.

To reduce the minimally required temperature after the compression of fuel pellets, a new scheme, the *fast ignition* (Meyer-ter-Vehn 2001), is currently under investigation. In this scheme, in contrast to conventional *central ignition*, the driver compresses the fuel to a temperature just lower than required for fusion, and the pre-compressed fuel is ignited by a very powerful short-wavelength laser of femtosecond pulse duration. The main advantage of this scheme is that the compression of the fuel pellet to lower temperatures than that in the case of central ignition requires substantially less energy, and so the ratio of the generated to the used energy (the “efficiency” of the scheme) is much better.

As mentioned earlier, a very homogeneous and symmetrical target illumination is one of the keys to success in inertial confinement research. This follows from the fact that the interface between the accelerated solid state and the ablating plasma is subject to Rayleigh-Taylor instability, as a heavy material is leaning on the more tenuous plasma. The instability grows exponentially from an initial perturbation caused by nonuniformities. Better than 1% uniform compression reduces the initial perturbation to such a level that, in the final stage, the pellet is still sufficiently compressed. The quest to reach uniform ablation has led to what is known as indirect drive (Lindl 1995). The distinction between this approach and the direct drive is as follows.

The indirect drive target consists of both a fuel pellet and a small cylindrical cavity, inside which the pellet is located (see  Fig. 60.2).

The cylindrical vessel, known as a *hohlraum* (from the German word for cavity), is a few centimeters long, is made of a high-*Z* material such as gold, and has windows that are transparent to the driver on each end. Then, instead of requiring all the driver’s beams to strike symmetrically on the pellet – as in direct drive – the beams enter both ends of the *hohlraum* obliquely and ablate the inner surface of the cavity. The high-*Z* material of the *hohlraum* emits X-rays, and by focusing the driver beams to appropriate points in the cavity, the resulted irradiation of the pellet is highly symmetric.

Crucial aspects of the indirect drive are (inter alia)

- Finding the optimum pointing position of the driver beam.
- Overcoming the difficulties and costs of target manufacturing.
- Increasing the overall efficiency of the energy coupling from the driver to the fuel pellet.

■ Fig. 60.2

The indirect drive target system, showing the fuel pellet, the hohlraum and the driver beams with the resulting X-rays

Another studied variant of the indirect drive scheme is wire array Z-pinch drive (Olson 2005). In this scheme, the pellet is enclosed inside a cylinder formed by an array of metal (typically tungsten) wires. A short and powerful current pulse of several MA is driven in the wires, which transforms them into thin plasma filaments confined by the magnetic field formed around the current channels (pinch effect). The plasma filaments are further heated by the current into the 100 eV temperature range. This way, an X-ray radiation hohlraum is formed, as in indirect-drive laser fusion experiments. The potential advantage of the wire-array drive is the better overall coupling efficiency of energy from electricity to X-ray radiation. For wire array experiments, this is expected to be at least 10%, while for present laser technology, even the conversion efficiency to the driver laser light is much less.

One last word on inertial confinement: the protection of a future reactor chamber from radiation and debris released in the micro-explosion is a unique and challenging aspect of ICF reactor design. Other challenges of this field include pellet handling and positioning in the chamber, protection of mirrors and other optical elements, etc.

60.3 Basic Schemes of Magnetic Confinement

In ICF, the main technical and physical difficulties are associated with the requirement to reach a certain threshold density, whereas the confinement time is given by the process itself. In MCF, the situation is inverted: required densities are rather easy to achieve, while required confinement times are very difficult. It has to be stressed that the MCF scheme basically aims at steady-state operation; the energy confinement time is not the lifetime of the plasma but is related to the magnitude of power losses.

The basic idea of magnetic confinement is that charged particles – like the deuterium and tritium nuclei in a fusion plasma – can move freely along the lines of a magnetic field, but the same ions move very slowly (with *drift velocities* only) across the field.

In the early years of magnetic confinement research, *open configurations* were constructed, which essentially means that the magnetic field lines did not close onto themselves inside the experimental device, but only outside. In *mirror configurations* (see ► Fig. 60.3), a magnetic field gradient is applied at the ends of the vessel. It can be shown that an adiabatic invariant of the motion of charged particles in magnetic field is their magnetic moment: $\mu = mv_{\perp}^2 / (2B)$, where m is the mass of the particle, v_{\perp} is the magnitude of its velocity component normal to the

■ Fig. 60.3

The concept of a magnetic mirror configuration

local magnetic field, and B is the magnitude of the magnetic flux density. To conserve the magnetic moment and the total energy $E_{\text{tot}} = [mv_{\parallel}^2/(2B) + \mu]B$ at the same time, the particles must decelerate along the field lines while approaching the high- B regions. These high- B areas are called magnetic mirrors. The ratio of the maximum magnetic induction B_{\max} to the magnetic induction B_0 in the plasma confinement region limits the class of confined particles to those where $v/v_{\perp} < B_{\max}/B_0$. This defines a so-called loss cone in particle velocity space from which particles can escape from the mirror device. The loss cone is gradually populated by collisions between particles and the overall result is a continuous particle and energy loss reducing the confinement time. Some versions of the mirror configuration (tandem mirror) aim at adding electrical barriers to the ends of the devices so as the mirror loss is reduced. However, the end losses from mirror devices remain relatively high.

To reduce the parallel losses, *closed configurations* were developed. In these, the magnetic field lines close onto themselves at least in some finite plasma volume (the *confined region*). Concerning this closed magnetic field geometry, one point needs to be specially emphasized:

According to Shafranov's virial theorem (Shafranov 1966), there are no self-confining magnetic equilibria; the plasma in equilibrium must necessarily "lean against" some mechanical structure – that is, there is no plasma equilibrium with currents only, and no mechanical constraints. It is clear that the plasma must be manipulated ultimately and confined with external magnetic fields, and the mechanical structure that supports the external coils generating the magnetic field is finally the cause of the confinement.

In the followings, the plasma will be considered to be in equilibrium.

Following the Magnetohydrodynamics (MHD) theory, the equation of equilibrium (the equation of force balance) is

$$\mathbf{J} \times \mathbf{B} = \nabla P. \quad (60.10)$$

Here P is the plasma pressure, \mathbf{J} is the current density flowing both inside the plasma and in some coils of some mechanical structure, and \mathbf{B} is the resulted magnetic induction.

► Equation (60.10) states that both \mathbf{J} and \mathbf{B} must be perpendicular to ∇P . This means that \mathbf{J} and \mathbf{B} must lie on a surface with no components perpendicular to it. Then, the question arises: What can the shape of the surface to which the \mathbf{J} and \mathbf{B} are bound be. The answer is a consequence of the Poincaré–Hopf theorem, namely, that the surface must have the form of a topological torus, where the field lines lie on nested surfaces, and there are no field lines connecting one surface with the other.

► Equation (60.10) does not determine the total current density, only its component normal to \mathbf{B} (take the cross product of the first equation with the magnetic induction!). To

have the total current, one also needs the charge conservation equation, $\nabla \cdot \mathbf{J} = 0$, which, in turn, implies the existence of a parallel current (i.e., parallel to the magnetic induction). The existence of a parallel and a perpendicular current at the same time means that the lines of both \mathbf{J} and \mathbf{B} must be helical, that is, wind around the torus.

The measure of this helical nature is the so-called *rotational transform*. For field lines closing upon themselves, the rotational transform is the number of toroidal turns (the long way around the torus) necessary for the magnetic field line at the given magnetic surface to reach its original poloidal position (i.e., make one turn the short way around).

At this point, it has to be stressed that equilibrium configurations are not necessarily stable at the same time: some equilibria are not stable at all, and a fast growing instability destroys the plasma within fractions of a microsecond.

During the past 50 years of magnetic fusion research, there have been many different toroidal configurations with rotational transform constructed and exploited (see, e.g., Braams and Stott 2000), but currently two special configurations seem to be most promising and form the mainstream of the research: the *stellarators* and the *tokamaks*. In this chapter, only these two types will be introduced.

In a stellarator, the rotational transform of the magnetic field is produced by external coils only. External coils alone cannot produce rotational transform in an axisymmetric configuration. Here, the axis of symmetry is the major axis of an ideal (geometrical) torus. Due to this reason, stellarator devices must be non-axisymmetric either by a 3D distortion of the torus (e.g., ▶ Fig. 60.4a) or by non-axisymmetric external coils (▶ Fig. 60.4b). However, there are always some in-plasma currents driven by the plasma itself that distort the externally applied (vacuum) field, which can be taken into account in the design of the machine. The stellarator concept dates back to 1958 (Spitzer 1958), when L. Spitzer, Jr. had shown how to create rotational transform in current-free closed field-line systems. Modern stellarator designs make use of advances in computer technology to optimize the magnetic field geometry following some criteria. These optimization techniques can be very much different leading to vastly different configurations.

The tokamak concept was created in the early 1950s by I.Y. Tamm and A.D. Sakharov (Sakharov 1951; Tamm 1951), but, due to political reasons, their work had not been known in the west until 1958. In a tokamak, the rotational transform is created by the (poloidal magnetic field of the) plasma current itself that is driven in the toroidal direction. This toroidal current drive is a basic requirement of the tokamak configuration.

At the beginning of this section, it was mentioned that the achievement of the required density in MCF is rather easy. This is true, but one also wants to achieve a density as high as possible to maximize the fusion power. However, the density, unfortunately, cannot be

■ Fig. 60.4

Figure-eight stellarator (a), classical stellarator (b), tokamak (c)

arbitrarily high, because instabilities set in that destroy or decrease the efficiency of the confinement. To be more precise, the key parameter governing the instability threshold is not the density itself, but the ratio of the plasma kinetic pressure to the pressure of the magnetic field. This quantity is called *plasma beta*

$$\beta = \frac{P}{B^2/2\mu_0}, \quad (60.11)$$

and the instability limit associated with this quantity is called the beta limit.

In tokamaks, due to the externally driven plasma current, beside the beta-limit, there is another factor limiting the operational space. Namely, the magnitude of the plasma current should not exceed a given value. A practical quantification of the rotational transform is the *safety factor* denoted by q and expressing the ratio by how many times the field lines twist the long way around the torus while winding in the short one, $q \propto B_{\text{tor}}/B_{\text{pol}}$. In tokamaks, the poloidal field is produced by the driven plasma current alone, and so the safety factor is proportional to the inverse of the current. If the safety factor drops below a given value (i.e., the current is too high), a fatal instability called kink instability develops that terminates the discharge.

When the tokamaks appeared in the 1960s, most of the countries and laboratories switched to tokamak research, and abandoned or rebuilt their stellarators into tokamaks. The overwhelming success of tokamaks lies in their robust equilibrium within the operational space and relative simplicity of design. Achieved values of the fusion triple product had doubled every 1.8 years and now (in 2010) it is believed, that the first fusion reactors will be tokamak based.

The stellarator research, although cut back 50 years ago, had not been stopped. Stellarators have two advantages compared to tokamaks: as there is no driven current, (1) stellarators are better candidates for steady-state operation; and (2) they lack the current driven instability. The drawback of stellarators is that they require a very sophisticated design and state-of-the art industrial technology. At the time of writing of this chapter, stellarators seem to have their share on fusion reactor market as second-generation devices.

Later in this chapter, the role of the aspect ratio (the ratio of the major radius of a torus to its minor one) in the technology of fusion devices will be emphasized. It is to mention, that those configurations that have an aspect ratio close to unity (compact devices) have a larger beta limit and so a more favorable possible fusion performance.

60.4 Technology of Magnetic Confinement Fusion Devices

After 50 years of research and development, modern magnetic fusion devices are complex industrial-like objects where physics research meets technological development. This section gives an overview of the key technologies used in fusion research.

Most of the power flux from DT fusion plasmas will be carried by neutrons that slow down in the blanket of the device in a typically 1 m thick layer. As the final aim of fusion research is the construction of GW class power plants, practical power flux handling limits set the volume of the blanket into the $1,000 \text{ m}^3$ order of magnitude. This means the device linear size must be in the 10 m range. Present day fusion experiments do not produce substantial fusion powers; therefore, their sizes can be much smaller: the torus major radius (R) is 2–3 m, while the minor radius is typically 0.5–1 m.

As shown in the previous sections, the $3nk_B T$ kinetic pressure of fusion plasmas acts on the magnetic coil system, which finally operates as some kind of container. Engineering practice limits the pressure in several meter size systems maximum to the 100-atmosphere range, and as the plasma temperature is set by the fusion processes to 10^8 kelvins, the plasma density cannot be higher than 10^{-4} atmospheric density, that is, about 10^{21} particles per cubic meter. Additionally, this tenuous hydrogen gas should also be clean as the plasma bremsstrahlung radiation increases with the square of the ion charge (Chen 1984). One percent contamination in the $Z = 10$ –20 range would increase the radiation loss by 1–10 times, therefore, the base pressure of the plasma container should be in the 10^{-6} mbar range at most. This is high vacuum condition although requirements are not as strict as in many laboratory solid-state experiments. Standard high-vacuum practices (Kohl 1995) are a must in fusion experiments, including two-stage pumping with rotary, turbomolecular and/or cryogenic pumps, baking, and other wall-conditioning techniques. Cleanliness of the vacuum vessel inner wall is extremely critical; therefore, plasma–wall interaction will be discussed separately in the following section.

The magnetic field is generated by coil systems located outside the vacuum vessel. As described before, the plasma beta is limited by instabilities; therefore, magnetic fields in the Tesla range are required. The toroidal component of the magnetic field is the dominant one, which is generated by a set (15–20) of coils surrounding the vacuum vessel (► Fig. 60.5). Coil currents must be in the 1–10 MA range. Taking into account the available space and the conductivity of copper, the power needed for maintaining the magnetic field is in the several 100 MW range even for larger present-day fusion devices. This amount of power cannot be continuously extracted from the coils; therefore, copper coil devices operate in pulses lasting less than a minute. Copper coil technology would also prohibit positive energy balance for a fusion power plant; therefore, superconductive coils must be used on the long term. Several experimental devices have been built using superconductive coils (Tore Supra Team 1999) and experience shows that standard liquid-helium cooled superconductive technology can meet the requirements for fusion power plants. However, for plasma confinement studies superconductive technology is not absolutely required. As shown above, the energy confinement time is

► Fig. 60.5

The toroidal (left) and poloidal(right) coil set of JET (Wesson 2000a) (Copyright EFDA-JET)

in the second range, therefore a few-second pulse (achievable with copper coils) can be considered as steady state from the confinement point of view.

Additionally to the toroidal field coils, plasma stability and shape control requires poloidal field (PF) coils as well. Part of the PF coil set is a central solenoid, which can produce a magnetic flux increase along the axis of symmetry of the torus. The current in the toroidal field coils is essentially DC during operation, but the PF coils must be operated dynamically to counteract expansion of the plasma ring by plasma pressure and plasma current and to set the required plasma shape. Some lower current correction coils are also installed in order to compensate for small field distortions caused by tolerances in the mechanical construction. Additional coils can be placed inside the toroidal field coils for creating divertors, as described in the following section.

The strong magnetic fields and high coil currents induce huge forces on the coils, in the 10 T/m range; therefore, mechanical stability of the coil system is a key issue.

In stellarators, coil geometries are more complex. ▶ [Figure 60.6](#) shows Wendelstein 7-AS, a partly optimized modular stellarator (Hirsch et al. 2008) with copper coils. In stellarators, all coil currents can be operated as DC, but due to the shape, the forces might be more difficult to handle.

As soon as good vacuum conditions are achieved and the magnetic field is established, the working gas (typically deuterium in present-day devices) is introduced into the vacuum chamber with a pressure in the 10^{-2} Pa range. Ionization (breakdown) is achieved either by inductively inducing a toroidal electric field (via the central solenoid in the case of tokamaks) or by intense micro- or radiofrequency electromagnetic waves. In the case of tokamaks, the breakdown is followed by a current ramp-up phase in which the toroidal plasma current reaches the value required for establishing the rotational transform. To drive the current, the magnetic flux is increased inside the opening of the torus in time by increasing the current in the central solenoid coil. The induction lines emerging from the central solenoid can be closed around the torus either with or without an iron core. During the ramp-up phase, the

■ **Fig. 60.6**

Coil set and plasma cross sections in the Wendelstein 7-AS stellarator (Hirsch et al. 2008)
(Copyright IOP)

poloidal-field coils need to be carefully controlled to keep the plasma column in place and achieve the required plasma shape. In the case of stellarators, the startup procedure is simpler as no plasma current is required for the target magnetic configuration and both breakdown and heating are achieved by electromagnetic waves.

In tokamaks during the ramp-up phase, the plasma current ohmic heating power heats the plasma to 0.1–1 keV temperature. The value of the toroidal plasma current is set by the magnetic configuration, therefore the ohmic heating power is determined by the plasma resistance R . Unfortunately $R \propto T_e^{-3/2}$ and thus with increasing electron temperature T_e the heating power is decreasing. This effect limits the plasma temperature to a few keV with ohmic heating alone, and therefore fusion conditions cannot be reached.

As soon as plasma with at least a few hundred eV temperature is achieved, additional heating should be applied to reach fusion (10–20 keV temperatures). Several electromagnetic wave heating schemes that are capable of delivering up to several 10 MW power have been developed. The key in these schemes is to launch a wave into the plasma, which propagates into a region where a resonance occurs with the cyclotron motion of particles and at least part of the wave energy is converted to thermal particle motion. In a plasma, a large number of waves can propagate, but, depending on frequency, polarization, magnetic field, and plasma density, there are several regions where these waves are non-propagating. Due to the curved geometry, the toroidal magnetic field decreases as $B_t \propto 1/R$, and therefore, the cyclotron frequency $f_c = eB/(2\pi m)$ also depends on R . The results of the above are lines of resonances and areas of non-propagating zones for a given wave frequency in the cross-section of the plasma. Additionally, at the boundary of non-propagating zones, wave conversion can take place, whereas energy is transferred from one type of wave propagating on one side of the region to a different but identical frequency wave propagating on the other side. Different heating schemes can be designed making use of detailed knowledge of these wave propagation features (Wesson 2000b).

Two wave heating schemes are used most often in fusion experiments; *Electron Cyclotron Resonance Heating* (ECRH) relies on the cyclotron motion of the electrons. In most implementations, an electromagnetic wave with twice the electron cyclotron frequency is launched from the outer side of the torus. The wave can freely propagate to the plasma layer where $2f_c = f_{\text{wave}}$ and a considerable part of it is absorbed there (► Fig. 60.7). Typical frequencies are 50–170 GHz, where the wavelength is in the millimeter range. The waves can be transmitted in several centimeters or 10-cm wide beams using mirrors and launched into the plasma through highly transparent, cooled windows. With suitably aligned steering mirrors, the absorption volume can be moved to different locations along the minor radius. As the temperature quickly equilibrates along magnetic surfaces, ECRH can change the plasma temperature well localized to a certain minor radius range.

The microwaves for ECRH are generated by powerful gyrotron devices (Nusinovich 2004), which convert the energy of an electron beam to the electromagnetic wave. Gyrotrons developed for fusion application can currently reach up to 1–2 MW power at 140–170 GHz for a few seconds or somewhat lower power in CW (continuous wave) mode. It is expected that 1–2 MW CW gyrotrons can soon be developed with about 50% overall wave generation efficiency (Kasugai et al. 2006). Several of such gyrotrons are used on a single fusion device to reach ECRH heating power in the 10 MW range (Erckmann et al. 2007).

As the thermal coupling between the electron and ion fluids is relatively loose and losses through the electron fluid can be high (Doyle et al. 2007) ECRH is not the most efficient way of heating the ions. This task can be more efficiently done by waves resonating in the ion cyclotron

■ Fig. 60.7

Fusion heating schemes: (a) ECRH (b) ICRH (c) NBI

range of frequencies (10s of MHz). Unfortunately, at this frequency the wavelength is larger than the device size, therefore quasi-optical propagation is not possible and heating cannot be so localized as in the case of ECRH. Due to the above reason, *Ion Cyclotron Resonance Heating* (ICRH) uses a different approach. A simple loop antenna is placed inside the vacuum vessel, close to the plasma. Electromagnetic waves are generated by high-power amplifiers and transmitted to the antenna via coaxial lines. The difficulty in ICRH is to match the coupling impedance of the wave to the plasma with the impedance of the transmission line, otherwise the wave is reflected back into the waveguide. The coupling impedance depends on the plasma to antenna distance and the plasma conditions as well; therefore, it can easily change during a plasma discharge. Another problem of ICRH antennas is the strong electric field arising close to the antenna at the plasma edge. This can accelerate ions to high speeds, which bombard either the antenna or other structures in the vacuum vessel. The resulting impurities enter the plasma and increase its radiation. Nevertheless, by careful choice of the materials utilized in the antenna and surrounding structures and by optimizing the wave coupling several MW of ICRH power can be injected into the plasma.

Another, even more powerful ion heating mechanism is *Neutral Beam Injection* (NBI). In this, a low-temperature plasma ion source (Brown 2004) is placed to a high, typically 50–100 kV electric potential. An ion beam is extracted from it and accelerated by the high voltage. The beam passes through a gas box, where ions pick up electrons from gas atoms by charge exchange process (Dolan 2000) and therefore they become neutralized. The neutralization efficiency is energy dependent, typically 50–80%. The residual ion beam is bent by a magnet and its energy damped in an ion dump. The neutralized high-energy atomic beam penetrates the magnetic field of the fusion device and in the plasma it gets ionized by collisions with plasma particles. The fast ions are confined by the magnetic field and they form a high-energy ion population, which gradually slows down and heats the plasma thermal ions and electrons. The overall efficiency of an NBI system depends on several parameters, but 30–50% can be typically reached. NBI is the most effective ion heating method on present day devices capable

of delivering several 10 MW of power. For reactor-scale devices, the NBI technique needs further development. In a large and dense plasma, the penetration of a 100 keV neutral beam is insufficient; therefore, the energy needs to be increased to 0.5–1 MeV. At this energy, the efficiency of the charge exchange process is negligible; therefore, positive ions cannot be used as ion source. As an alternative, negative-ion sources are being developed (Brown 2004) where an additional electron is loosely bound to the atom. This can easily be removed in the neutralization cell, therefore negative-ion NBI is expected to be a powerful tool for reactor-scale plasma heating.

In tokamaks, the helical magnetic field structure is generated by the current flowing in the plasma loop. As described above, this current can be driven inductively for a few tens of seconds, or – with careful design – up to a few hundred seconds. However, for DC current drive inductive technique is unsuitable. For current drive purpose, most of the above described heating techniques can be applied with some modification. For instance, an ECRH wave directed in one direction in the torus is capable of driving an asymmetric electron velocity distribution, thus driving toroidal current. The current drive efficiency of various heating schemes have been assessed for present day devices and a technique called *Lower Hybrid Current Drive* (LHCD) (Gormezano 1986) was found to be the most suitable. This relies on generating waves in the plasma with frequencies in the 1 GHz range. A special waveguide array is placed close to the plasma whereby appropriate phasing of the individual waveguides can launch a wave with high B -parallel wave vector component. These waves can capture plasma electrons and produce a high-energy B -parallel tail in their velocity distribution, thus drive a toroidal current. However, LHCD is best applicable at low plasma densities; therefore, it is not clear whether reactor-scale devices can make use of it. For fusion reactors, a more promising candidate is the Neutral Beam Current Drive (NBCD), where heating neutral beams injected in one toroidal direction drive the current. With this technique, up to 1 MA current drive has been demonstrated (Oikawa et al. 2001) albeit with a power comparable to the total NBI heating power.

In addition to external current drive, the high-pressure fusion plasma itself can drive a so-called *bootstrap current* (Peeters 2000). This is generated by the radial pressure gradient, and therefore it is negligible in the center of the plasma and cannot be used for full current drive, but can substitute 50–70% of the total current in future high-pressure tokamak plasmas.

After the development of the above-mentioned heating techniques, a general tendency called *power degradation* was observed. This means that regardless of the heating technique used, the energy confinement time of the plasma becomes inversely proportional to the heating power (Doyle et al. 2007), that is, confinement deteriorates with heating power. With detailed experimental studies, it was also found that the local heat transport coefficient is an instantaneous function of the heating power and not the local plasma parameters (Stroth et al. 1996). A spontaneous transition to an improved confinement state, called *H-mode*, was found (Wagner 2007) and reproduced on both tokamaks and stellarators. The H-mode is considered as the candidate operating scenario of a fusion reactor.

The above findings are in contrast to neoclassical transport theory (Helander and Sigmar 2002), which predicts diffusive transport across the magnetic field lines, with heat and particle diffusivity coefficients dependent on local plasma parameters. As even the magnitude of the experimentally found transport coefficients is much higher than the neoclassical result, it is believed that heat and particle transport in fusion plasmas is dominated by small-scale plasma turbulence driven by spatial inhomogeneities of various plasma parameters. This is called anomalous transport. According to the present understanding, the turbulent state is a dynamic equilibrium of interacting small-scale waves and flows (Diamond et al. 2005): waves excite ExB

flows across the magnetic field and these flows tear turbulent eddies apart before they can cause transport. Several elements of this process have been found experimentally (Fusjisawa 2008). Such a system often settles to a state close to some critical gradient where avalanches can cause fast nonlocal response to external perturbations. Recent simulations of turbulence in fusion plasmas give reasonable predictions (Doyle et al. 2007) but it is thought that still a long time is needed until reliable predictions can be given to transport in magnetically confined fusion plasmas.

In the above-described turbulent plasma state, the H-mode is a state where a strong DC flow develops at the plasma edge and inhibits turbulent transport. As shearing of flow means a continuous radial change of the flow velocity, the affected layer must have a limited extent. This is called the pedestal, a few centimeters radial range at the plasma edge. In the pedestal region, transport is close to the neoclassical prediction and the temperature and density exhibit steep gradients, called transport barrier. The gradient can be so steep that pressure- and current-driven MHD instabilities can develop and periodically open up the pedestal for a short time. These are called *Edge Localized Modes* (ELM), and they are a key element of an H-mode plasma. Without ELMs, the He ash could not be extracted through the pedestal. Under certain circumstances, internal transport barriers (ITB) can also be induced in deeper layers of the plasma, further improving H-mode confinement quality. As turbulent transport is not fully understood quantitatively, the physics of H-mode and ELMs are also at the infancy of their understanding.

For the study and control of fusion plasmas, the confinement parameters need to be measured. For this purpose, a large collection of plasma diagnostic tools have been developed (Hutchinson 2002) utilizing a broad choice of physical effects and technical tools. Simple magnetic loops and coils can measure external components of the magnetic and electric fields. At the plasma edge, measurements with immersed probes can provide valuable information, but in the plasma core, no material probes can be used. This region is only accessible with laser, microwave, or atomic beam probes, or the radiation of the plasma at microwave, visible, infrared, and X-ray wavelength can be used. Based on the above techniques, at present key plasma parameters (density, electron and ion temperature, electric potential, flow velocity, current density, radiation intensity, etc.) can be measured with temporal and spatial resolution. Depending on the technique, there are inherent constraints on spatial and temporal resolution; therefore, multiple techniques are often used for even the same plasma parameters. A special class of diagnostics have been recently developed for the study of plasma turbulence, where microsecond temporal, sub-percent amplitude, and at least centimeter spatial resolution is needed at the same time.

Control of plasma parameters is becoming more and more critical as plasmas approach reactor conditions. In present-day experiments, only a few parameters are actively controlled, such as mean density, plasma current (in tokamaks), and plasma shape, but with the improved theoretical understanding of the turbulent transport in plasmas, it is becoming increasingly important to control profiles as well. For this purpose, some real-time data evaluation and intelligent control schemes have already been demonstrated (Felton et al. 2005).

60.5 Plasma–Wall Interaction in Nuclear Fusion Devices

Introductory remarks

This section deals with plasma–wall-interaction (PWI) processes in magnetically confined fusion (MCF) devices only. In inertial confinement fusion (ICF), the interaction is

unidirectional in the sense that during the nanosecond-timescale fusion process, no interaction can take place between the plasma and the chamber wall. However, debris from the micro-explosion and fusion reaction products will reach the wall and cause the same, if not greater, damage as in MCF. At present, little is known about these effects.

An area of particular interest for MCF is the understanding of physical and chemical processes in the boundary plasma and the interaction of this boundary plasma with the surrounding walls. It has been shown earlier that fusion plasmas cannot be maintained at sufficiently high temperatures if they are allowed to come into contact with the surrounding walls. On the other hand, a fusion device cannot be run without a certain degree of plasma–wall interaction. Two indispensable functions have to be assured by plasma–wall-interaction processes: The power generated in the core plasma has to be transferred through the wall to the cooling medium, and the ash of the fusion reaction, that is, helium, has to be removed from the core plasma.

Plasma–wall interaction comprises a large variety of physical, chemical, nuclear, and thermo-mechanical processes. In this respect, the term “plasma–wall interaction” (PWI) is the more general phrase including all these various processes, while the term “plasma–surface interaction” (PSI) more specifically concentrates on the physical and chemical interaction processes at the surface of plasma-facing components. While the PSI processes depend only on the plasma-facing material (PFM), that is, the material used at the surface of wall components, and the impinging power and particle fluxes, PWI is also strongly influenced by the choice of other materials used for the fabrication of wall components and the corresponding physical and material aspects. The latter is particularly important for the thermo-mechanical behavior of wall components and the nuclear processes caused by the immense neutron flux.

The field of PWI is challenging, multifaceted, and highly interdisciplinary. It comprises research fields such as plasma physics, surface physics, solid-state physics, atomic and molecular physics, nuclear physics, chemistry, materials science, and mechanical engineering. In the following, focus will be put on the PSI processes at the plasma-facing surfaces, because they are of special importance for the operation of fusion plasmas. The selection of a specific plasma-facing material is closely linked to the operational scenario of the plasma and vice versa. Some other aspects of PWI will shortly be presented at the end of this section. Basic questions related to plasma–material interaction in magnetically confined fusion are discussed in the textbook of Naujoks (2006).

Three aspects of PSI processes have to be considered. The first and most important is impurity generation. Particle fluxes impinging on the surface of surrounding walls can cause material release. If these released species are transported into the core plasma, they contribute to plasma dilution and increase of radiation. If the impurity fraction in the core exceeds certain limits, the thermonuclear plasma will be extinguished. Therefore, reducing the plasma impurity fraction is an important aim of the control of PSI processes. Second, net erosion has to be taken into account as a lifetime-limiting process for plasma-facing components. Third, fuel species that are permanently retained in plasma-facing materials contribute to the total fuel inventory in the device. In particular, tritium is an issue in that respect, because the total tritium handling allowance in a nuclear fusion plant will be limited by regulatory authorities. Consequently, the tritium inventory in the device has to be minimized.

In MCF, a toroidal magnetic field is applied to isolate the hot fusion plasma (= *plasma core*) from the surrounding walls. It has already been discussed in [Sect. 60.3](#) that a field line in the core does not close with itself after one cycle around the torus but makes an infinite number of cycles and forms a so-called magnetic surface. The confining field in the core comprises nested

toroidal magnetic surfaces that have no intersection with the wall. The toroidal field is in the range of 2–5 tesla, while the poloidal component is about a factor of 10 lower. The D–T fuel mixture has to be heated to temperatures on the order of 10 keV or more. Fusion reactions can occur only in this fully ionized core plasma. The products of a D–T reaction are a ^4He nucleus with about 3.5 MeV and a neutron with about 14 MeV (see ▶ Sect. 60.1). As described above, the chargeless neutron can pass the surface layers of the wall with virtually no interaction. Charged particles of the thermal plasma-particle population are bound to the magnetic surfaces within a Larmor radius; therefore, they can leave the core plasma only by cross-field transport. Fast particles such as ^4He nuclei have Larmor radii in the 5–10 cm range and some plasma waves or nonideal magnetic fields might cause them to reach the wall. In addition to the charged-particle load, there are always some neutralized plasma species that can leave the plasma and interact with the surface of the wall.

In contrast to the core plasma, magnetic field lines in the boundary plasma do have intersections with the wall. The core and boundary plasma are separated by the so-called last closed flux surface (LCFS = surface defined by those magnetic field lines that do not yet have an intersection with the wall). Charged-particle transport parallel to the magnetic field is much more efficient than either the above-described neoclassical or anomalous transport acting perpendicular to the field. Therefore, charged species that leave the core plasma across the LCFS and enter the boundary plasma are quickly transported along the field lines to the wall. This transport parallel to the magnetic field occurs in a rather thin plasma sheath of the order of about 1 cm. This layer, denominated *scrape of layer* (SOL), carries most of the particles and power leaving the core plasma to the walls. Consequently, the power and particle fluxes at those wall areas where the SOL strikes a surface are extremely high. Strong electric fields also build up in the sheath layer due to the different mobility of electrons and ions, which cause charge separation. The resulting ExB flows and instabilities make the SOL a complex plasma layer. Basic SOL physics is thoroughly discussed in the textbook by P. Stangeby (2002). Most work to date has focused on the investigation of the tokamak concept, this being particularly true for the study of SOL physics. However, the basic physical processes and the related PSI problems are very similar in a stellarator (Hirsch et al. 2008).

In present-day MCF devices, investigations are almost exclusively carried out using hydrogen and deuterium. It remains a challenge to extrapolate present-day results on transport, operational scenarios, or plasma–wall-interaction processes to future devices working with D–T mixtures. A detail that cannot be studied in H–D mixtures is the physics of fast alpha particles in the core plasma. On the one hand, the fast alpha particles produced by the fusion reaction have to be confined sufficiently long to allow them to transfer their kinetic energy to the other plasma species (alpha heating). This thermalization contributes substantially to plasma heating. On the other hand, after thermalization they quickly have to be removed from the core plasma because they are a plasma impurity and would eventually quench the fusion plasma. Removal of He from the core plasma is strongly determined by SOL and PSI processes. Particle and energy confinement in the core plasma has to be sufficiently high, but as just discussed, particle confinement must not be too good to allow for removal of the ^4He particles and other possible impurities.

In the boundary plasma or edge plasma, the plasma density and temperature are much lower than in the core. The areas where the SOL hits the wall are relatively small so that the particle and power flux densities to these areas are very high. Plasma–wall-interaction processes are mainly determined by these areas. Two concepts have been developed to control plasma–surface interaction to some extent. The first one is the *limiter concept*. The limiter is

a compact solid component that intersects the magnetic field lines in the main chamber. It limits the plasma and protects other wall areas. Consequently, in such a setup the LCFS position is determined by the position of the limiter. The second concept is the *divertor concept*. The boundary plasma is guided by the magnetic field to somewhat remote target plates (divertor plates) so that the dominant PSI region is, compared with a limiter machine, further away from the core plasma. In contrast to the limiter setup, the LCFS position in a divertor setup is determined by the magnetic field. It, therefore, allows a higher flexibility in shaping the plasma. In a divertor device, the magnetic surface that defines the LCFS is called *separatrix*. **► Figure 60.8** shows a sketch of a limiter and divertor setup. In most cases, limiters are also used in divertor machines to protect special components in the main chamber, but not to define the LCFS position. Particle energies and particle fluxes onto limiter and divertor surfaces differ significantly. Divertor and limiter machines also differ in some other aspects of SOL physics.

60.5.1 Basic PSI Processes

Before discussing the plasma–surface–interaction processes (PSI processes) in a MCF device, it is favorable to briefly discuss the most important microscopic processes. Note that these processes are basic in the sense that they occur whenever energetic or reactive species interact with solid surfaces. These processes are in no way restricted to PSI processes in a fusion device. For example, such processes are exploited in many technical plasma applications or occur in different kinds of ion–solid interaction.

The basic PSI processes can be divided in two major classes: processes due to energetic species and processes due to low-energy (thermal) species. The term energetic species is often

■ Fig. 60.8

Schematic representation of the cross section of a thermonuclear plasma device in a limiter and divertor configuration. In the divertor configuration, the edge plasma is guided to the divertor with the magnetic field created by additional divertor coils (Figure by courtesy of Karl Krieger, IPP)

used synonymously for ions and vice versa, but in the parameter space relevant here, energetic neutrals undergo identical interactions with surfaces as ions. In MCF, energetic neutrals contribute substantially to the energetic particle flux to the surface, because charge exchange collisions between ions and neutrals in the boundary plasma produce energetic neutrals.

The interaction of energetic species with surfaces is dominated by physical processes due to momentum transfer by collisions. The most important microscopic processes are *physical sputtering*, *implantation*, and *reflection*. Other processes that can also occur are *material mixing* and *preferential sputtering*, (Behrisch 1981, 1983; Behrisch and Wittmaack 1991; Behrisch and Eckstein 2007). Thermal species with low energies do not have sufficient kinetic energy to trigger physical processes, but they can react with surface species through chemical reactions. This process will be called *chemical erosion*. There is no unambiguous definition of thermal species and what is meant by low energy, but in the present context it is useful to consider species with energies well below typical surface binding energies or chemical bond energies as thermal species. This means that one should consider species with kinetic energies below about 1 eV as low-energy or thermal species. This use of the phrase thermal should not be confused with a thermal energy distribution of species in hot fusion plasma. With respect to surface interactions, species with thermal energy distributions corresponding to temperatures of about 10 keV are very energetic. A third class of process can occur if energetic and chemically reactive species interact simultaneously with the surface. This process is named *chemical sputtering*. These three different classes of PSI process and their relevance for MCF are discussed to some more detail in the following subsections.

60.5.2 Physical Sputtering

Physical sputtering is a well-understood process that is made use of in many technical applications. In MCF, however, it is an unwanted but unavoidable process. Physical sputtering is a process that occurs if energetic species impinge on a surface. It is caused by momentum transfer from the impinging projectiles to target atoms. It takes place for all target materials and incident particles with energy above certain threshold energy. This threshold energy depends strongly on the mass ratio of the projectile-target combination and lies in the range of about 30 to a few 100 eV.

Physical sputtering was thoroughly reviewed by Eckstein (2007). Various aspects of physical sputtering can be excellently modeled by computer simulations (Eckstein and Urbassek 2007). In systems where the interaction is dominated by kinetic processes, excellent agreement between experimental data and simulation results is generally achieved (Eckstein 2007). Simulation codes for physical sputtering, which are based on the binary collision approximation, are TRIM.SP (Eckstein 2007) and SRIM (Ziegler et al. 1985). Physical sputtering depends on the angle of incidence and, to some extent, on the surface roughness (Eckstein 2007). As long as the temperature is well below the melting point of the material, physical sputtering shows negligible temperature dependence (Schmid et al. 2006). However, for carbon a strong increase of the sputtering yield close to the sublimation temperature was reported. This process was named radiation-enhanced sublimation (RES) (Roth et al. 1982).

Sputtered particles originate predominantly from the topmost surface layer. In general, they are monatomic and have mean energies in the eV range. If chemical reactions between projectile and target atoms start to play a role or if activated surface atoms can react with neutral species from the ambient atmosphere, the situation becomes more complicated. These

chemical reactions can cause an increase as well as a decrease of the sputtering yield. The reaction products can have a lower surface binding energy compared with the pure material and, consequently, are more easily sputtered so that the sputtering yield increases. Alternatively, they can have a higher surface binding energy and, as a consequence, the sputtering yield decreases. The latter is, for example, the case for oxygen, carbon, or nitrogen bombardment of various metals where metal oxides (Al_2O_3 , SiO_2 , TiO_2 , etc.), carbides (TiC , WC , SiC , etc.), and nitrides (TiN) are formed. Such chemical processes create a significant problem for the reliable control of reactive sputtering processes as recently discussed by Sproul et al. (2005).

The sputtering yield combined with the maximum tolerable concentration of the sputtered species in the core plasma (Stangeby 2002) is one of the most important selection criteria for plasma-facing materials. The actual choice for ITER (International Thermonuclear Experimental Reactor) is to use beryllium as PFM for the main chamber wall and tungsten and/or carbon in the divertor. Furthermore, it is anticipated that the only possible option for a future power reactor will be tungsten. The sputter yields of Be, C, and W due to bombardment with deuterium are presented in ▶ Fig. 60.9. From these three materials, tungsten has the lowest sputter yield and the highest threshold energy. Due to the large difference in atomic mass between deuterium and tungsten (~ 2 u versus ~ 184 u), deuterium can, in a binary collision, transfer only a small amount of its kinetic energy to tungsten. The maximum transferable energy in a central collision is given by the kinematic factor, $\gamma = 4 M_1 M_2 / (M_1 + M_2)^2$; for the combination deuterium (D) on tungsten (W), $\gamma = 0.043$; for H (i.e., ^1H) on W, $\gamma = 0.022$; and for T on W, $\gamma = 0.063$. This is the main reason for the high threshold energy. As a consequence of

■ Fig. 60.9

Sputtering yields of the plasma-facing materials Be, C, and W due to bombardment with the hydrogen isotope deuterium (normal incidence, 300 K). The lines are model results describing physical sputtering only. While data for Be (squares) and W (triangles) show good agreement with the physical sputtering model, data for C (circles) deviate strongly at low particle energies (lower than 100 eV). This is due to chemical sputtering

the higher γ factor of T compared with D, the sputter yield for T will be slightly higher than for D. The corresponding γ values for D impinging on the other plasma-facing materials C and Be are 0.49 and 0.60, respectively.

The threshold energy for sputtering of tungsten by deuterium impact is about 230 eV (Eckstein 2007). With increasing energy, the sputter yield increases monotonically reaching values in the range of a few times 10^{-3} at energies of several keV. The data are well described by TRIM.SP simulations and other analytical descriptions of physical sputtering. The sputter yield for beryllium is high already for low energies. The threshold energy for D on Be is about 9 eV (Eckstein 2007). It reaches a maximum at about 100 eV (maximum yield is about 0.7). For higher energies, the yield decreases again. Similar to the sputtering of W, the sputter yield of Be is well described by the corresponding model curve. The sputtering of Be and W by D is dominated by physical sputtering.

In contrast to Be and W, the sputtering of C by D shows a disagreement between model and experiment. While for energies higher than about 200 eV, good agreement can be found between data and model, model and data deviate strongly for lower energies. The measured yields remain high also for low energies, while the model predicts a strong decrease with decreasing energy. Even below the threshold energy for physical sputtering of about 28 eV, the sputter yield is still increasing with decreasing ion energy. The existing data show no threshold for this process. The reason for this disagreement at low energies is due to the fact that the sputtering of carbon by hydrogen isotopes at low projectile energies is dominated by chemical sputtering effects. These will be discussed further below. Physical sputtering effects seem to dominate only for energies higher than about 200 eV.

Impurity sputtering and selfsputtering: The data in [Fig. 60.9](#) describe the physical sputtering for deuterium impact. The other species that contributes dominantly to the impinging particle flux in a fusion device, tritium, shows, according to model predictions, very similar behavior. However, the yield is slightly higher due to the higher mass of T. In addition to fuel species, impurity ions also contribute to the energetic particle flux from the boundary plasma. With respect to physical sputtering, two effects have to be considered. First, in contrast to hydrogen isotopes, impurity ions can be multiply charged. Therefore, they can gain higher energies due to acceleration in the plasma sheath. For example, in present fusion devices with carbon walls, the dominant impurity species is carbon and the dominant charge state of carbon ions is 4 so that impinging C^{4+} ions will gain four times the energy in the plasma sheath compared with the impinging fuel ions. In addition, due to the higher mass the kinematic factor (γ) of these species is significantly higher than that of D. For tungsten as surface material, the γ value of D is 0.043 while that of C is 0.23. That means that even a small impurity fraction in the impinging flux may contribute with a similar (or even larger) amount to the total sputtered flux as the fuel ions. The situation becomes particularly critical if the corresponding impurity species is identical to the wall species. In this case – this process is called selfsputtering – the kinematic factor equals to 1, the sputtering yield can be very high and so, a runaway situation may occur.

Other processes related to the impact of energetic species on PFMs are reflection and implantation. Impinging energetic species may be reflected due to collision with surface atoms. Depending on the kinematic factor and the scattering angle, they will transfer a certain fraction of their kinetic energy to the surface. In general, reflected species are neutral and are thus not guided by the magnetic field. Reflected species will penetrate the boundary plasma and will finally be ionized by an inelastic collision with a plasma electron. The penetration depth depends strongly on the energy of the species after reflection. The higher the mass of the target atom, the higher its mean energy after reflection. In particular, hydrogen isotopes

reflected from a tungsten surface have much higher mean energies than those reflected from carbon or beryllium surfaces. This is one reason why plasma edge physics is closely linked to the chosen surface material.

Impinging species that are not reflected penetrate into the solid. They are decelerated due to interaction with the electrons and nuclei of the target and finally come to rest. The penetration depth depends on the projectiles energy and on the specific projectile-target combination. With increasing fluence, the local concentration of implanted species in the target material increases. The maximum tolerable local concentrations depend critically on the specific chemical and physical interactions between target atoms and projectiles. If this maximum concentration is reached, other physical processes will set in. The implanted species may diffuse to the surface and be reemitted, may diffuse into the bulk of the material, or, in extreme cases, lead to local bubble formation. Apart from that, in particular hydrogen in tungsten or other metals may significantly deteriorate the mechanical and other physical properties of the material. Such material-related issues of PSI in MCF have recently been reviewed by Federici et al. (2001).

60.5.3 Chemical Erosion

Chemical erosion is the process initiated by chemical reactions between thermal neutral species and surface atoms. Out of the three nuclear fusion materials, only carbon is subject to chemical erosion with a variety of impinging species. The most important interaction in that respect is that of atomic hydrogen with carbon. Some other species play an additional role. In particular, the interaction of oxygen with carbon has to be considered. The underlying microscopic processes are in general thermally activated so that chemical erosion exhibits strong temperature dependence. Further, it does not require impact of high-energy projectiles. This lack of threshold energy is the major difference to physical sputtering. Erosion processes involving chemical reactions have recently been reviewed by Jacob and Roth (2007).

The atomistic steps of the interaction of hydrogen atoms with carbon surfaces were investigated in detail by Küppers and coworkers (Küppers 1995). Using a thin amorphous hydrogenated carbon layer as model system, they revealed and quantified the individual steps in the erosion process. According to their model, hydrogen atoms attack even at low temperatures sp^2 -hybridized carbon atoms at the edges of graphitic planes or with broken bonds. Via different intermediate steps, the surface is increasingly hydrogenated and most of the surface carbon atoms are rehybridized to sp^3 . This hydrogenation reaction is not thermally activated, but proportional to a cross section for the addition of hydrogen. Further impinging atomic hydrogen will abstract bonded hydrogen via formation of H_2 molecules producing an intermediate radical stage with a broken bond at the surface or add to an existing broken bond. In steady state, hydrogen abstraction and hydrogen addition lead to an equilibrium concentration of broken bonds of about 2–4% of the available surface sites. With increasing temperature, different thermally activated processes become possible and at temperatures around 400 K chemical erosion can occur. The sp^3 hydrocarbon complexes in the neighborhood of broken bonds can be desorbed by simultaneously reforming a C–C double bond with the neighboring free bond, thus returning to the graphitic sp^2 hybridization. This process has a lower activation energy than the release of a similar hydrocarbon complex on a site with no neighboring free bond. On a fully hydrogenated surface, the hydrogen abstraction reaction leading to a broken (dangling) bond is the rate-limiting step for chemical erosion. With further increasing

temperature, bonded hydrogen can be thermally released thus interrupting the hydrogenation process. This hydrogen release process becomes significant at temperatures above about 600 K and leads to a reduction of chemical erosion. Thus, the erosion rate will exhibit a maximum at intermediate temperatures. For typical experimental parameters, this maximum occurs around 600 K. The dominant release product of this process is CH_4 , but it contributes only about 1/3 of the total carbon erosion yield. Hydrocarbon species containing more than one C atom contribute the remaining 2/3. The product spectrum is very rich and species with up to 6 C atoms were detected.

60.5.4 Chemical Sputtering

Chemical sputtering is defined as “a process whereby ion bombardment causes or allows a chemical reaction to occur which produces a particle that is weakly bound to the surface and hence easily desorbed into the gas phase” (Jacob and Roth 2007). The erosion process depends on both the kinetic energy and the chemical reactivity of the impinging species. In general, chemical sputtering is used to describe an increase of the sputtering yield compared to physical sputtering. As mentioned before, chemical effects can also lead to a decrease of the sputtering yield. Such chemical effects are usually not subsumed under the phrase chemical sputtering. Ion bombardment can trigger two mechanisms. Either it can lead to creation of reactive sites at the surface, which in turn interact with chemically reactive species to produce volatile species, or it can break the terminal bond of a surface group thus leading to ejection of this group. While in the first case the desorbing species have a kinetic energy distribution mostly determined by the surface temperature, in the latter case the species is ejected with substantial kinetic energy in the range of a few eV.

Chemical sputtering is characterized by a number of different experimental observations:

- The process depends strongly on the projectile–target combination.
- Molecules containing projectile and target atoms are formed.
- The threshold energy is substantially lower than for physical sputtering.
- The sputtering yield shows pronounced temperature dependence.
- Chemical sputtering yields are substantially higher compared with physical sputtering data or predictions from computer simulations. In contrast, data for physical sputtering with noble gases or self-sputtering (target and projectile atoms are identical) are, in general, in excellent agreement with such model predictions.

Chemical sputtering with the emphasis on the sputtering of carbon by hydrogen isotopes was recently thoroughly reviewed by Jacob and Roth (2007). If a carbon-containing surface is bombarded with hydrogen ions, the dominant erosion products are hydrocarbon species. The process is thermally activated and exhibits similar temperature dependence as chemical erosion (see preceding section). The position of the maximum, T_{max} , depends on the ion energy and on the ion flux. As can be seen in ► Fig. 60.9, the yield for sputtering of C by D (circles) remains high even at the lowest energies.

The elementary processes for the chemical sputtering mechanism are as follows. Impinging ions break carbon–carbon bonds at the surface and within the ion penetration range. Locally available hydrogen reacts with these broken bonds, forming C–H bonds and thus stabilizing them. Consecutive C–C bond breaking and C–H bond formation processes lead to the production of stable, volatile hydrocarbon entities, and/or loosely bound terminal groups at

and below the surface (within the ion penetration range). Finally, the formed volatile hydrocarbon molecules or erosion precursors are either desorbed directly due to ion impact or first diffuse to the surface and desorb there. At room temperature, subsurface hydrocarbon species can desorb only from a limited near-surface layer of the order of 2 nm.

On the basis of this model, a mathematical description was devised that is able to consistently describe all experimental observations, which can be extrapolated to other projectiles. In particular, the model correctly reproduces experimentally observed isotope dependence for bombardment with H and D and allows extrapolation to tritium (Hopf and Jacob 2005). The chemical sputtering yield of carbon due to bombardment with D is about a factor of 2 higher than that of H. Due to the higher mass of tritium, the predicted chemical sputtering yield of tritium will be about 50% higher than that for deuterium (Hopf and Jacob 2005).

It has to be mentioned here that similar effects as for bombardment of carbon surfaces with hydrogen isotopes are observed if a carbon surface is bombarded by any kind of energetic species in the presence of atomic hydrogen. In such a situation, the energetic species provides the kinetic energy required to break bonds and the chemical reactivity is provided by the atomic hydrogen species (Jacob and Roth 2007).

Another species that causes chemical sputtering of carbon and is of relevance for MCF is oxygen. On the one hand, oxygen is an almost unavoidable impurity in any vacuum system mostly introduced in the form of water; on the other hand, this process is relevant for the removal of redeposited carbon layers in fusion devices (see below). It is interesting to note that the interaction of oxygen with carbonaceous layers is also of significant relevance in different technological applications, for example, in microelectronics (ashing, resist stripping), for modification or patterning of polymers using oxygen plasmas, and for sterilization. If carbon materials are bombarded with energetic oxygen ions (Jacob 2007), the impinging oxygen is trapped or reemitted in the form of CO and CO₂. At 300 K, the saturation concentration of oxygen in graphite is 0.25 O/C. At 300 K and ion energies higher than 50 eV, the chemical sputtering yield is around 0.7 removed C atoms per impinging O atom. In the range from 50 eV to 10 keV, the yield increases slightly with increasing energy. For energies higher than 500 eV, it is even higher than 1 due to the increasing contribution of physical sputtering. The maximum of the yield occurs at about 3 keV. For energies lower than 50 eV, the yield decreases significantly. Erosion of carbon surfaces due to impinging oxygen impurities is an issue of significant relevance for fusion, because dissociation of the released CO and CO₂ species in the edge plasma produces new oxygen ions and neutrals, which again can erode carbon so that oxygen atoms can participate multiple times in an erosion process. This contributes to lifetime problems of carbon PFCs in areas where significant oxygen fluxes may reach the surface. Therefore, the oxygen impurity content in a fusion device with carbon PFCs has to be minimized.

Oxygen plasmas can be used to remove redeposited hydrocarbon films. In oxygen plasmas, not only energetic oxygen ions, but also reactive excited neutral oxygen species such as O atoms and ozone may interact with the surface. At present, the determining microscopic processes are not well known, but experimental results indicate that a synergism between ion bombardment and O₂ molecules exists and may play a significant role in this process. Very high erosion yields can be achieved with oxygen-containing plasmas on areas that receive a sufficiently high ion flux. In fact, for the time being this is the most effective method for removing carbon and hydrocarbon layers. For removal of hydrocarbon layers in fusion devices, neutral species are of particular importance. On surfaces having no direct plasma contact, so-called remote areas, ion-induced processes cannot prevail because such areas receive no ion bombardment. In such

situations, erosion has to be driven by neutral species from the plasma. Possible candidates are oxygen atoms, ozone, or excited oxygen molecules. The erosion efficiency of neutral activated oxygen species was investigated by Schwarz-Selinger et al. (2009a, b). They found that the erosion caused by activated species from the plasma increases with increasing temperature by about two orders of magnitude and follows an Arrhenius-type dependence on substrate temperature with effective activation energy of 0.25 eV (temperature range 290–580 K). The precise nature of the activated species is, however, still unknown. Nevertheless, removal of redeposited hydrocarbon films in fusion devices seems to be possible at elevated surface temperatures. However, before this method can be really applied in future devices, many accompanying problems – such as collateral damage during cleaning and removal of oxygen from the vacuum system after oxygen treatment – have to be solved.

60.5.5 Redeposition and Co-Deposition

Eroded species can redeposit; this process is generally called redeposition. Redeposition can occur very close to the place of erosion or in areas very far away. The details of this process depend on a great number of different parameters. Only surface atoms transformed by PSI processes into chemically stable volatile species can be transported to the vacuum pumps and be pumped away. All other species will remain inside the vacuum vessel. They only will be transported from one location to another. On plasma-facing surfaces, the probability is high that a redeposited species will be eroded again. The long-range transport of first-wall materials in a fusion device is usually due to a series of many erosion-deposition cycles. Redeposition reduces the net erosion rate and contributes, therefore, to the extension of the component lifetime in net erosion areas. The fuel inventory in PFMs in net erosion areas is only due to implantation and diffusion into the bulk. On the other hand, in net deposition areas, a constantly growing layer of eroded material will redeposit and a certain amount of fuel species will be incorporated in the growing film. The amount of retained fuel species depends on the chemical affinity to incorporate hydrogen during film growth. In addition, due to PSI processes thermodynamically metastable phases may be formed. For instance, implantation of energetic hydrogen species into the growing film may lead to higher hydrogen concentrations than incorporation due to adsorption and surface reactions. The incorporation of fuel species into a growing redeposited film is usually named co-deposition because hydrogen isotopes are not film-forming species and are only deposited together with film-forming species.

On all surfaces, there is an ongoing competition between erosion and deposition processes. The answer to the question where net erosion and net deposition areas occur depends on the impinging particle fluxes and on the transport of eroded species through the edge plasma. In general, the higher the ion energy and the higher the ion flux density the higher is the probability that erosion exceeds deposition. These are net erosion areas. In contrast, high fluxes of depositing species and low ion energies are indicative of net deposition areas.

Sputtered metal or carbon atoms have sticking probability close to 1 and stick on the next surface they come in contact with. If they are ionized during their transport through the boundary plasma and impinge as ions on the surface, the sticking probability is also very close to 1. Consequently, they will redeposit only on areas that have direct line of sight to the erosion area or on so-called plasma-wetted areas, that is, surfaces that have direct contact with the boundary plasma. On the other hand, surfaces that are neither in direct line of sight nor plasma-wetted will receive a negligible flux of sputtered atoms.

Hydrocarbon species, the erosion products of chemical erosion and chemical sputtering of carbon surfaces, lead to much more complex redeposition phenomena. Stable species such as methane do not stick at surfaces and may be transported to the vacuum pumps and thus removed from the vacuum system. However, they may be dissociated or ionized during their transport through the boundary plasma and thus they may become redeposited. Furthermore, some of the released products may already be radical species. The sticking of such hydrocarbon radicals can vary over orders of magnitude from 10^{-4} for CH_3 radicals to about 0.8 for C_2H radicals (Jacob 2005). Low-sticking neutral species can survive many wall collisions and can, therefore, be transported to remote areas in the fusion device before they become redeposited. As re-erosion on such areas is typically negligible, this process leads to deposition of stable hydrocarbon films with typical hydrogen fractions of 50%. These redeposited hydrocarbon films constitute a constantly growing D and T reservoir and are a major safety concern. Based on present knowledge, long-term tritium retention in ITER will be dominated by tritium bound in such redeposited hydrocarbon films.

60.5.6 Edge Plasmas in Magnetically Confined Fusion Devices

As said before, the core and edge plasmas are separated by the LCFS (= separatrix in divertor devices). The core plasma is fully ionized. The plasma number density, n_e , in the core is of the order of 10^{20} – 10^{21} m^{-3} and the plasma temperature, T_e , is of the order of 10 keV. The plasma number density in the boundary plasma or edge plasma, n_e , is of the order of 10^{19} – 10^{20} m^{-3} , decaying exponentially toward the walls. T_e is in the range of 1–100 eV.

The main chamber wall of a fusion device will be exposed to large fluxes of charge exchange (CX) neutrals. These CX neutrals are produced if a neutral hydrogen atom collides with an energetic ion from the plasma. While charged species are confined by the magnetic field, energetic neutrals are no longer confined and will impinge on the surrounding walls. In fusion devices, this CX flux is a significant contribution to the total flux of energetic species reaching the main chamber wall. The particle energies of the CX species can be very high (beyond 1 keV) (Stangeby 2002) and the corresponding physical sputtering of wall material is an unavoidable process in a fusion device. The sputtered species can penetrate and contaminate the core plasma. Impurity radiation cools the core plasma. Because the radiated energy increases strongly with the atomic number Z , much lower concentrations of high- Z atoms than low- Z atoms are acceptable in the core plasma. While, for example, beryllium concentrations of the order of 10^{-2} are tolerable, only about 10^{-5} are tolerable for tungsten (Stangeby 2002). On the other hand, the sputtering yield of Be is much higher than that of W (► Fig. 60.9). On the main chamber walls, the tradeoff between high sputtering yield and high tolerable concentration has led to the decision to use Be as PFM. However, it is also clear that Be is no option for a future power reactor. For this purpose, tungsten will have to be used and plasma scenarios will have to be developed to allow operation of fusion plasmas with a tungsten first wall. The local CX flux depends on the neutral density. Consequently, it is high where the neutral density is high and that is around the main recycling areas. For a fusion device employing the limiter concept (see ► Fig. 60.8), this means that the limiter and the surrounding areas are exposed to a high CX flux. In addition, the limiter is in this case the main interaction area for PSI and suffers a high ion flux. Since the limiters in a limiter machine are inevitably close to the core plasma, the energies of the impinging ions and CX neutral are rather high so that the sputtering yields are also rather high. Consequently, limiters produce a lot of impurities. Due to the proximity to the

LCFS, these impurities have a very high probability to penetrate the core plasma and contribute strongly, therefore, to plasma contamination. As a result, the limiter concept is no option for future fusion devices.

Almost all modern fusion devices rely on the divertor concept and all planned devices comprise a divertor. The divertor was initially a separate chamber to which the boundary plasma was diverted by additional divertor coils. In the divertor, the plasma is guided onto target plates. The dominant and most important process at the target plate is neutralization. The impinging plasma ions are neutralized and reemitted into the gas phase. Therefore, the neutral gas pressure in the divertor is substantially higher than in the main chamber. The pump ducts to the vacuum pumps are located underneath the divertor to pump the neutral gas. Naturally, the pumped gas is dominantly composed of fuel species, but in addition, the helium ash and other volatile impurities will be removed in this way. The pumped fuel will be recycled in the gas handling facility and pumped impurities will be permanently removed. The other important function of the divertor is to handle the arriving power flux. This will be discussed further below.

Depending on the type of plasma-facing material, surface temperature, and mean energy of the impinging particle flux, different basic PSI processes can occur. In ITER, it is presently foreseen to use either carbon and tungsten in combination in different areas of the divertor, or only tungsten alone. Due to the co-deposition issue, carbon does not seem to be a realistic choice for future power reactors. Energetic species impinging on the divertor target plates will lead to physical sputtering. This process occurs for carbon as well as for tungsten surfaces. For carbon, in addition to physical sputtering, chemical erosion and chemical sputtering contribute to target plate erosion. Due to the higher density in the divertor (compared with the main chamber), mean particle energies are much lower than at a limiter surface. The lower particle energies, however, are compensated by larger fluxes, since the total power flux to the wall has to be maintained. However, the sputter yield decreases over proportional with decreasing energy, so that the total sputtered flux is lower in the divertor concept. In addition, to reach the core plasma, released species from the target plate have to migrate through the incoming plasma flux. The probability is high that species are ionized due to interaction with the boundary plasma and are transported back to the target plate where they might be redeposited. The probability for a species eroded from the divertor surface to enter the core plasma is much lower than for a species created at a limiter surface. In summary, the contribution of PSI processes to plasma contamination is much lower in a divertor device than in a limiter device. Consequently, all next-step fusion devices will operate with a divertor.

Different divertor operational scenarios exist. At low divertor density, particle transport processes are dominated by charged species, which are guided by the magnetic field. The power flux is dominated by the kinetic energy of the impinging ions. Due to the high ion flux density in the region where the separatrix strikes the target plates ("strike point"), the power flux is strongly localized. This strong localization can create extreme conditions for plasma-facing materials at the divertor target plates. Predictions for ITER yield power flux densities of the order of 10 MW/m^2 for normal steady-state phases. During off-normal events such as ELMs (see below), these power flux densities can increase by factors of 5–10 and to even higher values for disruptions (see below). No component can tolerate such power fluxes so that this low-density scenario is not compatible with requirements for a future power reactor.

This challenge can be overcome if the divertor is operated at higher density. Inelastic collisions between electrons and heavy particles decrease the electron temperature, so that mean particle energies decrease. With increasing density, the number of collisions of ions with

neutrals further increases. This causes cross field transport and tends to broaden the strike area of the plasma ions on the target plate. In addition, CX collisions produce fast neutrals that also contribute to a distribution of the energetic particle flux onto a larger area. At sufficiently low electron temperature and sufficiently high neutral density, volume recombination (i.e., electrons and protons recombine to form neutral hydrogen atoms and molecules) sets in. The neutral flux is again distributed to a larger area, but, even more important, hydrogen atoms and molecules can radiate line radiation, which then contributes to cooling of the divertor plasma. Emission of radiation goes into the full solid angle, so that enhanced radiation is a very efficient concept to distribute the power flux to a much larger area. Consequently, the local power flux density around the strike point position is significantly reduced if a substantial fraction of the power flux can be converted into radiation. At high divertor density, n_e can reach values of 10^{21} m^{-3} . Under such conditions, electron temperature is 1 eV and below.

The cooling of the divertor plasma due to enhanced radiation, the so-called radiative cooling, can be systematically exploited by the intentional injection of impurities into the divertor plasma. For example, argon, neon, or nitrogen are considered for injection into the divertor plasma to reduce the power flux in ITER to tolerable limits.

60.5.7 Other PWI Processes

Another requirement that plays an important role in plasma–wall interaction in MCF devices is the handling of the extreme power-flux densities. This is a substantial challenge for the plasma-facing materials and the design of the components to be used in the divertor. As an example, ITER is designed for a fusion power of 500 MW. Twenty percent of this power is generated in the form of energetic alpha particles that are used to heat the core plasma. With an additional foreseen external heating power of about 73 MW, the total heating power that has to be removed via PWI processes and to be conducted to the heat sinks of the cooling system of the wall components is of the order of 170 MW. Since the radial extend of the SOL is only of the order of a centimeter and most of this heating power is transported along the SOL to the target plates in the divertor, the local power densities at the target plate are extremely high. Inclining the target plates can increase the strike area by about a factor of 6. Nevertheless, the total strike area is still only about 6–8 m². In the ITER reference scenario, it is estimated that about half of the total heating power is convected to the target plates leading to a mean power density of 10 MW/m². The other half of the heating power is distributed onto the whole inner-wall area of about 680 m² dominantly by radiation. The corresponding power density of about 0.1 MW/m² can easily be removed by active cooling. Neutrons deploy their energy much deeper in the wall, therefore they are not considered as a plasma–wall interaction problem here.

Prototype components for divertor elements, which can reliably remove the predicted power flux densities of about 10 MW/m², have been produced and successfully tested (Samm 2008). However, the impact of transient effects such as disruptions and ELMs impose a further very serious challenge for the integrity of divertor components (Federici et al. 2001). These events may cause surface damage and high erosion losses due to surface melting and melt layer losses, surface vaporization, cracking, and spallation. A disruption is the usually unplanned sudden termination of the plasma current that may occur if operational limits of plasma confinement are exceeded. One but not the only example of such an operational limit is the density limit. A disruption always leads to the sudden loss of plasma confinement and the

complete stored energy in the plasma is dumped onto the first wall. Typical thermal quench times anticipated for ITER are several milliseconds. The spatial distribution of the power is hard to predict, but based on present experience a substantial fraction goes to the divertor. This means that maximum power loads during disruptions are more than a factor of 10 up to 100 higher than the above-mentioned mean power density of 10 MW/m². Since ITER will be an experimental device, it must be able to withstand a few disruptions. On the other hand, disruptions have to be completely avoided in future power reactors. Avoidance and mitigation strategies for disruption are explored to extent the lifetime of in-vessel components (Federici et al. 2001).

As described in the previous section, ELMs are edge-localized instabilities occurring during H mode plasma operation. ELMs are repetitive transient phenomena with a typical duration of some 10⁻⁴ s and lead to a periodic expulsion of particles and power from the core plasma into the SOL and finally onto the surfaces of the divertor target and the first wall. ELMs seem to be required to avoid impurity accumulation in the core plasma.

Three different types of ELMs exist. Type I ELMs lead to large power loads. They have a large amplitude and relatively low frequency. Up to 10% of the stored energy in the main plasma can be ejected during one type I ELM. The spatial distribution is inhomogeneous, but most energy is dumped to the inner divertor target plates. This extreme power flux can cause melting of the surface, even for tungsten, and lead to melt layer loss (evaporation and splashing). It is obvious that this has severe consequences for the involved plasma-facing materials and components. Plasma operation with type I ELMs is not compatible with lifetime requirements of a power reactor and has to be avoided. Type II ELMs are relatively uncommon. They have a rather low energy content and pose no problems for wall materials. For practical purposes, they play no role. Type III ELMs have a much higher frequency than type I ELMs (0.1–1 kHz) and lower amplitude (about 1% of energy content). They are compatible with material requirements and are the favored operational mode for ITER. Mitigation methods for type I ELMs and triggering of type III ELMs are actively investigated. However, different types of ELMs occur in different plasma-operation scenarios. The best confinement is coupled to large type I ELMs, while small-ELM regimes have their price in confinement quality. The choice of plasma operation scenario is therefore a compromise between tolerable divertor load and good confinement.

A further aspect of PWI is the fact that plasma-facing materials and structural materials have in general different requirements. The plasma-facing materials are optimized for lifetime, low impurity generation, and low tritium inventory, which require low atomic number or low sputtering yield. On the other hand, structural materials have to guarantee the structural stability of divertor and first-wall components and must be able to conduct the impinging energy fluxes to the cooling system. In general, this leads to a different choice for PFM and structural material. This allows a higher flexibility in designing plasma-facing components, but creates also new problems. Since, in general, thermal expansion coefficients of different materials differ, significant stresses are created at the interfaces of different materials. This represents a major challenge for the development of joining methods and remains a very active and important field of material science and for the further development for MCF.

Certain consequences of PSI processes – apart from sputtering and deposition – have strong implications for the properties of the materials of the first wall as well. Important issues in this context are the change of material properties due to implantation of hydrogen as well as radiation damage and transmutation due to neutron irradiation. Such material-related topics have recently been reviewed in depth by Federici et al. (2001).

60.6 Prospects of Practical Application

Present day fusion devices are practically plasma confinement experiments, albeit at sizes and power close to fusion reactor needs. As discussed in [Sect. 60.1.1](#), positive energy balance requires good enough thermal insulation of the plasma, which is characterized by the energy confinement time τ_E . As this single parameter includes all kinds of losses (radiation, conduction, particles), it cannot be described in an easy analytical form. Even at the present state of research, it cannot be derived from first principle simulations. Due to the complexity, empirical scalings have been established on the basis of experiments (ITER 2007). For the energy confinement time, the most often used IPB98(y,2) scaling is a regression fit to a compilation of selected well characterized H-mode confinement results from 19 present and past tokamak experiments (ITER 2007) in the form:

$$\tau_E = 0.0562 I_p^{0.93} B_t^{0.15} n^{0.41} P^{-0.69} R^{1.97} \varepsilon^{0.58} \kappa_a^{0.78} M^{0.19}, \quad (60.12)$$

where I_p is the plasma current in MA, B_t is the toroidal field in tesla, n is the plasma-electron density in units of 10^{19} particles/m³, P is the heating power in MW under stationary conditions (which equals the power loss from the plasma), R is the torus major radius, $\varepsilon = a/R$ is the inverse aspect ratio, a is the mean plasma minor radius, κ_a is the plasma elongation defined as the ratio of the plasma cross section to $a^2\pi$, and M is the mean ion mass relative to hydrogen H (¹H). This scaling has been established mostly in deuterium discharges but the weak atomic-mass dependency makes one hope it is applicable to DT plasmas as well.

Although IPB98(y,2) is dimensionally incorrect and hides complex physical processes, it is very useful for a first estimation for the performance of a future device. Similar scalings have been established for stellarators as well, for example, ISS95/04 (Yamada 2005). Other scalings provide the H-mode access and other necessary conditions. Limits on certain parameters or parameter combinations arising from understood physics or empirical scalings bound the operating space of the devices. This prevents changing the parameters in, for example, IPB98(y,2) independently. For example, the increase of density (n) would be beneficial for the confinement time and volume fusion power ($P_f \propto n^2$) as well. However, for tokamaks, but not for stellarators, the so-called Greenwald empirical disruption limit represents an upper bound for the density in the form $n_{\max} \propto I_p/\pi a^2$. Therefore, operation close to the density limit means an effective $\tau_E \propto I_p^{1.34}$ scaling, which would call for increasing the plasma current. On the other hand, the rotational transform in tokamaks is $q = (B_t 2\pi a^2)/(R\mu_0 I_p)$ and it must be above 2 because of the well-understood magnetohydrodynamic kink-instability limit. Therefore, at high density, high current, fixed plasma geometry, and heating, the scaling effectively becomes $\tau_E \propto B_t^{1.49}$, that is, finally, a high magnetic field is required. Ultimately, the technical limit on the magnetic field strength renders the IPB98(y,2) scaling a function of geometrical parameters and the power only. Of course, the device size and the needed power are again interdependent, but in any case the increase of the major radius R and the inverse aspect ratio $\varepsilon = a/R$ is beneficial, calling for large and compact devices.

Following IPB98(y,2), present day fusion devices are not capable of reaching positive energy balance simply due to their size. The largest tokamak devices are just about to reach the breakeven limit in DT plasma, but in reality, this is not demonstrated as the neutron flux during high-power DT operation, which would activate the device and would inhibit manned access for a considerable period of time. Only two devices were capable of operating in DT mixture: TFTR (Strachan 1997) in USA and JET (Keilhacker 1999) in Europe. The larger and

even presently operational JET devices demonstrated $Q = 0.2$ – 0.3 in quasi steady-state operation and up to 0.55 transiently. Comparison between pure deuterium and DT discharges confirmed that Q can be reliably calculated for DT discharges on the basis of deuterium ones.

According to the scaling, a device at twice the size of the presently largest tokamak (JET) could reach about $Q = 10$, and at nearly three times the size, it would ignite (Jacquot 1999), that is, alpha heating would replace the external heating. To reach that condition, an international tokamak device has been proposed already in 1985 (Braams and Stott 2000). By 1998, the engineering design of an $R = 8$ m tokamak was completed (ITER 1999) with full superconducting coil set and all technical equipment capable of demonstrating fusion ignition for few 100 s long pulses. Due to financial problems, this device could not be built, but a downscaled version of the plans at $R = 6.2$ m was created by 2001 (Aymar et al. 2002). This is the basis of ongoing efforts, which are generally hoped to conclude latest by 2020, in the startup of the ITER experiment.

It is important to understand that ITER (● Fig. 60.10) will not be a fusion reactor, but a combined plasma confinement and fusion technology experiment. From the plasma physics point of view, it should demonstrate plasma operation under reactor conditions with $Q = 10$ in 500 s pulses. The plasma current would be driven inductively. Long pulse operations are planned with noninductive current drive at about $Q = 3$ fusion performance. ITER should demonstrate plasma operation with dominant alpha particle heating and should be capable of exploring diagnostics and plasma control schemes toward a reactor.

However, it will utilize techniques, which will not be possible on a reactor due to the continuous operation and/or higher neutron dose. From the technology point of view, one important aim is to demonstrate tritium-breeding technologies. ITER will not be self-sustaining of tritium as only a few test blanket modules (TBM) will be installed for the testing

■ Fig. 60.10
Cutaway view of ITER

of various technologies (Giancarli et al. 2006). Several competing concepts will be explored: water or helium gas cooled mixture of lithium-silicate and beryllium pebbles or lithium-lead liquid.

ITER will have 73 MW external heating capability and 500 MW fusion-power production is expected. This is quite a large technological step compared to JET, which is similar in construction. The most important difference is that ITER will be a nuclear device with several hundred kW/m^2 neutron power deposited in the blanket. This is a major hurdle for heating and diagnostics devices, which will have to place all sensitive components behind shielding and must cool all structures seen by the neutron flux. Nearly all of such equipment will be installed in port plugs, which can be removed by remote handling equipment as maintenance operations can be carried out only in hot cells.

ITER will be able to test plasma confinement and key technologies needed for a fusion reactor but will not be able to test how structural materials behave under the extreme neutron dose expected in a fusion reactor. Most of the difference in the dose comes from the fact that ITER will operate in short pulses only, while a fusion reactor will have to have a high availability. The expected irradiation damage to structural materials in a fusion reactor will also be much higher than in present-day fission reactors for two reasons. Firstly, in a fission reaction only a few percent of the energy is taken away by the neutrons, while in a fusion one 80%. Secondly, the fusion plasma is tenuous and therefore all neutrons reach the wall of the reaction chamber. This neutron load will certainly cause serious damage to the materials, but the nature of this is largely unknown as fission reactors can simulate the fusion neutron load only to a certain extent.

Another question for materials' scientists is the activation of structural materials by neutrons. As no radioactive material is generated in a fusion reactor, the careful choice of the structural materials would allow minimization of the nuclear waste production to rather low levels. For this purpose, a special fusion steel called EUROFER97 has been developed and characterized inside fission reactors up to 30 displacement per atom (dpa) dose (Lindau et al. 2005). The results indeed show that after about 100 years, the fusion reactor components could be recycled as nonradioactive materials. Concerning the neutron damage, an irradiation with fusion-relevant neutron spectrum must be carried out up to the ~ 150 dpa level expected in a reactor. For this, an accelerator-based device called IFMIF (Moeslang et al. 2006) is being designed. It would generate 14 MeV neutrons by firing two deuterium beams onto a liquid lithium target. Small material samples would be investigated and, based on the results, the materials for fusion power plants could be designed. Some experts also consider the construction of steady-state $Q < 1$ tokamak devices as neutron sources for testing full fusion reactor components.

Even if using special fusion materials, it cannot be expected that the blanket of the fusion power plant would survive the full lifetime of the reactor. At present, it is estimated that the blanket and the divertor will have to be replaced every 2–5 years. This is a major intervention, which has to be done completely with remote handling operations, as the materials will be strongly activated. It has been found that the engineering design of the blanket system is extremely important and will largely determine the time needed for blanket replacement (Ihli et al. 2007), and through this the availability of the power plant.

In addition to the status of magnetic confinement fusion, it is worth briefly considering the status of inertial confinement fusion developments as well. This field has been combined with military research for the study of materials under extreme conditions experienced during nuclear bomb explosions; therefore, its progress was only partly visible to the public. However, recently two major laser ICF facilities are being built or operated: Laser Megajoule (LMJ)

(Cavailler 2005) in France and the National Ignition Facility (NIF) (Hammel 2006) in USA. Both of them are expected to demonstrate positive energy balance processes (breakeven) in a few years time. This is going to be a major achievement of many decades of laser fusion research, but similarly to ITER, it is not going to demonstrate practical energy production. Several technical challenges need to be solved for the construction of an ICF-based power plant. At present, lasers can fire only a few times a day; for a fusion reactor, 10 Hz CW operation would be needed. Similar development is necessary in the efficiency of the lasers, which need to reach about 10%, an increase of an order of magnitude from present systems. Automated 10 Hz production of precise, multilayer pellets at low price (a few 10 Eurocents) seems to be a comparable challenge. Wall damage, especially in the case of highly sensitive high-power optical elements is also a major issue, in this context IFE shares the problems of MCF. These technological issues have been considered in the past in less depth by the IFE community, but the demonstration of breakeven will certainly give a boost to these developments. One important proposed experiment is the HIPER project (HIPER 2007), which aims at testing the fast ignitor concept described above. NIF, LMJ, and HIPER would test the physics and technology for the IFE-based energy production power plant.

In the MCF field, the results from ITER and IFMIF would provide the basis of the construction of a demonstration magnetic fusion power plant dubbed DEMO. There is no agreement yet on how such a device would look in detail. Several conceptual studies have been concluded on fusion power plants during the past decades. They are based on different tokamak variants (Najbadi et al. 2003, 2006; EFDA 2005), stellarators (Raffray 2007), and assume different blanket technology (EFDA 2005). These studies indicate that fusion energy production would be possible at a cost comparable to present energy prices. However, all of these studies make assumptions on the solution of several problems, which will be available only after ITER or even later. The key elements have been described in the sections above, here they are listed just for reference. The problem of structural material damage will be addressed in IFMIF. The selection of plasma-facing materials is a major issue, which will partly be tested in ITER albeit DEMO might impose higher heat loads and the long-term issues might also pose problems. The control of plasma operation at a desired operational point might require advanced current drive, heating, and diagnostic techniques. Although some of these are readily available, their operation in the harsh nuclear environment of DEMO might be problematic or at least require further development. This leads to the final difficulty, the complexity of the fusion device. A fusion power plant assumes simultaneous operation of a large number of components, which are all extremely complex themselves. No matter which of the two basic concepts wins (i.e., IFE or MFE) one thing for sure is: reliability, robust engineering design, and good management are going to be key issues in the construction and operation of fusion power plants, as these devices will be most probably the most complex instruments humankind has ever devised.

Abstract: Issues related to the management of radioactive wastes are presented with specific emphasis on high-level wastes generated as a result of energy and materials production using nuclear reactors. The final disposition of these high-level wastes depends on which nuclear fuel cycle is pursued, and range from once-through burning of fuel in a light water reactor followed by direct disposal in a geologic repository to more advanced fuel cycles (AFCs) where the spent fuel is reprocessed or partitioned to recover the fissile material (primarily ^{235}U and ^{239}Pu) as well as the minor actinides (MAs) (neptunium, americium, and curium) and some long-lived fission products (e.g., ^{99}Tc and ^{129}I). In the latter fuel cycle, the fissile materials are recycled through a reactor to produce more energy, the short-lived fission products are vitrified and disposed of in a geologic repository, and the minor actinides and long-lived fission products are converted to less radiotoxic or otherwise stable nuclides by a process called transmutation. The advantages and disadvantages of the various fuel cycle options and the challenges to the management of nuclear wastes they represent are discussed.

61.1 Radioactive Wastes

Radioactive wastes, like most other waste forms, contain a variety of materials differing widely in chemical composition, physical state, and origin, either naturally occurring or man-made. This range of materials necessitates equally variant strategies for managing the waste while protecting humans and the environment and being attentive to social and economic considerations.

There are two major sources of radioactive waste both derived from the industrial production of radionuclides: (1) wastes derived from the production of material to support the manufacture of nuclear weapons, often referred to as *defense waste*; (2) wastes resulting from the generation of nuclear power, often referred to as *civilian waste*. There is also nuclear waste associated with other industrial practices (e.g., medical radionuclide production, X-ray sources, or neutron sources) and general scientific research, but the volume and resultant hazard level from these sources is considerably less than from either of the two primary sources.

A number of schemes exist for the classification of nuclear wastes. Most simply, they can be separated by level of radioactivity (high, intermediate, or low) and by type of radiation (alpha, beta, gamma, or X-ray). Further classification often contains information about the physical nature of the waste, either solid or liquid, or the half-life of the contained material (short or long-lived). Another characteristic of radioactive waste that must be considered when developing waste management strategies is the thermal heat content of the waste. The half-life of the radioactive materials determines how long the waste requires management and the total amount of radioactivity as well as the heat content dictate how to handle the waste.

There are two general principles or options that are used to manage both radioactive and nonradioactive wastes. These are (1) to concentrate and isolate wastes (i.e., *concentrate-and-contain*) and, (2) to dilute to regulatory-accepted levels and then discharge the wastes to the environment (i.e., *dilute-and-disperse*).

A third option, which is unique to the management of radioactive wastes, is *delay-and-decay*. In this case, the waste is stored and allowed to decay until the level of radioactivity has decreased to a more manageable, or even background, level.

A number of good, general references about radioactive waste generation and management are available, e.g., see ref. Web (2003a).

61.1.1 Classification of Radioactive Waste

61.1.1.1 Exempt Waste

Exempt waste, sometimes identified as “below regulatory concern”, contains very low concentrations of radioactivity. The associated radiological hazards are generally considered to be negligible as they are less than naturally occurring radioactivity.

61.1.1.2 Low-Level Waste (LLW)

LLW is generated from hospitals, laboratories and industry, as well as from the nuclear fuel and defense program cycle. It comprises paper, rags, tools, clothing, filters, and other lightly contaminated materials that contain small amounts of mostly short-lived radionuclides. It is not dangerous to handle, but must be disposed of more carefully than normal garbage. Often it is buried in shallow monitored landfill sites. To reduce its volume, it can be compacted or incinerated (in a closed container) before disposal. Worldwide it constitutes 90% of the volume but only 1% of the radioactivity associated with all radioactive waste.

61.1.1.3 Intermediate-Level Waste (ILW)

ILW contains higher amounts of radioactivity and may require the use of special shielding to assure worker safety. It typically contains materials like resins, filters, chemical sludge, reactor components, and contaminated materials from reactor decommissioning. It may be solidified in concrete or bitumen for disposal. Generally, short-lived waste (mainly from reactors) is buried, but long-lived waste (from reprocessing nuclear fuel) is usually subject to deep geologic disposal. Worldwide it makes up 7% of the volume and has 4% of the radioactivity of all radioactive wastes.

61.1.1.4 High-Level Waste (HLW)

HLW generally refers to materials requiring permanent isolation from the environment. It frequently arises as a by-product of nuclear power generation (reprocessing streams or spent fuel) or from the isolation of fissile radionuclides from irradiated materials to be used in nuclear weapons production. When nuclear fuel from reactor operations (civilian or defense) is chemically processed, the radioactive wastes include highly concentrated liquid solutions of nuclear fission products. Typically, these waste streams are solidified either in a glass (vitrification) or in another matrix. Both the liquid solutions and the vitrified solids are considered HLW. If the nuclear fuel is not processed, it too, is considered as HLW and must be dispositioned. The path most often proposed is direct, deep geologic isolation.

Although the relative amount of HLW is small with respect to the total volume of radioactive waste produced, it contains 95% of the radioactivity.

HLW in the form of spent nuclear fuel or vitrified reprocessing waste generates intense levels of both radioactivity and heat, requiring heavy shielding and thermal cooling during its

handling and storage. Frequently wastes are stored in cooling ponds or vaults prior to their disposal. While stored, both the temperature and radioactivity of the wastes gradually decrease, simplifying their handling and disposal considerably.

Wastes that contain large quantities of alpha-bearing materials require similar isolation in their ultimate disposal. These wastes are sometimes referred to as transuranic (TRU) or higher actinide wastes and do not generate the thermal heat described above. These wastes are produced in volumes greater by a factor of 5–10 than the HLW previously discussed.

The disposal of HLW is an urgent public policy issue. These political aspects have led to the need for the nuclear community to demonstrate the feasibility and safety of HLW disposal and, in some countries, to implement laws that require operational HLW disposal capability in the next 10–50 years. Many European countries, the USA, and Japan have programs dedicated to the disposal of HLW. Currently, all HLW produced to date is being stored; no permanent disposal has yet occurred.

61.2 The Nuclear Fuel Cycle

Since the dominant sources of all radioactive wastes are associated with energy production via nuclear reactors, it seems prudent to discuss nuclear waste in the context of the nuclear fuel cycle. The nuclear fuel cycle consists of all the relevant activities that must be undertaken to produce electricity from nuclear reactions. The schematic of the nuclear fuel cycle is shown in

• Fig. 61.1.

When discussing how to manage wastes from the nuclear power industry, it is often convenient to break the fuel cycle up into two parts: The *front-end* consists of all the activities beginning with mining and milling up through and including burning the uranium fuel in a nuclear reactor. The remaining activities or *back-end* of the nuclear fuel cycle is where the vast majority of the waste is generated and managed.

As the term nuclear fuel cycle suggests, the standard scenario envisioned by the nuclear power industry was to reprocess the spent fuel because uranium and plutonium would be recovered and recycled to generate additional energy. In addition, by recovering uranium and returning it to the fuel cycle, the demand for new uranium as well as the need for enrichment services could be reduced by about 30% compared to “once-through” fuel management (Choppin et al. 1995). The advantage of reprocessing with respect to waste management is of course, the large reduction in volume (factor of ~100) of the materials to be disposed of as HLW. Some countries, most notably the USA and Canada, have elected not to reprocess fuel, and thus not to close the fuel cycle.

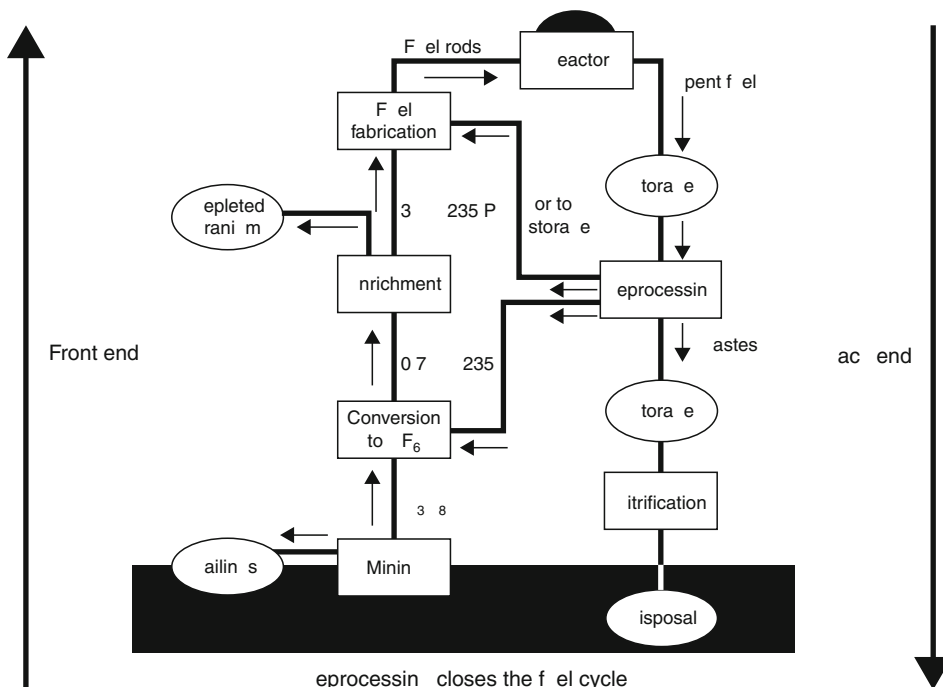

61.2.1 Options in the Fuel Cycle That Impact Waste Management

The three major *back-end* fuel cycle options currently under consideration by various countries are the following:

- Once through cycle with direct disposal of spent fuel as HLW.
- Reprocessing fuel cycle (RFC) with mixed oxide (MOX) recycle of U and Pu in light water or fast breeder reactors (FBRs) and disposal of HLW.

■ Fig. 61.1

Schematic of the nuclear fuel cycle (Courtesy of the World Nuclear Association (Web 2003b))

- Advanced fuel cycle (AFC), an extension of RFC in which the wastes are partitioned and some are transmuted (P&T) to reduce the long-term radiotoxicity.¹

These variations in the fuel cycles each have different advantages and disadvantages and pose different challenges to the management of nuclear wastes that vary in nature and complexity. The sections on “Spent Fuel,” “Fuel Reprocessing,” and “Partitioning and Transmutation” discuss these variations in more detail.

61.2.1.1 Material Balance in the Nuclear Fuel Cycle

A material balance of the nuclear fuel cycle gives one a sense of the quantities of nuclear materials and wastes that are generated and must be managed. Table 61.1 shows the balance of materials in the nuclear fuel cycle needed for the operation of a typical 1,000 MWe power plant.²

61.3 The Front-End of the Nuclear Fuel Cycle

This section describes the wastes generated at each point in the fuel cycle and strategies for handling them. A general discussion is also available in ref. Web (2003c).

Table 61.1

Balance of materials in the nuclear fuel cycle needed for the operation of a typical 1,000 MWe power plant. Uranium concentrations are sometimes expressed in terms of U_3O_8 content (U_3O_8 is a mixture of two uranium oxides, approximately as they occur in nature). Pure U_3O_8 product contains about 85% uranium by mass. Concentrate is 80% U, enrichment to 4% U-235 with 0.3% tails assay, 80% load factor for reactor, core load 72 t U, refueling annually with one third replaced

Fuel cycle step	Nuclear materials handled
Mining	22,400 t of 1% uranium ore
Milling	280 t of uranium oxide concentrate (with 224 t U)
Conversion	331 t UF_6 (with 224 t U)
Enrichment	35 t UF_6 (with 24 t enriched U) – balance is “tails”
Fuel fabrication	27 t UO_2 (with 24 t enriched U)
Reactor operation	7,000 million kW h (7 TW h) of electricity
Spent fuel	27 t containing 240 kg Pu, 23 t U (0.8% U-235), 720 kg fission products, also some transuranium elements

Courtesy of the World Nuclear Association (Web [2003b](#)).

61.3.1 Uranium Mining and Milling

Uranium is a naturally occurring ore that can be excavated or recovered using in situ techniques. The decision as to which mining method to use for a particular deposit is governed by the nature of the ore body, safety, and economic considerations. When excavation is chosen either underground mining or open pit technologies is utilized. In general, open pit mining is used where deposits are close to the surface while deeper deposits require underground mining. Owing to access considerations, open pit mining results in large quantities of materials having to be removed. In contrast, underground mining operations exhibit small surface disturbances, with much less material having to be removed. Examples of open pit uranium mining include the Ranger mine in the Northern Territory of Australia and many of Canada's older mines (e.g., at Cluff Lake, Key Lake, and Rabbit Lake). Examples of underground mines include the Olympic Dam mine in Southern Australia, which also produces copper and some gold and silver, as well as the newer mines in Canada, McArthur River and Cigar Lake. McArthur River and Cigar Lake are somewhat atypical underground mines because they contain a very high-grade ore. Thus, these mines require special remote handling equipment.

An increasing proportion of the world's uranium now comes from in situ leaching, where oxygenated groundwater is circulated through a very porous ore body to dissolve the uranium and bring it to the surface. In situ leaching may be with slightly acidic or with alkaline solutions to keep the uranium in solution. With in situ leach mining, dissolved materials other than uranium are simply returned to their underground location. The uranium is then recovered from the solution as in a conventional mill.

At the mill, usually located close to the mine, the ore is crushed and ground to a fine slurry. Sulfuric acid, in which uranium is soluble, is used to leach the product from the bulk material. The residue, consisting of undissolved solids (waste rock) is referred to as the tailings. This material contains most of the radioactivity including radium and toxic materials such as heavy

metals. Frequently the tailings are pumped into engineered ponds designed to retain the solids and prevent any seepage of the liquid. Eventually the tailings may be returned to the mine or covered with rock and clay, then replanted with vegetation. The tailings are about ten times more radioactive than typical granites.

The uranium is recovered from the sulfuric acid solution by precipitation with a base. The resulting product, uranium oxide (U_3O_8) is often referred to as “yellowcake” and is only mildly radioactive. Yellowcake generally contains more than 80% uranium by weight in contrast to the original ore that may have contained as little as 0.1% uranium.

61.3.2 Conversion to UF_6

Although the uranium concentration has been raised substantially in the milling operation, the relative abundance of the fissile isotope, ^{235}U , is too low. Natural uranium contains about 0.7% by weight ^{235}U . To sustain a nuclear reaction in most commercial power reactors, the fuel must be enriched to about 3.5%. Enrichment is often with gaseous feedstock achieved by converting U_3O_8 to the gaseous UF_6 . Uranium conversion plants that produce UF_6 as a feedstock for enrichment processes are currently in operation in both Europe and North America.

61.3.3 Enrichment

Using uranium hexafluoride as the feedstock, the enrichment process exploits the 1% mass difference between the ^{235}U and the ^{238}U isotopes. The USA constructed the first enrichment facilities in Oak Ridge, Tennessee using gaseous diffusion technology. Over time, the technology has transitioned to gas centrifugation.³ In this process, the feedstock is supplied to a rotating cylinder where the heavier isotope is moved to the outer part of the cylinder because of the gravitational field. The lighter isotope is then fed to the next stage in the process and enrichment is realized in a multistep process. The centrifugation process also consumes less power per unit of product.

A newer, potentially more economic technology that has been explored in the USA, France, and Australia is laser isotope separation (LIS).⁴ This technology depends on the use of laser photons to selectively excite and ionize only the ^{235}U isotope in a mixture and the use of a magnetic field to preferentially extract ^{235}U away from the more dominant ^{238}U isotope.

During enrichment, every ton of uranium hexafluoride processed yields about 130 kg of enriched UF_6 (about 3.5% ^{235}U) and 870 kg of “depleted” UF_6 (mostly ^{238}U). The enriched UF_6 is subsequently converted at specialized fuel fabrication facilities into uranium dioxide (UO_2) powder and pressed into fuel pellets. The “depleted uranium” has found use in its metal form as counterweights in yacht keels, as antitank ammunition or radiation shielding, since it is only slightly radioactive (less radioactive than natural uranium) and 1.7 times more dense than lead.

Not all commercial power reactors require the uranium fuel to be enriched. A small number of reactors, notably the Canadian CANDU reactors, can operate using natural uranium because they use heavy water (D_2O) rather than light water (H_2O) as the neutron moderator. Additionally, some early British gas-cooled reactors do not require enriched uranium.

61.3.4 Fuel Fabrication

At the fuel fabrication facility, enriched UF_6 is converted to uranium dioxide (UO_2) powder that is pressed into small ceramic pellets and sintered at a high temperature (over $1,400^\circ\text{C}$). These pellets are inserted into thin tubes, usually of a zirconium alloy (zircaloy) or stainless steel, to form fuel rods. The rods are then sealed and assembled in clusters to form fuel elements or assemblies for use in the core of the nuclear reactor. Some 25 t of fresh fuel is required each year by a 1,000 MWe reactor.

61.3.5 Commercial Nuclear Power Generation

Nuclear power produces energy by splitting the atom, most notably ^{235}U or ^{239}Pu . Energetically, when these nuclides split or fission, the resulting pieces called fission fragments have a combined rest mass less than the parent nuclide. The difference in mass is converted to energy during the fission process and this process of transforming matter directly into energy results in the release of about 200 MeV of energy (or 3.2×10^{-11} J) for every atom that fissions. (By capturing the fission products this energy is converted to heat and used to drive turbines to produce electricity.) In contrast, the burning of fossil fuels involves only the breaking of chemical bonds, and as a result, only 4 eV or 6.5×10^{-19} J/molecule of CO_2 is released for the combustion of carbon. Thus, the great advantage of nuclear power is its ability to extract a tremendous amount of energy from a small volume of fuel (Beller and Rhodes 2000). A second major advantage of nuclear power is related to the inherent characteristics of the fuel itself. Aside from its potential use in nuclear weapons, uranium ore has little use for humankind other than for the production of electricity. In contrast, fossil fuels can potentially be used for a wide variety of applications from the production of pharmaceuticals to various important synthetic materials production and to transportation. A third inherent advantage of nuclear power is that under normal operations, energy is produced with minimal environmental impact in terms of air and water pollution compared with burning of fossil fuel, particularly coal. Fossil fuels release large quantities of CO_2 and sulfur and nitrogen oxides (acid rain) to the atmosphere and substantial amounts of fly ash as solid waste. Energy created by splitting the atom does not produce these greenhouse gases.

Presently, nuclear energy provides over 16% of the world's total electricity as base load power. Approximately 435 commercial nuclear reactors operating in 31 countries produce this electricity with a total generating capacity of over 350 GWe. Of the existing commercial power reactors shown in [Table 61.2](#), the overwhelming majority (>99%) are thermal reactors, which means that fission is induced by low energy, thermal neutrons (~ 0.025 eV). Of the thermal reactors, greater than 80% are light water reactors (LWRs). In a LWR, normal hydrogen in water is used as the moderating material that, by successive scattering events, reduces the energy of the neutrons born in the fission event from approximately 2–3 MeV to the thermal regime (~ 0.025 eV). If the neutrons are not moderated, as in a fast reactor, a much harder or more energetic neutron spectrum (10s to 100s of keV) is used to induce fission.

Several hundred uranium dioxide fuel assemblies make up the core of a reactor. For a reactor with an output of 1,000 MWe, a typical core contains about 75 t of low-enrichment uranium ($\sim 3.5\%$ ^{235}U). During the operating cycle of a nuclear reactor, several competing processes determine the final radionuclide inventory in the spent fuel. These processes are

■ **Table 61.2**

Types of commercial nuclear reactors

Reactor type	Main countries	Number	GWe	Fuel	Coolant	Moderator
Pressurized water reactor (PWR)	USA, France, Japan, Russia	252	235	Enriched UO_2	Water	Water
Boiling water reactor (BWR)	USA, Japan, Sweden	93	83	Enriched UO_2	Water	Water
Gas-cooled reactor (Magnox & AGR)	UK	34	13	Natural U (metal), Enriched UO_2	CO_2	Graphite
Pressurized heavy water reactor "CANDU" (PHWR)	Canada	33	18	Natural UO_2	Heavy water	Heavy water
Light water graphite reactor (RBMK)	Russia	14	14	Enriched UO_2	Water	Graphite
Fast neutron reactor (FBR)	Japan, France, Russia	4	1.3	PuO_2	Liquid sodium	None
Other	Russia, Japan	5	0.2			
Total		435	364			

Courtesy of the World Nuclear Association (Web [2003d](#)).

- Neutron-induced fission, a process that produces energy and two fission products for each atom that fissions.
- Neutron capture, a process that produces an isotope of the same element but of one mass unit higher.
- Radioactive decay. (In a nuclear reactor, there are two primary modes of decay, beta minus decay and alpha decay. For the process of beta minus decay, a nucleus of mass number A and atomic number Z is transformed into another nucleus of mass number A but with atomic number $Z + 1$. Alpha decay, on the other hand, results in the loss of a helium nucleus leaving the original nucleus four A units and two Z units lighter.)

Consequently, in a nuclear reactor, fission products as well as isotopes of heavier elements are produced. These heavy elements are formed by the neutron capture followed by beta decay and are often referred to as the transuranic elements. Because the fission process is asymmetric,⁵ the products of the fission reaction tend to distribute themselves around mass 83–105 (light fragment) and mass 129–149 (heavy fragment). Some of the more common light fragments are ^{85}Kr , ^{90}Sr , ^{95}Zr , ^{99}Tc , and the corresponding heavy fragments are ^{129}I , ^{137}Cs , ^{144}Ce , and ^{147}Nd .

To maintain efficient performance over the reactor volume for nominally 1,000 MWe LWR, about one third or about 25 t of spent fuel is removed from the reactor core every year or so, the spent fuel being replaced with fresh fuel. However, over time, the concentration of fission fragments and heavy elements in a fuel bundle will increase to the point where it is no longer practical to continue to use the fuel. Therefore, after 24–36 months the core is removed from the reactor.

61.3.6 Fast Reactors

Fast reactor technology was developed during the same time frame that thermal reactor technology was being pursued for commercial power production. Since less than 1% of the energy content of mined uranium is realized in burning uranium in conventional LWRs, the initial motivation for fast reactors was to breed plutonium from uranium to maximize uranium fuel utilization. In order to exploit a higher fraction of the energy content of uranium, Pu could be produced in fast “breeder” reactors (FBRs) by placing a “blanket of uranium” around the core. In the blanket, ^{238}U would capture fast neutrons and produce more Pu than consumed in the reactor. In fact, of the order of 70% of all ^{238}U placed in a fast reactor can be converted to ^{239}Pu . Since the natural abundance of ^{238}U is 99.3%, this conversion results in the production of an almost infinite supply of fissile fuel for future generations.

There are several major differences in the design and operation of fast reactors compared with thermal reactors. First, in a fast reactor, no moderator is used and neutrons induce fission at or near the energies created (~ 2 MeV or neutron speed $u = 2 \times 10^7$ m/s). Although fast reactors do not require a moderator, they do require a coolant. Since water is such an efficient neutron moderator, it cannot be used as a coolant; therefore, liquid metals such as sodium, lead, or lead-bismuth or gases, such as helium and carbon dioxide have been used. Second, because neutrons travel at such high speeds in fast reactors, the probability of neutrons escaping to the surroundings is much higher. As a result of this “neutron leakage,” fewer neutrons are available to react with other fissile nuclei to sustain the chain reaction in fast reactors. To overcome this problem, fast reactor fuel contains a higher ratio of fissile-to-fertile nuclides/isotopes.⁶ Common fast reactor fuel is either highly enriched ^{235}U or a mixture of Pu and ^{238}U . Because Pu has a rather low, fast neutron absorption cross section, a loading of Pu of at least 20–30% is required. The remaining 70–80% of the fuel is ^{238}U .

In the mid-1980s, because the expected shortage of uranium never materialized and uranium remained abundant and cheap, the need for fast reactors to breed plutonium was no longer compelling or economical. This, along with concerns related to the potential proliferation of plutonium, caused interest in fast reactors to wane. This happened just as large prototype demonstration fast reactors such as the BN-600 (600 MWe) in Russia (1980) and the Superphenix (1,240 MWe) in France (1985) started coming online. About the same time, 1984, the USA initiated the Integral Fast Reactor Program, a fast reactor concept developed by Argonne National Laboratory (ANL) in conjunction with an industrial partner, General Electric Corp. This program was built on the successful operation of ANL's experimental breeder reactor, EBR-II, a liquid metal (Na) cooled fast reactor and its associated pyrochemical process that enabled the practical recycling of a metallic alloy fuel. However, for political reasons (in 1977, under President Carter reprocessing was halted in the USA because of proliferation concerns about Pu) and economic reasons (readily available supply of low-cost uranium) the USA terminated its fast reactor program in 1994. Likewise, the Superphenix reactor in France was shut down about 5 years later in 1999. The Japanese currently have the most active FBR program in the world with both the Joyo (100 MWth, where MWth stands for megawatts of thermal power) and the Monju (280 MWe) reactors still in operation.

61.4 The “Back-End” of the Nuclear Fuel Cycle

61.4.1 Spent Fuel

To first order, the specific amounts of fission products and transuranic nuclides produced during the operating cycle of a nuclear reactor will depend on the original composition of the fuel and how the reactor is operated. This includes the energy (thermal or low energy, or fast or high energy) and the flux density of the neutrons (number of neutrons/unit area/unit time) inducing the reactions and, the exposure time or time the reactor is in operation. The result is a wide range of radioactive species found in the spent fuel:

- Fission products that range in half-life from very short, days or less, to those that are very long-lived, hundreds of thousands to millions of years. ➤ [Table 61.3](#) lists some of the longer-lived fission products of concern for waste management.
- Unreacted uranium, primarily ²³⁵U and ²³⁸U along with ²³⁶U ($T_{1/2} = 2.4 \times 10^7$ years) formed by neutron capture on ²³⁵U.
- Isotopes of the heavier actinides including Np, Pu, primarily as ²³⁹Pu, and isotopes of Am and Cm.

In general, by volume the uranium isotopes represent about 95% of LWR spent fuel, the fission products ~3.4%, all the plutonium isotopes about 1%, and the minor actinides (MAs) (minor actinides = Np, Am, and Cm) about 0.6%. Of the plutonium isotopes, the fissile isotopes ²³⁹Pu + ²⁴¹Pu account for about two third of the total mass. From ➤ [Table 61.4](#), the nominal isotopic composition of plutonium resulting from the operation of LWRs at discharge is roughly A: 238 (2.5%), 239 (57.7%), 240 (24.3%), 241 (11.5%), and 242 (4.0%).

The relative amounts of the various actinide nuclides in spent fuel as a function of time after discharge from a pressurized water reactor (PWR) are shown in ➤ [Fig. 61.2](#).⁷

The nuclidic and elemental composition of spent fuel will vary depending on the history of operation of the reactor and the extent of fuel burnup where *burnup* is usually expressed in terms of *megawatt-days per metric ton* (MW d/t). As a result, the radionuclide content of spent fuel from thermal reactors can vary in composition not only from reactor type to reactor type (pressurized water reactor, boiling water reactor, high-temperature gas reactor, etc.) but also

■ **Table 61.3**

Some long-lived fission products from a thermal reactor (a typical PWR) after 10 years of cooling of spent UO₂ fuel containing 1 t of U (3.2% enriched) with 33 MW d/kg U burnup at an average flux of $3.24 \times 10^{18} \text{ n m}^{-2} \text{ s}^{-1}$

Fission product	Half-life/year	Activity (TBq/t U)
⁹⁹ Tc	2.13×10^5	0.484
¹²⁹ I	1.57×10^7	0.0012
¹³⁵ Cs	3.0×10^6	0.0098
⁹³ Zr	1.5×10^6	0.068
¹²⁶ Sn	1.0×10^5	0.029
⁷⁹ Se	6.5×10^4	0.0151

Data taken from ref. Choppin et al. (1995).

■ **Table 61.4**

Major and minor actinide content of spent LWR fuel (NAS 1996). Uranium-fueled 1,000 MWe PWR, 150 days after discharge (Benedict et al. 1981)

Actinide isotope	Half-life/year	Kg/year in spent fuel
²³⁴ U	2.5×10^5	3.1×10^0
²³⁵ U	7.1×10^8	2.1×10^2
²³⁶ U	2.4×10^7	1.1×10^2
²³⁷ U	1.8×10^{-2}	9.1×10^{-7}
²³⁸ U	4.5×10^9	2.6×10^4
²³⁷ Np	2.1×10^6	2.0×10^1
²³⁹ Np	6.4×10^{-3}	2.0×10^{-6}
²³⁶ Pu	2.6×10^0	2.5×10^{-4}
²³⁸ Pu	8.6×10^1	6.0×10^0
²³⁹ Pu	2.4×10^4	1.4×10^2
²⁴⁰ Pu	6.6×10^3	5.9×10^1
²⁴¹ Pu	1.3×10^1	2.8×10^1
²⁴² Pu	3.8×10^5	9.7×10^0
²⁴¹ Am	4.6×10^2	1.3×10^0
^{242m} Am	1.5×10^2	1.2×10^{-2}
²⁴³ Am	7.9×10^3	2.5×10^0
²⁴² Cm	4.0×10^{-1}	1.3×10^{-1}
²⁴³ Cm	3.2×10^1	2.0×10^{-3}
²⁴⁴ Cm	1.8×10^2	9.1×10^{-1}
²⁴⁵ Cm	9.3×10^3	5.5×10^{-2}
²⁴⁶ Cm	5.5×10^3	6.2×10^{-3}

from reactor to reactor of the same type. In general, reactors operated to a higher fuel burnup will result in an increase in the content of both the fission products and transuranic elements in the spent fuel. Of course, longer irradiation times will result in the production of more long-lived fission products.

The relative levels of dominant fission products and some actinides elements in spent fuel in terms of ingestion radiotoxicity as a function of decay time after discharge from a PWR is also shown in ► *Fig. 61.2*. In the short-term, fission products with half-lives of 30–50 years dominate spent nuclear fuel and represent the most limiting radiological factor impacting the design of a repository for spent fuel. This is due to the intense gamma radiation and the resulting decay heat associated with the fission products. The heat load initially comes from the decay of ¹³⁷Cs ($T_{1/2} = 30$ years) and ⁹⁰Sr ($T_{1/2} = 28$ years). Since the spent fuel is both highly radioactive and thermally hot, it is usually stored in special cooling ponds on the reactor site. The cooling ponds are water-filled basins with geometrically arranged racks to hold the fuel element to prevent criticality. These cooling ponds serve two purposes. First, the water absorbs the heat from the spent fuel and second, it serves as a radiation barrier to shield workers from the intense radiation.

■ Fig. 61.2

Relative ingestion radiotoxicity of representative fission products and some actinides in spent fuel as a function of time after discharge from a pressurized water reactor (PWR) (NAS 1996) (Courtesy of the Oak Ridge National Laboratory, managed by UT-Battelle, LLC, for the U.S. Department of Energy (1995))

Cooling times can vary depending on the ultimate fate of the spent fuel. Because of the lack of or nonexistence of reprocessing capacity, spent fuel is being held at reactor sites for of the order of 7–10 years. At some sites, spent fuel has been stored in such ponds for over 20 years. For reactor sites in the USA where reprocessing is not an option, the strain on spent fuel storage capacity is problematic for the commercial power industry. Requirements now include the construction of additional wet storage capacity or building containment for above ground dry cask storage for fuel that has been allowed to cool in cooling ponds for at least 1 year. For dry

cask storage, spent fuel is loaded into steel casks that are either welded or bolted shut after an inert gas blanket has been placed over the spent fuel. The casks are then placed in a metal or concrete vault that serves as the radiation shielding. Centralized storage facilities either exist, or are being built, in some countries to manage the spent fuel until it is ultimately taken for reprocessing or prepared for permanent disposal.

After about 100 years, 99% of heat load comes from the decay of the actinides. In fact, strategies for long-term management of spent fuel may require a cooling period of 40–50 years to reduce the heat load on a repository. By storing spent fuel for this period of time in above ground wet or dry storage facilities, the radioactivity decreases to about 0.1% of its original value. After this cooling period, the spent fuel will be easier to handle but nonetheless require encapsulation in appropriate corrosion resistant containers for its long-term management in the repository.

61.4.2 Fuel Reprocessing

In the Reprocessing Fuel Cycle (RFC) option, the unused uranium and the plutonium produced in the reactor are recovered leaving the minor actinides with the fission products as HLW. (The radiotoxicity of these wastes will be significantly less than that of the spent fuel although the toxic lifetime is determined by the minor actinides – neptunium, americium, curium – and, to a lesser extent, by some of the long-lived fission products content of the waste.) As mentioned previously, this was the scenario initially envisioned by the nuclear power industry to reprocess fuel for two reasons:

- Uranium and plutonium would be recovered and recycled to make more energy.
- The volume of material to be disposed of as HLW would be significantly reduced since uranium and plutonium combined comprise about 97% of mass of spent fuel.

Compared with the strategy of once-through burning of fuel in an LWR followed by direct disposal in a repository, the most effective way to reduce the total mass of HLW is to remove the uranium and plutonium, store the uranium, burn the plutonium to make energy, vitrify the remaining waste, and dispose of it as HLW in a repository. In addition, if the uranium is recovered, re-enriched, and returned to the LWR fuel cycle, there is the side benefit of reducing the demand for mining and milling new uranium and the need for enrichment services by about 30%.

In the late 1960s and early 1970s, the combination of the value of the recovered uranium and plutonium, the reduced volume of HLW, and the reduced demand for new uranium and enrichment services appeared to offset the cost of reprocessing, which was considered economically viable. Nevertheless, from the point of view of the USA, uranium is cheap and highly enriched uranium from the weapons stockpiles of both the USA and Russia is available in sufficient supply to be downblended, i.e., mixed with either natural or depleted uranium to make fuel for LWRs for the near future. (Albright 1992; Albright et al. 1997) For this reason and because of concerns about proliferation of nuclear materials, especially plutonium, the USA continues its policy not to reprocess. On the other hand, reprocessing facilities are in operation in the UK at Sellafield (THORP), in France at La Hague and Marcoule, and in Russia at Chelyabinsk (Mayak). Smaller plants are also in operation in India and Japan. Through the years, over 75,000 t of commercial spent fuel has been processed to recover uranium and plutonium worldwide and the annual capacity now stands at about 5,000 t per year (Web 2003e). The nonreusable part of the spent fuel, the fission products, and the minor

actinides, are currently being incorporated into glass and allowed to solidify inside corrosion-resistant canisters through a process called vitrification. The operation of a 1,000 MWe reactor would generate about 12 canisters of vitrified waste annually, each containing about 400 kg of highly radioactive glass (Web [2003f](#)).

61.4.2.1 PUREX, the Industry Standard

Currently aqueous techniques are the main industrial-scale separation methods used in the nuclear power industry. Continuous processes, such as solvent extraction, are preferred over semicontinuous processes such as ion exchange in the nuclear industry because of the volume of materials to be processed and because continuous processes are typically more efficient, more reliable, and show less degradation in high radiation fields. The main steps that are involved in reprocessing spent fuel from commercial (primarily, zircaloy clad, uranium-oxide) fuels include the following: removal of the cladding and dissolution of the oxide fuel using the head-end treatment; chemical separation of U and Pu from the majority of the fission products in what is called the first extraction cycle in the partitioning stage, where Pu is separated from U; purification of the individual fractions of U and Pu using a multiple cycle process; and finally, conversion of the nitrates of U and Pu to metal-oxides.

The gaseous and volatile fission products (primarily Kr, Xe, I₂, and tritium as T₂ and HTO, and RuO₄) are released in the head-end step and treated in an off-gas scrubber system using sodium-hydroxide. Further removal of I₂ may be accomplished by passing the off-gas through filters impregnated with either silver nitrate or potassium-iodide. The recovered iodine is commonly disposed of as a liquid effluent and discharged to the sea. (Raisbeck et al. [1995](#)). Of the rare gases, only ⁸⁵Kr poses a problem because it is produced in significant quantities and it has a relatively long 10.7 year half-life. In contrast, the other Kr and Xe isotopes have considerably shorter half-lives and decay within about a year. The most common method for removal of ⁸⁵Kr is to cryogenically trap it with liquid N₂, separate it, and store it after fractional distillation. In most cases, the gaseous effluents from reprocessing are released directly into the atmosphere in a controlled fashion, although this practice is becoming less favorable.

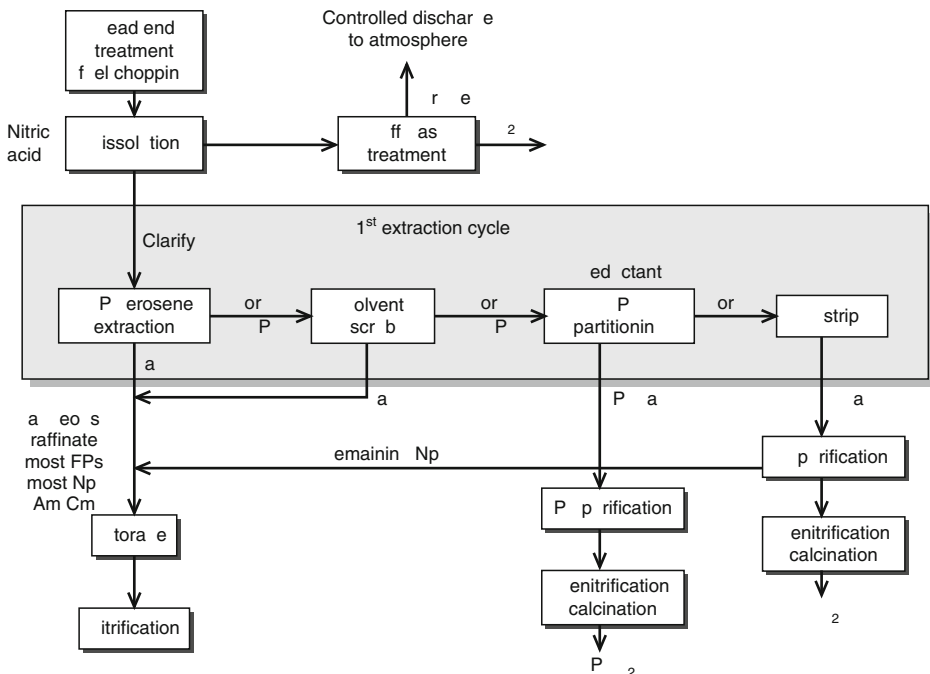

Presently, the PUREX process (Plutonium Uranium Redox EXtraction) is universally employed as the preferred aqueous chemical processing technology for reprocessing irradiated/spent fuels. PUREX has also been the primary separation technology used to separate U and Pu from production reactor fuels in the weapons programs for defense applications. PUREX is a wet chemical process that uses tributyl phosphate (TBP) in kerosene (or dodecane) to co-extract U(VI) and Pu(IV) from a strongly acidic nitrate solution (3–4 M HNO₃) leaving the bulk of the nonvolatile fission products, including the trivalent lanthanides, in the aqueous phase (Culler [1956](#)). The cladding hulls are not dissolved but rather recovered from the dissolver, checked for residual U and Pu, and then disposed of as high-level solid waste. Because Am and Cm exist in aqueous solution as 3+ cations, they are not extracted by TBP and thus behave like the 3+ lanthanides. For comparison, the combined mass of Am and Cm is about one tenth that of the lanthanides, and the lanthanides represent about one third of the total mass of the fission product inventory in spent fuel. Neptunium, whose stable oxidation state is +5 under these high acidity conditions, is extracted only slightly by TBP.

In the partitioning stage of the PUREX process, Pu is reduced to the +3 state by the addition of a reductant (U(IV) or Fe(II) sulfamate), to allow back extraction into a fresh aqueous phase. The U, as U(VI), the residual U(IV), and the small amount of Np extracted during the first

where the subscripts (aq) and (org) indicate the aqueous and the organic liquid phase, respectively. The PUREX process yields two product streams, one containing chemically purified uranium and the other, chemically purified plutonium. The major waste stream is generated in the first PUREX extraction cycle and contains the vast majority of the fission products, the minor actinides, and small amounts of uranium and plutonium lost during processing. This waste stream is often referred to as the aqueous raffinate from the first extraction cycle. By definition, this is a high-level liquid waste stream. The schematic diagram of the PUREX process is shown in [Fig. 61.3](#).

Schematic diagram of the PUREX process

Residual quantities of minor actinides and fission products that are removed from the purification parts of the cycle are usually reduced in volume and then combined in the aqueous raffinate HLW stream. The cladding hulls are managed as high-level solid waste by packaging them in drums and storing the drums in a dry disposal site.

During the PUREX process, solvents undergo radiolysis and degrade as a result of the intense radiation arising primarily from fission product decay. In modern PUREX plants, most solvents are treated to remove these degradation products and then recycled back in to the process. For example, dibutyl- or monobutylphosphate are degradation compounds formed by the radiolysis of TBP. Since these compounds form strong complexes with many of the fission products as well as plutonium, they must be removed from the TBP/kerosene phase as time goes on; otherwise, the desired levels of decontamination will not be achieved in the first extraction cycle. Normally, the compounds are removed by washing the TBP organic phase with successive aqueous phases containing sodium carbonate, sodium hydroxide, and then dilute nitric acid.

Similarly, nitric acid is treated and recycled reducing the aqueous waste generated in the overall process. These wastes can be further reduced by the proper choice of equipment. For example, centrifugal contactors, which can achieve high extraction efficiencies while minimizing the contact time between the aqueous and organic phases, are commonly used to reduce solvent degradation in the first extraction cycle where radiolysis is most problematic. Because of the costs associated with waste disposal, as a matter of economics and sound business practice, considerable attention is paid to eliminating or reducing the number and volume of waste streams in modern PUREX plants. The pursuit of any option involving reprocessing requires building and operating geologic repositories because fission products or alpha-bearing waste from reprocessing are forms of HLW that will require isolation. For an in-depth discussion of the treatment of spent nuclear fuel, see ref. Choppin and Rydberg (1980).

61.4.2.2 Vitrification

High-level liquid waste must be solidified before disposal. Typically, this is achieved by calcining the aqueous HLW waste stream resulting from reprocessing the spent fuel. Calcining converts the aqueous waste into a dry powder containing the radioactivity. The powder is incorporated into borosilicate glass to immobilize the waste. The resulting glass mixture is poured into stainless steel canisters, typically holding hundreds of kilograms of glass. A year's supply of waste from a 1,000 MWe reactor is contained in 5 t of such glass, or about 12 canisters, 1.3 m high and 0.4 m in diameter (Web 2003f). With appropriate shielding, these canisters can be readily transported and stored. This material is also slated for geologic disposal.

61.4.2.3 Recycling plutonium as mixed-oxide fuel (MOX)

Reprocessed plutonium can be used as fuel in specially modified LWRs. With minor modifications, typically adding more control rods to manage the reactivity over the reactor volume, LWRs can be configured to operate using fuel consisting of both uranium and plutonium-oxide or what is termed mixed-oxide or MOX fuel. Over the past 10 years, specially licensed reactors in France, Germany, Switzerland, and Belgium have used MOX fuel to generate electricity. Japan plans to have one third of its 53 reactors using MOX by 2010 (Web 2003g).

MOX fuel is made by mixing plutonium with depleted uranium, a by-product of the uranium enrichment process, or with natural uranium. Two sources of plutonium are available. The first is reprocessed plutonium from commercial spent fuel and the second is weapons-grade plutonium surplus from the nuclear stockpiles of both the USA and Russia (Albright 1992; Albright et al. 1997). These sources, reactor-grade plutonium and weapons-grade plutonium, differ in the content of ^{239}Pu and the minor plutonium isotopes, especially ^{240}Pu . Commercial reactor-grade plutonium is nominally about 55–60% ^{239}Pu and has a relatively high amount ~20–25% of ^{240}Pu whereas weapons-grade plutonium contains greater than 95% ^{239}Pu and a minor amount of ^{240}Pu .

MOX fuel fabrication facilities are currently operating in France, Belgium, the UK, India, and Japan and collectively produce about 460 t per year (Web 2003b). For the fabrication of MOX fuel, the “age” of the plutonium, or rather the time since the plutonium was last separated from americium, is very important. ^{241}Am , which results from the decay of short-lived ^{241}Pu ($T_{1/2} = 14.4$ years), builds up at a rate of about 2 parts per million per month or about 0.5% per year. Because ^{241}Am emits a 60 keV γ ray, additional shielding and remote handling is required during MOX fabrication if the ^{241}Am content becomes greater than 5–6%. As a result, MOX is usually made with recently reprocessed plutonium.

As part of a long-term strategy for reducing the inventory of weapons-grade plutonium, both the USA and Russia expect to construct MOX fabrication facilities in their respective countries and eventually burn plutonium in LWRs. Fabrication plants using weapons-grade plutonium will have to incorporate additional controls to prevent possible diversion of plutonium that is not required at other MOX plants.

In practice, MOX fuel can be made with fairly high (>50%) loadings of plutonium, but to burn such a fuel would require specially designed reactors. Loadings of the order of 5% (for weapons-grade Pu) to 7% (for LWR reprocessed Pu) are more common for use in modified LWRs. The characteristics of MOX fuel containing 5–7% plutonium are very similar to those of the more conventional (4–5% enriched) uranium-oxide fuel. As a result, MOX fuel can be substituted for part of a reactor’s fuel loading without any significant changes in the reactor’s operating conditions and performance. However, reactors burning MOX will typically limit the MOX loading to about one third of the fuel assemblies in the core.

Since most plutonium isotopes have small thermal neutron fission cross sections, the minor actinides build up in the fuel over time and the recycling of plutonium in LWRs has serious limitations. Nonetheless, burning plutonium in MOX fuel using conventional LWRs has two advantages (1) economically, burning plutonium in the reactor produces usable energy and, (2) burning plutonium reduces the inventory and thus prevents the accumulation of separated plutonium resulting from reprocessing commercial power reactor spent fuel. If weapons-grade plutonium is burned as MOX fuel, there are additional advantages over and above reducing the inventory of weapons-grade plutonium. The first is that while in the reactor, the weapons-grade plutonium in the fuel would be protected against diversion by the intense radioactive field of the fission products. This is similar to the argument used by those who are against any reprocessing of fuel and claim that by not reprocessing, plutonium left in spent fuel is protected against proliferation by the fission products in the fuel or what is called the “spent fuel standard” (NAS 1994). Second, while in the reactor, the isotopic composition of the weapons-grade Pu would be degraded and eventually closely resemble reactor-grade plutonium (ca. 65% ^{239}Pu + ^{241}Pu and high ^{240}Pu content). Burning plutonium in MOX fuel reduces the overall radiotoxicity compared with untreated LWR spent fuel but the resulting minor actinides and fission products will nonetheless require disposition in a geologic

repository. Within the commercial nuclear power community, recycling of plutonium in MOX fuel in LWRs is viewed as a mature industry.

61.4.2.4 Recycling U

The uranium recovered from the reprocessing of commercial spent fuel usually contains about 1% ^{235}U , and because the PUREX process does not remove 100% of the fission products and other actinides, reprocessed uranium is slightly more radioactive than natural uranium. The increased radioactivity is primarily due to the presence of other α -emitting contaminants. (According to the International Atomic Energy Agency, IAEA 1977, the level of fission products in reprocessed uranium cannot exceed 19 MBq/kg of U. Similarly, reprocessed U can contain no more than 250 kBq/kg U of other non-uranium alpha activity.) During irradiation, the level of ^{234}U increases over that found in natural uranium. In addition, ^{232}U , not present in natural uranium, is produced by the decay of 2.85 year ^{236}Pu . Although the total accumulation of ^{232}U is small, it decays with a 72-year half-life by α emission down through a chain of other α - and γ -ray emitters including the 1.9 year ^{228}Th . The decay chain finally culminates with ^{208}Tl , a hard γ -ray emitter. The long-lived ^{236}U ($T_{1/2} = 2.4 \times 10^7$ years) is also produced by the (n, γ) reaction on ^{235}U but adds little to the α -activity. The (n, γ) reaction on ^{236}U produces the 6.75 d ^{237}U isotope that decays by beta-emission to ^{237}Np . This decay occurs during storage prior to reprocessing and does not impact the radioactivity associated with reprocessed uranium. In addition to these uranium isotopes, small amounts of plutonium and neptunium left in the uranium fraction after reprocessing add to the α -activity of reprocessed uranium.

For reprocessed uranium to be used again in a reactor, it must again be enriched to about 3.5%. Because new uranium is in plentiful supply, it has not been necessary to re-enrich uranium recovered from reprocessing to meet the requirements for new fuel. If and when it becomes necessary to enrich reprocessed uranium, the potential occupational hazard associated with UF_6 conversion, enrichment, and fuel fabrication processes due to the small amounts of residual fission products in the uranium will have to be addressed.

61.4.3 Direct Disposal of High-Level Waste

At the current time, all the spent fuel identified as waste, all reprocessing waste, and all waste resulting from the isolation of fission products remains in storage as no disposal sites have been established. In the interim, extended storage, either at reactor sites or in a more centralized location, is considered an acceptable waste management strategy. A number of disposal options have been or are being considered including the following:

- Geologic disposal:
 - Subsurface burial (hard rock such as granite, clay, salt, unsaturated tuff)
 - Disposal on the ocean floor in some kind of highly engineered containment.
 - Disposal in glaciated areas, in Antarctica for example.
- Ocean dilution.
- Disposal into space.
- Nuclear transmutation, the conversion of long-lived radionuclides into shorter-lived or even stable nuclides.

Each of these options has serious political, environmental, and/or technical issues that must be addressed. Among the options discussed for disposing of these materials, an international consensus has emerged that deep geologic disposal is the most appropriate means for isolating such wastes permanently from man's environment (NAS 1957).

61.4.3.1 Geologic Disposal

The basic concept of geologic disposal is to contain and isolate the HLW from the environment for an extended (up to tens of thousands of years) period of time. A strategy known as "*defense-in-depth*" is employed in most proposed repository designs. In simple terms, this concept relies on a series of redundant barriers to increase reliability in the safety argument. These barriers generally include (1) the leach-resistant waste form, (2) corrosion-resistant containers into which the wastes are encapsulated, (3) special radionuclides and groundwater-retarding materials placed around the waste containers, commonly referred to as backfill, and (4) the host geological formation. These barriers both retard the transport of radionuclides in groundwater flow, and serve to isolate the waste from man's environment.

It is anticipated that geologic disposal of HLW will be preceded by some period of interim storage, either at the reactor site, at a centralized location or at the disposal site, during which time the temperature and radioactivity of the HLW will decrease systematically. This is in fact the situation by default as no current disposal site exists. Transport of the waste materials from the storage location to the disposal site will be necessary. Under consideration are specially constructed collision-and fire-resistant shipping casks, transported via designated ship, train, or truck. Each national program must address its specific issues. Some type of waste packaging is planned. Liquid wastes resulting from isolation of the fission products or reprocess will need to be solidified before transport, packaging, or disposal.

Conceptually, waste packages will be lowered down vertical shafts or transported into the repository through sloping, horizontal tunnels. Once at the repository, the waste packages will be emplaced into holes predilled into the sides or floor of the repository using equipment developed for this purpose. In some concepts, these holes will then be backfilled with suitable material. Filling the repository may require anywhere from 10 to 50 years or more, depending on the national program. Finally, the repository itself may be backfilled and sealed, including all shafts, boreholes, and tunnels that may have been drilled during repository construction. With a suitable choice of waste packaging, backfill, and geological environment, the radioactive materials should remain isolated from man's environment for many tens of thousands of years.

The long-term safety of HLW disposal can be systematically assessed through predictive modeling of the gradual failure of the engineered barriers (i.e., the waste form, waste package, and backfill) and the subsequent transport to man's environment of radionuclides by groundwater flow. Such safety assessments must be based on a good physical understanding of the fundamental processes involved in the release and transport of radionuclides, as well as those acting on, or likely to act on, the repository and the geological formation. In addition, the potential interplay (coupling) between these processes must be understood. Finally, substantial site monitoring efforts will be needed, involving the collection of data at the surface as well as in situ, at the proposed repository location.

Each country with an interest in HLW disposal is conducting or collaborating on long-term, extensive scientific research programs to understand how better to dispose of this waste

and to understand the possible long-term consequences of the disposition. These enduring missions cover the areas of geology, geochemistry, geophysics, hydrology, materials science, radiochemistry, design engineering, safety analysis, and risk analysis. Several countries have constructed underground research facilities in support of their national programs, including Belgium (Mol), Sweden (Stripa), Germany (Gorleben), Switzerland (Grimsel), and the USA (Yucca Mountain).

There is extensive technical literature in many international, peer-reviewed journals covering the range of technical, political, and risk issues that are being studied by the national programs. The reader is also directed to the Internet web pages of the various national programs to understand the specific conditions and constraints each is striving to understand.

61.5 Partitioning and Transmutation (P&T)

The third and most futuristic back-end option to the nuclear fuel cycle is termed the advanced fuel cycle (AFC). The AFC not only closes the fuel cycle but also offers a potential way around the long-term hazards of radioactive wastes by significantly reducing the radiotoxic inventory. In the AFC option, in addition to the removal of uranium and plutonium, a complex series of aqueous chemical and/or nonaqueous metallurgical operations are performed to selectively remove the minor actinides (minor actinides are neptunium, americium, and curium, and small amounts of the heavier actinides) and some of the long-lived fission products (long-lived fission products are principally, technetium, and iodine) from the HLW before vitrification and disposal. This process is called *partitioning*. Once the minor actinides and long-lived fission products are removed from the waste stream, the idea is to convert them into less radiotoxic or otherwise stable isotopes by a process called “*transmutation*” or “*incineration*.” Transmutation involves using nuclear reactions and processes such as neutron capture followed by fast radioactive decay, (n,2n) reactions with energetic neutrons, or neutron-induced fission to achieve the desired transformation. Transmutation can be accomplished through a combination of LWRs, fast reactors (configured either as breeders or as minor actinide or transuranic [TRU] “burners”), and subcritical, accelerated-based transmutation devices.

In a recent report by the Nuclear Energy Agency (OECD/NEA 2002), a group of experts determined that a 100-fold reduction in the actinide content of HLW would be the minimum requirement for any partitioning and transmutation strategy to be technically viable. Similar arguments have been put forward by experts in the USA, France, and the UK. In the NEA report, this level was set in on the basis of reducing the radiotoxicity of the HLW (assuming uranium-oxide fuel with an average burnup of 50 GW d/t HM and reprocessed 4 years after discharge from the reactor, where HM stands for heavy metal) remaining after removal of 99.9% of the U and Pu, to the natural toxicity level for LWRs that is the equilibrium radiotoxicity of the natural uranium required to fabricate the fuel. Without partitioning and transmutation, this level would be reached by spent fuel after a few hundred thousand years (➤ Fig. 61.2). However, by decreasing the actinide content as defined above, this level would be reached in about 1,000 years – within a time span as pointed out in the report, “during which the HLW container can be expected to fulfill its safety function.” A transmutation scheme that includes only the recycle of plutonium and not the minor actinides, will reduce the long-term radiotoxicity of the waste only by about a factor of five. Therefore, plutonium and the minor actinides have to be considered together for any transmutation scheme to be beneficial. It should be further recognized that any fuel cycle strategy involving partition and transmutation

but not including breeding of plutonium only addresses the long-term waste issues but does nothing to improve the resource utilization of uranium.

61.5.1 Transmutation of Minor Actinides

For the purpose of transmutation, the minor actinides of concern in spent fuel are neptunium, americium, and curium although small amounts of the higher actinides, berkelium, californium, einsteinium, and fermium can be made under the right conditions. The reaction pathways leading to the production of the transuranium elements are given in [Fig. 61.4](#).

For the minor actinides, the transmutation process consists of the capture of one or more neutrons until a more fissionable isotope is formed. For the actinides, the most important transmutation reaction is fission because it results in the removal of the isotope from the minor actinide inventory and replaces it with two typically shorter-lived, less toxic fission fragments. With more energetic neutrons, the $(n,2n)$ reaction is also useful because this reaction transforms fertile actinides with low fission probabilities to more fissile actinides with higher fission probabilities. Neutron capture reactions that produce less fissionable isotopes merely add to the inventory of minor actinides.

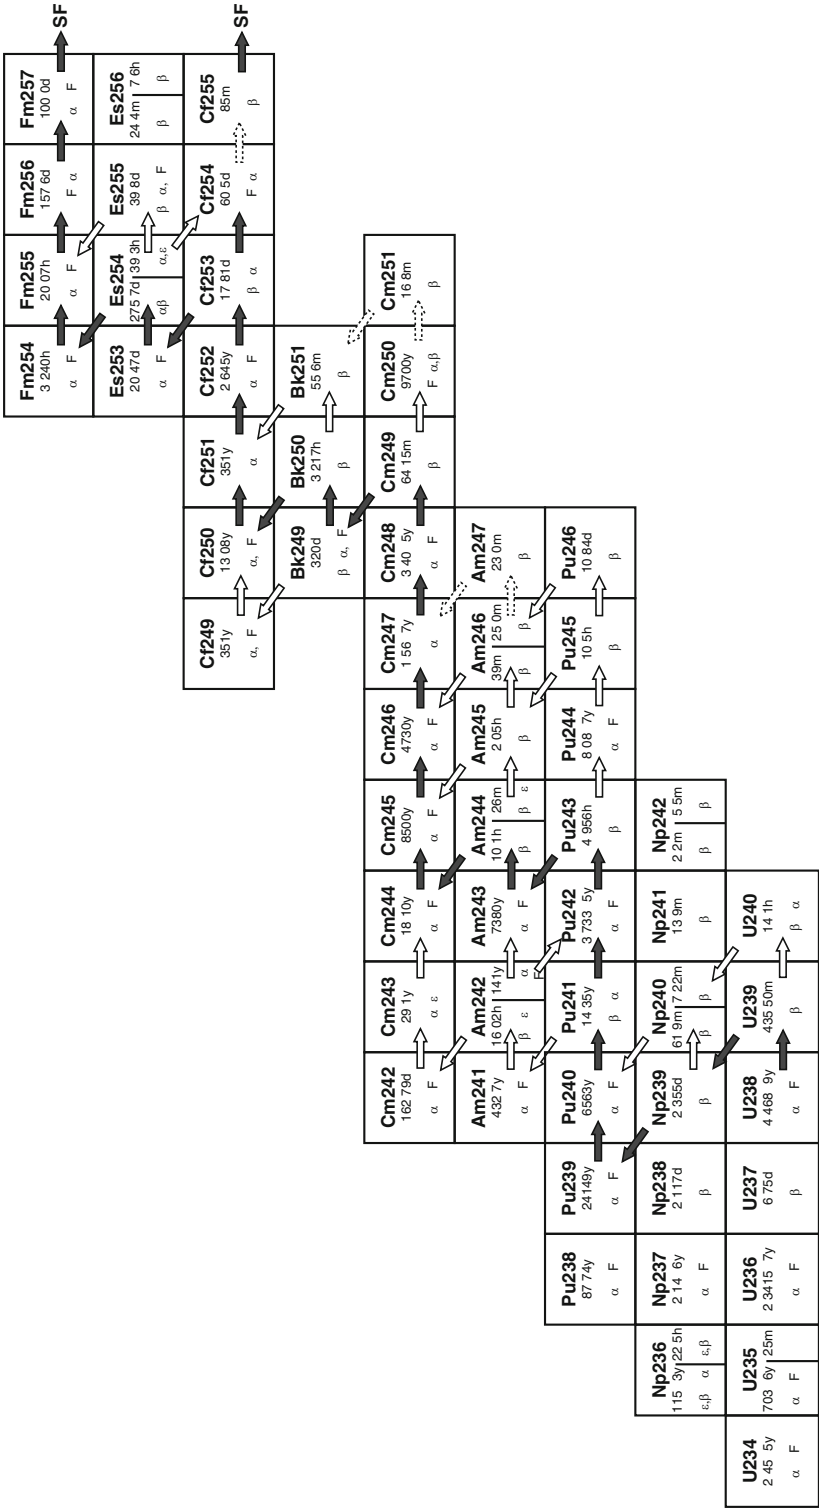

Conventional LWRs alone cannot be used to transmute minor actinides because thermal neutrons are not as effective for inducing the fission reaction. As a result, minor actinides (especially, non-fissile even isotopes of plutonium) build up as a function of time. Therefore, thermal reactors tend to preferentially produce minor actinides. Fast reactors or fast neutron spectrum devices on the other hand tend to more effectively destroy the minor actinides because the probability of fission for both the even and odd isotopes of plutonium fission with fast neutrons is considerably higher than with thermal neutrons. Thus, fast reactors are heavily preferred for the recycle of plutonium and the ultimate complete destruction of all of the minor actinides.

Transmutation of neptunium, which exists as a single isotope ^{237}Np with a half-life of about 2 million years, is possible in both thermal and fast reactors through either homogeneous or heterogeneous means though there seems to be no clear advantage to the heterogeneous route. Putting neptunium in either LWR- UO_2 or MOX fuel, then burning it homogeneously with UO_2 or as a mixture of UO_2 and PuO_2 does not present any significant problems with respect to reactor operation at small loadings (a few percent). Fuel fabrication though is a bit more difficult because ^{237}Np decays to protactinium-233 and ^{233}Pa emits a number of penetrating γ rays that require additional shielding. For conventional UO_2 fuel fabrication, the addition of neptunium adds significantly to both the alpha activity and gamma radiation levels. For MOX fuel fabrication the impact is much less as the presence of neptunium does not add as much to the alpha activity as to the gamma radiation level. However, upon multiple recycling of MOX fuel, neutron capture on ^{237}Np leads to the build up of the short-lived ^{238}Pu ($T_{1/2} = 88$ years).

Plutonium-238 decays by alpha emission with a high decay energy and thus adds considerably to the heat load during processing. Also, because of the high decay energy, neutron emission from (α,n) reactions on light elements from the decay of ^{238}Pu leads to other complications not only for fuel fabrication but also for transportation and storage of fuel. The transmutation of ^{237}Np is important because it is considered to be the dominant long-term dose contributor in performance assessments for geologic repositories in oxidizing environments such as Yucca Mountain in the USA.

Fig. 61.4

Neutron capture pathways of importance for the production of actinides (NAS 1996) (Reprinted with permission from Nuclear Wastes, Technologies for Separations and Transmutation, p. 22, courtesy of the National Academy Press, Washington, DC)

For the transmutation of americium, there are primarily two isotopes with which to be concerned in developing any transmutation scheme. They are ^{241}Am ($T_{1/2} = 460$ years) and the longer-lived ^{243}Am ($T_{1/2} = 7,900$ years) produced by the beta decay of ^{241}Pu and ^{243}Pu , respectively. The 152 year $^{242\text{m}}\text{Am}$ isotope, formed by the (n,γ) reaction on ^{241}Am is also of importance because its decay leads to ^{242}Cm . Curium-242 with its very short 163 d half-life is the most intense α -emitting nuclide in spent fuel. Successive neutron captures on ^{243}Am followed by beta decay lead to the production of curium with masses of 244, 245, and 246. The transmutation pathways for the production and destruction of Am isotopes are shown in

► Fig. 61.4.

As mentioned previously, because of the emission of 60 keV γ rays from the decay of ^{241}Am , fuel fabrication involving substantial quantities of Am is not compatible with using conventional facilities involving contact handling conventional glove-box methods. Instead, a shielded facility with equipment modified to operate remotely will be required. For these reasons, the transmutation of americium via specially prepared heterogeneous targets appears to be the preferred method while transmutation of neptunium in MOX fuels may be more than adequate. The transmutation of ^{241}Am in particular is important because it is the parent of long-lived ^{237}Np .

The transmutation of curium in reactors poses yet another set of problems compared with neptunium and americium because the curium isotopes have both shorter half-lives and higher spontaneous fission branches. In spent fuel, ^{242}Cm ($T_{1/2} = 163$ d) is by mass about 100 times less abundant than the 18 year ^{244}Cm isotope, but its specific activity is about six times higher. Both the high specific activity and the neutron intensity associated with curium makes handling operations and fuel fabrication much more difficult than even americium. The situation is made more interesting because the curium isotopes decay primarily by α emission to produce isotopes of plutonium. Curium-242 α -decays to ^{238}Pu , ^{243}Cm to ^{239}Pu , ^{244}Cm to ^{240}Pu , and ^{245}Cm to ^{241}Pu , etc. For the case of transmuting the most abundant curium isotope by mass in spent fuel, ^{244}Cm , the in-growth of ^{240}Pu causes problems because of its low thermal fission cross section. As a result, transmutation of ^{244}Cm in a LWR is not practical. If, however, curium were to be stored for about 100 years, it would decay to $\sim 2\%$ of its original amount and then the remaining decay product, ^{240}Pu , could be transmuted in a fast reactor along with normal plutonium recycling operations.

When developing transmutation scenarios for the minor actinides (MAs), consideration of their transmutation yield in reactors using either thermal or fast neutrons is important, but not the only factor that must be taken into account. Of equal or even more importance is the impact of loading of MAs on the operation of the reactor. For example, the neutron economy over the reactor volume must be considered as well as issues related to reactivity such as spikes or transients and the associated safety parameters covering situations such as loss-of-coolant incidents. For a discussion of the impacts on reactor performance caused by the loading of minor actinides, see Chap. 2 in ref. OECD/NEA (1999).

With respect to the partitioning stage, in addition to the total amount or inventory of a given nuclide to be transmuted, other factors have to be considered. Several factors become important when determining the optimum partitioning flow sheet. Some of these factors include process chemical yield and/or loss of material, product purity or effectiveness of the separation with respect to fission products and other actinides, impact of decay properties in terms of decay heat and neutron emission and, of course, the generation of secondary wastes. For a more detailed discussion of challenges associated with partitioning actinides for transmutation see Subchapter 3.4 in ref. OECD/NEA (2002).

61.5.2 Transmutation of the Long-Lived Fission Products

The fission products that are the most important long-term risks associated with spent fuel are technetium, (exists only as ^{99}Tc), iodine, and possibly cesium. See [Table 61.3](#) for a list of other long-lived fission products. The transmutation process for fission products is basically the capture of a neutron (or several neutrons) followed by beta decay until a less toxic (shorter-lived) or stable isotope is formed. For technetium (i.e., for β^- decaying ^{99}Tc with $T_{1/2} = 2.13 \times 10^5$ years) and iodine (i.e., stable ^{127}I and β^- decaying ^{129}I with $T_{1/2} = 1.6 \times 10^7$ years), the transmutation can be accomplished in thermal reactors through the following pathways:

For both technetium and iodine, capture of a single neutron followed by β^- decay results in the production of stable isotopes of ruthenium and xenon, respectively. Further, as the irradiation proceeds, additional neutrons can be captured but these products are also stable. In practice, the transmutation of technetium and iodine in conventional thermal reactors will be difficult for several reasons. First, because these are major fission products, they are produced in high yield and thus result in large inventories that must be separated from the HLW and transmuted. Second, the thermal neutron capture cross sections are not particularly large and therefore much higher neutron fluxes are required to significantly reduce the inventory in a reasonable amount of time. Third, the available neutron flux from conventional LWRs is too small (10^{13} neutrons $\text{cm}^{-2} \text{s}^{-1}$) to achieve the required level of transmutation in a reasonable length of time.

For cesium, the problematic isotope is ^{135}Cs but transmutation is possible by capture of a neutron followed by beta decay to produce the stable ^{136}Ba isotope. However, ^{135}Cs is not the only cesium isotope present in spent fuel. The short-lived ^{137}Cs ($T_{1/2} = 30$ years) isotope and stable ^{133}Cs are both present in about the same amount as ^{135}Cs . In theory, you can transmute ^{137}Cs to produce ^{138}Ba , which is stable, but the intense gamma radiation from ^{137}Cs makes fabrication of transmutation targets or mixing cesium back into fresh fuel impractical. On the other hand, transmuting stable ^{133}Cs creates more ^{135}Cs by neutron capture on ^{133}Cs to form ^{134}Cs . Because ^{134}Cs does not decay immediately but rather has a half-life of about 2 years, it would be present long enough in the reactor to capture another neutron and produce more ^{135}Cs . The only way around the problem of producing additional ^{135}Cs from ^{133}Cs would be to first isotope separate ^{133}Cs from ^{135}Cs before beginning the transmutation. This process is not practical for two reasons: (1) the highly radioactive ^{137}Cs isotope would make handling the material extremely difficult and (2) isotope separation is a very costly process. Similar arguments can be made for transmuting the long-lived isotopes of zirconium (^{93}Zr), selenium (^{79}Se), and tin (^{126}Sn).

Although some of the long-lived fission products have thermal neutron capture cross sections suitable for transmutation in reasonable irradiation times, others do not and would require reactors with very high neutron fluxes to reduce inventories significantly. As a result, dedicated reactors with large thermal fluxes and/or dedicated accelerator-driven systems

(ADSs) with thermal neutron fluxes of the order of 10^{16} neutrons $\text{cm}^{-2} \text{s}^{-1}$ are being proposed.⁸ Fast neutron capture cross sections for most long-lived fission products are several orders of magnitude smaller than those for thermal neutrons making transmutation by fast reactors less appealing. Again, because of the relatively low transmutation rates for long-lived fission products, transmutation of these radionuclides is expected to be very expensive.

In general, transmutation of long-lived fission products, although theoretically possible, is very difficult. It will require significant development to be successful, and economically, is not very compelling. Fission products under transmutation conditions are only consumers of neutrons, and unlike the actinides, they do not produce additional neutrons useful for transmutation. Consequently, the product of the capture cross section and the neutron flux must ensure faster neutron capture than the decay rate of the radionuclide for it to be a realistic candidate for transmutation. For this reason, without prior isotopic separation the transmutation of only a few long-lived fission products, namely iodine and technetium and, possibly ^{107}Pd , are feasible. Thus, the most prudent way to minimize the long-term radiological impact of most long-lived fission products is to separate and immobilize them in specially designed, stable waste forms.

61.5.3 Strategies for the Transmutation of Minor Actinides and Long-Lived Fission Products

A number of different strategies for transmuting the minor actinides have been suggested. In general, the different approaches depend on trade-offs between the effectiveness of the partitioning steps (chemical yields and acceptable losses of the desired elements) and the degree of transmutation that can be achieved by various types of devices.

Currently, there are two schools of thought on the transmutation of actinides present in LWR spent fuel. The first addresses in a systematic way the *utilization of plutonium* as an energy source and the management of the minor actinides as a waste product. It also allows for advances in technology to be incorporated in the process as they become available. In this scenario, the fuel cycle is closed in an evolutionary way. In successive steps, beginning with recycling plutonium in LWRs and then later, in fast reactors using MOX fuel and conventional reprocessing technology, plutonium is recovered and burned to produce energy. The final steps involve different methodologies aimed at significantly reducing or eliminating the inventory of minor actinides. One of the ways is to gradually reduce the inventory of minor actinides by irradiating them as special targets (heterogeneous recycling) in conventional reactors. In the end, however, dedicated fast spectrum devices with multiple recycling enabled by nonaqueous or “pyroprocessing” must be implemented to completely eliminate the minor actinides.

The second approach is quite different – to never separate plutonium and the minor actinides during the processing of LWR fuel. Here, the principal driver is to reduce the risk for proliferation of plutonium rather than reduce the long-term radiological impact of commercial spent fuel. The waste stream in this case contains all of the transuranic (TRU) elements and is managed as a single unit. To accomplish the transmutation of this waste stream, a “TRU burner” is required that operates in a closed cycle where the wastes are recycled multiple times. Further, to be effective, nonaqueous chemical processing will be necessary to minimize the time between irradiations and shorten the overall recycle time. The main difference between the nonaqueous scheme in the evolutionary approach and this one is that in the former, plutonium would first be removed by conventional wet chemical processing and only the minor actinides sent forward and later reprocessed using nonaqueous methods.

The waste stream from the IFR concept was designed to contain only fission products and little or no transuranium elements. In the IFR concept, the reactor and the reprocessing/fuel fabrication facilities are colocated and all fuel handling operations from fueling and defueling through reprocessing and fuel fabrication are all carried out remotely behind extensive shielding. This process allows fuels that are much more radioactive to be handled safely and reduces any vulnerability associated with proliferation of plutonium in a truly closed fuel cycle.

Because of wide use of thermal reactors and its associated infrastructure for power production, it is unlikely that in the future the nuclear industry will ever move toward a strategy based solely on fast reactors. It is more likely that the industry will evolve to “reactor parks” where thermal and fast reactors are used to generate power as well as manage the resultant wastes that are produced.

61.5.4 Partitioning Schemes for the Minor Actinides and Long-Lived Fission Products

In order to realize the AFC and significantly reduce the inventories of minor actinides and possibly, certain long-lived fission products, advances are required in the chemical processes used to separate or partition these elements from spent fuel. Two approaches are being considered. One is based on aqueous processes that are either variations or extensions of the conventional PUREX process. The other is based on nonaqueous processes. (Coops et al. 1983) In some of the AFC scenarios, combinations of both aqueous and nonaqueous processes are envisioned. For example, in addition to separating uranium and plutonium for recycle as fuel, aqueous processes could be used for the initial separation of selected long-lived fission products and the minor actinides from spent fuel. Nonaqueous processes have a clear advantage in transmutation schemes requiring multiple recycle in dedicated transmutation devices where minimizing the time between fuel discharge and fuel reprocessing is critical. This is because aqueous processes cannot accommodate the decay heat and the intense radiation fields from “fresh” spent fuel. In addition to developing new chemical processes, a significant amount of development is needed to make targets of minor actinides and long-lived fission products compatible with the appropriate transmutation devices.

61.5.4.1 Improved PUREX Process

Over the past 10 years, modifications to the PUREX process have made it possible to more effectively separate neptunium. To effect the efficient separation of Np within the conventional PUREX process, Np is oxidized to VI state by nitrous acid and is extracted in the first cycle along with U and Pu into the organic phase. The extracted Np(VI) follows the uranium stream and is later separated during the second purification cycle of uranium. In the RFC, the neptunium is sent to vitrification and disposed of as HLW; but in an AFC option, the neptunium can be blended with MOX fuel or fabricated into special targets for later transmutation. The other minor actinides, americium and curium cannot be separated by reasonable modifications to the PUREX process. These elements will require the addition of special processing steps to separate them from the PUREX high-level waste stream.

Modifications to the traditional PUREX process can also lead to the separation of two of the long-lived fission products, technetium and iodine. During dissolution, 10–20% of the

technetium remains as an insoluble residue with the noble metals Ru, Rh, and Pd with the cladding hulls. The technetium that *does* dissolve in the nitric acid is Tc(VII) in the TcO_4^- form and is extracted by TBP. Subsequently, technetium can then be scrubbed from the organic phase. Iodine is released as a gas in the dissolution step and is separated by simply trapping it from the off-gas. Like Am and Cm, other fission products of potential concern with respect to waste disposal, Cs and Sr, and probably Pd, Se, and Sn cannot be removed by reasonable modifications to the PUREX process. However, separation schemes to remove Sr and Cs from HLW using crown ethers, calixarenes, zeolites, and dicarbollides are currently under investigation (Horwitz et al. 1990, 1991; Esimantovskii et al. 1992; Kumar et al. 1997; Dozol et al. 2000; Jain et al. 1995; Selucky et al. 1979).

The reprocessing of conventional LWR-MOX fuel with a view of recycling the transuranium elements (TRU) and burning them either in fast reactors or in dedicated transmutation devices is conceptually possible in present PUREX reprocessing plants. The same PUREX process used for the removal of transuranium elements from HLW from the reprocessing of once-through LWR- UO_2 fuel from conventional nuclear power plants can be used for MOX. However, reprocessing of MOX fuel is more difficult because the radiotoxicity is about eight times higher for MOX compared with once-through spent LWR- UO_2 fuel. Subsequent reprocessing of recycled MOX fuel will undoubtedly require dedicated facilities with more shielding and remote handling capabilities and new, nonaqueous processes.

61.5.4.2 Aqueous Schemes for the Separation of Minor Actinides from HLW from PUREX

A number of aqueous processes to separate minor actinides from HLW are under investigation in various laboratories around the world (Mathur et al. 2001; Horwitz and Schulz 1999; Musikas 1999; Madic 2000). Some of these processes are relatively mature and have been tested on a pilot plant-scale with either simulated or actual wastes while others are in their infancy. By far, the largest number of separation schemes have been developed to separate the trivalent lanthanide elements, Ln(III), from the trivalent actinide elements, An(III) in HLW. This separation is difficult not only because the Ln(III) behave similarly to the An(III) (are similar in size and exist as 3+ cations in aqueous solution) but also because they are present in HLW in quantities that are a factor of 10 higher than the amount of Am and Cm combined. In addition, the Ln(III) constitute about one third of the total mass of all the fission products in the HLW stream from PUREX. If the An(III) are to be efficiently transmuted, it is important that Ln(III) be removed because some Ln(III) have high thermal neutron absorption cross sections and thus would interfere with the process. Once the Ln(III)–An(III) are separated from the remaining fission products, the An(III) are normally selectively stripped in a second step. In some waste management strategies, Am and Cm would be handled and either transmuted or stored separately. Under this scenario, the separation of Am from Cm would be required. However, separating Am from Cm is even more difficult because both are trivalent cations in solution and their ionic radii differ by only 0.1–0.2 nm. (Shannon 1976; Shannon and Prewitt 1969, 1970)

The *TRUEX process*, developed at ANL in the early 1980s (Schulz and Horwitz 1988; Mathur et al. 1995), was found to be a very efficient process for co-extracting the An(III) with the Ln(III) from HLW. The process uses a phosphine oxide derivative, CMPO(*n*-octyl-phenyl-di-isobutyl-carbamoylmethyl-phosphine-oxide) to co-extract the An(III)–Ln(III)

elements from a strong nitric acid solution. As a result, the TRUEX process is directly applicable to the HLW stream coming from PUREX. Although selective stripping steps can be used to remove Am and Cm, coupling TRUEX to a process such as TALSPEAK results in the best An(III)–Ln(III) separation. The *TALSPEAK process*, developed at Oak Ridge National Laboratory (ORNL) in the 1960s (Weaver and Kappelmann 1964; Kolarik et al. 1972; Liljenzin et al. 1984; Persson et al. 1984) uses HDEHP (di-ethyl-hexyl-phosphoric acid), an acidic organophosphorus extractant, to co-extract the An(III)–Ln(III) and then the An(III) are selectively stripped by contacting the organic phase with an aqueous phase containing a strong complexing agent such as glycolic acid or DTPA (di-ethylenetriamine-pentaacetic acid). Since the complexing agent forms a stronger complex with the An(III), the An(III) are back extracted into the aqueous phase leaving the Ln(III) behind. The Japanese developed a similar process to co-extract an An(III)–Ln(III) and then to selectively strip the An(III) using DPTA. The Japanese process (Tachimori et al. 1979, Tachimori and Nakamura 1982; Morita et al. 1991) used *DIDPA* (di-isodecylphosphoric acid) for the co-extraction step.

Other processes that are being investigated for the co-extraction of An(III) and Ln(III) include TRPO and DIAMEX. *TRPO* under development in China (Zhu et al. 1989) uses a trialkyl phosphine oxide to co-extract the An(III)–Ln(III) from a solution containing low to moderate concentrations of nitric acid (~ 1 M) and then back extracts both into a high nitric-acid solution. The high nitric-acid medium makes it difficult to subsequently separate the An(III) from the Ln(III). The *DIAMEX* (DIAMide EXtraction), developed in a collaborative effort by France and UK, (Musikas and Hubert 1987; Cuillerdier et al. 1991; Musikas and Schultz 1992; Weigl et al. 2001) uses non-phosphorous-based compounds, the malonamides as extractants. These extractants appear to be similar in efficiency to CMPO but offer the advantage of producing no solid secondary waste because the diamide extractants upon combustion yield only carbon dioxide and water.

In addition to TALSPEAK and DIDPA, other separation schemes of note that are being developed for separating the An(III) from the Ln(III) include those based on ligands with nitrogen-donor atoms such as tripyridyltriazine and ligands with sulfur-donor atoms such as Cyanex 301, a commercial product consisting primarily of bis (2,4,4-trimethylpentyl) dithiophosphinic acid. (Vitorge 1984; Musikas 1984, 1985; Ensor et al. 1988; Chen et al. 1996; Zhu 1995)

For the separation of Am from Cm, the only processes that offer promise are SESAME and one based on the precipitation of Am(V). *SESAME*, being developed in both France and Japan, is a process by which, under strong oxidizing conditions, Am(III) is oxidized to Am(VI) and then separated from Cm(III) by extraction. The French work (Donnet et al. 1997; Chartier et al. 1998) uses a heteropolyanion catalyst coupled with electrolysis to affect the oxidation. Ammonium persulfate is used for the same purpose in the SESAME process by the Japanese (Madic 2000). Am(V) produced either chemically or electrochemically and then precipitated as a double carbonate is the basis for the other process (Yakovlev and Gorbenko-Germanov 1956).

There are advantages and disadvantages to all of the processes just described. Some are easier to implement than others. Some require adjustment of parameters such as pH or nitrate concentration. Some have problems with third phase formation and solvent degradation or become impractical for industrial applications because of the limited loading capacities of the extractants. In all cases, however, adding separation steps to the PUREX process to remove the minor actinides will generate additional secondary waste streams that will have to be managed.

61.5.4.3 Advantages of Nonaqueous Processes for Partitioning and Transmutation

Alternatives to aqueous processing or “dry” or nonaqueous processing techniques have been tried but none, until recently, have been used on a “true” industrial scale for fuel reprocessing. Examples of these include separations based on (1) differences in volatility of the halides, especially fluorine compounds; (2) molten salt (liquid–liquid) extraction where fuel dissolved in a molten salt is then contacted with a heat resistant low volatility second phase such as 100% TBP or a liquid metal; and, (3) electrorefining, where controlling the cell potential results in removal of a metal from a molten salt by the selective deposition (reduction) on a cathode.

Probably the most inviting and challenging R&D area impacting waste management for the advanced fuel cycle is the development of nonaqueous processes. Because of the higher burnup needed for transmutation as well as the need for multiple recycling with minimum cooling time between fuel discharge and reprocessing, nonaqueous processes offer several important advantages. Nonaqueous processes are much more radiation resistant compared with aqueous processes and thus they can be used to reprocess spent fuel after considerably shorter cooling periods. Other advantages include the potential to produce much smaller quantities of secondary waste and waste forms suitable for long-term disposal, the ease of recycling of reagents used in separations, and finally, the compactness of equipment reduces the physical size of the plant needed, thus capital costs are reduced. Currently, the major drawback is that separation factors are usually smaller requiring multiple stages to achieve the relatively high levels of decontamination. Also, processes must be conducted under highly controlled atmospheres, e.g., dry argon, to avoid hydrolysis and precipitation reactions. Nonaqueous processes typically have a rather limited throughput because these are usually operated as batches rather than as continuous processes. However, this is not a severe limitation in a transmutation scenario because after the initial processing of the spent fuel, the volume of material to be processed once the transmutation cycle begins is only a fraction of the initial fuel volume.

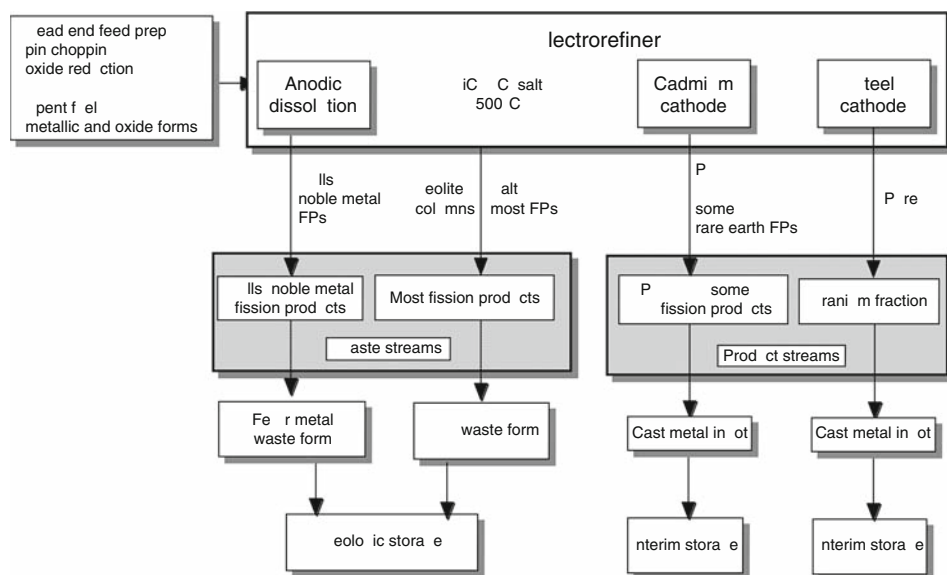

Nonaqueous Processing: Electrometallurgical Treatment: ANL

Currently, nonaqueous separation schemes are under investigation in several countries including the USA, Russia, and Japan. Probably the most advanced nonaqueous processing scheme to date has been developed at ANL (NAS 2000). This process termed “electrometallurgical processing” has been demonstrated on the engineering scale and used recently by ANL to successfully process driver fuel and blanket spent fuel from the Experimental Breeder Reactor (EBR-II). EBR-II *driver fuel* consists of highly enriched uranium metal alloyed with about 10% Zr and clad in stainless steel. The *blanket fuel* is depleted uranium metal that also uses stainless steel cladding.

Briefly, the electrometallurgical treatment, shown schematically in ► Fig. 61.6, involves chopping the spent fuel into small pieces and placing it in an anode basket inside an electrorefiner vessel containing a LiCl/KCl salt mixture heated to about 500°C. Prior to electrolysis, an oxidant such as CdCl₂ or UCl₃ is added to the salt. Upon passage of a constant electrolysis current between the anode basket and a steel cathode, elements that form very stable chloride compounds (e.g., actinides, alkali, alkaline earth, and rare earth elements) dissolve into the salt leaving the less stable chloride compounds (e.g., Cd, Fe, Nb, Mo, and noble metals) with the cladding hulls in the anode basket.

■ Fig. 61.6

Schematic diagram of ANL's nonaqueous electrometallurgical process used to reprocess spent fuel from an experimental fast breeder reactor (EBR-II) (NAS 2000) (Reprinted with permission from Electrometallurgical Techniques for DOE Spent Fuel – Final Report, p. 21, courtesy of the National Academy Press, Washington, DC)

The electrolysis is carried out under controlled current conditions such that principally U^{3+} is reduced to the metal at the cathode. After a period of time, the cathode is removed from the electrorefiner and the U metal is harvested after the adhering salt is removed by volatilization in a vacuum furnace. The U is then cast into an ingot in a high-temperature furnace and stored. ANL also demonstrated a variation to this flow sheet that uses a liquid Cd cathode in addition to the steel cathode. The Cd cathode permitted the separation of Pu, the transuranium elements, and some rare earth fission products from the salt. Without the Cd cathode, these elements remained along with most of the fission products in the salt. The salt was subsequently processed by adding zeolite, heating to adsorb the salt into the zeolite, adding glass, and then hot isostatically pressing the mixture to form a glass-bonded sodalite ceramic waste form. The cladding hulls, noble metal fission products, and any unoxidized material that remained in the anode basket were subjected to removal of adherent salt by volatilization and converted to a metallic waste form by adding more Zr and cast into an ingot in a furnace.

By changing the head end treatment steps, other types of fuel can be accommodated in this nonaqueous process. For example, an initial Li/Li₂O step can be added to convert oxide fuel to the metallic form. To be compatible with the electrometallurgical treatment just described, the electrorefiner requires the spent fuel to be in a metallic form.

This electrometallurgical process with some modifications and additional development could be used in transmutation schemes involving other fuel types such as metal-oxides and nitrides and in situations where cooling periods as short as 3–5 months are required. ANL has already developed an electrochemical head end process to convert oxide fuel to the metallic form by reducing the oxide in a LiCl/Li₂O molten salt bath. The resulting metal fuel could then

be electrorefined using the process just described for EBR-II fuel. For an in-depth description and assessment of ANL's electrometallurgical process for the processing of EBR-II core and blanket fuel, see (NAS 2000).

A variation of the PUREX process is being proposed by the US Department of Energy as a possible alternative partitioning scheme for the transmutation of wastes. This aqueous process called *UREX*, only removes uranium from spent commercial LWR fuel and leaves plutonium in the HLW stream with the other minor actinides and fission products. Nonaqueous pyroprocessing, a variation of the ANL electrorefining process, is then proposed to be used to separate both the plutonium and minor actinides so that they can be transmuted in an ADS. For further information related to potential modifications of this process for other accelerator transmutation of waste applications, see ANL-99/15 (1999).

61.5.5 Transmutation Devices for the Advanced Fuel Cycle

For the AFC to be most effective and reduce the inventory of minor actinides at a reasonable rate, dedicated devices that produce a “hard” or “fast” neutron spectrum will be required. Such devices include the advanced liquid metal reactors (ALMRs), a fast reactor configured to operate as an actinide “incinerator” rather than “breeder” and accelerator-driven systems (ADSs). Fast reactor technology discussed earlier in this chapter is relatively mature whereas the development of ADS is in its infancy. Accelerator-based waste transmutation programs are ongoing in France, Japan, USA, and CERN.

An ADS facility consists of (1) a high power proton accelerator; (2) a subcritical target that produces a high neutron flux upon bombardment with high-energy protons; (3) a blanket system that utilizes this intense source-driven neutron flux to fission actinides and transmute fission products; and, a support chemical processing plant. The heart of the system is the subcritical target where an intense (>100 mA), high-energy (1–2 GeV) proton beam impinges on a high Z target to produce neutrons in a process called spallation. The effectiveness of an ADS target is usually given by the number of neutrons produced per incident proton and is linearly proportional to both the atomic number and density of the target. For this reason, targets such as molten lead or lead/bismuth eutectic are being proposed as the spallation source. Accelerator-driven systems producing 40 or more neutrons per incident proton are also being proposed. The waste material is loaded into the blanket where it is “incinerated” by capturing one of the neutrons causing it either to fission or to be converted to a short-lived or stable isotope. This process therefore reduces the radiotoxic inventory of the waste material. The heat produced from the transmuter, (the combination of the target and blanket) can then be used to generate power, $\sim 10\%$ of which can be used to run the accelerator, and the remaining 90% can be put on the power grid.

Unlike fast reactors that operate on the criticality principle where the nuclear reaction is sustained, ADS systems are subcritical. When the proton beam is off in an ADS, no neutrons are created and no nuclear reaction occurs. An often overlooked key component of an ADS is the supporting chemical processing plant. Within the plant, separation processes are used to first partition the spent fuel to obtain the waste material that is introduced into the ADS and then later to support multiple recycle, fuel fabrication, and finally the production of the final waste forms acceptable to a geologic repository. All of these activities are crucial to the success of transmutation using ADS and considerable R&D is needed to make this a reality.

For an in-depth comparison of fast reactors and accelerator-driven systems for transmutation of actinides and long-lived fission products, see (OECD/NEA 2002). For more information on accelerator transmutation of waste (ATW) program in the USA, see refs. Jarvinen et al. (1992), LANL (1999), and DOE (2001).

61.5.5.1 Future of P&T

Japan, France, and the USA are the most active pursuers of partitioning and transmutation technologies. In addition, several international groups (NEA, IAEA, and the EC) are pursuing studies. Each organization regularly publishes its progress, status, and future activities, with many of these reports being available on the respective Web sites.

Japan has recently completed Phase I of their program, having demonstrated a P&T process with expected performance. R&D work is being conducted by JNC, JAERI, and CRIEPI. This work will need to be coordinated with the restructuring of the FBR program. The Japanese are proposing cooperation among domestic and international organizations to efficiently use experimental facilities that will be needed in the R&D program. It is anticipated that the P&T R&D plan will be reviewed again in 2005, especially with respect to FBR's being used jointly for power generation and transmutation.

France's goal is to demonstrate the scientific feasibility of transmutation in various reactor types by 2006. This includes the feasibility of downstream separation from reprocessing and conditioning of separated long-lived radionuclides. These are joint collaborative efforts with government, industry, and academia. Progress is reviewed annually by the National Evaluation Commission.

In the past several years, the US program has changed significantly. The program's budget doubled from fiscal year 2000 to 2001 and allowed for an expanded experimental program. The new program *Advanced Accelerator Application* (AAA) combines two former programs: the defense Accelerator Production of Tritium (APT) and the civilian Accelerator Transmutation of Waste (ATW). AAA has four principal objectives:

- Demonstrate the practical performance of an accelerator-driven subcritical multiplier;
- Demonstrate the viability of transmutation for waste and spent fuel management;
- Enhance the Nation's nuclear science and advanced technology education infrastructure;
- Provide a more robust backup tritium production capability for national security.

The accelerator-driven test facility (ADTF) envisioned to be operational by 2010 will be the program's focal facility.

Within the EC, a technical working group has been established to develop a 10-year R&D plan for ADS. The goals of their activities are to

- Reduce the risks associated with radioactive waste using transmutation;
- Develop a technical plan that could lead to a demonstration of experimental ADS in 10 years;
- Identify advantages this program could have in the nuclear community, and how competence can be maintained.

Several reports discuss, in greater detail, the various national programs (NEA 2000, 2002; DOE 2001). In response to continued growth in population and economic prosperity, and growing understanding of both resource limits and environmental impacts of fossil fuel use, it is likely that nuclear power use will grow substantially, both nationally and globally over the

next half century. If so, advanced nuclear power systems must be designed and deployed to meet modern safety and security standards, meet nonproliferation imperatives, and resolve the lingering nuclear waste issue. Current US energy policy points toward continued and increasing use of nuclear energy, and acknowledges the potential benefits of moving to advanced fuel cycles. DOE⁹ has begun a cooperative effort with industry for near term deployment of new nuclear reactors in the USA. These plants would be current technology (Generation-III) and require little R&D. However, it only makes sense to attack the barriers to building new nuclear power plants if society intends to use large amounts of nuclear energy for a long time. Sustained, large-scale use of nuclear energy creates the need to transition to a sustainable fuel cycle, where uranium is recycled and used entirely, and both plutonium and minor actinides are cycled to minimize the long-term environmental hazard of the waste. Several DOE programs are moving toward R&D on advanced nuclear fuel cycles and advanced (Generation-IV) reactor systems. At some scale of nuclear energy deployment, fuel cost, availability, waste management cost, and capacity will create a compelling need for a fully closed fuel cycle, which maximizes the energy derived from fissionable resources and minimizes wastes. While it is not yet known at what point this will become compelling, it is known that it will take many decades to complete the transition to such a sustainable nuclear fuel cycle.

61.6 Editors' Notes

1. Radiotoxicity of a radionuclide is inversely proportional to its maximum permissible concentration, MPC. Ingestion radiotoxicity – see the vertical axis of [Fig. 61.2](#) – can be expressed as a minimum of water that is still drinkable if the unit mass of the substance containing the given radionuclide is dissolved in it (p. 2802).
2. MWe means megawatts of electric power (p. 2802).
3. For more details on gaseous diffusion and gas centrifugation see [Sects. 51.4.4 and 51.4.5, respectively, in Chap. 51, Vol. 5](#), on “Isotope Separation” (p. 2804).
4. For details of LIS see [Sect. 51.7.3 in Chap. 51, Vol. 5](#) (p. 2804).
5. See [Fig. 4.10 in Chap. 4, Vol. 1](#), on “Nuclear Fission” (p. 2806).
6. A fertile nuclide by definition means a non-fissile nuclide, which, however, can be converted into a fissile nuclide via neutron-induced nuclear reactions (p. 2807).
7. What [Fig. 61.2](#) actually shows is the ingestion radiotoxicity of the various nuclides. However, larger radiotoxicity means larger activity/number of atoms/mass of the given radionuclide per mass unit, i.e., the shapes of the curves are also characteristic of the relative amounts of radionuclides (p. 2808).
8. For more details about ADS see [Sect. 61.5.5 in this Chapter](#), and [Sect. 57.4.2.5 in Chap. 57 of this volume](#) on “Technical Application of Nuclear Fission” (p. 2823).
9. DOE means US Department of Energy (p. 2832).

Acknowledgments

The authors would like to thank Prof. W. F. Kinard and Dr. W.G. Halsey for their insightful comments made during the preparation of the manuscript. The authors also gratefully acknowledge the technical editing efforts of Ms. D. Schliech and Ms. K. Ramirez for their

careful attention to detail in preparing this document in the proper camera-ready format. This work was performed under the auspices of the US Department of Energy by the Lawrence Livermore National Laboratory under Contract No. W-7405-Eng-48.

Abstract: A short history and treatment of the various aspects of nuclear forensic analysis is followed by a discussion of the most common chemical procedures, including applications of tracers, radioisotopic generators, and sample chronometry. Analytic methodology discussed includes sample preparation, radiation detection, various forms of microscopy, and mass-spectrometric techniques. The chapter concludes with methods for the production and treatment of special nuclear materials and with a description of several actual case studies conducted at Livermore.

62.1 Introduction

62.1.1 Nuclear Smuggling

The end of the Cold War in 1991 was accompanied by the disassembly of the USSR into a dozen independent countries. The ensuing social instabilities and decline in safeguarding special nuclear material (SNM) resulted in elevated occurrences of nuclear smuggling and sales of radioactive contraband on the international black market (Williams and Woessner 1996; Stone 2001). The large majority of these trafficking incidents to date have been scams or hoaxes, but seizures of significant quantities of weapons-grade or weapons-usable SNM have occurred.

During the mid-1990s, interdictions of weapons-usable SNM were characterized by relatively large quantities and frequencies. For example, in 1994, three reported seizures were indicative. In St. Petersburg, Russia, 3.05 kg of 90% high-enriched uranium (HEU), likely from Elektrostal in the Russian Federation, was confiscated from three perpetrators by the Federal Security Service. Later in the year, the German BND conducted a successful undercover

operation that resulted in the arrest of a Colombian national (with ties to a drug cartel) and two Spaniards. They had smuggled 560 g of mixed U/Pu-oxide and 210 g of ^6Li -enriched Li metal into the Munich airport in a lead-reinforced suitcase. The Pu component was approximately two-thirds of the mixed-oxide (MOX) powder and was enriched to 87.6% in ^{239}Pu . Finally, 2.7 kg of 88% HEU, probably stolen from Obninsk, were intercepted in a parked car in Prague.

By the beginning of the new millennium, however, seizures of worthy material became less frequent and the associated SNM specimens less substantial. Similar to the world of illicit drug trafficking, the tactic of nuclear smuggling seemed to evolve toward the presentation of smaller samples for technical analysis by possible customers, with the claim of much larger available quantities secured elsewhere. Thus, 4 g of 73% HEU in the trunk of a car was interdicted at the Bulgaria–Romania border in 1999. From the forensic analyses of the nuclear material, as well as those of the accompanying collateral evidence, the SNM was most likely derived from the former Soviet Union (Moody et al. 2005). The smuggler claimed that he had obtained the U specimen in Moldova, and a very similar seizure occurred in Paris 2 years later.

The most recent episodes of nuclear smuggling cited in the open literature have occurred in Georgia (Sokova and Potter 2008). In 2003, guards at the Georgia–Armenia border arrested a man with 170 g of $\sim 90\%$ HEU. Three years later, in a sting operation in Tbilisi, Georgian security forces arrested a Russian national and accomplices and confiscated ~ 80 g of $\sim 90\%$ HEU. The origin of these materials is still unknown or unconfirmed, but is suspected to be Russia from the ensuing investigations.

62.1.2 Historic Considerations

Although some investigators have asserted that nuclear forensic analysis (NFA) is a new science, invented at the Institute for Transuranium Elements, Karlsruhe, in March 1992 (e.g., Mayer et al. 2007), such claims are based merely on the start of analysis of smuggled nuclear materials by a non-weapons laboratory. The authors believe this view to be an unduly narrow definition of NFA and prefer a broader perspective. In fact, the contemporary methods and analytes of interest in NFA derive largely from Cold War nuclear weapons programs and intelligence operations. Although advances in instrumentation (such as ICP-MS and SIMS) have improved analytic capabilities in the current era, measured species have remained largely unchanged, with some exceptions for novel application areas such as specimen chronometry and geolocation.

Indeed, the first presently unclassified NFA activities with tangible results were likely those conducted by Enrico Fermi at the first nuclear weapon test, the US Trinity event on July 16, 1945. He made the first prompt explosive yield estimate by measuring the displacement of small pieces of paper dropped as the blast wave passed (Rhodes 1986, p. 674). A few hours later, Fermi and Herb Anderson sampled Trinity ground zero in lead-lined tanks equipped with trap doors in the floor to sample post-shot debris from the crater. Later NFA (radiochemical) gave a yield of 18.6 kt for Trinity (Rhodes 1986, p. 677). (1 kt of TNT = 4.184 TJ.)

Three weeks later, Kazuo (Paul) Kuroda made fallout measurements after the detonation of a “new kind of bomb” over the Aioi Bridge in Hiroshima, and correctly deduced that ^{235}U was the fissile fuel in *Little Boy*. Such activities are most definitely considered within the scope of NFA today.

Indeed, a broader view of the discipline would also incorporate one of the more impressive NFA investigations ever conducted. In 1972, French scientists measured a 0.003% discrepancy

in uranium isotopic composition in ore from the Oklo mine in Gabon, Central Africa. The ensuing investigation into prehistoric geologic conditions, existing Nd and Ru isotopic residues, and other considerations led to the stunning forensic inference of a natural nuclear reactor that had operated at an average power output of ~ 100 kW for a few hundred thousand years approximately 2 billion years ago (Cowan 1976).

The present authors both applied and developed NFA techniques within the US nuclear test program from the early 1980s to the cessation of testing in 1992, but the authors were but third-generation radiochemistry staff at the Livermore and Los Alamos National Laboratories. The true pioneers of NFA came much earlier. The results of their investigations were classified and therefore not published in the open literature, but such restriction did not negate the enterprise.

The narrow view of NFA would also exclude the authors' investigation into the January 1992 fatal explosion of a purported "cold fusion" apparatus. Although cold fusion was (and is) not mainstream nuclear science, the authors consider it their first NFA in the public domain, and it comprised both nuclear source forensic exhibits and associated collateral evidence (Grant et al. 1995a, b).

62.1.3 Facets of Nuclear Forensic Analysis

What is true of late, however, is that NFA has attracted international attention beyond the confines of weapons laboratories and intelligence agencies. A driving force behind this elevated political and public interest has been the confluence of increased transnational terrorism, indiscriminant use of chemical and biologic weapons of mass destruction (WMD) against civilian populations, suicide bombers in general (September 11, 2001 in particular), and widespread popularity of the CSI television series. One consequence of this focused attention by persons of diverse backgrounds has been the delineation of various NFA activities into categories based on effort areas.

62.1.3.1 Improvised Nuclear Device (IND) and Radiologic Dispersal Device (RDD)

While nuclear smuggling, nonproliferation, weapons diagnostics, and other topics are all of interest in NFA, two formidable weapon types are of special concern. The improvised nuclear device (IND) is a hypothetical, ad-hoc apparatus, fabricated by a subnational group or rogue nation, containing fissionable and perhaps fusionable materials, and designed to produce a nuclear explosion. A nuclear weapon stolen from a weapons state would generally also be considered an IND and within the purview of this area of concern. A radiologic dispersal device (RDD) is also a terrorist contrivance that contains radioactive material(s). However, the radionuclide(s) need not have nuclear yield potential, and the design is intended to disperse the material within its near environment via conventional high explosives (HE).

Because of the enormous difficulty and expense to produce either HEU or weapons-grade plutonium, an IND is considered a low-probability threat. However, it is one with potentially catastrophic consequences. Just the opposite is true of an RDD. The widespread commercial availability of large industrial radiation sources, such as ^{60}Co , ^{90}Sr , ^{137}Cs , ^{192}Ir , and others,

makes the prospect of an RDD attack much higher probability, but with greatly diminished effects in comparison to an IND.

Some nations addressing nuclear terrorism are heavily focused on the IND threat, choosing to weight the possible consequences of such an attack over the probability of its occurrence. This choice is reflected in their level of funding, training, and exercises for nuclear counterterrorism, which include NFA. Other nations are completely focused on the RDD danger, playing the probability odds for their preparedness posture.

The adopted nomenclature for these effort areas is somewhat contrived. Despite the fact that both the IND and RDD depend on radioactive substances at their core, the non-fissionable isotopes have been labeled “rad” materials, while SNM is differentiated as “true” nuclear stuff. Thus the clumsy term “rad-nuke” has entered the lexicon to arbitrarily divide radionuclides into categories based on terrorist end use or terror-induced results. (Does ^{239}Pu in an IND metamorphose into rad material if the device fizzles, but the HE disperses the device across the neighborhood? The answer, apparently, is yes.) Consequently, an original all-WMD acronym, “NBC” (for nuclear, biologic, and chemical), has today become “CBRN” or “CBRNE” (explosives) as descriptors for various national technical units, expert panels, government offices, and trade magazines.

62.1.3.2 Pre-det and Post-det

Another line of demarcation separates whether an IND or RDD was successfully exploded (a post-detonation scenario), or whether the device was interdicted or failed to fire (pre-detonation situation). This differentiation reflects very different incident consequences, as well as the ensuing NFA.

For an IND, the post-det world is predominantly an extrapolation of methods and measurements from radiochemical and other diagnostics developed during nuclear weapons testing. Assays are typically made of residual actinide species, major and high-value-minor fission products, and induced activation products. These data allow inferences or conclusions about device composition, design, performance, near environment, and other characteristics. Analyses of a post-det RDD would also have roots in historic radiochemistry, and would be supplemented by conventional forensic analyses. The latter would include high-explosive residues, perpetrator-specific specimens (DNA, hair, latent prints), and other possible evidence (tool marks, fibers, paints, tapes, paper, etc.). The problem of contaminated evidence (conventional criminalistics examinations of radioactively tainted exhibits) is likely most acute for a post-det RDD, as a successful IND should vaporize any such specimens proximate to the device.

The pre-det investigation of either an IND or RDD would seek to detect many of the same radionuclear analytes as for a post-det inquiry. Therefore, materials analysis of IND components would focus on actinide species and their isotopic ratios to estimate threat credibility. Fission products, perhaps at trace levels, could provide clues about radiochemical separation tactics used for reprocessed material. Even activation products, if the nuclear pit contained Pu, might supply information on the time elapsed since a device was assembled.

Much more NFA is possible in a pre-det investigation. Interrogation of nuclear source materials in an IND would additionally investigate, for example, device design, metal

components and their trace-element compositions, densities, alloying species, initiator, possible boost apparatus, and general metallurgy. With inputs of measured forensic data and physical design, performance potential of the weapon may be assessed via detailed computer calculations. Analyses of collateral criminalistics evidence would also be paramount in this situation.

For an RDD in either scenario, collection and analyses of conventional forensic specimens would be most important because attribution of the radioactive source would be less imperative than for an IND. Criminalistics examinations would be the most likely to identify and locate the perpetrators.

62.1.3.3 Source and Route

Pre-det investigations of smuggled nuclear samples at Livermore have been conveniently divided into source and route (or pathway) efforts for optimum information return. Source analyses allow assessments of the identity and quality of the nuclear material, as well as perhaps its origin, production modality, and supply potential. Route analyses are the province of criminalistics examinations and geolocation measurements. They provide insights into the identities of the traffickers, their methods and habits, pathway(s) of the material after legitimate control was lost, frequency of shipment, and potential end-user applications. More detailed discussion of source and route forensic analyses can be found in (Moody et al. 2005).

Some NFA investigators believe that too much focus is placed on the IND post-det scenario at present. Their opinion is that, should such a catastrophe become reality, the counterterrorism enterprise of any organization had failed in a most fundamental way, and perhaps more assets should have been devoted to enhanced surveillance, improved radiation instrumentation, device detection, etc. A similar view is sometimes expressed for source NFA in the pre-det arena. Although very important to know the identity and isotopic composition of a radioactive threat, additional source analyses would perhaps provide nuclear production details, facility identification, and the time since last chemical processing. However, were the material or an assembled weapon stolen, such source information would likely be but nominally productive in attribution efforts. Indeed, only pre- or post-det (RDD) route analyses have the potential to identify terrorist personnel and places of interest, a point sometimes unappreciated by NFA programmatic efforts.

62.2 Chemical Aspects of Nuclear Forensic Science

Radiochemical separations are the backbone of much of nuclear forensic science, since they provide a means by which small forensic signatures may be isolated from an overwhelming radiochemical background due to the sample matrix. This is particularly important for chronometry, where one compares analyte concentrations that can differ by 15 orders of magnitude or more. For the measurement of the relative concentrations of analytes that are isotopes of different chemical elements, the key issue is accurate chemical yielding. When two or more analytes of the same element have vastly different concentrations, standard chemical separations cannot address the issue of dynamic range; in this case, a collection of techniques known as radiochemical milking can be used to determine the minor isotope.

62.2.1 Commonly Used Chemical Methods in the Radiochemical Forensic Laboratory

Chemical methods apply to the separation and purification of radioactive substances in the same way they apply to stable substances. A radiochemical separation is judged in terms of both the yield and the purity of the separated material; this is particularly important when analyte concentrations are low or contaminant levels are high. Purity and fractional recovery are often evaluated with the tracer technique. Radiochemical and mass spectrometric detection methods are quite sensitive, and it is possible to work with trace amounts of analyte. However, radiochemical procedures involving the presence of an isotopic carrier (which can also function as a tracer) are often simpler to design than are carrier-free procedures; losses from adsorption on vessel walls or suspended particles may negatively affect the recovery of the analyte in a tracer-level sample.

In any chemical separation scheme, the original sample becomes divided into at least two fractions through the application of a driving force across a functional boundary in such a way that the resulting fractions have a chemical fingerprint that is distinctly different from that of the initial sample. Typical driving forces are concentration gradients, solvent flow, or electrochemical potential. Typical separation boundaries include immiscible liquid–liquid or liquid–solid interfaces. The effectiveness of the separation of contaminant A from desired material B can be expressed in terms of a decontamination factor D :

$$D = \{[A]_i \times [B]_i\} / \{[A]_f \times [B]_f\}, \quad (62.1)$$

where $[A]_i$ and $[B]_i$ are the concentrations of A and B in the initial sample, and $[A]_f$ and $[B]_f$ are their concentrations in an isolated chemical fraction of A or B. The decontamination factor can be calculated for one or more steps in a chemical process or for the process as a whole.

Separation by precipitation is a procedure that is familiar to most chemists, and is a common method used in the analytical chemistry laboratory. At the tracer level, where the concentration of an analyte nuclide is small, the concentration in solution before precipitation is too low to permit precipitation by exceeding the solubility of even the most insoluble of compounds. It is necessary that a carrier be present that can be removed from solution by precipitation.

There are two types of carrier (Hahn 1936). The first is referred to as an isotopic carrier, and is a compound of the element of which the trace analyte is an isotope. For instance, 12.8-day ^{140}Ba can be carried from solution by adding a soluble barium salt, mixing to give a uniform solution, and precipitating BaSO_4 with the addition of a soluble sulfate. The second is termed a non-isotopic carrier, or co-precipitant. In the elements beyond bismuth, where there are no stable nuclides, co-precipitation is particularly important. Non-isotopic carriers are often used to separate “weightless” radioactive material when it is necessary to retain a high specific activity. An example of co-precipitation: ^{140}La is a 40 h activity that builds up to transient equilibrium in samples containing ^{140}Ba . It is carried on BaSO_4 , which is a non-isotopic carrier for tracer lanthanum. The amount of ^{140}La carried on BaSO_4 can be decreased through the addition of a lanthanum isotopic carrier, which holds the ^{140}La in solution.

With radiochemical forensic samples, isotopic carrying is used mainly for yielding; the presence of excess isotopic carrier can interfere with subsequent mass-spectrometric and radiation-counting measurements. Non-isotopic carrying, however, has many applications to the radiochemical analysis of the actinides. Iron hydroxide is very effective in carrying the

actinides. Lanthanum fluoride is often used to concentrate plutonium, americium, and curium from large solution volumes; it is a poor carrier of uranium. Typically, these precipitates are separated from their associated mother liquids through centrifugation and decantation rather than by filtration, unless a counting source is being prepared.

Solvent extractions are also commonly performed in the radiochemical forensic laboratory. Unlike precipitation, solvent extraction does not require visible amounts of material for success; in fact, if a carrier is present, the analyst must pay attention to the solubility of the analyte in the various phases. Generally, liquid–liquid extraction systems involve intimate contact between immiscible liquid phases, which leads to a partitioning of the analytes between the two phases.

The extent to which a given solute B distributes itself between organic and aqueous phases is usually represented by a partition coefficient, P :

$$P = [B]_{\text{org}}/[B]_{\text{aq}}, \quad (62.2)$$

where $[B]_{\text{org}}$ and $[B]_{\text{aq}}$ are the concentrations of analyte B in the organic and aqueous phases, respectively. For an ideal system, in which the solutes do not alter the properties of the solvents, and where solvent immiscibility is not affected as a result of the extraction, the partition coefficient is independent of the amount of analyte present. With carrier present, there are very few extracting systems that approach the ideal (Grahame and Seaborg 1938; Myers et al. 1950). P tends to decrease with an increase in temperature. The use of volumes of different size also affects P ; this is particularly important in partition chromatography. P is also affected by the addition of an inert diluent to the organic phase.

The solvent extraction method with which the analytical chemist is most familiar involves placing both liquid phases in a separatory funnel and agitating by hand to effect the partition; due to issues of contamination control and limited solution volumes, this implementation is little used in nuclear forensic analysis. Often, phases are mixed in a capped centrifuge cone using a vortex mixer; this is particularly convenient in a gloved box, where the loss of manual dexterity impedes the manipulation of a separatory funnel and stopcock. Phase separation is facilitated through the use of a centrifuge.

Reversed-phase partition chromatography is a special case of solvent extraction: An extractant is attached to an immobile support, and an immiscible mobile phase flows past. Molecular species containing the analyte partition between the two phases. It is usually the organic phase that is attached to the support and the aqueous phase that flows (Hulet 1964; Bark et al. 1967). The standard solvent extraction processes are carried out on the column. The organic phase is distributed on the surface of small, equally sized particles that are placed in a glass tube, called a chromatographic column.

The radioanalytical chemist finds several applications of the use of solvent extractions as mass-reduction steps prior to performing chromatographic procedures, particularly following non-isotopic carrying steps, or for samples whose dissolution included a substrate or container. For example, if iron hydroxide has been used as a co-precipitant, the subsequent removal of the iron can be accomplished by extraction from a hydrochloric acid solution into hexone (methyl isobutyl ketone). Nickel can be removed from a nitric acid solution by extraction into a chloroform solution of dimethylglyoxime.

Extractions involving the chelating agent thenoyltrifluoroacetone (TTA) in an organic solvent are particularly useful in the isolation of uranium, neptunium, and plutonium from nitric acid solutions; some of the radiochemical milking experiments used to determine the

concentrations of small amounts of ^{236}Pu , ^{232}U , ^{233}U , or ^{243}Am in the presence of much larger amounts of other isotopes of the same elements begin with a TTA extraction. Extractions involving organophosphorus compounds leave residual phosphates in the aqueous phase that can interfere with subsequent purification steps; consequently, this class of reagents, used in procedures that are common in the chemical industry, is rarely employed in the nuclear forensic laboratory.

Ion exchange is a powerful technique for the radiochemical isolation of most of the species of interest to the nuclear forensic analyst (Hyde 1956; Katz and Seaborg 1957). Ion-exchange resins usually consist of a cross-linked styrene-divinylbenzene polymer to which ionizable functional groups are attached. These materials are fabricated into small spherical beads over which an aqueous solvent is passed. Optimal separations are obtained when the beads are all approximately the same size, which helps prevent channeling of the solvent through a column packed with the beads. Resin beads are available in most mesh sizes from about 18 mesh down to colloidal size, but most resins of use in the radioanalytical laboratory are between 100 and 200 mesh ($\sim 0.152\text{--}0.075\text{ mm}$).

Resins are classified as either cation-exchangers or anion-exchangers, depending on the nature of the incorporated functional groups, which are derived from strong or weak acids or bases. A typical strong cation-exchange resin contains sulfonic acid groups, which exchange a coordinated hydrogen ion for another cation under the proper conditions. For example:

Similarly, a typical strong anion-exchange resin contains quaternary amine bases, which exchange hydroxyl ions with anions from the solvent, for example,

The capacity of the resin for binding analyte ions is usually expressed in terms of milliequivalents per milliliter of wet resin, and depends on the structure of the polymer and the nature of the functional group. For a standard strong anion-exchange resin, a typical capacity is 1.2 meq/ml; for a strong cation-exchanger, a typical capacity is 2.0 meq/ml.

Because of the limited chemical capacity of most resins, an increase in the size of the sample being processed often requires an increase in the size of the chromatographic column. This limits the size of samples input to chromatographic steps to less than a gram. However, the intrinsically high separation factors and high chemical yields attainable with column chromatography make this technique among the most powerful available to the radioanalyst (Girardi and Pietra 1976).

There are two techniques for separating ions by means of an ion-exchange column, referred to as “elution” and “chromatographic.” In the elution technique, ions are adsorbed from a solution that is passed through the column. Some ions have no affinity for the resin and pass through the column unhindered, while others interact strongly with the resin and are adsorbed in a narrow band at the top of the column. This is often used as a concentration step from large solution volumes. In chromatographic ion exchange, the solution of ionic species is passed through the column and the ions migrate down the column at rates dependent on their affinities for the functional groups on the resin. The most weakly adsorbed ions are the ones that appear first in the effluent. The successful separation of the analytes from one another depends on loading the sample in a small volume. Many cation-exchange procedures operate on the chromatographic principle.

The isolation of a chemical fraction is only the first part of a radiochemical analysis. The relative concentrations of the analytes must be measured, a chemical yield applied, and the absolute concentrations of the analytes in the original sample must then be derived. Chronometric determinations can be based directly on relative concentrations, often with smaller propagated errors. Concentration data arise from mass spectrometry or by radiation counting. Samples submitted for mass spectrometry typically require no special handling beyond the requirements of cleanliness; these samples are submitted in small volumes of dilute nitric acid or as a dry deposit, preferably in a Teflon container. For radiation counting, the geometric extent of the radionuclide sample, and whether liquid or solid, affects the efficiency of the detector and the accuracy with which the concentrations of the radionuclides can be determined.

62.2.2 Tracers in Inorganic Analysis

The basis of the application of radiochemical separations to the measurement of concentrations involves the use of tracers to follow the yield of an element through a chemical process. A tracer may consist of a short-lived radionuclide, measured through radiation counting, or a long-lived or stable separated nuclide that can be measured through mass spectrometry. The tracer nuclide is usually selected so as not to be present among the analytes, or is added in excess to significantly change the relative concentration of that isotope. A tracer is usually added to a nuclear forensic sample by the analyst, but there are cases in which it arises in situ through decay processes. The nuclear forensic analyst's main use of the tracer technique involves the determination of the efficiency of a series of general chemical operations, such as precipitation, filtration, solvent extraction, ion-exchange chromatography, volatilization, etc.

The identity and amount of a radioactive tracer that should be added to a particular sample depend on several factors. The analyst must be careful to add enough tracer activity that it can be accurately measured in the final sample; this includes considerations of decay during chemical separation and purification prior to counting, the efficiency of the radiation counter for detecting the characteristic emissions of the tracer nuclide, and the level of activity of any radioactive sample analytes that might interfere with the observation of the tracer. Similarly, the analyst must not add so much tracer that it overwhelms the signature of the other nuclides of the same element or causes extra purification issues if it spreads into another chemical fraction. In traditional radiochemistry, quantities of radionuclides that are quite undetectable by ordinary means emit easily detectable levels of radiation; in the nuclear forensic laboratory, it is often assumed that a "weightless" amount of a radionuclide is added as a tracer activity.

Use of a radioactive tracer to determine a chemical yield is part of a broad suite of techniques known as "isotope dilution": The analyst wishes to measure the amount of a stable element X in a sample from which a pure chemical fraction of X can be only incompletely separated. A tracer aliquot containing a known mass of X (M_X), labeled with a radioactive isotope of X characterized by radioactivity of a known intensity (C), is added to the sample. A separation is performed to obtain a pure sample of X of mass M_S and a measured radioactive intensity of C' which is less than C due to losses in the separation procedure; M_S is determined by any suitable standard quantitative-analysis method (e.g., gravimetry of a stoichiometric compound of X). The specific activity of the chemical fraction, C'/M_S , is equal to the specific activity of the element X in the mixture after tracing but prior to

separation, $C/(M_X + M_0)$, where M_0 is the mass of element X in the original sample. This yields the isotope dilution formula

$$M_0 = (C/C')M_S - M_X. \quad (62.5)$$

When the tracer aliquot contains only a “weightless” quantity of X, one arrives at the classical tracer equation

$$M_S/M_0 = C'/C; \quad (62.6)$$

The fraction of the initial activity C present in the final sample is equal to the fraction of the initial mass M_0 in that sample.

With the introduction of sensitive mass spectrometric techniques, the tracer concept has been expanded to include the use of long-lived radionuclides and separated stable isotopes. Often, an element may not have an available isotope with properties suitable for radiation counting (e.g., Ne or Al). In experiments in which a mass spectrometric measurement is to be performed on the analytes, incorporation of a more appropriate tracer, rather than a radiometric tracer, may be expedient, since it relieves the analyst of an unnecessary measurement. For example, in forensic radiochemistry, one is frequently required to measure the isotopic content of a mixture of naturally occurring isotopes in a uranium fraction through mass spectrometry; this is a consequence of the long half-lives of the uranium isotopes, which makes the radiation counting of small samples difficult. Since the mass-spectrometric measurement must be made anyway, one often avoids adding tracer aliquots of 69-year ^{232}U or 6.7-day ^{237}U , both of which are easily measured through their radioactivity, and add instead 1.6×10^5 -year ^{233}U or 2.34×10^7 -year ^{236}U tracer. If a known amount of ^{233}U (M_{233}) is added to the original sample, which contained no ^{233}U to begin with, then the amount of ^{238}U (M_{238}) in the original sample can be determined from the isotopic ratio of $^{238}\text{U}/^{233}\text{U}$ in the chemical fraction:

$$M_{238} = M_{233} \times \left(^{238}\text{U}/^{233}\text{U} \right)_{\text{atom}} (238/233), \quad (62.7)$$

where the factor $(238/233) = 1.0215$ converts the $^{238}\text{U}/^{233}\text{U}$ atom ratio determined by mass-spectrometric atom counting to a mass ratio.

Even when the sample contains ^{233}U as an analyte, the use of ^{233}U as a tracer is not precluded. In this case the techniques of isotope dilution are called a “spiked/unspiked” analysis. The sample is subdivided quantitatively into two or more aliquots. One of these aliquots is traced with a known amount of ^{233}U (the spiked fraction), while a second aliquot is untraced (the unspiked fraction); since the results of the analysis of the unspiked fraction enter the determination only through an isotope ratio, the aliquot need not be quantitative. A purified uranium fraction is recovered from each sample, and they are then analyzed by mass spectrometry. The unspiked isotope ratio, $(^{238}\text{U}/^{233}\text{U})_{\text{atom,U}}$, and the spiked isotope ratio $(^{238}\text{U}/^{233}\text{U})_{\text{atom,S}}$, combined with the mass of ^{233}U in the tracer aliquot, M_T , can be used to determine the mass of ^{238}U in the spiked aliquot, M_{238} :

$$M_{238} = M_T(238/233) \left[\left(^{238}\text{U}/^{233}\text{U} \right)_{\text{atom,U}} \times \left(^{238}\text{U}/^{233}\text{U} \right)_{\text{atom,S}} \right] / \left[\left(^{238}\text{U}/^{233}\text{U} \right)_{\text{atom,U}} - \left(^{238}\text{U}/^{233}\text{U} \right)_{\text{atom,S}} \right] \quad (62.8)$$

Isotope ratios measured in the unspiked sample can be used with M_{238} to determine the masses of each of the other uranium isotopes in the sample.

Another example involving the use of a mass tracer: Gallium is commonly alloyed with plutonium in weapons applications; the admixture of a small amount of gallium stabilizes the δ -plutonium metallic phase, which is more workable than is α -phase plutonium. Though there are appropriate radioactive isotopes for classical tracer applications (e.g., 78 h ^{67}Ga or 14 h ^{72}Ga), these nuclides are often not available on a convenient schedule. Natural gallium consists of two stable isotopes, ^{69}Ga (60.1%) and ^{71}Ga (39.9%), so tracing with stable isotopes is possible. Separated stable isotopes have also been used to determine the concentration of iron in plutonium. Since nominally separated isotopes are usually not completely monoisotopic, the mathematics of calculating a chemical yield becomes more complicated; a recursion relationship is often set up, which converges in two-to-three iterations.

When a given nuclide is used to trace the yield of its element in a chemical reaction, the fundamental assumption is that the chemical state of all isotopes of the same element is identical; this is ensured through mixing and performing isotopic-exchange reactions. In tracer chemistry, it is important that there be no isotopic fractionation. If a significant period of time has elapsed between the characterization of the concentration of the tracer nuclide and the measurement of its concentration in the final sample, then an appropriate radioactive decay correction must be applied.

In a simple chemical apparatus, isotopic fractionation occurs by two mechanisms. The first is isotopic disequilibrium, in which the mass difference between the isotopes causes a significant difference between the equilibrium constants or rates of reactions in which the two isotopic species are involved. The magnitude of the isotopic fractionation is greater for traced elements in which there is a large fractional difference between the mass number of the tracer and that of the traced element; this effect is considered negligible for isotopes of all elements with atomic numbers >10 (Duncan and Cook 1968).

The second mechanism by which isotopic fractionation can occur is through hot-atom chemistry. In a radioactive decay process, the daughter nuclide is often formed with an energy in excess of its surroundings, attaining an oxidation state differing from both its precursor atom and from other isotopes of the same element already in solution or in the sample matrix. This can be demonstrated by an example: The main isotope of neptunium present in a heavy element sample is 2.14×10^6 -year ^{237}Np . It is usually present at a concentration that requires chemical purification prior to detection and quantification. Consequently, a yield tracer is required to relate the concentration in the final fraction to that of the original sample. For this purpose, 2.35-day ^{239}Np is used. A common way of tracing with ^{239}Np is to add an aliquot of α -decaying 7,400-year ^{243}Am , in which the ^{239}Np decay daughter is in secular radioactive equilibrium. In this way the analyst can “cheat” the decay process; the concentration of ^{239}Np does not begin decaying with its characteristic half-life until a chemical separation from americium disrupts the equilibrium. During this time, the analyst can ensure that exchange has taken place between the sample atoms and the tracer atoms; however, the separation must be effected immediately after the isotopic exchange because of hot-atom chemistry. The ^{239}Np concentration in equilibrium is constant, but is not stagnant. The ^{239}Np atoms that decay are constantly replaced by ^{239}Np atoms supplied by the ^{243}Am decay process, which may not be in the same oxidation state or chemical form as the other neptunium atoms. This can result in the chemical yields of ^{239}Np and ^{237}Np in a purified neptunium fraction being unequal. For truly precise tracing of neptunium, the ^{239}Np tracer should be chemically purified from ^{243}Am prior to addition to the experimental sample and isotopic exchange.

The chemical behavior of trace elements can be unpredictable (Lavrukhina et al. 1967); to avoid these effects, “carriers” are added to the sample. Under the proper conditions, an added carrier can serve the function of a tracer. If several milligrams of an element are placed in solution with a radionuclide that is one of its isotopes, and a stoichiometric compound exists such that the element concentration can be determined by weight, the gravimetric yield of the carrier can be applied to the radionuclide (Ruzicki 1968). This was a popular technique in the determination of the yields of the rare-earth fission products; aliquots containing known amounts of the rare earths were added to dissolved reactor targets, after which the individual rare earths were isolated, precipitated as oxalates, and fired to stoichiometric oxides. The chemical yields determined from the weights of the samples were applied to the radionuclide concentrations determined from radiation counting to give the final fission-product yields.

62.2.3 Radiochemical Milking

The dynamic range in the measurement of nuclide concentrations required by chronometry makes it impossible to perform accurate age assessments without radiochemical separations. However, when the nuclide to be determined is present as a minor component in an overwhelming concentration of isotopes of the same element, chemical separations are of limited use. In these instances, the method of radiochemical milking has proven to be valuable.

In a milking experiment, a purified sample is prepared of the element that includes the trace nuclide to be measured. The time at which the sample was purified must be well characterized. The sample is set aside for a predetermined length of time to allow radioactive decay to partially replenish the daughter activities. At an accurately determined time, the daughter activities are isolated from the parent activities and are purified; the decay interval and the half-lives of the nuclides relate the isotope ratios among the daughter activities to the isotope ratios among the parent activities. If one or more concentrations of the parent isotopes are known, and the daughter of the nuclide to be quantified can be observed and measured, the concentration of the “invisible” isotope of the parent element can be determined.

This is best illustrated by an example: The ^{236}Pu content of a plutonium sample cannot be directly measured by any means at the analyst’s disposal. Even though ^{236}Pu has a relatively short half-life (2.858 years), its characteristic decay γ -rays are weak; its emitted α particles are of higher energy than are the α particles emitted by the other plutonium isotopes, but its decay rate is so low compared to the decay rates of the other isotopes that it is not possible to fabricate a source from which one can observe the ^{236}Pu peak in the α spectrum over random pileup events.

Several tenths of a gram of weapons-grade plutonium is required for the measurement. The sample is dissolved in nitric acid containing a drop of hydrofluoric acid and is evaporated to a moist deposit, after which it is dissolved in warm 0.5 M HNO_3 (containing nitrite ion); plutonium is extracted into 0.02 M TTA in benzene, leaving the uranium and americium decay daughters behind in the aqueous phase. The organic phase is scrubbed several times with 0.5 M HNO_3 , discarding the aqueous phase each time; the time of the last solvent-extraction phase separation is recorded as the uranium-plutonium separation time. The plutonium sample, still in the organic solvent, is capped and set aside. After a month, the sample is agitated with 0.5 M HNO_3 , and the aqueous phase is retained as the uranium fraction; this sample contains the uranium atoms that grew into the plutonium sample as a consequence of radioactive decay during the storage period. The uranium fraction is further purified from residual plutonium and is then volatilized onto a platinum counting plate.

Two uranium activities are observed in the α -particle pulse-height spectrum taken of the uranium sample, ^{234}U (from the decay of ^{238}Pu) and ^{232}U (from the decay of ^{236}Pu). The ratio of the α -decay rates of $^{236}\text{Pu}/^{238}\text{Pu}$ in the original sample are related to the ratio of the daughter concentrations through their half-lives and the in-growth time; the milking technique takes advantage of the shorter half-lives of ^{236}Pu and ^{232}U relative to ^{238}Pu and ^{234}U , respectively, to produce an activity ratio that is more amenable to measurement.

Other examples of measurements made possible by radiochemical milking include the following:

1. Plutonium recovered via the PUREX process often contains a trace quantity of 7,400-year ^{243}Am , a reactor flux indicator that is an artifact of incomplete fuel reprocessing. The decay signature of ^{243}Am is quickly overwhelmed and obscured by the in-growth of 430-year ^{241}Am from the decay of 14-year ^{241}Pu . In a purified americium sample, the 2.4-day ^{239}Np daughter of the α decay of ^{243}Am quickly approaches radioactive equilibrium with the mother activity while the 2.1×10^6 -year ^{237}Np daughter of ^{241}Am α decay grows into the sample slowly, and linearly, with time. A neptunium sample, separated from purified americium at a well-defined time, can be used to determine the $^{243}\text{Am}/^{241}\text{Am}$ concentration at the time that the americium was isolated from plutonium.
2. The amount of 1.6×10^5 -year ^{233}U in a sample of enriched uranium can be a key signature of the enrichment process that produced the material. Unfortunately, ^{233}U has virtually the same α -decay energy as does 2.4×10^5 -year ^{234}U , and is usually present at such a low concentration as to preclude a sufficiently accurate mass spectrometric determination. The value of $^{233}\text{U}/^{234}\text{U}$ in enriched uranium can be determined using a double-milking technique, in which a large purified uranium sample is allowed to decay for several months, after which thorium is isolated and purified. The relative amounts of the thorium isotopes in this sample are not favorable for measurement; however, after a month, radium is isolated from the thorium sample and the relative activities of ^{224}Ra , ^{225}Ra , and ^{226}Ra can be related to the relative concentrations of ^{232}U , ^{233}U , and ^{234}U , respectively, in the original sample. The limiting accuracy of the technique depends on the ability of the analyst to establish the separation time of radium from the thorium sample; from milked fractions, the present authors have made ^{233}U concentration measurements with uncertainties of less than 10%.

Radiochemical milking procedures are very labor-intensive and require large amounts of sample and in-growth periods of long duration. This causes a considerable delay in the return of analytical data. The fundamental accuracy of the technique depends on how well separation times and in-growth periods can be established. When sequential milkings are performed, the activities in the second milk step are no more than, and usually significantly less than, those in the first milk step; this can result in counting fractions that emit radiation with so little intensity that an accurate measurement is problematic.

62.2.4 Reagent Blanks

Chemicals of normal reagent-grade purity suffice for the separation of analytes that do not occur in nature; there should be no important impact on the analyses of samples of neptunium, plutonium, americium, or curium, provided reagent volumes are kept small so that mass is not introduced into the final samples. For all other analytes, reagents that

have been double-distilled in Teflon should be used, even in the early stages of the chemistry, and contact with glass should be minimized; reagent-grade chemicals and glass both contain significant levels of uranium and thorium. Small quantities of commercial-grade chemicals of sufficient volatility can usually be vacuum-distilled in the radioanalytical laboratory.

The reagent blank can negatively impact a chronometric analysis. For example, ^{242}Pu has a small concentration in most plutonium samples, and is also usually the plutonium analyte with the longest half-life (3.8×10^5 years). The daughter of its radioactive decay is 4.5×10^9 -year ^{238}U , which is the major isotope of uranium in the reagent blank. As a result of the combination of these factors, a reasonable age cannot be reliably determined from the $^{242}\text{Pu}/^{238}\text{U}$ chronometric pair; the derived age is always significantly longer than that calculated from the other plutonium chronometers. If reagents of sufficient purity are used, one can interpret the excess ^{238}U as an indicator of the industrial process that resulted in the plutonium sample. The uranium content of reagent-grade chemicals can obliterate this signature.

In the analysis of actinide metal samples, the interpretation of the trace constituents are also affected by the reagents. Reduction to metal is usually performed by reaction of the actinide salt with alkaline-earth metals; the solvated ions of these materials are significant components of the reagent blank, as are the impurities that are common in the alkaline earths.

62.3 Radionuclide Chronometry

Using a variety of techniques, the radiochemical analyst measures the concentrations of various radioactive and stable nuclides in a nuclear forensic sample. The resultant table of concentrations is the radioanalytical “fingerprint” of the sample. However, unlike an actual fingerprint, which is interpreted by comparison with a database, the fingerprint of a sample of special nuclear material is forged by the methods used in its creation, and information about the origin of the material can be obtained from scientific principles by the informed analyst.

From experience, the present authors have found that examination of a table of concentrations that are the primary result of a nuclear forensic measurement campaign is seldom illuminating. The uranium and plutonium data are best examined as isotope ratios. Nuclides that grow into any radioactive sample are best presented as a “time since purification,” the chronometric age of the material. Generally, any mixture of heavy-element isotopes will incorporate several chronometers, and deviations among the resulting ages can be attributed to incomplete chemical processing, or to an intentional attempt to fool the analyst (spoofing). Examination of a table of ages calculated from the concentration data is the most convenient way of interpreting information on the relative concentrations of nuclides related by radioactive decay.

62.3.1 Chronometry Versus Age-Dating

The rate of decay of a pure sample of a large quantity of radionuclide is proportional to the number of atoms in the sample, with the constant of proportionality being the characteristic decay constant, λ :

$$-dN/dt = \lambda N \quad (62.9)$$

This leads to the law of simple radioactive decay,

$$N = N_0 \exp(-\lambda t) \quad (62.10)$$

and consequently to the Bateman equations that describe in-growth, sequential decays, and more complicated decay schemes (see [Chap. 7 in Vol. 1](#)). Here, N_0 is the original number of atoms in the sample at a reference time defined as $t = 0$, and N is the number of atoms that remain after a time t . If this equation is solved for the time-interval required for one half of the atoms to decay ($N = N_0/2$), one obtains the half-life ($t_{1/2}$) associated with the radionuclide, which depends only on the decay constant:

$$t_{1/2} = \ln 2 / \lambda \quad (62.11)$$

This leads to the concept of a radionuclide sample acting as a clock, and radiometric chronometry.

Chronometry is related to radioactive dating (see [Chap. 17 in Vol. 2](#)), but is not exactly the same thing. In age-dating, the analyst measures the concentration of a radioactive nuclide relative to the concentration of a reference isotope of the same element, usually very long-lived or stable. If the isotope ratio at a given time is known, the measurement of the change of that isotope ratio at a later time, taking into account the half-lives of the nuclides involved, determines the age. The limitation of the technique is that it cannot be used to measure ages that are much smaller than the half-life of the shorter-lived nuclide; for small values of the age, uncertainties in the measurement of the isotope ratio are larger than the change in the ratio due to decay. An example: The half-life of ^{14}C is 5,730 years, making it convenient for the determination of the age of samples that span the range of human civilization. The ratio of the concentrations of ^{14}C and stable ^{13}C changes by a factor of 2 every 5,730 years; if the analyst knows the zero-time isotope ratio, $^{14}\text{C}/^{13}\text{C}$ at measurement time determines the age of the sample on the time scale of millennia. If, however, the analyst is working with a sample that is only a year old, the change in the $^{14}\text{C}/^{13}\text{C}$ value is only 0.013%; consequently, the accuracy of the measurement must be better than that or the data cannot be interpreted as an age other than as a limit. (This particular example is somewhat complicated in actual practice due to the bomb pulse of ^{14}C injected into the biosphere by atmospheric nuclear testing.)

In chronometry, the age of the sample is defined not in terms of the decay of a parent nuclide, but rather as the in-growth of a daughter activity. Radionuclides that are linked to one another by the processes of radioactive decay have relative concentrations that can be calculated with the Bateman equations, which express the simple laws of radioactive decay and in-growth. If there exists a time at which all the descendant radionuclides have been removed from the mother material, that time can be determined through the measurement of the relative concentrations of the mother and daughter nuclides at a later time. The time interval between the purification of the sample and the subsequent analysis of the sample is defined as the “age” of the material at the analysis time. The technique does not apply when the half-life of the daughter nuclide involved in the determination is significantly shorter than the elapsed time.

This technique offers two distinct advantages when working with long-lived nuclides: (1) the initial concentration ratio of the parent nuclide relative to a reference isotope need not be known; and (2) the in-growth of the daughter activity is roughly linear with age.

The major drawback is that an accurate age determination requires that at some reference time the daughter of the radioactive decay of the parent was completely removed from the material by a chemical procedure. The α decay of 24,100-year ^{239}Pu results in the in-growth of 7.04×10^8 -year ^{235}U . In a chemically purified sample of ^{239}Pu , the change in the ^{239}Pu

concentration in a year is 0.003%; in an age-dating experiment, this would be hard to observe. If the ^{235}U is quantitatively isolated from a 1 g ^{239}Pu sample after a year, the fraction will contain 28 μg of ^{235}U , easily quantifiable by either radiation counting or mass spectrometry. If the in-growth period is twice as long, twice as much ^{235}U can be isolated.

A sample consisting of mixed uranium or plutonium isotopes provides the means of measuring the age of the sample through as many as a dozen different chronometers. If the sample was completely purified at the reference time, all of the chronometers should yield the same age. The present authors usually find that in a plutonium sample all the $^{232}\text{U}/^{236}\text{Pu}$, $^{234}\text{U}/^{238}\text{Pu}$, $^{235}\text{U}/^{239}\text{Pu}$, and $^{236}\text{U}/^{240}\text{Pu}$ chronometers yield the same age (as they should, since the removal of each uranium isotope from a plutonium sample should be equally effective). When these ages agree with those determined from $^{241}\text{Am}/^{241}\text{Pu}$ and $^{230}\text{Th}/^{238}\text{Pu}$, which are chronometric pairs that can be measured with great precision and are based on the chemical properties of elements different than those of uranium, it is inferred that the sample was completely purified at the time of separation. However, for the US weapons-grade plutonium, the authors often find that $^{241}\text{Am}/^{241}\text{Pu}$ gives a significantly larger value for the age than do the uranium isotopes. The only reasonable explanation for this is that the procedure for removing the uranium isotopes from the plutonium sample was less effective in removing americium from the material. This means that at any later time, there will be more ^{241}Am in the plutonium sample than can be explained by in-growth, making it appear as if the decay process had been proceeding for a longer time, resulting in a value for the age that is too large.

In general, the decay properties of the radionuclides are known with greater accuracy than are the concentrations that the analyst is likely to measure. The uncertainties associated with the chronometric atom concentration ratios represent almost the entire uncertainty budget associated with the age determination. However, these error bars do not translate directly to identical error bars on the derived sample ages; that is, a 5% error bar on the value of a concentration ratio does not necessarily translate into a 5% error bar on the age, instead being dependent on the functional form relating the age and the ratio.

The chronometry of plutonium samples is not limited to nuclides related by α and β decay. The mass-240 plutonium isotope decays almost completely by α emission; however, one in every 1.7×10^7 decays is by spontaneous fission. In spontaneous fission, the parent atom subdivides into two similar, but not identical, daughter atoms, with the yield being distributed over products covering a wide range of atomic numbers and masses (Laidler and Brown 1962). The intrinsic radioactivity of plutonium is high enough that 1 g of weapons-grade plutonium containing 6% ^{240}Pu by mass undergoes approximately 1,500 spontaneous-fission decays every minute. Krypton and xenon are gaseous elements that are chemically inert. The chemical properties of the fission-product Kr and Xe nuclides provide an opportunity to determine a sample age more associated with metallurgy than with chemical reprocessing: Plutonium is converted to the metal from a salt at some time after the last chemical purification step. Most of the fission products and the daughters of α and β decays are chemically reactive species; even fairly volatile elements will be retained to some extent in the melt; however, the inert gases will be completely flushed out of the melt by the by-product process gases. The subsequent in-growth of Kr and Xe by spontaneous fission defines the casting time of a metal sample. Since the isotopic distributions of fission-product Kr and Xe are different than those of the naturally occurring gases, a small admixture of the natural isotopes can be deconvoluted. However, the measurement becomes impossible in the presence of a significant amount of air, which must be rigorously excluded in the early stages of the analytical procedure; 1 cm^3 of air at standard temperature and pressure contains 3×10^{13} atoms of Kr and 2×10^{12} atoms of Xe. This can

introduce a background that would interfere with the observation of the radiogenic species through mass spectrometry.

The ratio of the concentrations of nuclides that are related by radioactive decay is interpreted as an age through the application of the rate laws, which are formulated in terms of characteristic decay constants, which are related to half-lives as discussed above. Radioactive decay is a statistical process, and in the limit of a small number of decays of atoms, the rate laws break down and the statistics of small numbers dominates (Schmidt et al. 1984). (See [▶ Fig. 9.10 in Chap. 9, Vol. 1.](#)) Measurement of the product of a small number of decays and interpretation of that measurement as an age is the fundamental limitation of the technique at short times.

62.3.2 Granddaughters and the Detection of Spoofing

The radiochemical analyst should always measure multiple chronometric concentration ratios to guard against intentional misdirection (“spoofing”). An individual signature can be introduced into the sample during its fabrication; this can mislead the analyst if that is the only measurement performed. For instance, someone might implement the idea of adding americium to their plutonium stream with the intent of making the material look older than it really is. Material whose apparent age could be demonstrated to predate a known reprocessing era would have to be attributed to another source. Adding ^{241}Am to a plutonium sample would deceive nondestructive γ -spectrometry measurements in common use by the safeguards community, but it would not deceive a full forensic analysis of multiple chronometers.

To fool the forensic analyst, the fabricator would have to successfully predict the suite of chronometric signatures that would be quantified. In the absence of this information, it would be necessary to modify them all. To adjust the age of the uranium chronometers in a sample of plutonium of US weapons-grade composition, a peculiar mixture of uranium isotopes containing $\sim 2\%$ ^{234}U , 79% ^{235}U , and 19% ^{238}U (all in atomic percent) would have to be added, in an amount necessary to match the ^{241}Am chronometer. If a significant amount of this material is added, the fabricator must concern himself or herself with the distribution of the contaminant throughout the matrix of the plutonium. Uranium isotopes arising through decay processes should be distributed uniformly with the parent plutonium isotopes. Uranium added to the process solutions before precipitation and calcination might end up inhomogeneously mixed in the final product. Furthermore, if added through insertion into the metallurgical process, the uranium contaminant is more likely to concentrate in the slag than in the billet. Adding uranium to the host metal in the form of a melt is of limited use since uranium is not very soluble in molten plutonium.

Imagine that the fabricator has solved the technical problem of distributing americium and the uranium isotopes through the plutonium matrix, uniformly and in the proper proportions, so as to make it look older. He must still consider the second- and third-order chronometers (involving granddaughter and great-granddaughter decay products, respectively). If he wants to make the ^{238}Pu in a freshly separated plutonium sample appear to be 8 years old, the $^{234}\text{U}/^{238}\text{Pu}$ value must be adjusted to 0.0653. The $^{230}\text{Th}/^{238}\text{Pu}$ value must be adjusted simultaneously to 7.54×10^{-7} . To make a sample of ^{238}Pu appear to be 8 years older, it is necessary to add ^{234}U that is 4.07 years old in order to match the concentrations comprising the ^{230}Th chronometer; however, even if this is done, the resultant $^{226}\text{Ra}/^{238}\text{Pu}$ signature will still be off by 24%.

The difficulty of uniformly dispersing the required amounts of properly aged contaminants to achieve a consistent false age makes it essentially impossible to fool a full forensic analysis. When samples are large (or old) enough, the determination of second- and third-order chronometers makes spoofing prohibitively difficult.

62.3.3 Detection of Incomplete Fuel Reprocessing

The incomplete removal of a daughter nuclide from a sample containing its parent activity will result in the value of the age determined from that chronometric pair being too large. This can be thought of as being analogous to traveling to a different time zone without resetting one's watch. The unremoved daughter will be in excess of what has grown into the sample, making it appear as if in-growth had occurred for a longer time, until the sample becomes so old that the daughter activity approaches secular equilibrium with the parent. This means that, in addition to the detection of spoofing, a chronometric analysis based on several pairs of genetically related nuclides can be a sensitive way of obtaining details about the chemical processes used to produce the analytical sample.

The authors' experience has been that US weapons-grade plutonium, which is produced via the PUREX process, always contains a small excess of americium and a larger excess of neptunium relative to the uranium chronometers that result in a consistent, smaller age. One might speculate that the americium was in fact completely removed, but at an earlier time than was the uranium, giving it extra time to grow into the sample; however, trace amounts of ^{243}Am have been observed in plutonium samples, which does not arise in the radioactive decay of mixed long-lived plutonium isotopes. The ^{243}Am can only be present if it is residual from the original spent reactor fuel, where it was produced in neutron reactions on ^{242}Pu ; therefore, americium was never completely removed from plutonium in the PUREX process. However, PUREX is much more effective at removing fission products; the authors have performed several consistent chronometric determinations from the measurements of $^{125}\text{Sb}/^{240}\text{Pu}$ and $^{137}\text{Cs}/^{240}\text{Pu}$.

62.4 Analytical Methods

62.4.1 Application of Radiochemical Procedures

Radioanalytical chemistry is a destructive technique. It is always advisable to save some portion of the sample if there is enough material to do so. Before radiochemical analysis, classical forensic measurements (e.g., fingerprinting and isolation of hair and pollen) should be performed, and particles for morphological measurements should be segregated from the bulk. It must be remembered that the sample is not necessarily uniform, and significant fractionation of the bulk material should be avoided. The radiochemical sample itself can be subjected to nondestructive assay by γ -ray spectrometry and neutron counting, and in the past the authors have heated this sample prior to dissolution to obtain a specimen for organic gas chromatography. The results of measurements made on the sample prior to dissolution can be related to the subsequent radiochemical analysis by quantitative dissolution of an accurately weighed solid sample, followed by dilution to a precisely measured solution volume or weight.

A radiochemical analysis begins with the creation of an analytical mother solution from the sample. The quantitative dissolution of a solid sample to create a stable solution can be the most difficult part of the radiochemical analysis. Since the results of individual radiochemical procedures are related back to this “pot” solution based on a “per-volume” or “per-gram-solution” basis, it is critical that the product of the dissolution procedure is as close to a true solution as possible; if there is a possibility of colloidal material, the solution should be agitated during aliquoting, if possible. Samples of plutonium and uranium metal dissolve readily in hydrochloric acid, but even with heating, often leave a residue. If chronometry beyond that involving the heavy elements is to be performed, collection of the noble gases and volatile fission products should be accomplished during the dissolution of plutonium metal samples. The addition of nitric acid to uranium residuals, followed by digestion, can result in a solution since most uranium salts dissolve readily in nitric acid. Plutonium oxide will not necessarily dissolve completely in nitric acid, particularly if it has been high-fired. Any sample containing a significant amount of plutonium must be treated with hydrofluoric acid, no matter what the initial chemical form; invisibly small colloidal plutonium oxide particles are stable against reactions with most mineral acids, and their presence interferes with the chemistry. For most actinide samples, the preferred pot solution matrix is hydrochloric acid with a concentration between 2 and 6 M. If the matrix of the analytical sample is other than a metal or a mixture of the salts of the heavy elements, the ingenuity of the analyst may be taxed in preparing the analytical pot. The primary rule in the preparation of the pot is to avoid more than trace quantities of fluoride or phosphate in the stock solution, as these can interfere with the subsequent chemical purification steps.

Chemical yields are determined from tracer activities added to the analytical aliquots; however, the yields can also be determined from short-lived activities that are present in the sample due to secular radioactive equilibrium. For example, the chemical yield of uranium can be determined from the recovery of an added ^{232}U tracer activity, but in plutonium samples it can also be determined from ^{237}U : There is a 0.00245% branch for the decay of ^{241}Pu by α -particle emission. If it is known that the plutonium sample was last purified more than a month ago, one can assume that 6.75-day ^{237}U in the analytical samples is in equilibrium with ^{241}Pu , with a concentration defined by the branching ratio of activity(^{237}U)/activity(^{241}Pu) = 2.45×10^{-5} . Similarly, radium is traced with 3.66-day ^{224}Ra , in secular equilibrium with the decay of 1.9-year ^{228}Th . Use of intrinsic short-lived radionuclides as tracers requires that the time at which they were isolated from their parent activities is known precisely.

62.4.2 Preparation of Counting Sources

Samples for α counting must be sufficiently thin so that range straggling does not impact the widths of the peaks in the α spectrum. This is accomplished by the purification of α -emitting chemical fractions to minimize mass. In the case of long-lived α emitters like the isotopes of uranium and thorium, care must be taken to balance the decay rate of the analyte against its mass. Distribution of an α -emitting sample over a larger area helps alleviate this problem, until the dimensions of the source became comparable to the area subtended by the counter, at which point the counting geometry reduces counting efficiency. Samples for absolute α -particle intensity measurements must be mounted on the same substrate as is the calibration standard (usually platinum), so that the “back-bounce” of α particles emitted into the sample substrate and scattered backward into the detector volume is the same.

Samples for α counting are prepared by stippling, by vacuum volatilization, or by electrodeposition. In stippling, the substrate is warmed and small drops of a solution containing the analyte are delivered from a transfer pipet, making sure that the activity is distributed over the substrate in a quasi-uniform fashion. Stippling can be quantitative, with 100% of the analyte transferred from the solution to the substrate, but the preparations are of inferior quality for spectrometric measurements. In vacuum volatilization, the analyte solution is dried on a tungsten filament and mounted in vacuum between two electrodes. The filament is then heated white-hot through the sudden application of an electric current, resulting in the analyte being volatilized from the filament and onto a substrate mounted above it. The technique is not quantitative, with losses (often more than 50%) caused by some of the volatilized analyte not encountering the substrate foil; however, it results in uniform, thin deposits that are very appropriate for α spectrometry. In electrodeposition (Aumann and Muellen 1975; Muellen and Aumann 1976), the analyte is dissolved in a plating solution that is placed in a cell whose bottom surface incorporates the conductive sample substrate; an electrode is suspended in the solution, a current is passed through the cell, and the analyte is electrodeposited onto the substrate. Electrodeposition (also called “electroplating” or “molecular plating”) can be nearly quantitative and results in a thin, uniform counting source appropriate for spectrometry, but the technique is labor-intensive and time-consuming. In all three cases, activity can be fixed to the substrate and extraneous mass removed by passing the final sample through a Bunsen burner flame (except in cases of elements, e.g., polonium, that are volatile at low temperatures).

There have been advances in α -source preparation using functionalized surfaces (Gonzalez and Peterson 2009) and co-precipitation on special filters (Sill and Williams 1981). These methods show promise, but information is still needed on the longevity of archived samples and the availability of appropriate efficiency standards.

Gamma- and X-ray-emitting samples can be prepared in a variety of ways, including those listed above for α counting. The penetrating nature of the radiation allows the analyst to prepare γ sources in a variety of different media and geometrical configurations. One of the standard geometries is 10 ml of solution in a cylindrical plastic vial with a lateral cross section of 10 cm². If a γ -ray source must be counted close to a detector, its physical dimensions relative to those of the detector should be small or benchmarked against a radionuclide standard of the same physical extent. Low-energy photons are attenuated by matter more severely than are high-energy photons, with high-atomic-number materials being more effective attenuators than low-atomic-number materials; the attenuation coefficients for photons below 100 keV are not perfectly known for the heavy elements. Thus, the analyst should not try to quantify low-energy photon emission through a lead sample container, but a plastic container or a volume of dilute aqueous solution is effective for this application. Solutions of radionuclides that are counted for γ rays must be stable; any precipitation taking place during the count changes the source geometry and adversely impacts the accuracy with which the concentration of radionuclides can be determined.

62.4.3 Radiation Counting Systems

A modern nuclear forensic analysis relies heavily on instrumentation. A well-equipped laboratory will have the means for making a variety of inorganic, isotopic, and organic analyses, in addition to having the support of a counting facility for radiation measurements.

62.4.3.1 Nuclear Counting

In addition to survey instrumentation, the radiochemical forensic lab requires basic radiation-counting support in order to monitor the progress of certain chemical separations. For example, the performance of a methanolic nitric acid separation of Am and Cm on an anion-exchange column is not always reproducible. In operation, the column eluent is collected as a sequence of small samples in a number of glass centrifuge cones. Americium, which emits γ radiation in its decay, follows curium off the column, and is located in the eluent stream with the aid of a laboratory radiation counter.

The authors have found that most general radiochemical separations can be successfully monitored with only three counters: (1) a flow-through argon-gas (or P10-gas: Ar with 10% CH₄) proportional counter for detecting α particles; (2) a flow-through methane-gas proportional counter for detecting β particles; and (3) a NaI(Tl) well counter for detecting γ rays. The first two counters output to scalars; the third counter yields γ -ray spectra that may utilize a multichannel analyzer with a display that permits peak identification and integration.

Quantitative nuclear counting measurements take place in a dedicated nuclear counting facility, close enough to the forensic laboratory for convenience, yet sufficiently isolated so that the radiation field and loose contamination associated with radiochemical operations do not affect the background levels. For the optimum detection of marginal signatures, a counting lab is often located underground to attenuate the cosmic-ray background. Air-conditioning is required; cryogenic- and counting-gas effluents must be removed; and the reliable operation of gas-filled counters requires a stable temperature. The counting facility must have separate electrical circuits, isolating the counting equipment from non-counting apparatus (e.g., vacuum pumps and the transient use of power tools). Since electrical noise impacts detector performance, the circuit for the counters should be filtered, should have sufficient battery backup power to survive power transients, and an auxiliary electric generator for longer outages. If the power to the detectors is interrupted, it should only be restored in an approved fashion; this is usually implemented with a cutoff circuit.

The counting laboratory requires plumbing for the supply of counting gases (principally Ar, P10, and methane); they are supplied at the pressures required by the counters (slightly above atmospheric pressure for flow-through proportional counters and ~ 1.5 bar for gridded ion chambers), with flows that are controlled by needle valves on the counters themselves. Counting gases should be delivered through metal tubes with in-line ceramic electrical insulators; plastic tubes eventually fail and should be avoided. Gases supplied in pressurized cylinders often contain a measurable quantity of 3.8-day ^{222}Rn , which can interfere with the low-level detection of ^{238}Pu and ^{241}Am α particles, as they are emitted with a similar energy. A supply of counting gases should be maintained, and no cylinder should be used until it has been stored for at least 2 weeks to allow ^{222}Rn decay.

Vacuum is also required in the counting laboratory, and these lines should be supplied with cold traps to prevent pump oil from back-streaming and depositing on sensitive counting apparatus (e.g., surface-barrier detectors).

Generally, α -particle counters do not require shielding for nuclear forensic applications; residual contamination in a low-level chemical fraction and nuclides that recoiled into the detector from previous counting sources are always more important contributions to the detector background than the natural radiation environment. Shielding from cosmic rays and environmental radiation (i.e., photons from ^{40}K and the natural U and Th decay chains) is required in the operation of γ - and X-ray counters. A thickness of 20 cm of Pb is sufficient for

this purpose, particularly if the counting lab is underground. However, cosmic-ray interactions with intervening structural materials and the shielding itself produce *bremsstrahlung* and neutrons that can adversely impact the detector background. The fluorescence of lead produces X-rays, and it is normal practice to line the interior of a Pb shield with layers of Cd, Cu, and Al, in that order. An air gap around the detector (~ 30 cm in any direction) can provide a decrease in the intensity of photons and electrons that have been down-scattered into the 150–200 keV range (Watt and Ramsden 1964).

Shielding should be constructed from low-background materials. Modern steels are often recycled and can contain 5.3-year ^{60}Co , introduced either by fallout from atmospheric nuclear weapons testing in the 1950s and 1960s, or by the improper disposal of γ irradiators (Lubenau and Yusko 1995; 1998). Natural sources of Pb contain 22-year ^{210}Pb , a member of the ^{238}U decay series; even though chemical recovery of Pb removes the U that is always present in the ore, it does not eliminate ^{210}Pb . The decay of ^{210}Pb results in the in-growth of 5-day ^{210}Bi (which emits 1.1 MeV β particles and, consequently, *bremsstrahlung*) and 138-day ^{210}Po (which emits α particles) until transient equilibrium is established. Batches of Pb from different sources are contaminated with ^{210}Pb to varying degrees (Alessandretto et al. 1993). Older materials are preferred in fabricating shielding for low-background counting applications, as the radionuclide content of these materials has been reduced by decay. Steel from World War I battleships and Pb ballast from eighteenth-century Spanish vessels are in high demand for low-background counting enclosures.

Quite often, the number of samples generated in a nuclear forensic analysis outnumbers the available radiation counters, requiring temporary storage. Counting samples should be stored in a shielded container near the laboratory door, both to prevent transfer of loose contamination and to avoid increasing the backgrounds of operating counters. Automated sample changers improve the throughput of a radiation counter. When a given analysis is completed, the sample is removed from the counter and replaced with another sample without requiring off-shift staff. Sample changers for α and β counters consist of a rotary turret; the detector itself is mounted behind a collimating shield so that the radiations emitted by nearby samples do not admix with those emitted by the current sample. Sample changers for γ counters usually consist of a turret or a belt coupled to an elevator; following the completion of an analysis, the sample is lowered into its position on the turret, the next sample is rotated into position, and is subsequently raised to proximity with the detector. In this way, intervening shielding material and distance effectively eliminate the radioactive emissions of other samples from the detector background. The efficiency of any radiation counter is dependent upon the position of the source relative to the detector volume during an analysis. For counters where efficiency is an issue, the turret or turret/elevator must deliver a sample to a well-defined location. Close-in counting can result in pileup and summing effects, which should be avoided whenever possible.

62.4.3.2 Particle Detection

Beta-Particle Counters

While useful for characterizing the performance of chemical separations in the laboratory, β counting is rarely employed as a quantitative technique. Most β -emitting analytes also emit γ rays, which are characteristic of the decaying nuclides; however, there are activities (including long-lived fission products such as ^{99}Tc and ^{147}Pm , and other potential analytes such as ^{14}C and ^3H) that β decay without accompanying photon emission. A set of attenuating Al foils of

various thicknesses can facilitate the identification of β -emitting nuclides in samples assayed with a gas-filled proportional counter. Access to a single β counter with an eight-position sample turret is recommended.

Alpha-Particle Counters

Alpha counting is used extensively in the nuclear forensic analysis of U, Pu, and other actinides. Windowless gas-proportional detectors are insensitive to decay energy and generate a scalar value defined by the absolute α -decay rate of a sample and the length of the count. Since the counter efficiency is often $\sim 50\%$, these are called 2π counters. Spectral data taken with Si surface-barrier detectors or gridded ionization (Frisch-grid) chambers can be used to divide the total decay rate obtained from 2π counting into contributions from the individual nuclides. Frisch-grid detectors, where the sample is inserted directly into the counting gas, have high efficiencies and are therefore useful for counting low-activity sources. However, conversion-electron summing can adversely affect the spectral peak shape when counting Am or Np isotopes. Solid-state detectors suffer less from electron-summing effects, and high-activity sources can be counted if the turret is designed so that samples can be backed away from the detector. Counting labs should maintain at least two 2π counters with four- or six-position turrets, four Si surface-barrier detectors with six-position turrets, and four Frisch-grid counters with six-position turrets.

Gamma-Ray Counters

Though a wide variety of high-purity Ge (HPGe) counters are commercially available, nuclear forensic measurements can be performed with two different detector types: a coaxial detector with an Al window and a nominal efficiency relative to standard NaI(Tl) of 30–40%, and a LEPS planar detector with a Be window. Downward-looking detector-dewar geometry is compatible with the implementation of an elevator/turret sample changer. Well-type detectors can be valuable to check the performance of chemistry procedures, but the attendant summing effects makes them of little use for quantitative γ -ray spectrometry. Many HPGe detectors are available with an incorporated annular, low-resolution photon detector to suppress Compton events. Events that take place in the Compton annulus coincident in time with an event in the HPGe detector are used as a criterion for excluding it from the spectrum. In this way, the continuum under low-energy photopeaks is reduced, which increases the precision with which low-energy photons can be measured in the presence of more intense high-energy photons. A nuclear-forensic counting laboratory should maintain at least three coaxial detectors, one with Compton suppression and at least one with a LEPS-type detector, each equipped with a multi-position sample changer.

Neutron Counters

Most of the utility of neutron counting is in the interrogation of a sample upon receipt, before the shipping container is opened. Neutron emission from a questioned sample could signal the presence of Pu. Spontaneously fissioning nuclides should be introduced into the counting facility only in limited quantity, as neutrons are penetrating and damage the function of HPGe detectors. Neutrons also potentially increase the background in the counting facility via nuclear activation reactions with surrounding materials.

62.4.3.3 Tritium Analysis

The $A = 3$ hydrogen isotope, tritium (^3H or T), is utilized in nuclear weapons as a component of thermonuclear fuel. Tritium is also widely used in industry and medicine, both as a source of

luminescence in wristwatches and building exit signs, and as an isotopic label in a wide variety of radiopharmaceuticals (Moskalev 1968; Cronkite 1979). Along with ^{241}Am in smoke detectors, T is a weapon-relevant material that is commercially distributed and could be diverted into proliferant channels.

Approximately 2,400 Ci of T are produced per electric MW in a heavy-water-moderated, CANDU-type reactor, a result of the continuous high-flux neutron irradiation of large quantities of deuterium (^2H or D) (Wong et al. 1984):

The small capture cross-section ensures that the product T will always be dilute relative to the other isotopes of hydrogen. Though this material can constitute a contamination hazard, it is of little use in the weapons world without prohibitively expensive isotope enrichment. The neutron irradiation of the minor ^3He component ($1.4 \times 10^{-4}\%$) of natural He (Firestone and Shirley 1996)

or enriched ^6Li targets

are both means of producing T in high concentration relative to the other isotopes of hydrogen. T-bearing material from any of these sources could appear on the black market.

In most of its chemical forms, T is highly dispersible, which is a serious problem when it is handled by persons with little or no training. Fortunately, the low energy of the β particles emitted in T decay [with a range of $\sim 0.5 \mu\text{m}$ in tissue (Moskalev 1968)], results in very low specific radiotoxicity.

However, this same property makes the detection and quantitation of T problematic. Since most radionuclides decay with the generation of more ionization than does T, and since no γ rays are emitted in its decay, other radionuclides present in a sample can mask the detection of low concentrations of tritium. As a result, the determination of T almost always involves a chemical step: either the preparation of a purified “hydrogen” sample (usually water) for direct radiation counting (Reinig et al. 1976) or the isolation of a helium fraction (containing the decay product ^3He) from the sample headspace after a defined in-growth interval for a mass-spectrometric measurement (Surano et al. 1992). These techniques and others (Chiarappa-Zucca et al. 2002) are also used for environmental monitoring, which can be quite relevant for the detection of T smuggling.

A nuclear forensic laboratory may encounter T in its molecular form (gaseous), but is most likely to encounter it in a liquid form. These samples can be aqueous (in which T is incorporated in either the water molecule or, in the case of radiopharmaceuticals, the solute) or organic. Organic T can be released in the form of water through a variety of wet or dry oxidation methods: Examples of wet oxidation include the destruction of the organic material with H_2O_2 in the presence of a ferrous-ion catalyst and the digestion of mixtures following the addition of HClO_4 . The evolved water fraction will contain hydrogen atoms from the reagents, which may impact the analytic data, depending on the method. Dry oxidation (combustion) is accomplished by heating the sample in the presence of oxygen; the gas-phase combustion products are passed over hot copper oxide, resulting in water that condenses in a cold-trap collector.

Liquid scintillation counting (LSC) is the usual method applied for the direct measurement of T radioactivity. Samples in which T is the major source of radioactivity are introduced into a scintillation cocktail. Prior conversion to water, followed by distillation to purify the sample from other radionuclides, is the preferred forensic method unless the analyst is certain that no other radionuclides are present. LSC on T-bearing aqueous specimens involves the use of an appropriate emulsifier to distribute the sample throughout the organic scintillator without degradation in performance. LSC calibration standards are available from NIST, and compensation for the efficiency change caused by the introduction of varying amounts of sample solution into the scintillator is discussed in Sansoni and Kracke (1971).

An indirect method for determination of T involves the quantitation of the T decay daughter, ^3He (Surano et al. 1992), a standard chronometric technique. An aqueous sample is cycled between 90°C and liquid-nitrogen temperature, evacuating and discarding the headspace gas each time, with the end of the last degassing cycle defining the beginning of the interval of in-growth of the daughter. After the in-growth period, the headspace gas is collected during the heating and cooling of the sample, and is introduced into a mass spectrometer. The number of daughter atoms produced during a well-defined in-growth interval and the length of that interval define the number of T atoms in the analytical specimen. The technique is sufficiently specific that very little sample preparation is necessary for aqueous samples. As few as 10^5 atoms of ^3He can be determined to an accuracy of a few percent. When the number of questioned samples to be analyzed is limited and the number of atoms of T in each sample is fairly large, this technique is superior to LSC; however, LSC is the preferred method when high sample throughput is required. There are advantages and disadvantages to both LSC and ^3He MS for the analysis of very dilute samples, however (Surano et al. 1992; Chiarappa-Zucca et al. 2002).

62.4.4 Imaging and Microscopy

The nuclear forensic analyst is conversant with instrumental techniques, but visualization of the features of a sample is particularly satisfying and can usually be performed nondestructively. The rapid identification and characterization of specimens without the compromise of integrity is the fundamental starting point of many forensic investigations. The unaided human eye can resolve features on the order of 50–100 μm in size; the role of microscopy is to provide a magnified image of a sample, allowing the observation of features requiring increased resolution. Microscopy techniques in nuclear forensic science use photons and electrons to probe the chemical, physical, and structural compositions of samples at spatial resolutions ranging from <1 Å to tens of micrometers. The nuclear forensic analyst most commonly uses forms of optical and electron microscopy for imaging.

62.4.4.1 Optical Microscopy

Light microscopy is one of the discipline's primary characterization techniques. It allows the forensic scientist to quickly address that most fundamental question, "what does the sample look like?" before proceeding with more extensive, often destructive, analyses. At all levels of sophistication (from hand lenses to compound microscopes), optical microscopy reveals

details of shape and size, color, surface morphology and texture, corrosion, tool marks, wear patterns, surficial coatings, and mineralogy (Davidson and Feigelson 1957; Horrocks 1974). The stereomicroscope and the polarizing microscope are both extensively used in the radio-chemical forensic laboratory. Both produce a magnified sample image through the use of a dual array of lenses (objective and eyepiece). The stereomicroscope produces three-dimensional images at relatively low magnification ($\sim 2\text{--}100\times$), and the subdivision of specimens into aliquots for subsequent analyses is facilitated by this instrument. The polarizing microscope, which can readily magnify an image to $1,000\times$, passes light through a set of polarizing filters to gain additional information about the nature of the sample from optical properties such as anisotropy, crystallinity, pleochroism, and birefringence. The wavelength of the incident light limits the resolution of an image: theoretically, the resolution of conventional microscopes is as good as 200 nm, but values better than 1 μm are rarely achieved. Both stereo and polarizing microscopes can be modified for digital photography, and an excellent description of the uses of optical microscopy in forensic science is given in Pluta (1988) and Peteraco and Kubic (2004).

62.4.4.2 Scanning Electron Microscopy

Optical microscopy is simple to use as little or no sample preparation is required, and samples can be analyzed rapidly. Despite these advantages, the most commonly used imaging tool in the nuclear forensic laboratory is not the optical microscope. Scanning electron microscopy (SEM) offers superior resolution and provides direct measurement of elemental compositions when combined with X-ray analysis. In SEM, a finely focused beam of electrons of energy $\sim 0.5\text{--}30$ keV is rastered over a sample. Sample preparation affects the quality of SEM images. Specimens must be compatible with the high vacuum of the SEM, and insulating materials must be coated with a thin conductive layer (usually 2–10 nm of Au, Pd, or C). With standard thermionic filament sources, image resolution is limited to ~ 10 nm, which translates to a maximum magnification of $\sim 100,000\times$. With field-emission electron sources, a resolution of 1 nm can be achieved (a maximum magnification of $1,000,000\times$). The interrogation of a questioned sample is limited by the physical dimensions of the SEM specimen chamber, typically <10 cm.

Backscattered electrons, secondary electrons, Auger electrons, and X-rays and other photons arise in the interaction of the incident electron beam with the sample. The intensity of one or more of these types of emission is measured as a function of raster position, resulting in the construction and display of an image of the sample. Each type of emission conveys different information about a sample, and morphologic or compositional information can be revealed in an image through choice of the appropriate detection mode (Reimer 1985; Newbury et al. 1986; Reed 1996). Secondary electrons arise from inelastic collisions between incident electrons and atomic electrons, and they sample only the outer few nanometers of the surface, providing information about sample topology. Backscattered electrons have energies comparable to that of the incident electron beam, and provide information about the mean atomic number of the sample; they are used to map the spatial distribution of phases of disparate chemical composition (Krinsley et al. 1998). Qualitative and quantitative information about chemical composition is carried by the characteristic X-rays of the elements (Reimer 1985; Newbury et al. 1986; Reed 1996).

62.4.4.3 Transmission Electron Microscopy

Transmission electron microscopy (TEM) is difficult to use and requires elaborate and time-consuming sample preparation; nevertheless, it provides a unique capability for ultrahigh spatial resolution (~ 0.1 nm, or $\sim 2,000\times$ that obtained by optical microscopy). It can reveal information about the microstructure of the sample via electron diffraction. TEM is capable of an extremely wide range of magnification (from $\sim 100\times$ to several million times) and provides information on extremely fine structural details, but at the expense of tight restrictions on sample thickness. A variety of techniques, from simple crushing to elaborate ion-beam milling, are used to produce electron-transparent specimens of the required thickness (Braverman et al. 1988; Anderson 1990). Just as in SEM, characteristic X-rays are generated by the interaction of the incident electron beam with the sample. X-ray analysis can be combined with TEM imaging and diffraction to provide comprehensive information about the internal microstructure of a questioned specimen, with nanometer spatial resolution (Joy et al. 1986).

TEM involves the use of a focused beam of high-energy (100–400 keV) electrons. The beam passes through a very thin sample (<250 nm thick) (Hirsch et al. 1971; Wenk et al. 1976; Reimer 1984; Joy et al. 1986) and scattered electrons are delivered to the detector (normally a high-resolution CCD) by a series of magnetic lenses. Imaging and diffraction modes are available in TEM: In imaging mode the incident electrons illuminate a region of the sample and produce a magnified image. The contrast in TEM images arises from several different mechanisms, and images may provide information on sample thickness, sample crystallinity, crystal orientation, and the density of defects and deformations. In diffraction mode the incident electrons produce an electron diffraction pattern, similar to an X-ray diffraction pattern, which can be indexed by modified X-ray diffraction procedures to identify solid phases at an extremely fine spatial scale.

62.4.4.4 Electron Microprobe Analysis

Electron microprobe analysis (EMPA) provides quantitative chemical characterization of spatially resolved areas of specimens. Element-specific X-rays are generated when a focused beam of energetic electrons (5–25 keV) strikes the sample. EMPA has many similarities to SEM (Newbury et al. 1986; Reed 1996); however, EMPA uses much higher beam currents (several hundreds of nanoamperes (nA)), which result in correspondingly poorer spatial resolution. EMPA uses both energy- and wavelength-dispersive spectrometers to measure the intensity of the characteristic elemental X-rays; elements from Be to Pu can be assayed, with accuracies approaching 1% and detection limits from 50 to 200 $\mu\text{g/g}$. Accurate quantitation requires flat, well-polished samples with stringent limitations on the magnitude of topographic features (Lister 1978). As with SEM, insulating materials must be coated with a conductive material prior to EMPA analysis; carbon is normally used to minimize absorption of low-energy X-rays.

62.4.4.5 X-Ray Microanalysis

The spectrum of characteristic X-rays generated by the interaction of energetic electrons with a sample in SEM, TEM, or EMPA is determined by the elemental composition of

that sample. These X-rays provide the means to measure elemental concentrations for most solid samples, including small particles. Characteristic X-rays are emitted with precisely defined energies, and are distinct from the continuum of X-ray energies found in *bremsstrahlung* (Newbury et al. 1986; Goldstein et al. 1992). These X-rays may be analyzed by either of two methods: energy-dispersive X-ray spectrometry (EDS) uses a semiconductor detector (usually Si(Li)) to simultaneously measure the energy and intensity of X-rays over a broad energy range (0.1–15 keV), and can detect elements from B to Pu. Detection limits of 0.1% can be achieved for silicate and oxide materials. Wavelength-dispersive spectrometry (WDS) uses an analyzing crystal. Incident X-rays are diffracted according to the Bragg principle, and they are dispersed according to wavelength rather than energy. Only X-rays satisfying the relation ($n\lambda = 2d \sin\theta$) are constructively reflected into a detector. WDS provides much higher energy resolution (eV compared to >100 eV) and much higher signal-to-noise ($\sim 10\times$) than EDS, but analyses tend to take longer and the instrument is much more expensive. WDS detects elements from Be to Pu and can achieve detection limits of 0.01% (Newbury et al. 1986; Goldstein et al. 1992).

62.4.5 Isotope Mass Spectrometry

Mass spectrometry (MS) is a workhorse of nuclear forensic analysis. Different instruments provide the means of measuring the isotopic, elemental, and molecular abundances of a wide variety of materials with high sensitivity, precision, and accuracy. In a mass spectrometer, a portion of a sample is converted into positively or negatively charged ions that are separated and analyzed according to their respective mass-to-charge ratios. Mass spectrometers are specialized instruments, and are usually classified according to the method of ion generation (e.g., thermal ionization, electron-impact ionization, or plasma ionization) and the type of mass analyzer (e.g., magnetic sector or radio-frequency quadrupole) (Duckworth et al. 1986; White and Wood 1986; Johnstone and Herbert 2002). A nuclear forensic investigation may employ as many as nine different types of mass spectrometers, depending on the analytic requirements for a given sample. Described below are the characteristics of the instruments most commonly used in nuclear forensic analyses.

62.4.5.1 Isotope-Ratio MS

Isotope-ratio mass spectrometry is used to determine the relative isotopic abundances of major and trace elements. Mass spectrometric methods are able to measure the relative concentrations of both radioactive and stable isotopes with a precision and accuracy of better than 0.001%. To achieve measurements of this quality, isotope-ratio MS relies almost exclusively on magnetic-sector instruments operated in temperature-controlled laboratories (Becker and Dietze 2000).

In thermal-ionization mass spectrometry (TIMS), samples consist of fg–ng quantities of chemically separated and purified analyte dissolved in a small volume (typically 1–10 μl). The solution is deposited on a refractory metal filament (e.g., high-purity W or Re), where it is evaporated to dryness. The filament is then heated to temperatures of 1,000–2,500°C in the ion source by resistive heating. If the ionization potential of the analyte is low compared to the work function of the filament, some of the analyte atoms will be ionized and emitted from the filament surface. TIMS ion sources commonly incorporate a second filament arranged

opposite that bearing the sample; evaporated neutral atoms and molecules are ionized on the hot surface of the second filament. Nearly all TIMS instruments employ single-focusing, magnetic-sector mass analyzers in which the electrostatically accelerated ions are separated according to their respective mass-to-charge ratios. TIMS instruments incorporate as many as 12 detectors (Faraday-cup and/or electron-multiplier modules) for the simultaneous collection of all isotopes of interest. TIMS achieves a precision for isotope-abundance ratios exceeding 1 part in 100,000 (Platzner 1997; Becker 2003; Richter and Goldberg 2003) through the accurate measurement of ion currents between 10^{-9} and 10^{-18} A. TIMS is the preferred technique for U and Pb isotope measurements.

Sample preparation for TIMS is time-consuming and labor-intensive; development of the techniques for purification, concentration, and filament-loading, specific to each element, can take months to develop and perfect. As a result, TIMS has been replaced by multi-collector, inductively coupled, plasma-source mass spectrometers (MC-ICPMS) in many laboratories. In MC-ICPMS, a sample is dissolved in an acid solution, which is nebulized in a spray chamber and aspirated into an Ar plasma. The analyte dissociates into its atomic constituents and ionizes in the high temperature of the plasma (5,000–8,000 K). Ionization proceeds with very high efficiency (>90% for elements with a first ionization potential of <8 eV). Positive ions are extracted from the plasma with a wide range of energies (up to several hundred electron volts), and MC-ICPMS instruments use either a gas-filled collision cell or double-focusing mass spectrometry to achieve adequate mass resolution and abundance sensitivity. Unlike a thermal ionization source, the plasma source is not adequately stable, requiring MC-ICPMS instruments to simultaneously collect and quantitate the different analyte masses to achieve high precisions and accuracies. The ion detection systems are similar to those used in TIMS. The detection limits for MC-ICPMS are generally <1 pg/g (10^{-12} g/g) and can reach the 10^{-15} g/g range for favorable elements. Precision and accuracy compare favorably to TIMS (Linge and Jarvis 2009). By virtue of its high-efficiency ion source, MC-ICPMS has enabled a wide spectrum of isotope-ratio measurements in nuclear forensic analysis (Wallenius et al. 2002).

Neither TIMS nor MC-ICPMS is applicable to the analysis of electronegative elements (C, N, O, and S) or noble gases (He, Ne, Ar, Kr, and Xe), whose isotope ratios are best measured with instruments known collectively as (gas-source) isotope-ratio mass spectrometers (IRMS). The analyte is prepared in a gaseous state (Duckworth et al. 1986; White and Wood 1986; Beyerle et al. 2000) and introduced into the ion source. An intense beam of 50–70 eV electrons induces ionization via electron impact (collisions between electrons and gas molecules). Positive ions are extracted from the source and mass-analyzed. A dual inlet system provides a parallel, intermittent source of gas of known isotopic composition, and the isotopic analysis of the unknown analyte is related to that of the standard. Stable-isotope MS requires milligram or larger samples, resulting in the determination of isotope ratios with precisions and accuracies of 0.01–0.1%. Noble-gas mass spectrometers use specially modified ion sources that have very small internal volumes to minimize analytical blanks, yet provide high efficiency for the ionization of chemically resistant analytes. Noble-gas spectrometers can achieve zeptomole (10^{-21} mole) detection limits.

62.4.5.2 Element MS

In contrast to isotope-ratio MS, elemental-composition MS provides analyses of relative elemental concentrations, and greater emphasis is placed on measurement of a wide variety

of disparate materials, rather than achieving very high accuracy. Accuracies of 1–10% are considered acceptable, compared to 0.001–0.01% for isotope ratios.

The low detection limits and multielement capability of inductively coupled, plasma-source mass spectrometry (ICP-MS) make it a technique of choice for nuclear forensic analysis. Acid solutions of analytes are nebulized in a spray chamber and aspirated into an Ar plasma. For rapid, multielement analysis of elements at trace and ultra-trace concentrations, ICP-MS is an optimum method, provided that solid samples are easily dissolved to produce aqueous solutions (Duckworth et al. 1986; Brundle et al. 1992; Linge and Jarvis 2009). Most commercial ICP-MS instruments use an rf quadrupole mass analyzer that can scan through a wide mass range very quickly (a measurement across 1–300 atomic mass units (amu) takes less than 1 s). Higher precision can be obtained through time-averaging multiple scans. A quadrupole has lower precision and stability than a magnetic-sector analyzer, but provides adequate mass resolution for most nuclear forensic applications. Detection limits are element dependent, on the order of 0.1–10 pg/l, with analyte requirements in the fg–ng range. The extraordinary sensitivity of ICP-MS is particularly important in nuclear forensic analysis for detecting ultra-trace quantities of long-lived actinides, and provides an advantage over α -spectroscopy of at least 1,000 \times for plutonium isotopes. Isotope dilution methods (Linge and Jarvis 2009) can improve the accuracy of trace-element analyses by ICP-MS to 2–5%. Simple sample-introduction methods for hyphenated techniques operating at near-atmospheric pressure (e.g., laser ablation, high-performance liquid chromatography, gas and ion chromatography, and capillary electrophoresis) have enabled ICP-MS to become a particularly versatile tool for many types of nuclear forensic investigation.

62.4.5.3 MS and In Situ Microanalysis

Most nuclear forensic samples are physically and chemically heterogeneous, while the MS techniques discussed in preceding paragraphs pertain to analyses of homogeneous bulk samples. Complementary techniques involving in situ microscale isotope and trace-element analyses also play a pivotal role in nuclear forensic investigations.

The most widely used technique for spatially resolved analysis of isotope and trace-element abundances is secondary-ion mass spectrometry (SIMS). The technique can be applied to any solid sample, and counterfeit currency, golf-ball-size pieces of metal, and sub-micrometer-sized grains of U-oxide have all been analyzed with SIMS (Wilson et al. 1989; Zinner 1989; Brundle et al. 1992; Ireland 1995; Vickerman 1998; Tamborini and Betti 2000; Gillen and Bright 2003). In SIMS, a focused, primary ion beam, typically O_2^+ , Cs^+ , or O^- , is used to sputter a sample surface. These primary ions have sufficient energy (keV) to penetrate a few nanometers into the surface of a sample and generate positive and negative secondary ions characteristic of the material. These secondary ions are produced with a broad energy distribution (maximum at a few electron volts and extending out to hundreds of electron volts), which requires the use of double-focusing mass analyzers. SIMS can be used to measure the concentration of any element, from H to Pu, over a dynamic range of more than nine orders of magnitude. The sputtering process is very matrix-dependent, making the limitation to accurate SIMS quantitation the acquisition of matrix-matched standards with sputtering behavior similar to that of the unknown analytes. If an appropriate standard is available, the accuracy of trace-element analyses by SIMS is \sim 2–10% (Wilson et al. 1989). The precision and accuracy

of isotope-ratio measurements are typically 0.02–0.4%, depending on ion yield and relative isotope abundances (Zinner 1989; Ireland 1995). Since the sputtering of chemically complex samples generates large numbers of molecular ions, a SIMS analysis that meets the needs of the nuclear forensic analyst requires a mass resolving power ($m/\Delta m > 5,000$) sufficient to separate elemental ions from molecular species of the same nominal mass (e.g., $^{24}\text{Mg}^{16}\text{O}^+$ and $^{40}\text{Ca}^+$ at mass 40).

Two SIMS operational modes are depth-profiling (used to observe changes in chemical or isotopic composition as a function of depth beneath a surface) and microprobe-mapping (used to observe changes in elemental and isotopic distributions across a sample surface). Both involve rastering the primary ion beam across the sample in a manner similar to that of the electron beam in SEM. The secondary-ion signal is correlated with the position of the primary ion beam where the secondary ions were generated. Sputtering of the sample by the primary beam produces a record of isotope and chemical variations in three dimensions (Ireland 1995). Resolution is determined by the lateral extent of the primary beam and can be as good as 50 nm with the NanoSIMS. Depth resolution is typically 1–2 nm. Another SIMS mode is bulk analysis (in which a static primary beam produces maximum sensitivity while sacrificing depth and lateral resolution); detection limits are generally in the range of 1–100 ng/g. Isotope-ratio measurements are carried out in analogous fashion, but with special attention to sample charging and alignment of the secondary ion beam in the mass spectrometer.

Isotope-ratio and impurity-concentration measurements of particle samples are most effectively conducted by SIMS. By virtue of its accurately focused primary beam, the operational characteristics of SIMS for micrometer-scale particles, most often weighing >1 pg, are precisions and accuracies of better than 0.5% (Ranebo et al. 2009). Real-world investigations often require consideration of complex environmental matrices (of little or no forensic value) for but a few Pu- or U-bearing particles. SIMS particle-search mode can find and analyze such important specimens. These searches may be performed in ion-microscope mode via a defocused ion beam (>100 μm diameter), or with the microprobe method previously discussed. Fully automatic particle searches, requiring only operator sample loading, may be executed to delineate interesting grains within a complex population of thousands of particles of ordinary constitution (Ranebo et al. 2009). Use is made of a conducting substrate, such as a polished, high-purity graphite disk or a double-sided, gummed support, for SIMS particle analyses.

Laser-ablation, inductively coupled-plasma mass spectrometry (LA-ICPMS) is an instrumental technique in which a laser-ablation cell and optical microscope supplant the spray chamber/nebulizer apparatus of a standard ICP-MS instrument. Subsamples of questioned material are ablated from a solid sample via laser (often a pulsed Nd-YAG tuned to 266 or 213 nm). Ablated specimens are transported in a stream of Ar to a plasma torch for ionization and mass discrimination as per solution ICP-MS. Only minimal sample prep is required, and few restrictions are placed on the nature of questioned solid samples (Brundle et al. 1992; Vickerman 1998). While laser spot sizes can be reduced to several micrometers, sensitivity is degraded as a result, and usual spatial resolutions are on the order of 10–100 μm . Matrix-matched standards are also necessary for accurate trace-element and isotopic quantitative analyses in LA-ICPMS. Depending on the quality of such primary standards, LA-ICPMS accuracies are typically 1–10%, with limits-of-detection in the parts-per-billion (ppb) range (► Table 62.1).

■ **Table 62.1**

Analytic methods for nuclear forensic analysis (adapted from Kristo et al. 2006)

Technique		Information return		Typical detection limit	
Bulk samples					
Radiochemistry		Isotopic		10 ⁴ atoms	
TIMS		Isotopic		pg-ng/g	
ICP-MS		Isotopic elemental		pg-ng/g	
GDMS		Isotopic elemental		pg-μg/g	
XRF		Elemental		0.01 wt%	
XRD		Molecular		~2 at.%	
Technique		Information return		Spatial resolution	
Microscopy					
Optical		Images		0.5 μm	
SEM		Images		1 nm	
TEM		Images		0.1 nm	
Technique	Information return		Typical detection limit		Spatial resolution
Microanalysis					
LA-ICPMS	Elemental isotopic		pg-ng/g		10–100 μm
SIMS	Elemental isotopic		1–100 ng/g		0.05–10 μm
SEM/EDS	Elemental		0.2–2 at.%		0.1 μm
EMPA	Elemental		0.01 at.%		1 μm

62.4.6 Organic GC-MS

62.4.6.1 General and Applications

Organic chemistry applications are often overlooked within the realm of NFA, a discipline highly skewed toward inorganic and isotopic measurements. However, an RDD or pre-det IND would dictate HE analyses, as would questioned specimens acquired from suspected hydrodynamic experiments for nuclear proliferation activities. Organic species can also be significant in pre-det route analyses, comprising target analytes in trace-evidence samples, inks, papers, adhesives, lubricants, and diverse materials for chemical “fingerprinting.” Although assorted organic instrumental techniques have been applied in specific NFA investigations, because of the sensitivity and specificity, as well as application to extremely complex sample matrices, the most versatile and valuable organic protocols in the authors’ laboratory have been based on GC-MS.

Complete textbooks are available on the general practice of GC-MS, and references with a specific forensic focus may be found as well (e.g., Yinon 1987; Saferstein 2002; Stafford 2005). The sensitivity of the technique is in the range of nanograms/liter (ng/l) for general analyses, improving to picograms/liter (pg/l) for selected-ion monitoring. Chemical separations of complex mixtures are accomplished by temperature-programmed capillary chromatography,

while exact identifications of eluted analytes are performed via compound ionization and mass spectrometry, in conjunction with reference standards and/or comparison libraries. Material profiling via GC-MS also has good potential for intelligence applications because it retains chemical information, in contrast to, for example, trace-element characterization of inorganic solids. Thus, minor components of a GC-MS spectrum positive for HE, in addition to contributing to the material fingerprint, may also be indicative of synthesis precursors, reaction by-products, side-reaction pathways, or other reactant/product impurities. Such data may often prove insightful for attribution of the synthetic method, process conditions, and (if very fortunate) perhaps the production lab.

62.4.6.2 Sample Prep

Sample-preparation practices for GC-MS can be grouped into several distinct categories based on complexity and separation tactic. The simplest technique is merely sampling a questioned vapor phase with a gas-tight syringe and introducing the specimen directly into the injection port of the GC.

Somewhat more involved, but similar in practice, is solid-phase micro-extraction (SPME; Pawliszyn 1997). SPME is a vehicle for the non-exhaustive extraction of volatile and semi-volatile species that is based on the partitioning of analytes between sample, sample headspace, and SPME fiber. The fiber consists of a glass substrate coated with specific chemical sorbent(s), and is available in several commercial variants depending on the nature of the sample and the diagnostic analytes. Protected within the barrel of a syringe needle, after exposure the SPME fiber is introduced directly into the GC injection port for thermal desorption and ensuing chromatography. Thermal equilibration of fiber with sample is typically performed over 20–30 min; collection and species concentration are performed simultaneously; no solvents are required; there is no hazardous waste stream; and potentially dangerous quantities of toxic materials are reduced to the nanogram (ng)–microgram (μg) levels appropriate to GC-MS analysis.

In contrast, solvent extraction is the most labor-intensive and chemically involved procedure for routine GC-MS sample prep, but it is also the most thorough. A questioned liquid or solid specimen is exhaustively extracted with suitable solvent, this process often aided by sonication. Methylene chloride (CH_2Cl_2) is an excellent reagent for removing nonpolar organic species from solid or aqueous samples. To increase the suite of analytes to a more expansive mix of general polar and nonpolar organic compounds, a solvent mixture of CH_2Cl_2 with acetone or an alcohol has proven effective. However, acetone alone is the reagent of choice for more selective extraction of nitro-based HE species. After volume reduction of the solution, with concomitant analyte concentration, the extract is injected into the GC.

Some polar species can be difficult to chromatograph, but such compounds may often be chemically derivatized to enhance the separation and detection of eluted analytes. Derivatization is a chemical reaction with an added reagent to produce specific products clearly derived from the reactants, but with improved GC-MS analytic properties. Thus, TMS (trimethylsilane) derivatives of alcohols are synthesized with *bis*(trimethylsilyl) trifluoroacetamide, primary and secondary amines are reacted with acylation reagents, and many other analogous reactions are likewise possible. Derivatives may also be implemented in conjunction with SPME, and derivatization reactions can be performed on-fiber.

62.4.6.3 Spectral Reduction and Compound Identification

The result of a GC-MS analysis is a large data file containing MS fragment-ion measurements (m/z^+ values and associated intensities) as a function of retention time of analytes on the GC column. If the investigator is interested only in compounds for which he/she has reliable primary standards, identifications based on matching retention times and corresponding ion-fragmentation patterns can be exact. Accurate quantitation may also be performed in this case by measuring a calibration curve (typically GC peak area versus known analyte concentration) and interpolating questioned-specimen empirical data between points on the fitted calibration function. However, as the CAS Registry currently comprises more than 50 million chemical substances, and the NIST/EPA/NIH (NIST08) MS database, for example, contains but 192,000 compounds, known comparison standards are generally not readily available for all analytes of potential interest to a forensic analysis. Consequently, an investigator often relies primarily on the evaluated match of experimental mass spectra with those in one or more comparison libraries.

Although GC-MS spectral analyses and compound identification can be performed manually, the effort can be tedious, inefficient, and problematic for highly complex chromatograms. The authors' laboratory makes productive use of a software package developed by the US Department of Defense and NIST for international treaty verification. The Automated Mass Spectral Deconvolution and Identification System (AMDIS) incorporates several algorithms to distill pure component spectra and associated data from intricate chromatograms, and then uses that information to assess whether the component can be attributed to a known compound in the reference database.

The authors use two primary AMDIS outputs to assess the degree of confidence of a potential identification. The first is the net match factor; it is the final match quality value for the correspondence between the deconvoluted empirical component and library spectra (perfect match $\equiv 100$). The other is the purity parameter, which is the fraction of the total ion signal at component maximum scan attributed to the deconvoluted component. For reporting purposes, the customarily used acceptance criteria in the authors' laboratory are: match factor $\geq \sim 80$ and purity $\geq \sim 60\text{--}70\%$. However, an identification with lower purity will sometimes be included if, in the estimation of an experienced analyst, the corresponding match factor is sufficiently high and individual interpretation of the experimental spectrum justifies it. (Analogous to computer-automated dermatoglyphic fingerprint matching, final assessment of a GC-MS spectrum by a skilled mass spectroscopist is essential for high-quality results.) However, an absence of a suitable standard reference material for confirmatory empirical measurements (both MS ion-fragmentation profile and GC retention time) requires that the analyst establish an identification largely reliant on a database match. Consequently, even though determination of a chemical species only via AMDIS may be believed to be a virtual certainty, a conservative forensic analyst will nevertheless label such identification as "tentative" only.

62.5 Special Nuclear Materials

The Atomic Energy Act of 1954 defines "special nuclear materials" (or SNM) as ^{233}U , plutonium, or uranium enriched in ^{235}U . These are the fissile isotopes (nuclides that undergo fission with high probability when irradiated with neutrons of any energy) that can be

produced in quantity, and the fundamental principle of nuclear nonproliferation efforts is limiting access to these materials. Of the three, only ^{235}U occurs in nature, where it constitutes $\sim 0.72\%$ of naturally occurring uranium; most of the balance of natural uranium consists of ^{238}U , which fissions efficiently only through interactions with high-energy (>1.2 MeV) neutrons. The boundary between low-enriched uranium (LEU) and highly enriched uranium (HEU) is arbitrarily set at 20% ^{235}U , where the well-reflected critical mass drops below 100 kg. The production of macroscale ^{239}Pu and ^{233}U is accomplished through reactor-irradiation of ^{238}U and ^{232}Th , respectively, and chemically recovering and purifying the desired product. While not part of the definition, SNM is usually assumed to refer to “weapons-grade” materials, in which the majority of the elemental content is the fissile isotope.

Nuclear forensic principles apply to all three of the special nuclear materials, including uranium of any enrichment (or depletion) in ^{235}U . They can also be applied to other materials arising in the nuclear fuel cycle (e.g., ^{237}Np , ^{241}Am) and to the natural-composition feed materials (uranium and thorium).

62.5.1 Natural Versus Synthetic Materials

Uranium and thorium are widely distributed in the earth’s crust, with average concentrations of ~ 2 and 8 ppm, respectively (Grainger 1958; Boyle 1982; Frondel et al. 1967; Wills 1997). Over 100 different uranium-based minerals are known, but deposits of high-grade ore (like uraninite and pitchblende, with as much as 70% uranium by weight) are rare. Most of the world’s supply of recovered uranium has been extracted from ores with a uranium content of only about 0.2% . Conversely, the mineralogy of thorium is less varied, and deposits of its principal mineral, monazite, are fairly common. The thorium content of pure monazite is typically between 5% and 10% .

Enrichment of ^{235}U (increasing its fractional concentration relative to ^{238}U) is one of three methods for producing fissile fuel for a nuclear explosive device. The other two involve the operation of nuclear reactors and the capture of neutrons by either ^{232}Th (to make ^{233}U) or ^{238}U (to make ^{239}Pu). The enrichment of ^{235}U is a difficult process, conducted on a very large scale. The production of uranium that is enriched in ^{235}U must necessarily be accompanied by the production of uranium that is depleted in ^{235}U . Enriched uranium and depleted uranium are synthetic materials, derived from natural uranium through the action of Man. While ^{233}U and ^{239}Pu are long-lived ($t_{1/2} = 1.59 \times 10^5$ years and $24,100$ years, respectively), neither exists in nature in significant concentration. Plutonium and ^{233}U are also synthetic materials; the mixtures of nuclides that make up a sample of either are defined by the engineering processes that give rise to the material. The presence of ^{233}U and/or ^{239}Pu in a sample can only come about through anthropogenic nuclear processes.

62.5.2 Separation of Uranium Isotopes and ^{235}U Enrichment

Natural uranium can be used as fuel in a nuclear reactor; however, as the proportion of ^{235}U increases, the ease with which a fission reactor can be used as an energy source increases. Modern light-water-moderated reactors are fueled by uranium enriched in ^{235}U from 0.71% (natural) to $3\text{--}5\%$. For greater ^{235}U enrichments, the size of a reactor for a given power level can decrease; reactors for ship propulsion use starting enrichments of at least 10% to minimize

the size and weight of the power plant, while submarines use fuels enriched to 90% or more (materials considered weapons-usable).

The mass number of the uranium nucleus influences the chemistry of the atom to which it is central by a miniscule amount; as a result, separation of uranium isotopes cannot be accomplished through the application of the standard chemical techniques used to purify or separate chemical substances. (See [▶ Chap. 15, Vol. 2](#) on isotope effects and [▶ Chap. 51, Vol. 5](#) on isotope separation in general.) Isotope separation must take advantage of those properties that are modified by changes in the number of neutrons in the nucleus. Most enrichment technologies currently used or under study rely on differences in mass, manifested either through differences in inertia (electromagnetic isotope separation) or the distribution of velocities at thermal equilibrium (gaseous diffusion, centrifugation, and aerodynamic techniques). All of these techniques take volatile compounds of uranium (such as UF_6) as feed material. Other techniques involve the interaction of laser light with an atomic or molecular vapor (laser isotope separation). The narrow frequency width of the delivered photons allows the selection of certain hyperfine electronic transitions that vary among the different isotopes of the element.

While other materials have been used as feed to uranium-enrichment processes, the most widely used volatile compound of uranium is the hexafluoride. At room temperature, UF_6 is a colorless solid with a density of 5.1 g/cm^3 . It sublimates at atmospheric pressure, and at room temperature has a vapor pressure of ~ 100 torr. The main disadvantage of working with UF_6 is its high chemical reactivity. It reacts vigorously with water, but is not very reactive with dry air. UF_6 reacts with most metals; however, nickel, copper, and aluminum are resistant. This holds only for pure UF_6 ; the presence of even small amounts of HF increases the rate of attack on even the resistant metals.

Electromagnetic isotope separation (EMIS) machines are often called Calutrons (Nier et al. 1940). The expense of running Calutrons is prohibitive, as they are inefficient in their consumption of both energy and resources, so the technique was abandoned in the United States in favor of gaseous diffusion. Though the method has drawbacks, it does offer the advantage of producing small quantities of weapons-usable materials almost immediately.

In EMIS techniques, a uranium-bearing volatile compound is introduced as a gas into an ion source, in which the molecules are destroyed and $+1$ uranium ions are produced. These ions are extracted and accelerated by means of an electrical potential of a few kilovolts. The initial thermal energy differences are relatively unimportant, so that ions of the same mass are deflected to virtually the same extent. The path radius of a particular ion is proportional to the square root of its mass. The separation of the masses can be related to the separation of the ion orbits at the point of collection. A homogeneous magnetic field provides for first-order focusing, so that if products with the same mass are emitted from the ion source over a small range of angles and velocities, they arrive at the same location after traveling through 180° of the path imposed by the magnetic field; the separated isotopes are usually harvested at the 180° position.

Another method that has been used to enrich uranium on the industrial scale is thermal diffusion (Vasaru 1975). Under the influence of a temperature gradient, the heavier molecular component of a mixture of two isotopes will tend to concentrate at the lower temperature. A thermal diffusion apparatus consists of two concentric, chemically resistant vertical tubes, where the inner tube carries high-temperature steam and the outer tube is jacketed and cooled by circulated water. The annular space between the two tubes is very narrow, less than 1 mm in thickness. UF_6 is introduced into the annulus between the two tubes at a pressure of

200 atmospheres, required to keep the UF_6 in the liquid phase near the hot inner wall. Lighter molecules tend to move toward the inner wall and rise to the top of the apparatus, while heavier molecules move outward and downward. The stringent requirements on the tolerances of the apparatus and the limited throughput make this method inferior to other diffusion-based enrichment technologies, and it has been abandoned.

Gaseous diffusion is the most widely used method for enriching uranium (Massignon 1958; Gowing 1964; Villani 1979), though it is being supplanted by gas-centrifuge technology. Gaseous diffusion has a proven efficacy and reliability, and is used in large-scale production facilities in several countries. Gaseous diffusion can be used as an enrichment method because the thermal equilibrium principle requires that all molecules of a gas mixture in equilibrium with its surroundings have the same average kinetic energy. Therefore, lighter molecules travel faster and strike the container walls more frequently than do heavier ones. As a consequence, a minute hole in the wall of the container, provided it is small enough to prevent the bulk outflow of the gas as a whole, will allow the passage of a larger proportion of light molecules than heavy ones, weighted by their relative concentrations. For uranium hexafluoride gas, made up of $^{235}\text{UF}_6$ and $^{238}\text{UF}_6$, the molecular masses are 349 and 352, respectively, and the ratio of average velocities is $(352/349)^{1/2} = 1.0043$, with $^{235}\text{UF}_6$ moving faster than $^{238}\text{UF}_6$.

The porous diffusion barrier is the central apparatus of the enrichment process. The holes in the barrier must have a characteristic diameter that is smaller than the mean free path of the molecule to be separated; if collisions between molecules can occur with significant frequency within the barrier, equipartition of energy will render the barrier ineffective. Also, the barrier must be thin enough so that it has adequate permeability at low pressure and be chemically resistant to hot UF_6 vapor. Diffusion barrier is usually fabricated in the form of tubes into which the UF_6 gas is introduced. These tubes are bundled, and the bundles are housed in cylindrical diffusers, each of which is associated with a compressor for manipulating and repressurizing the enriched gas that flows through the walls of the barrier tubes into interstitial space. There is also a heat exchanger for ensuring that adiabatically compressed or expanded UF_6 gas is at thermal equilibrium and never heats to the point that it becomes dangerously reactive or cools to a temperature at which it freezes; the gas is heated significantly by compression.

Gaseous diffusion operates at temperatures above and pressures below the UF_6 triple point, near 70°C and 0.5 atmospheres. Since the difference in average velocities between $^{235}\text{UF}_6$ and $^{238}\text{UF}_6$ is small, the enrichment that can be obtained in any single separation cell is minimal. The actual performance of a gaseous diffusion cell depends not only on the relative masses of the UF_6 molecules, but also on the pressure and temperature of the gas and the permeability, size, and geometrical configuration of the barrier. For instance, if the operating pressure of the cell increases, the mean free path of the UF_6 atoms gets shorter and the probability of molecular collisions inside the barrier pores increases; this reduces the efficiency of the barrier, though the flow of gas through the barrier is increased.

Typically, the input flow of UF_6 is adjusted so that roughly half of the feed diffuses through the walls of the barrier tubes into interstitial space, becoming enriched (product), while the rest remains in the tubes, becoming depleted (tails). To obtain significant enrichments, this process must be repeated multiple times (Krass et al. 1983). In a “cascade” of diffusion cells, the product of one enrichment cell is used as feedstock for another. The cascade is “simple” if the tails are discarded; the cascade is “countercurrent” if the tails are reintroduced as feed in a lower enrichment stage. Simple cascades are not used because of the potentially profligate waste of uranium. After the initial start up of a countercurrent cascade, feed material is introduced only in the amount necessary to balance the withdrawal of product and tails.

Early in the history of the US gaseous-diffusion plants, a shortage of uranium made it necessary to use material as cascade feedstock that had been recovered from reactor applications. This resulted in the cascades being contaminated with the nonnatural uranium isotopes ^{236}U , ^{233}U , and ^{232}U , a contamination that persists to this day due to the long cascade residence times for a given uranium atom. Incomplete fuel reprocessing resulted in significant amounts of Np, Pu, and Tc (all of which have volatile fluorides) being introduced into the cascade as contaminants in the feedstock.

Another way in which uranium can be enriched is by means of the gas centrifuge (London 1961; Olander 1978; Villani 1979). If a polyisotopic gas is subjected to an intense centrifugal force, the heavier molecules will move preferentially to the periphery of the rotor, producing a partial enrichment of the lighter molecules near the center of the apparatus. The separation factor increases with the centrifugal force supplied by the motion of the centrifuge and decreases with an increase in temperature. The separation factor also increases with the mass difference between the molecules, unlike gaseous diffusion where it increases with mass ratio; therefore, centrifugation is as effective a technique for heavy elements as for light ones.

The enrichment gain from a single centrifuge unit can be more than an order of magnitude greater than that for a gaseous diffusion cell, but the technical challenges associated with operating high-speed centrifuges are substantial. For instance, the required centrifugal acceleration to the wall of the rotor is more than 10^5 times the acceleration of gravity; issues of material strength are clearly important. It is still necessary to operate a centrifuge-based plant in cascade, requiring both the removal of product and tails and the introduction of feedstock with the centrifuge running at speed. The technical difficulty of the problem has taken many years to address, only recently bringing centrifuges into competition with gaseous diffusion as an enrichment technology. The mass load of a given centrifuge is limited by the necessity that the UF_6 remain in the gas phase under the operating conditions of the apparatus; otherwise there will be no diffusion and, consequently, no enrichment. If it is assumed that the pressure at the wall of the rotor during operation of the centrifuge must remain below 100 torr (the UF_6 vapor pressure at room temperature), then the resulting pressure at the center of the rotor comprises a good vacuum. The initial gas load of a stationary centrifuge with a radius of 10 cm must remain below 3.6×10^{-4} atmosphere so that the pressure at the rotor wall during operation does not induce a phase change; this is the limitation of the maximum load of UF_6 in a given centrifuge unit. A cascade of gas centrifuges draws considerably less power per unit of enrichment work than does a gaseous diffusion cascade, but operates in pretty much the same way. Uranium enrichment by gas centrifuge is economical on a smaller scale than is gaseous diffusion.

Similarly, structured cascades should result in the same $^{234}\text{U}/^{235}\text{U}$ isotopic signature from centrifuges as from gaseous diffusion; however, centrifuge plants have been competing with diffusion plants only recently, so they are not expected to be contaminated with the nonnatural uranium isotopes that persist in the products of gaseous diffusion. A sample of enriched uranium in which the relative enrichments of ^{234}U and ^{235}U are about the same, but in which ^{236}U is absent, is quite likely the product of a gas centrifuge plant.

Aerodynamic enrichment techniques have been demonstrated on the industrial scale (Becker et al. 1981; Grant et al. 1977). The separation of isotopes is produced by the centrifugal force applied to a stream of gas through deflection by a solid barrier. The feed gas is composed of UF_6 diluted in a much larger amount of a light auxiliary gas, usually hydrogen. The method provides a high stage throughput with a reasonably high single-stage separation factor, and offers the advantage that the technology is less complicated than that in high-speed centrifuges.

This is an emerging technology, and at this time the forensic radiochemist is unlikely to encounter a large sample of uranium enriched in ^{235}U by this technique.

Uranium can be enriched in ^{235}U through laser isotope separation (LIS). Lasers produce large numbers of photons, all having nearly the same frequency. Atomic or molecular ionization or excitation can be stimulated by these photons, but the process occurs with high probability only when the energies of transition and the photon are closely matched, relative to the energy widths associated with each. The energy associated with a given transition is broadened by collisions in a high pressure gas, and by the motions of the individual molecules toward or away from the photon source (Doppler effect). Still, with careful preparation, it is possible to selectively excite atoms or molecules of one of the isotopes of uranium in the presence of the others (Boehm et al. 1978; Villani 1979; Letokov 1979; Krass et al. 1983). Selective excitation of one isotopic species in the presence of one or more others requires a laser that is tunable with a precision of one part in 10^5 . This can be accomplished by modern dye lasers. In LIS, single-stage separation factors have been so good that reactor fuel compositions have been obtained in a single pass.

The isotopic signature of enriched uranium arising from LIS is more like that occurring in EMIS than from any of the cascade techniques. Both ^{234}U and ^{238}U should be depleted relative to ^{235}U in the product. The value of $^{234}\text{U}/^{238}\text{U}$ will depend on the frequency width of the laser beams as well as line broadening in the target atoms or molecules determined by the experimental setup.

An issue that all enrichment methods have in common is criticality safety during the later stages of procedures resulting in highly enriched ^{235}U . The danger of an accidental criticality can be eliminated if the concentration of enriched uranium in a single location is kept below the critical amount. Critical mass is also dependent on chemical form, density, geometrical configuration, and the presence of neutron reflectors or moderators; in general, successful forensic measurements can be made on samples that have masses that are far below the concerns of criticality. For the forensic radiochemist, the limitation on batch size may mean a greater variability in isotopic signatures between samples of highly enriched uranium than between samples of low-enriched uranium.

62.5.3 Nuclear Reactors and the Production of Plutonium and ^{233}U

A nuclear reactor is a device in which the fission process is controlled, either to produce power, radionuclides, or both. All nuclear reactors depend upon an initial load of fuel that contains fissile materials. Absorption of a neutron by a fissile nucleus produces another fission event with high probability, accompanied by the emission of more neutrons. If one of the neutrons emitted in each fission induces another fission, the number of neutrons in each succeeding “generation” will remain constant and the neutron economy is balanced. This is referred to as a self-sustaining chain reaction, and is the normal operating condition of a nuclear reactor. (See [Chaps. 57](#) and [58](#) in this Volume.)

Fission-produced neutrons can be absorbed by any of the materials present in the reactor, with relative probabilities proportional to the neutron-absorption cross sections of the nuclei in the materials. Even for the fissile nuclides, neutron-capture reactions compete favorably with neutron-induced-fission reactions. For example, low-energy neutron irradiation of a sample of ^{235}U results in the production of ^{236}U about half as often as it results in fission. Fuel containing the fissile actinides always contains some of the even-mass actinide nuclides as well, which are

called “fissionable” since the neutrons present in the reactor can cause fission in these nuclides with only low probability.

Power reactor fuel usually consists of uranium enriched in fissile ^{235}U to the level of a few percent; the balance is fissionable ^{238}U , which does not initially contribute much to the production of fissions in the reactor fuel. The ^{238}U in the fuel preferentially captures a neutron, resulting in the production of ^{239}U :

The nuclide ^{239}U is short-lived and decays to ^{239}Np , which in turn decays to ^{239}Pu , a fissile material:

If the reactor runs long enough that a significant fraction of the initial ^{238}U is transmuted into ^{239}Pu , the neutron economy must be corrected for fissions arising in neutron reactions with ^{239}Pu . ^{238}U is a “fertile” material under these conditions, since it produces fissile fuel under neutron irradiation. The other common fertile material is ^{232}Th , which produces ^{233}U in much the same way:

This is the origin of a separate fuel cycle, involving thorium and ^{233}U .

The reactor components of greatest interest to the forensic radiochemist are the “clean” fissionable material that constitutes fresh nuclear fuel, and the neutron-irradiated fuel that is the result of nuclear reactor operation. The design of the reactor determines both the ingoing fuel composition and the outgoing fuel isotopic content (Glasstone and Sesonske 1967).

The spent fuel from a nuclear reactor is a mixture of nuclides in which the percentage of each is a function of the isotopic content of the starting material, the temperature of the core and moderator, the period of irradiation, the energy distribution of the incident neutrons, and the radioactive half-lives of the nuclides produced. Fuel efficiency in production reactors is less important than is the isotopic composition of the plutonium product. Particularly important is the minimization of the amount of ^{240}Pu produced relative to ^{239}Pu ; ^{240}Pu has undesirable nuclear properties for use in nuclear explosives. The operation of a plutonium production reactor is often incompatible with the economical production of power, unless the reactor design permits refueling during power production.

With short reactor irradiation times, relatively pure ^{239}Pu is formed from natural or low-enriched uranium. The cross section for thermal neutron capture by ^{239}Pu is about 1,020 barns, and a sizable fraction produces ^{240}Pu rather than fission:

Consequently, when a fuel element containing uranium is subjected to a prolonged exposure to thermal neutrons, the amount of ^{240}Pu formed begins to increase relative to ^{239}Pu . The product ^{240}Pu is fissionable rather than fissile, and neutrons are captured to form ^{241}Pu ,

Higher-mass plutonium isotopes are produced by subsequent neutron captures. A fuel element in a plutonium production reactor is usually removed when $^{240}\text{Pu}/^{239}\text{Pu}$ is between

0.05 and 0.07, at which point there is generally considerable reactivity left in the fuel. In a natural-uranium-fueled reactor, this limits the burn-up of the initial uranium content of the fuel (sum of all isotopes) to 0.1–0.2%; in other words, at fuel discharge, ~99.8% of the original uranium remains in the form of uranium isotopes.

The plutonium recovered from irradiated uranium is always composed of a mixture of plutonium isotopes, providing the basis for “fingerprinting” the material. At very low burn-ups (low integrated neutron flux), ^{239}Pu dominates the mixture. At higher burn-ups, the concentrations of the other plutonium isotopes become more significant. For weapons applications, a compromise is struck between the production of unwanted plutonium isotopes and the inefficient use of the uranium starting material. Different countries strike somewhat different balances in defining the ^{240}Pu content of weapons-grade plutonium.

The ^{233}U – ^{232}Th fuel cycle offers many potential advantages in the generation of power when compared to reactors fueled with ^{235}U or ^{239}Pu ; even so, it is only a small factor in the nuclear power industry (Wymer 1968; Dukert 1970). This is mainly because thorium does not exhibit a fissile isotopic form in nature. A reactor cannot be fueled with thorium alone; thorium must be used in conjunction with one of the fissile materials as fuel. Another problem with the ^{233}U – ^{232}Th fuel cycle is the side production of ^{232}U . It has a half-life of ~70 years, so its intrinsic radioactivity is quite high, and one of the decay daughters (^{208}Tl) emits a 2.6-MeV γ ray, which is very hard to attenuate with shielding because of its very high energy. Even though the dose associated with freshly purified ^{233}U (containing ^{232}U) is low, a large sample quickly grows in dangerous amounts of daughter activities. Otherwise, the production of ^{233}U for weapons applications has many parallels with the production of plutonium. Irradiations tend to be of short duration at high flux, in order to minimize the buildup of undesirable uranium isotopes (including ^{232}U).

Analogous to plutonium produced in reactors, ^{233}U contains variable amounts of all the other uranium isotopes; this is particularly important when ^{235}U has been used to jump-start the breeding process. The heavier uranium isotopes eventually provide an avenue to the production of the plutonium isotopes, which may be dominated by ^{238}Pu rather than ^{239}Pu .

The application of nuclear forensic techniques to samples of purified heavy elements is well developed; however, when applied to unseparated spent reactor fuel, the methods become more complicated. The radionuclide content of a spent fuel sample is not controlled solely by radioactive decay, but is strongly influenced by neutron-induced transmutation. Chronometry based on the decay of the light plutonium isotopes cannot be performed due to the initial presence of an overwhelming quantity of uranium. The isotopic distribution of the plutonium isotopes and the concentration of fission products can provide a means by which the degree of transmutation can be estimated, unless the material started out as MOX fuel (where reprocessed plutonium is incorporated into fuel fabricated from uranium with insufficient fissile content to support the reactor application). More study is needed to extend the methodology to unprocessed fuel.

62.5.4 Recovery and Purification of Special Nuclear Materials from Reactor Products

Reprocessing is a general term that refers to the chemical recovery of a product heavy element following irradiation of fertile target material within an isotope production apparatus. A nuclear reactor is most often used for isotope production, with neutrons inducing the

desired nuclear transformations. For example, ^{237}Np targets are reprocessed for ^{238}Pu , and ^{232}Th blankets around breeder reactors are reprocessed for ^{233}U . The most important reprocessing efforts, contemporary and historic, have focused on the isolation of plutonium from irradiated uranium.

Most of the radioactivity in freshly discharged reactor fuel is due to the decays of the fission products (except for thorium-based fuels, where a significant fraction of the external dose is due to the decay of the daughters of ^{232}U). During the reactor irradiation, short-lived radioactive species quickly reach equilibrium concentrations, where the rate of loss due to decay (or neutron reactions) balances the rate of production. Products with half-lives comparable to, or longer than, the reactor irradiation interval continue to build up in the fuel. When reactor operations stop, radioactive decay provides a substantial reduction in total radioactivity over the next few months, leaving only longer-lived and stable species to be removed by fuel reprocessing.

Chemistry used in the recovery of plutonium from irradiated fuel must provide a separation from all these elements, other fission and activation products, and the actinides (including a large amount of unburned uranium), and still provide a complete recovery of plutonium. The same issues apply to the recovery of uranium from spent thorium fuel. Most of the processes must be performed remotely due to the intense radiation field associated with the spent fuel. As in the enrichment of uranium, the batch size in the later steps of the reprocessing procedure, where the fissile product has become more concentrated, is limited by the constraints of criticality safety. There is a balance between maximizing the yield of the precious fissile product and minimizing the concentrations of contaminant species left in the final product. These residual contaminants, which can be detected at very small concentrations using standard radiochemical techniques, provide a fingerprint of the industrial process used to recover the material.

A number of reprocessing methods have been used for the recovery of plutonium, and some are still undergoing active research. These techniques have included co-precipitation (e.g., with LaF_3 , BiPO_4), molten-salt extraction (in KCl , NaCl , MgCl_2), ion exchange, and fluoride volatility. However, the most-developed separation methods have been based on solvent extraction and are known by names such as PUREX, Redox, Halex, and Butex (Campbell and Burch 1990; Sood and Patil 1996). The Butex process, at one time employed at the Windscale works in Great Britain, involves a solvent extraction with dibutyl carbitol; the plutonium product was prone to contamination with fission-product ruthenium, for which the decontamination factor was only $\sim 10^3$. The Hexone process, used at the Hanford works in the early 1950s, involves a solvent extraction with methylisobutylketone; the plutonium product was characterized by contamination with fission product Zr , Nb , and Ce , for which the decontamination factors were $\sim 10^5$. Given an analytical sample of only tens of milligrams, the contaminant species from both processes are nevertheless readily observable in a clean chemical fraction by their emitted radiations.

Variants of the Purex (Pu-U Reduction EXtraction) process are the most widely used plutonium-reprocessing schemes worldwide. Purex on the industrial scale began at the US Savannah River Plant in 1954 and replaced the Redox process at the Hanford works in 1956; every country that has produced significant quantities of plutonium has exploited the method. In Purex, the organic extractant is tributyl phosphate (TBP). In addition to optimum complexation properties for nuclear analytes of interest, TBP has a low aqueous solubility and is chemically and radiolytically stable. The density of TBP (0.98 g/cm^3) is so close to that of water that it is common to dilute it in a lower density solvent. It is completely miscible with common organic solvents (e.g., kerosene, *n*-dodecane) at ordinary temperatures.

In preparation for a Purex separation, spent fuel undergoes decladding, after which the fuel matrix is dissolved in nitric acid. The oxidation state of the plutonium in solution is adjusted to Pu(IV) by the addition of a reagent such as NaNO_2 , N_2O_4 , or hydroxylamine. Pu(IV) and U(VI) are then extracted as $\text{Pu}(\text{NO}_3)_4 \cdot 2(\text{TBP})$ and $\text{UO}_2(\text{NO}_3)_2 \cdot 2(\text{TBP})$, respectively, into the TBP-bearing organic phase. This first step provides an effective decontamination from the fission products and the trivalent actinides. Ferrous sulfamate is then added to reduce Pu(IV) to Pu(III), after which it is back-extracted into another aqueous solution, separating uranium from plutonium. Another TBP extraction of the aqueous plutonium product stream provides additional decontamination from unwanted byproducts. The Pu(III) is then oxidized to Pu(IV) to prepare it for concentration from nitric acid solution by anion exchange, after which it is reduced and precipitated as PuF_3 . Subsequent roasting in an oxygen atmosphere converts the plutonium to the storage form, a mixture of PuF_4 and PuO_2 . PuO_2 is also produced through precipitation with hydrogen peroxide or oxalic acid, followed by calcination. Uranium is stripped from the initial TBP phase into a low-acid medium and subjected to a second extraction cycle for further purification. The purified uranium solutions are concentrated by evaporation, after which thermal denitration results in UO_3 as a final product for storage.

The recovery of uranium from irradiated thorium is also accomplished using a TBP extraction procedure, called Thorex (Long 1978). The main difference compared with Purex is that in Thorex the valuable fissile material is uranium, and care must be taken in both efficiency of recovery and limitation of batch size (criticality safety), while in Purex the uranium fraction is usually less valuable and it exhibits a ^{235}U enrichment that does not present a severe criticality concern. Another difference is that neither the uranium product nor the thorium matrix are oxidized or reduced from their initial valences. As with Purex, there is a built-in decay time before Thorex can be performed, required by the 27-day half-life of ^{233}Pa decay to fissile ^{233}U .

In a two-cycle Purex procedure, the recoveries of both Pu and U are on the order of 99.9%; the Pu/U separation factor is 10^6 . The literature reports that plutonium decontamination factors from the fission products are $\sim 10^8$, and that the only long-lived impurities detected in the final product are ^{93}Zr , ^{99}Tc , and ^{106}Ru . However, the authors' experience has been that the light rare earths (mainly La and Ce), thorium, neptunium, and the trivalent actinides (Am and Cm), which exhibit some degree of complexation in nitrate media (Guseva and Tikhomirova 1979), are present in a gram-sized plutonium sample at concentrations that are detectable by radiochemical means.

62.5.5 Heavy Element Metals and Alloys

The fuel in most nuclear reactors is in the form of a heat-resistant ceramic. The main use of the metallic forms of the special nuclear materials is as fuel in nuclear explosive devices. Consequently, interdiction of a metal sample is the “smoking gun” that points to a weapons application.

Even though there are substantial differences between the metallic properties of plutonium and uranium, there are a number of similarities, both in chemical properties and in methods of production. Both metals build up oxide coatings on exposure to air, resulting in their passivation. Consequently, strong nitric acid will not attack either of the metals without the presence of a complexing agent. Uranium and plutonium are pyrophoric in bulk, burning

with an intense white light. Fine powders of both metals (which can be produced by hydriding/dehydriding) can spontaneously ignite unless protected from air. Both metals exist in more than one solid allotropic form, and make a very limited number of intermetallic solutions; powder metallurgy techniques have been developed to produce useful alloys from materials that are insoluble in the molten elements (Warner 1953, Vol'skii and Sterlin 1970).

Uranium is a dense silvery metal. It is malleable, ductile, and slightly paramagnetic. Though it does not form many solid solutions, it forms a wide range of intermetallic compounds. Uranium metal is a poor electrical conductor, with conductivity only about one half that of iron. It is also semi-plastic, and tends to yield under load.

Uranium metal displays three allotropic forms between room temperature and its melting point at 1,135°C. The orthorhombic α phase exists at temperatures up to 668°C. Uranium metal is rolled only in this easily worked α phase, otherwise cracking occurs. At temperatures over 500°C the metal starts to soften, but heat generated in working the metal can cause transformation into the complex tetragonal β phase, which is hard and brittle; β -phase uranium exists at temperatures between ~668°C and 776°C. Above 776°C, uranium metal displays the body-centered-cubic γ phase; the metal is quite soft at these temperatures, deforming under its own weight. Consequently, the γ phase is easiest to extrude. Hot uranium metal reacts with steel dies and rollers; therefore other materials are used in its manipulation.

Impurities in a uranium sample can strongly affect the phase-transition temperatures. Both α and β phases of uranium are complex, and do not form many solid solutions; conversely, the γ phase forms extensive solid solutions. For instance, addition of molybdenum to uranium metal at 2% concentration causes the β phase to completely disappear and stabilizes the γ phase sufficiently that it can be preserved at room temperature by rapid quenching. Important alloys of uranium include U-Mo, which is fairly chemically inert and has applications in the aircraft industry; U-Nb and U-Nb-Zr, with applications in the nuclear industry; and U-Ti, a very strong alloy.

The formation of the halides of Ca and Mg are favored over the formation of the halides of uranium at all temperatures up to 1,500°C; therefore, the reaction of a uranium tetrahalide with Ca^0 or Mg^0 will proceed exothermically to produce uranium metal. However, UCl_4 , UBr_4 , and UI_4 are deliquescent and air-reactive; practicality dictates that the production of uranium metal involves the reaction of UF_4 with either Mg^0 or Ca^0 :

The reaction of Ca^0 with UF_4 is sufficiently exothermic that both CaF_2 and U^0 reaction products are molten; the equivalent Mg^0 reaction is less exothermic, so the reaction must be initiated at an elevated temperature to result in molten products. CaF_2 and MgF_2 are not soluble in molten uranium, so the reaction produces a dense metallic uranium phase and a lower-density salt phase; unreacted starting materials are more soluble in the salt phase and concentrate there. After cooling, the salt cake can be physically separated from the metal product and discarded.

The reaction of Ca^0 or Mg^0 with UO_2 produces uranium metal powder, a consequence of the refractory character of the CaO or MgO reaction products that interfere with the formation of a molten metal billet. Ca^0 is preferred over Mg^0 , which results in the formation of a U^0 powder of finer particles at a lower chemical yield; the smaller powder size increases the pyrophoricity hazard. Metal powder is also formed in the electrolysis of UCl_3 or UF_4 dissolved

in a molten KCl/NaCl, or KUF₅ or UF₄ dissolved in molten CaCl₂/NaCl, both under an argon atmosphere; particle size is governed by the temperature and the electrolytic current density. Very fine uranium powder results from a hydriding/dehydriding process, but the pyrophoricity of the final product makes it difficult to use.

Plutonium metal is a poor conductor of both heat and electricity. The electrical resistivity of α -phase plutonium is the highest of all metals, almost that of a semiconductor. The metal has six solid allotropic forms below its melting point at 640°C. This prevents solid unalloyed plutonium metal from being used in sustained applications where heat is generated (e.g., nuclear fuel elements); the expansion that occurs in going from α phase to δ phase is greater than that occurring in any other metal except tin. Monoclinic α -phase plutonium is stable at temperatures up to 115°C, and has a density of 19.8 g/cm³. It is hard and brittle and difficult to machine. From 115°C to 185°C, the body-centered monoclinic β phase is stable. From 185°C to 310°C, the orthorhombic γ phase is stable. Phase changes between α - and β -Pu and between β - and γ -Pu are sluggish, taking place over several degrees. From 310°C to 452°C, the face-centered-cubic δ phase is stable, which is easy to machine, roll, and extrude. It is one of the few materials that contracts on heating (negative linear expansion coefficient). From 452°C to 480°C, the cubic-close-packed δ' phase is stable, and between 480°C and the melting point (640°C) the body-centered-cubic ϵ phase is stable.

Plutonium forms refractory compounds with A-subgroup metals and metalloids, but only the δ and ϵ phases exhibit an affinity for solid solutions. Most δ -phase solid solutions can be retained at room temperature by rapid quenching. Significant solid solutions in the other Pu phases are rare; Np and Pu are mutually soluble in the α phase, and Th and U mix with Pu in both the β and γ phases. Alpha-phase plutonium is highly reactive with oxygen, while δ -phase plutonium alloys are not as reactive.

The methods of producing plutonium metal are similar to those used in the production of uranium metal. The best reactants are PuF₄ and either Ca⁰ or Mg⁰. PuF₃ can also be reduced by the alkaline earth metals under an argon atmosphere:

I₂ is often added as an accelerant (“booster”). The reaction products are molten, and the mutually insoluble phases are separated mechanically after cooling. Plutonium metal is also produced by the reaction of PuCl₃ with Ca⁰; however, even though the melting points of the products are lower, the reaction is considerably less exothermic and requires the addition of a booster. Plutonium metal can also be produced in the reaction of Ca⁰ or Mg⁰ with PuO₂:

This chemical system is fluorine-free, which reduces the neutron background in the laboratory caused by ¹⁹F(α ,n) reactions. The final product consists of small beads of the metal, coated with the CaO reaction product that prevents the formation of a billet. The beads are recovered by treatment with dilute acetic acid, followed by a nitric acid wash.

Plutonium metal is often purified by electrolytic refining; the plutonium sample is immersed in a molten chloride salt under an inert atmosphere, comprising the anode in an electrolytic cell. Liquid Pu metal is collected on the surface of a tungsten cathode and drips off into a collector. Transition-metal contaminants remain in the residue of the anode, and rare earths and other actinides concentrate in the molten salt. The yield of purified Pu metal can be as high as 97%. Zone melting is also used to purify metallic plutonium; the plutonium is fabricated into a bar along which a high-temperature zone is passed. As the melt zone is moved

along the bar, impurities tend to concentrate in the melt. After repeated passes, the ends of the bar contain most of the impurities and are discarded.

Plutonium alloys can be prepared by melting and mixing the constituent metals; however, it is possible to introduce oxides or halides of plutonium to a melt of the alloying element if it is sufficiently reducing, and may remove the need for an inert atmosphere while producing the alloy. Important δ -phase weapon alloys are made by adding PuF_3 to molten Ga or Al.

62.6 Case Studies

62.6.1 Overview

Although relevant exercises have been conducted, and Cold War nuclear weapons programs provide validated analytic platforms, there have been no actual post-det terrorist incidents involving an IND or RDD to date. Consequently, no technical investigations in the contemporary embodiment of nuclear forensic analysis exist for an actual post-det situation, and all discussed case studies necessarily focus on interdicted, pre-det materials. (However, a nuclear accident that is perhaps exemplary of maximum-credible consequences of successful terrorist activities was the uncontrolled criticality and resultant explosion of the Soviet RBMK power reactor at Chernobyl in 1986.)

Over 1993–2008, the IAEA recorded >1,500 incidents of worldwide nuclear trafficking in their database. Of course, not all of these cases involved perilous radioactive materials; less than half were actual seizures, and most were scams, but on the order of 15–20 of them entailed weapons-usable SNM. However, some scams on the nuclear black market have been so incredible that one seriously questions the technical competence of such individuals, even if they manage to actually obtain dangerous materials.

One such hoax is the “red-mercury” phenomenon. This mythical substance is alleged to induce the detonation of a thermonuclear bomb without requiring the inconvenience of developing a primary fission trigger (in its nuclear embodiment). The record of red-Hg sales indicates that it has also been offered as a substance for guided-missile control, gravity bombs, antiradar coatings, enriched-U production, heat conduction, and medicines. A specification sheet accompanying one such suite of samples analyzed at Livermore claimed a density of $>20 \text{ g/cm}^3$ and the presence of Lr as a transuranic impurity. But the longest-lived isotope of Lr has a half-life of only $\sim 3 \text{ h}$, and it can be produced only a few atoms at a time through heavy-ion irradiation of an actinide target. Despite such nonsense, however, red-Hg scams have a history dating to 1979, involve significant sums of money, and persist to the present day (indicating that underestimating the knowledge base of some nuclear profiteers and end-users may be difficult to do).

The rest of this section will give an overview of selected nuclear casework conducted at Lawrence Livermore National Laboratory (LLNL) during the 1990s. These investigations provide examples of various types of material specimens and scams that, despite their age, remain representative of the nature of questioned samples analyzed today. The time that has lapsed since primary investigation is indicative that they have been adjudicated; ongoing investigations and more recent cases remain restricted as a matter of laboratory policy and agreements with submitting agencies.

62.6.2 Hoax: Nonradioactive – Source Analyses Only

In 1996, US federal law enforcement requested accelerated forensic analyses of a small (0.37 g) fragment of gray metal, to be conducted in real time during an ongoing operation. The material was being advertised as a sample of a larger available quantity – a substance that could substitute for HEU in an atomic weapon. The specimen was determined to be high-purity Sc, and it was characterized at macro, minor, trace, and ultra-trace concentrations of diverse species by a comprehensive suite of analytic techniques. A full description of these various analyses, with photographs, tables, and figures, has been previously published in the refereed literature (Grant et al. 1998a).

Forensic radiochemical assays of a suite of heavy elements (Ra, Ac, Th, Pa, U, Np, Pu, Am, and Cm) were negative, with the exception of ^{230}Th at trace level. Th-230 is a daughter product of the decay of natural U and was present at a specific activity of (2.21 ± 0.74) dpm/g. As its half-life is not sufficiently long for independent existence derived from primal nucleosynthesis, the presence of ^{230}Th in the Sc specimen was indicative of a prior association with U (although only 0.15 ppm of residual U remained in the sample). Indeed, the commercial recovery of Sc from U-mining operations is an historic endeavor (Lash and Ross 1961; McGinley and Facer 1976).

Metallurgical examination of the Sc suggested that it originated in a casting pour. Quantitative assay of 55 elements revealed C, P, Cr, and Fe as the major impurities, and the presence of relatively high P concentration (0.3%) also supported a former connection to U mining or processing. Phosphoric acid, TBP, and HDEHP are often used in these enterprises. No fissionable species or weaponization indicators were detected in the specimen. Although Sc is chemically similar to U, their nuclear properties are quite different, and to assert its use as substitute HEU was clearly a hoax.

As passing interest, anomalous characteristics for which no clear explanation emerged were also observed for this particular sample. These included the enrichments of several parts-per-million-level lanthanides over their natural values by appreciable factors and the presence of synthetic, odd-chain fatty acids.

62.6.3 Hoax: Radioactive – Source Analyses Only

Attempts by subnational (and perhaps some national) groups to acquire nuclear materials for use in weapons projects created a cottage industry in illicit-material hoaxes, driven principally by the lure of large prospective profits. One such persistent scam, centered in Southeast Asia, trades in specimens of irregularly shaped metal alleged to be ^{235}U . These pieces often have markings of “uranium,” “made in USA,” a serial number, the skull-and-crossbones symbol, and others.

Such a metal object was discovered while cleaning an office in a consulate in 1996, and it had markings identical to those in illicit sales casework that had been assessed by LLNL in 1988. The sample was proffered by a local military official as nuclear-weapons-grade HEU. Although “lost” in the embassy for 8 years, the part submitted for analysis in 1996 was derived from the 1988 investigation and may actually be the specimen that began the Southeast Asian uranium scam.

This questioned sample was at least radioactive, and it weighed 8.96 kg. It had a complex shape, and a number of arc-shaped scratches on the surface led to the suggestion that it may

have been part of a hinge, possibly from a shipping container. The density was measured to be 17 g/cm^3 . Material composition was “U-10Moly,” an alloy of U with 9.9 wt% Mo, and it had been electroplated with a thin ($90 \text{ }\mu\text{m}$) surface layer of pure ($>99\%$) Ni. The U was significantly depleted (D-38) to $\sim 0.3 \text{ wt}\%$, but not to the modern D-38 standard: concentrations of the minor U isotopes were too elevated. Chronometry gave the last chemical purification of the U as $1961 \pm 3 \text{ years}$. An open-source, primary reference for this investigation is Grant et al. (1998b).

No evidence could be found for an association of use or fabrication of the item by the nuclear industry. The part had been made by the National Lead Company of New York, but the company was out of business. The D-38 specimen was most likely a component of an aircraft counterweight unit, and was probably military in origin.

62.6.4 Incident: Natural Radioactivity – Source Analyses Only

In 1998, a high-school student in the San Francisco Bay Area purchased a vial of yellow powder at a local flea market. It was labeled “97% pure uranium.” The student brought the material to school, where a teacher recognized it as a potential sample of yellowcake. The teacher confiscated the material and gave the entire specimen to knowledgeable staff at UC Berkeley, which then requested assistance from the Department of Energy (DOE) Oakland Office for sample identification. DOE deployed a regional RAP team (Internet 2009) to transport the sample to the Livermore Forensic Science Center.

Primary containment of the specimen was a snap-top plastic vial $\sim 3 \text{ cm}$ in diameter and 8.5 cm long. It was nearly full of the questioned powder, which weighed $\sim 100 \text{ g}$. Secondary containment during RAP transport was a coffee can, while an outer container consisted of a cardboard box. Exposure rate readings ($\beta + \gamma$) were $\leq 0.1 \text{ mR/h}$ at the surfaces of both the box and the coffee can, and was $\sim 0.5 \text{ mR/h}$ at the wall of the primary vial. No external α radioactivity was detected.

The material was a light-yellow, very fine powder, without the “wet” appearance associated with U nitrates or chlorides. It was insoluble in water and did not appreciably affect the pH of the supernatant liquid, but it readily dissolved in only slightly acidified solution. Approximately 0.2 g was quantitatively dissolved in 25 ml of dilute HNO_3 , and suitable aliquots were analyzed by γ -ray and α spectrometry.

No radionuclides, other than the naturally occurring isotopes of U and their daughters, were measured in excess of background activities in any of the α or γ spectra. The weighted averages and 1s uncertainties of empirical data from these counting results were $^{235/238}\text{U} = (7.02 \pm 0.04) \times 10^{-3}$ and $^{234/238}\text{U} = (5.11 \pm 0.03) \times 10^{-5}$ (mass ratios). Additionally, upper limits were placed on the following isotopic ratios with ^{238}U : $^{232}\text{U} (\leq 7 \times 10^{-13})$, $^{232}\text{Th} (\leq 1.5 \times 10^{-3})$, $^{239}\text{Pu} (\leq 4 \times 10^{-10})$, and $^{238}\text{Pu} (\leq 8 \times 10^{-13})$. Further, quantitative dilution gave the concentration of U in the oxide powder as $(0.744 \pm 0.022) \text{ g U/g specimen}$.

Thus, the questioned material was a U salt with an isotopic composition very close to that of natural abundance. Based on the chemical behavior, its color, and the grams-per-gram assay, it is likely that the specimen was, in fact, anhydrous uranyl hydroxide or yellowcake ($0.78 \text{ g U/g sample}$). Although a relatively routine investigation, the officials involved requested and received expedited, overnight analyses. Apparently, the innocuous student was at some risk for potential legal repercussions had the material been other than natural U.

62.6.5 Real: Radioactive – Source and Route Analyses

A Turkish national was stopped by Bulgarian border guards in 1999, who then discovered a Pb container secreted in the trunk of the car. The Pb shield contained a yellow cushioning material, paper molding, and, at the center, a sealed-glass ampoule with gray-black powder inside. A full rendering of the timeline, case details, photographs, tables, and figures for this investigation may be found in Moody et al. (2005). This was perhaps the most complete and expansive interrogation of illicit nuclear material ever conducted to that point, including both source and route forensic analyses, and it served as an exemplar for subsequent nuclear forensic investigations undertaken at LLNL.

The black powder weighed ~ 4 g, had a density of 2.1 g/cm^3 , and appeared effectively homogeneous under stereomicroscope examination. X-ray diffraction analysis identified the material as predominantly U_3O_8 , with a much lesser component consisting of a hydrated uranyl fluoride compound. Quantitative analysis of 72 elements (from Li to Th) by ICP-MS and other techniques measured the total impurity level between 500 and 800 ppmw, indicative of a batch reprocessing operation. SEM and TEM measurements revealed that the oxide powder comprised extremely friable, loosely compacted clumps of $<100 \text{ }\mu\text{m}$ in size. Much smaller particles made up the clumps, and were characterized by a very fine grain-size distribution of <0.1 to $\sim 1 \text{ }\mu\text{m}$, with the mean size of an empirical measurement of 816 grains being $\sim 160 \text{ nm}$. Such particle size was unusual within the authors' experience, in that it is unnecessary for operations in US facilities and constitutes a considerable respiratory hazard.

Radiochemical analyses of the sample disclosed that it had been recovered from reactor-irradiated material. Quantitative measurements were made of ^{232}U – ^{236}U and ^{238}U , and ^{234}U was enriched to 1.1 wt% and ^{236}U to 12 wt%. The enrichment of ^{235}U was 73 wt%, making the specimen weapons-usable material. This was clearly no hoax.

The sample also contained ppb levels of Pu and ^{237}Np , and high ^{238}Pu content was consistent with reactor burn-up of light-mass U isotopes. The residual fission products ^{134}Cs , ^{137}Cs , and ^{125}Sb were also detected, providing supplemental evidence of reactor irradiation and reprocessing. The absence of other fission products gave some clues to the reprocessing chemistry.

With the forensic actinide measurements as input, and the assumption of a simple cross-section model, the isotopic composition of the starting material could be computationally reconstructed. The results were $^{235}\text{U} = 90\%$, $^{238}\text{U} = 9\%$, and $^{234}\text{U} = 1\%$. The material had been used as fuel in a nuclear reactor, and the reactor type was light-water research or propulsion (in fact, a pressurized-water reactor (PWR)). The high ^{236}U concentration signified a long irradiation history that had consumed $\sim 50\%$ of the initial ^{235}U .

Two Pu and seven U radiochronometers were measured to determine the time elapsed since the sample was last chemically processed. All but one chronometer were reasonably consistent, and the weighted average of the data was (6.46 ± 0.14) years before the LLNL assay date of April 17, 2000. The processing date was therefore approximately October 30, 1993, with an uncertainty of <2 months (2s). Only ^{237}Np from ^{241}Pu – ^{237}Np was present in large excess over the in-growth concentration, and it gave an anomalous age of ~ 130 years. Reprocessing was thus less successful in removing trivalent species (e.g., PUREX). The ^{241}Pu – ^{241}Am contaminant age was the same as the U age, indicating that Pu was also likely present during purification and not introduced later. There was no evidence of spoofing.

Forensic analyses of the collateral route evidence were also important for attribution in this case. The yellow material inside the Pb shield was determined via FTIR and GC-MS to be paraffin wax (C_nH_{2n+2}). Gel-permeation chromatography measured a MW ~ 390 Da and an average C number ~ 26 . The distinctive yellow color was due to an appreciable loading (64–77 wt%) of $BaCrO_4$ of 1–4 μm size dispersion. The organic component was characterized by SPME/GC-MS, and the result was a chemical fingerprint consisting of 47 individual species, with five naphthalene varieties being relatively unusual compounds.

Assessment of the wax was facilitated by the fact that the inorganic $BaCrO_4$ is seldom used by Western countries today because of the environmental toxicity of Cr. However, it is used as yellow pigment in paint, ceramics, and other applications, as well as an oxidizer in energetic materials in South America, Asia, and Eastern Europe.

Optical microscopy of the paper in the mold liner, as well as a gummed label on the Pb, was used to identify and quantitate the hardwood and softwood fibers composing the papers. The species of trees represented included Scotch pine, spruce, aspen, alder, and birch. The fibers were determined to be definitely not North American, inconsistent with those found in Western Europe or Scandinavia, but consistent with an Eastern European origin.

Metallurgy of the Pb shield concluded that it had been cast in a crude mold, probably sand, and fashioned by hand. Exterior markings gave clear evidence of coarse hand-filing for contouring and smoothing, but no indication of the use of machine tools. The Pb was an alloy containing ~ 5 wt% Sb to increase metal malleability. The isotopic composition of the Pb was inconsistent with mining operations in the United States, but similar to ores obtained from Asia or Europe.

In contrast to the Pb container, the glass ampoule represented skilled craftsmanship. The material composition was consistent with commercial soft borosilicate glass.

Overall attribution of this sample attempted to integrate the various forensic results into a self-consistent picture. The HEU was definitely not of US origin, as an initial enrichment of 90% ^{235}U is distinctly different from the $\sim 93.5\%$ composition of US Oralloy. This conclusion was further supported by the extremely fine grain-size distribution. Moreover, while the collateral pathway indicators (paraffin wax, paper composition, and Pb-shield isotope ratios) both excluded and implicated multiple regions of the world, Eastern Europe was linked as a potential source of materials by all of these diverse analyses.

Comprehensive attribution of the Bulgarian HEU is still incomplete. However, a ^{235}U enrichment of 89–90% was the material standard employed by the USSR for its nuclear weapons and nuclear power programs and, in conjunction with the other forensic analyses, connects the former Soviet Union to the likely origin of this sample.

Abstract: This chapter deals with the “nuclear safeguards” verification system and describes procedures and measurement methods that allow the safeguards inspectorates/authorities to verify that nuclear materials or facilities are not used to further undeclared military activities. These procedures and methods provide the strong technical basis upon which the safeguards inspectorates/authorities issue their conclusions and receive the broadest international acceptance regarding the compliance of participating states with their obligations.

63.1 Introduction

Nuclear safeguards stands for the “methods developed to safeguard the peaceful activities against diversion of nuclear material by the risk of early detection – controlling nuclear material as a measure of arms reduction” (IAEA 1985). More specifically, IAEA safeguards has been described as a comprehensive set of internationally approved technical and legal measures, applied by the IAEA, to verify the political undertakings of states not to use nuclear material to manufacture nuclear weapons and to deter any such use (IAEA 1998b). *Nuclear material* is defined as any source material (natural uranium, depleted uranium and thorium, excluding uranium ore) or special fissionable material (plutonium-239, uranium-233, uranium enriched in the isotopes 235 or 233) (IAEA 2002, No. 4.1) encountered in the applications of nuclear energy. Nuclear safeguards systems have been introduced because of the fears raised by the devastating effects of the nuclear bombs detonated over Hiroshima and Nagasaki at the end of the Second World War in August 1945 (Fisher 1997).

This chapter focuses on safeguards verification techniques and does not address other important safeguards measures such as containment and surveillance, near real time accountancy (NRTA), collection and analysis of satellite imagery, and “external information” on national programs and international trade and exchanges. These measures merit separate chapters outside the scope of this handbook. The chapter emphasizes the procedures and methods used to verify the accuracy of declared inventories and flows of nuclear materials but also those involving trace elements in “environmental samples” and novel technologies searching for undeclared nuclear material and activities. All procedures and methods (except new and novel technologies) discussed here are implemented by the IAEA and to a great extent by national or regional inspectorates.

In the wake of the arms race, which started between the Atlantic Alliance and the Soviet Union, the United Nations set up the International Atomic Energy Agency (IAEA) in 1957. The UN delegated to IAEA the task of promoting the peaceful uses of atomic energy and establishing an international safeguards system, with the aim to stop the proliferation of nuclear weapons and foster disarmament. Yet up to 1971, IAEA was limited to exercise its safeguards on nuclear materials or facilities that were acquired through its technical assistance or were placed voluntarily in its custody (IAEA 1961; IAEA 1968). The nuclear Non-Proliferation Treaty (NPT) (IAEA 1970), which was open for signature in 1968, earmarked a major step toward a global international safeguards system. As of 2010, more than 190 states have become signatories of the treaty, covering indeed the dominant part of nuclear activities in the world. NPT entered into force in 1970. It requires the signatories to enter a safeguards agreement with the IAEA, whereby they renounce to nuclear weapons and place all their nuclear materials under IAEA control. Based on its Statute, the IAEA obtained approval of its NPT safeguards system (IAEA 1971) in 1971. NPT assures the international community that all nuclear materials and activities under safeguards outside the so-called Nuclear Weapon States (the five states that possessed nuclear weapons when the NPT entered into force: China, France,

Soviet Union (now Russia), United Kingdom, and United States of America) are used exclusively for peaceful purposes, contributing to dispel mistrust among states (IAEA 2002). With the expulsion of Iraqi armed forces from the territory of Kuwait in early 1991, the UNSCOM Special Commission and the IAEA (UNSC687 resolution) uncovered a comprehensive nuclear weapon program that Iraq had failed to declare in breach of its commitments as party to NPT. This led the IAEA member states to endorse a strengthening of IAEA safeguards measures providing the framework to detect undeclared nuclear material and activities. In 1997, the IAEA Board approved the model of “Additional Protocols (AP)” (IAEA 1997), and by 2009, the IAEA had concluded APs with 136 states and the European Atomic Energy Community (EURATOM). The AP spells out measures beyond the scope of INFCIRC-26, -66 or -153 type agreements providing broader access for the inspectorate to virtually all locations where nuclear material is handled or suspected and to detailed information on the state’s nuclear activities. The combination of activities under the comprehensive safeguards agreement and AP could determine that a state’s nuclear program is for peaceful purpose only and has been completely and correctly declared. This has drastically changed the safeguards system toward an information driven, state-level approach whereby the IAEA concludes for a state with increased confidence that no nuclear material has been diverted from declared sites and that there is no evidence of clandestine nuclear activities elsewhere. This state-level approach takes into account all available information to the IAEA such as inspection results, design information verification, open source evaluation including tracking of black-market nuclear networks, satellite imagery and environmental sampling.

EURATOM, instituted as early as 1958 by its six founding states (Belgium, France, Germany, Italy, Luxembourg and the Netherlands), established a comprehensive international nuclear safeguards system soon after the signature of a US-EURATOM Cooperation Agreement (1959). Argentina and Brazil set up a joint safeguards inspectorate (ABACC) in 1991. IAEA safeguards agreements foresee operating safeguards state systems of accounting and control over nuclear materials (SSAC). Partnerships between the SSACs, ABACC, EURATOM, and the IAEA are a strong factor in optimizing the resources of all parties, while the IAEA retains the capability to reach independent conclusions. With the indefinite extension of the NPT in 2005, the IAEA has been confirmed into its responsibilities in the operation and strengthening of a worldwide nuclear safeguards system in cooperation with the relevant national and regional institutions and the United Nations Organization.

International safeguards systems have certainly succeeded in limiting proliferation of nuclear weapons, but the world is still a long way from being free from their menace. Most non-nuclear weapons states are weary of unfair burden upon those subject to NPT, while nuclear weapon states appear reluctant to progress toward nuclear disarmament. A few states continue to use this as an argument for not signing NPT at the cost of mistrust by neighboring countries and international community. Others like Israel consider that existing safeguards systems or other treaties are not sufficient to ensure their national security and refuse to renounce to nuclear weapons. Serious conflicts in the Middle East, in the Korean peninsula, and Asia make much current headlines about further risks of proliferation. International safeguards, evidently, can at best contribute to build and maintain international confidence. However, their effectiveness (but also their limitations) had a positive impact on the negotiations of the successive arms limitation treaties and on the declaration of seven Nuclear Weapon Free Zones: the Antarctic (1961), Space (1967), South America (Tlatelolco Treaty 1968), Seabeds and Ocean Floors (1972), the Pacific (Rarotonga Treaty 1986), South East Asia (Bangkok Treaty 1995), and Afrika (Pelindaba 1996). The signatories of the four regional

treaties have the obligation to enter comprehensive safeguards agreements with the IAEA. Synergies between nuclear safeguards measures and future progresses toward a global nuclear disarmament, could be considered for the IAEA and CTBTO – the UN organization created for the control of the compliance with the Comprehensive Nuclear Weapon Test Ban Treaty, yet under ratification – as both are based in Vienna. The IAEA has acquired vast experience in safeguards verification techniques. It may be called to take on new roles in the future, such as verifying fissile material from dismantled weapons or verifying compliance with a potential global ban on the production of fissile material for weapons. It could thus contribute to both nonproliferation and disarmament.

The IAEA and a commission of eminent persons (IAEA 2008) have recently reviewed IAEA activities to meet future challenges up to 2020 and beyond. The increasing spread of nuclear material, technology, and know-how may pose increased proliferation risks in a globalized world. Safeguards, which will remain a core mission for the IAEA, must be further strengthened to cope with expanded growth and spread of nuclear power generation – and particularly, the establishment of new facilities for uranium enrichment, spent-fuel reprocessing, or processing of direct-use nuclear material. This will require new technologies to make safeguards more effective and efficient. Multilateral fuel-cycle centers and proliferation-resistant nuclear facilities could facilitate future safeguards implementation.

Meeting future challenges will require a robust IAEA “toolbox” containing: the necessary legal authority to gather information and carry out inspections, state-of-the-art technology, particularly for the detection of clandestine nuclear activities, a high-caliber workforce, and sufficient resources.

63.2 Safeguards Verification Measurement Procedures

The safeguards systems, based on regional and international treaties, consist of activities at the headquarters and on-site inspections to verify that states comply with their obligations derived from the related specific agreements. At Headquarters, state reports and declarations are being received and evaluated in context with all other available information such as inspection data, open source information and satellite imagery to assess the peaceful nature of a state’s nuclear program. Databases on nuclear material inventories and transfers are being maintained. In addition, inspection data acquired from implementing technical devices in the field are being archived and used for preparing and coordinating on-site inspections. On-site inspections are performed to independently verify nuclear material and activities and are considered the most powerful tool for safeguards purposes.

The *technical objective* of NPT is “the timely detection of diversion of significant quantities of nuclear material from peaceful nuclear activities to the manufacture of nuclear weapons and other nuclear explosive devices or for purposes unknown and deterrence of such diversion by risk of early detection” (IAEA 2002). To this aim, safeguards inspectorates regularly physically verify the inventories and transfers of declared nuclear materials subject to safeguards agreements. The type and amount of nuclear material are thereby inspected by direct physical and/or analytical measurements, using in the first place the nuclear characteristics of the material (emitted gamma or neutron radiation, isotopic composition, etc.) but also other “non-nuclear”-type measurements, such as weighing, calorimetry, Cherenkov radiation detection, etc. The goal is to verify the correctness and completeness of the nuclear material accountancy reports of the state and to confirm that no “safeguards significant quantities” of nuclear

materials are missing. In addition, IAEA inspectors are authorized to take “environmental samples” in specified locations within or near nuclear facilities in states having signed an “additional protocol,” which defines means for the IAEA to confirm the absence of signatures of undeclared activities in the facility process or its environment. All these measures are implemented in close cooperation with the facility operator and the state or regional safeguards authorities, but in a way that guarantees that the IAEA can draw its own independent conclusions.

International safeguards systems have thus two basic pillars, the first one being the state’s declaration regarding the nuclear activities and nuclear material inventory and accountancy in the nuclear facilities in the state, the second being a complex verification system to confirm that the state’s accountancy system and its declarations are both correct and complete. The state accountancy reports are expected to be based on operator’s own accountability data.

The following definitions and descriptions are used in order to quantify and qualify the inspection goals (IAEA 2002).

63.2.1 Diversion Strategy

Diversion of nuclear material, a particular case of noncompliance, could include:

The undeclared removal of declared nuclear material from a safeguarded facility.

The use of a safeguarded facility for the production of undeclared nuclear material (e.g., production of high enriched uranium in an enrichment plant or plutonium in a reactor through irradiation).

The use of nuclear material specified and placed under safeguards in such a way as to further any military purpose (applicable to specific safeguards systems).

The diversion strategy is a hypothetical scheme, which the diverter could consider to divert nuclear material or to misuse items subject to safeguards. It could include one or more concealment methods, i.e., actions to reduce the probability of detection, such as tampering safeguards equipment or accountancy, falsifying documents and declarations, etc. Verification principles, methods, and procedures are designed to uncover possible diversion strategies according to the type of nuclear material and the characteristics of the facility.

63.2.2 Type of Material

Nuclear material is classified according to the element contained and, for uranium the degree of enrichment. Six classes are defined at this time: plutonium (Pu), high enriched uranium (HEU), uranium-233 (^{233}U), depleted uranium (DU), natural uranium (NU), low enriched uranium (LEU), and thorium (Th).

63.2.3 Significant Quantity

To set a target for the quantification of the inspection goal, the IAEA currently adopts the following quantities (► [Table 63.1](#)) called “significant quantities” (SQs) as estimates of the amount of material that would be sufficient to manufacture a nuclear explosive device.

■ **Table 63.1**

IAEA Significant Quantities (SQs)

Material type	Isotopic composition	SQ
HEU	$^{235}\text{U} > 20\%$	25 kg ^{235}U
LEU	$^{235}\text{U} < 20\%$	75 kg ^{235}U
Natural U (NU)	$^{235}\text{U} = 0.7\%$	10 t NU
Depleted U	$^{235}\text{U} < 0.7\%$	20 t DU
^{233}U		8 kg ^{233}U
Plutonium	$< 80\% \text{ } ^{238}\text{Pu}$	8 kg Pu
Thorium		20 t Th

63.2.4 Type of Facility

Safeguards procedures vary also according to the type of facility and the physical form under which nuclear materials appear. Two types of facilities are considered.

Item facility: Power reactors (Light Water Reactor (LWR), On-load Reactor (OLR)), Research Reactor (Material Testing Reactor (MTR), Fast Breeder Reactor (FBR), (TRIGA) and Critical Assemblies, Nuclear Material Storage (dry and wet).

Bulk handling facility: fuel fabrication, reprocessing, conversion, and enrichment.

63.2.5 Material Balance Area and Measurement Points

A material balance area (MBA) defines an area in or outside of a facility such that:

- The quantity of nuclear material in each transfer into or out of each MBA can be determined.
- The physical inventory of nuclear material in each MBA can be determined when necessary, in accordance to specified procedures.

A key measurement point (KMP) is a location where nuclear material appears in a form that may be measured to determine material flow or inventory.

In addition to the above, whenever the state has accepted the additional measures foreseen in the model protocol INFCIRC/540, IAEA inspectors are granted access to “location-specific” environmental sampling points where they may take samples of air, water, vegetation, soil, smears, etc., to confirm the absence of undeclared nuclear material or activities at the specified location (IAEA 1997).

63.2.6 Material Stratification for Sampling

In order to make a meaningful statistical evaluation of the results of accountancy verifications, the inspector’s measurements must be planned in a way, which will provide independent estimates of the overall measurement uncertainties. All factors influencing these uncertainties must be considered, such as the material type and form, the sampling procedure, and the measurement method. According to theory and experience, the inspectorate detection

capability is optimal if the materials (items, batches, and lots) being verified are grouped into “material strata” having similar features, and physical and chemical properties. In practice, the inspector and the operator agree on a common stratification.

63.2.7 Type of Defect

A difference between the declared amount of nuclear material or nonnuclear material and the material actually present for verification purposes is called a *defect*. *Gross defect* refers to an item or batch that has been falsified to the maximum extent possible so that all or most of the nuclear material is missing (e.g., a spent fuel (SF) assembly is substituted with a dummy assembly containing no nuclear material).

Partial defect refers to an item or batch that has been falsified in such a way that some fraction of the declared amount is yet actually present.

Bias defect refers to an item or batch that has been slightly falsified so that only a small fraction of the declared amount is missing.

63.2.8 Sampling Plan

The term sample has two meanings:

- In statistical sampling, a sample is a subset of items selected from a defined group (population) of items.
- In material sampling for analysis, a sample is a small quantity of material taken from one item or container for measurement.

Statistical sampling plan procedures are applied to determine, in a given stratum, the number of items to be verified by each of the relevant measurement methods (nondestructive assay (NDA), weighing, sampling, and destructive analysis (DA)). The sampling plan is based on inspection by attributes and ensures that – based on the assumption that the operator’s declaration has been falsified by the goal amount – at least one defect will be correctly identified as a defect with probability $(1-\beta)$, where β is the nondetection probability. The preselected value of $1-\beta$ is typically 90% for high and 20% for low probability levels. The goal amount is usually 1 SQ (see [Sect. 63.2.3](#)).

63.2.9 Inspection Activities for Safeguards Verification Measurements

The physical verification activities consist of the following steps (IAEA 1997, 2004):

1. Advance planning of an inspection is done at the inspectorate headquarter or inspectors’ regional office and includes:
 - (a) A review of the facility design information and the accountancy reports.
 - (b) A stratification of the declared nuclear material available for verification in groups or “strata” of items of similar characteristics at each KMP.
 - (c) A statistical sampling plan for each material stratum to ensure a predetermined detection probability for the specific types of verification measurements and defect testing.

- 2. During inspection at the facility:
 - (a) For each KMP:
 - (i) Selected items or batches are measured using NDA.
 - (ii) Their weight or volume are determined, the operator’s scales or tanks calibration and declared tare weights are confirmed.
 - (iii) Statistically significant defects in the above tests are investigated.
 - (iv) Material samples are taken, as required by the sampling plan, and conditioned, to ensure that the integrity of the analytical information is maintained during transport.
 - (b) Environmental samples are taken at each “environmental sampling point,” as specified in the sampling plan.
- 3. The samples are analyzed in the laboratory selected by the inspectorate.
- 4. The inspection data and the results of the analyses are collected and evaluated statistically, usually at the inspectorate headquarter.

63.2.10 Inspection Frequency

A minimum time necessary for manufacturing a nuclear explosive device has been defined according to the material *category*, its irradiation status and suitability for conversion into components of nuclear explosive devices. *Direct use material* (such as Pu containing less than 80% ²³⁸Pu, HEU and ²³³U) can be used without transmutation or further enrichment. *Unirradiated material* does not contain substantial amounts of fission products thus it requires less time and effort to be converted to components of nuclear explosive devices than irradiated direct use material like spent reactor fuel. *Indirect use material* (DU, NU, LEU and Th) must be further processed to produce direct use material.

These categories set the period of time used as the objective for timely detection of a diversion (timeliness component of the inspection goal) and govern the *inspection frequencies* (number of inspections per year). Material categories and typical inspection frequencies are shown in [▶ Table 63.2](#).

63.2.11 Detection Probability

Because safeguards systems cannot in practice cover all material during an inspection, the inspectors take only random samples of the total population for verification. The goal is to assure that the detection probability for detecting a defect (a falsified or missing item, a certain

■ **Table 63.2**
Material categories and typical inspection frequencies

Material category	Material type	Inspection frequency
Direct use material unirradiated*	Purified Pu, HEU	1 month
Direct use material irradiated	Spent fuels	3 months
Indirect use material	(²³⁵ U < 20%, NU, DU, Th)	1 year

quantity missing from items or bulk material) applied to each material stratum is not below a predetermined level.

63.2.12 Safeguards Approach

The type of the safeguards agreement and facility, as well as all the above factors are taken into consideration when the safeguards approach for the particular facility is prepared. This approach will determine also the verification methods and the instruments that will be installed permanently at facilities and applied during inspections or used in the analytical laboratories on samples taken by the inspectors.

63.2.13 Classification of Methods

► [Table 63.3](#) lists the four classes of methods and instruments implemented for safeguards verification measurements.

63.2.13.1 Nondestructive Assay

A nondestructive assay is a measurement of the nuclear material content or of the element or isotopic concentration of an item without producing significant physical or chemical changes in the item. It is generally carried out by observing the radiometric emission or response from the item and by comparing that emission or response with a calibration based on essentially similar items whose contents have been determined through destructive analysis. There are two broad categories of NDA:

- (a) *Passive assay*, in which the measurement refers to spontaneous emissions of neutrons or gamma rays or to the total decay energy.
- (b) *Active assay*, in which the measurement refers to a stimulated emission (e.g., neutron- or photon-induced fission).

■ [Table 63.3](#)

Classification of methods and instruments

Class	Implementation mode
NDA unattended mode	Instruments permanently installed, possibly combined with remote monitoring via satellites or other communication means
NDA attended mode	Instruments kept at the facility or hand-carried/shipped by the inspector
Nuclear material sample DA	samples taken at the facility and shipped to an analytical laboratory for elemental and isotopic assay of fissile element
Environmental sampling	Environmental samples, mainly swipes taken from inside or outside surfaces at facilities or any other location, analyzed in specialized laboratories for signatures of potential undeclared activities

63.2.13.2 Destructive Analysis

Determination of nuclear material content and, if required, of the isotopic composition of chemical elements present in the sample. Destructive analysis normally involves destruction of the physical form of the sample. In the context of IAEA safeguards, determination of the nuclear material content of an item sampled usually involves:

- (a) Measurement of the mass of the sample.
- (b) The taking of a representative sample.
- (c) Sample conditioning (if necessary) prior to shipment to the Safeguards Analytical Laboratory for analysis.
- (d) Processing of the sample to the chemical state required for the analysis (e.g., dissolution in nitric acid).
- (e) Determination of the concentration of the nuclear material (U, Pu, Th) present in the sample (i.e., elemental analysis) using techniques such as chemical titration, controlled potential coulometry, gravimetric analysis, isotope dilution mass spectrometry, and K-edge densitometry.
- (f) Determination of the isotopic abundance ratios of U or Pu isotopes (i.e., isotopic analysis) using, inter alia, techniques such as mass spectrometry, gas mass spectrometry, and thermal ionization mass spectrometry.

63.2.14 Evaluations of Accountability Verification Measurements

The majority of the nuclear material samples, collected during safeguards inspections and sent to an analytical laboratory for measurements, serve several purposes. (i) They are taken to verify the correctness of declarations for the amounts of nuclear material (element (U, Pu, Th) and isotope amounts (^{235}U , ^{233}U)) in inventories and in transfers into or out of a facility; (ii) The analytical results obtained for the verification samples are also evaluated for the purpose of verifying the quality and functioning of the operators' measurement systems; these should "...conform to the latest international standards or be equivalent in quality to such standards" (IAEA 1972).

The operator-declared data and the measurement results, obtained for the inspection samples, are stored in the inspectorate in a central operator-inspector database where they can be accessed for subsequent evaluations (IAEA 2004). This database also contains the results of verification measurements by nondestructive assay (NDA) methods.

In the IAEA data analysis, various statistical techniques (IAEA 1998a) are used to derive separate estimates of the operator's and inspector's uncertainty parameters based on the collection of historical operator-inspector differences. The results of these evaluations are "performance values," typical for a specific facility and for each stratum (material type) and measurement method combination. The actually observed "verification measurement performance" is then used for the planning (sample size calculations), the conduct (establishing reject limits), and the evaluation (material balance) of inspections in a given facility.

The nuclear material contained and processed in a facility is stratified into items or batches that have similar physical and chemical characteristics. Grouping the material into strata simplifies verification and makes it possible to formulate the sampling plans needed to verify a material balance and to calculate its uncertainty. In calculating sampling plans, generally

three levels of “defects” (differences between the declared amount of nuclear material and the material actually present) are considered. In most situations NDA measurements serve for the purpose of detecting “partial and gross defects,” while sampling for DA copes with the detection of “bias defects.”

The sample size for a stratum defines the number of items to be verified in order to be able to draw conclusions about the total population. The total sample size can then be allocated among the accountancy verification methods for gross, partial and bias defects (IAEA 1998a; Jaech and Russell 1991). The uncertainty values generally used are the verification performance estimates for the given facility and strata. The International Target Values could serve as a substitute (IAEA 2001).

For every inspection, the analytical results are evaluated by an operator–inspector paired comparison. Differences exceeding the 3-sigma limits, calculated from the respective verification performance estimates, are classified as discrepant and subject to further investigations.

The “material unaccounted for” (MUF) over a “material balance period,” declared by the operator for each “material balance area” and its statistical significance are examined, where:

$$MUF = PB + X - Y - PE$$

with PB being the beginning inventory, X the sum of all inventory increases, Y the sum of all inventory decreases, PE the ending inventory.

For the declared MUF , its uncertainty σ_{MUF} is calculated from the verification performance estimates, as derived from the historical operator–inspector differences for this facility. The declared MUF is expected not to exceed $3 \times \sigma_{MUF}$; otherwise it is concluded that MUF is statistically significant. The calculated σ_{MUF} value is also compared to the International Standard of Accountancy (IAEA 2002, No 6.35) which is based on the operating experience at the various types of bulk handling facilities and defines the uncertainty with which a facility operator is expected to be able to close a material balance. If σ_{MUF} is larger, it is concluded that the facility measurement system does not meet this standard. In both cases, a significant finding will trigger follow-up evaluations, and activities with respect to the facility accountancy and measurement system will be initiated.

For all samples collected during inspections, the analytical results and their evaluation will be reported to the corresponding state as part of an inspection statement. Any significant finding in the material balance evaluations will also be reflected in the annual Safeguards Implementation Report.

63.3 Non-Destructive Assay (NDA)

63.3.1 Introduction

Nondestructive assay (NDA) for safeguards describes analytical techniques to measure, check, and verify the amount of nuclear material or of the elemental or isotopic concentration of an item without producing significant physical or chemical changes in the item. It allows inspectors to determine both the quantity and composition of nuclear material without ever sampling it directly. Ultimately, NDA techniques provide for the independent verification of the total amount of nuclear material held at a nuclear facility. The main nuclear materials of interest are uranium (U) and plutonium (Pu). Usually, no single measurement method can

directly determine the total amount of either Pu or U and only a combination of appropriate NDA techniques provide the total mass of the respective element.

The most widely used NDA instruments rely on the detection of nuclear radiation such as gamma rays and/or neutrons. Physical measurement techniques are also used with available instruments that measure heat, weight, liquid volume, thickness, and light emission/absorption. These physical techniques may be applied by themselves, or they may be used in combination with other nuclear measurements to provide quantitative measurements of the nuclear material. The general reference on the theory and application of passive NDA (PANDA) is given by reference (Reilly et al. 1991) and its addendum (Reilly et al. 2007).

The development of NDA instruments for the measurement of nuclear materials has evolved over many years. Various national and international institutions have developed NDA techniques with the goal of increasing the technical competence of safeguards systems. NDA instruments range in size and complexity from small portable units for use by safeguards inspectors during on-site verification of nuclear materials, to large in situ NDA systems designed for routine in-plant use (e.g., plant operator equipment, subject to independent authentication). Most of the NDA equipment has to withstand demanding environments such as high radiation fields, variable humidity, and high and low temperatures. In addition, such equipment must be reliable with consistently reproduced performance when operated by different users.

In general, NDA techniques are less expensive, nonintrusive on the operation of the nuclear facility, less time consuming than destructive analysis (DA) techniques, and are amenable to automation. NDA measurements can be performed on large quantities of nuclear material without breaching the container or containment of the material. Principally, NDA significantly reduces the need for DA sampling. However, the accuracy associated with NDA verification measurements is generally less than it would be if the items were verified at the final process stage at which sampling for DA and direct measurement of the nuclear material content become possible.

In many instances, NDA is the only technically feasible solution to perform verification, e.g., for valuable finished products (such as fresh fuel assemblies/pins) and also when direct access to nuclear material is impossible or undesirable (e.g., spent fuel). NDA measurements can be made outside of glove boxes, transport containers, on solutions inside processing systems, and on materials packaged for storage and disposition. NDA methods are also well suited to the verification of inhomogeneous bulk materials such as waste, where representative DA sampling cannot be performed. NDA offers another important advantage over traditional DA methods: measurements can be performed in a timely manner, both in situ and during inspection activities.

In the context of neutron and gamma-ray measurements, NDA techniques used by the inspectorate can be categorized as *passive* NDA or *active* NDA. Passive NDA refers to techniques that measure radiation emitted spontaneously from nuclear material. This method is often applied to Pu samples, because of the large spontaneous fission rate of the even-even Pu isotopes. Active NDA, on the other hand, refers to techniques that measure induced radiation responses from a sample, often using an external neutron source. These active methods are usually applied to perform uranium measurements where the spontaneous fission rate is low.

In addition to the quantitative measurements performed by an inspector, in some cases a qualitative measurement (attribute testing) is sufficient, e.g., simply confirming the presence of a representative isotope based on a typical gamma ray.

63.3.2 Safeguards Environment and Measurement Conditions

Safeguards inspectors routinely use NDA to perform the verification of nuclear materials present in the complete range of nuclear fuel cycle facilities. Today, a broad range of modern NDA instruments and techniques are available for the detection, identification, assay and verification of nuclear material in a wide variety of physical and chemical forms. The IAEA alone has authorized over 100 different types of NDA instruments for inspection use, while several NDA instruments are under evaluation and others under development (IAEA 2003; Zendel 2008). If safeguards verification is to be effective, inspectors have to perform independent measurements in order to verify declared material quantities. Selection of the correct equipment for a particular measurement task is a very important part of inspection activities and a thorough knowledge of an NDA technique's capability to meet the goal of the inspection activity is required. A high level of standardization of NDA equipment can reduce implementation costs significantly because less maintenance and training is required.

The diversity of nuclear materials present in the large variety of nuclear facilities to be safeguarded necessitates an equally diverse “toolbox” of NDA instrumentation. Nuclear material can be grouped into two main types: bulk material and item material. The first group comprises powders, pellets, solutions, scrap, and metals contained in various process and storage containers, whereas the second group consists mainly of fuel elements and pins in various storage configurations. Further distinctions are made in respect of the strategic value of the nuclear material as unirradiated direct use (e.g., Pu-oxide and mixed oxide (MOX) powders), irradiated direct use (e.g., spent fuel), and indirect use material (depleted, natural and low enriched uranium).

The hardware and software of an NDA system depend on the specific conditions (e.g., environment, sample matrix, etc.) of the measurement task. In most cases, different NDA instruments are required to obtain the total quantity for a given nuclear material sample. Only a combination of the results of several calibrated NDA techniques provides for a credible assessment of the type and quantity of nuclear material.

The nature of a particular inspection activity may require the customization of equipment and methods applied. The equipment and method should be simple and user friendly, and should provide results in a short time period, because the available inspection time is usually very limited. Furthermore, emphasis is placed on compact, lightweight, rugged, and reasonably priced equipment, which can be carried by the inspectors and thus remain completely under their control.

For large and complex facilities, the inspectorates require facility resident and specific safeguards equipment systems with features for attended, unattended, and remotely controlled operations. Some of the safeguards systems are integrated in the process equipment of the facility. The dimensions of the measurement head (the sensor) for these systems are often strongly conditioned by factors like sample geometry, plant requirements and detection efficiency, all of which factors impose boundary conditions that demand an individual design.

Calibration is necessary in all quantitative NDA measurements to relate measured responses (e.g., neutron coincidence rate or specific gamma intensity) to nuclear material characteristics. An accurate measurement depends crucially on the effective calibration of measurement instrumentation. This calibration is based on similar items whose nuclear material content is very accurately known. The resulting calibration functions including all necessary correction factors (such as those relating to neutron multiplication or gamma-ray

absorption effects) are incorporated into the software or firmware associated with a given measurement technique. In certain specific cases, the procurement and use of standards that are nominally identical to the measured items is possible. The use of calibration standards on a one-to-one basis is, in general, not feasible. Other alternatives, such as predictive modeling methods based on Monte Carlo calculations (mainly with the code MCNP (Monte Carlo Nuclear Particle)) are being increasingly employed for the prediction of responses for given samples under well-defined conditions (Bourva et al. 2007; Lebrun et al. 2007). A recent version of the Monte Carlo code, MCNPX (Monte Carlo Nuclear Particle Extended), can directly simulate the singles, doubles, and triples count rates from a known neutron source (see ► Sect. 63.3.4.3). In addition to meeting the urgent practical need for the reduction of the number of calibration standards, a good computational method, once developed, could play an important role in helping to identify false physical standards.

Measurement accuracy and quality control (QC) are important issues and require a regular measurement control program to provide standards against which to check the measurement performance of equipment. Normalization standards are applied independently of calibration standards to verify that an instrument is working properly and providing authentic data. Such a standard may be: (a) a well-characterized radiation source (e.g., ^{252}Cf source for neutron coincidence counters or sources of known energy and intensity for gamma spectrometers); or, (b) a properly authenticated sample of plant-specific material that has been kept under safeguards seal.

In some instances, safeguards inspectorates do not own the NDA equipment and need to share the instruments with third parties, e.g., operators. In this case, documented joint-use procedures should define arrangements for data sharing, authentication, recalibration and use of standards and software, maintenance, repair, storage, and transportation.

Sensors, together with their electronics and data generators, are security critical components, as they are the prime sources of independent safeguards data. Therefore, any unauthorized access to potentially vulnerable components must be prevented by containing these components in tamper-indicating housings and by restricting their servicing, repair, and replacement to inspectorate staff. A sensor mounted with its data generator in a single tamper-indicating enclosure constitutes a “smart sensor.”

NDA measurements are usually performed on a well-stratified inventory grouping items with similar weights, locations, and properties together. The inspector applies a random sampling plan based on the number of items per stratum, the measurement performance of the selected NDA instrument, the significant quantity and the non-detection probability. For verification purposes, random sampling plans are calculated to detect three types of defects: gross, partial, and bias. In some cases, where it is not possible to take samples or to obtain representative samples (e.g., inhomogeneous material such as dirty scrap), partial defect NDA measurements are performed in lieu of bias defect tests. The rejection limit for a given NDA measurement is set at three-sigma level of the performance-based measurement errors. Performance-based measurement errors are derived from the collection of historical operator–inspector differences obtained for each MBA/stratum/measurement method combination. The performance-based measurement error provides the overall uncertainty combining all sources of uncertainties associated with the measurement (Aigner et al. 2002; IAEA 2001). Real performance values for NDA techniques applied to safeguards have been reviewed extensively (Guardini et al. 2004).

The hypothesis of the random sampling plan is based on the assumption that no defect and hence no “outlier” is present in the stratum; otherwise the verification of the stratum has failed.

In most cases, partial and bias defect testing by NDA are accomplished through the application of destructive analysis (DA) methods to random samples derived from the selected items.

63.3.3 Gamma Ray Spectrometry

Most nuclear materials of concern to safeguards emit gamma rays that can be used for identification and quantitative measurement purposes. Gamma-ray devices measure the energy and intensity of gamma rays emitted from nuclear material. The transmitted gamma ray intensity is mainly a function of gamma ray energy, absorber composition, absorber thickness, and measurement geometry – each of these parameters must be carefully considered in the final analysis. Spectral analysis of emitted radiation identifies the type of a nuclear material by its characteristic gamma rays. Further analysis of selected gamma ray intensities provides quantitative characteristics such as enrichment and isotopic composition. In some cases, additional parameters must be measured (e.g., active length, weight, etc.) to calculate the total mass of the element.

The gamma spectrometry technique, used in nuclear safeguards for measuring enrichment, requires less expensive equipment than the mass spectrometry technique and the equipment required is very easy to operate and maintain. Gamma spectrometry techniques, if properly implemented, can offer very precise results within relatively short measurement times. Both low- and high-resolution gamma-spectrometric measurements are essential verification tools for safeguards purposes. Main attributes of various gamma ray-detector systems are listed in

➤ [Table 63.4](#).

63.3.3.1 Gamma Ray Detectors

Three main types of instruments are presently used for gamma spectrometry: inorganic scintillation counters (usually activated sodium iodide – NaI – crystals), semiconductor detectors (usually high-purity germanium – HPGe – crystals), and gas-filled detectors (e.g., high-pressure xenon ionization chambers). In all cases, the interaction of a gamma ray with the detector results in an electrical signal, whose intensity is proportional to the energy of the incoming gamma ray. The signal is amplified, processed in a pulse processing electronic chain, counted, and analyzed by a multichannel analyzer (MCA). The resulting gamma spectrum (which shows the number of events as a function of gamma energy) exhibits isotope-characteristic gamma peaks. Finally, the spectrum is analyzed using specialized software, performing peak fitting, background subtraction, peak intensity calculation, external or intrinsic calibration and calculation of the relative isotopic abundances.

Semiconductor detectors change their conductivity upon the impact of radiation by producing a flow of free electrons (n-type) or positive holes (p-type) in the semiconductor material. This results in a collection of charge at the electrodes, when a voltage is applied to the semiconductor. Germanium detectors presently offer the best resolution but must be cooled by liquid nitrogen – they are capable of resolving complex gamma spectra and determining the isotopic composition of essentially all nuclear materials present in the nuclear fuel cycle. Recently, electrically cooled HPGe became available with sufficient resolution to measure the isotopic composition of Pu-samples. These systems are especially important for future unattended and remote systems as well as for field applications where liquid nitrogen is not available.

■ **Table 63.4**

Gamma-ray systems

System	Detector	Verification task	Typical performance values (%) ^a
HRGS	HPGe	²⁴⁰ Pu-effective (%) in fresh PuO ₂ , MOX, scrap	0.3–1
		²⁴⁰ Pu-effective (%) in fresh fuel	1
		Uranium enrichment in UF ₆ cylinder	2 (LEU)-10 (DU)
HM-5	NaI	Search and Identify nuclear material	Attribute
		Active length	0.5 cm
		²³⁵ U enrichment in fresh fuel (NAIGEM)	3
MMCN		²³⁵ U enrichment powder/pellets	3
UBVS		²³⁵ U enrichment in UO ₃	3
MMCC	CdZnTe	²³⁵ U enrichment in fresh fuel assemblies	5
FMAT		Fresh MOX assemblies underwater	Attribute
IRAT		Irradiated nonfuel items	Attribute
SFAT		Spent fuel (no movement required)	Attribute
CBVB		Spent fuel bundles (CANDU)	Attribute
CBVS		Spent fuel bundles in stacks (CANDU)	Attribute
SMOPY	CdZnTe + FC	LWR spent fuel	5(attribute/consistency)
CRPS	CdZnTe (+FC)	Radiation profiling of dry storage casks	Attribute
HSGM	IC	Dose rate of irradiated items	Attribute
FDET	IC + FC	Burnup and SF confirmation	10(attribute/consistency)

^aAverage measurement time ~300 s.

Room temperature semiconductor detectors – cadmium/zinc/telluride (CdZnTe) and CdTe detectors in particular – have a proven record in safeguards verification measurements and related applications and have been in use for more than 15 years (Arlt et al. 1992, 1993; Arlt and Rundquist 1996). Peltier-cooled CdTe detectors operated at just below 0°C can achieve a resolution at relatively low gamma-ray energies (<200 keV), which are sufficient to perform selected isotopic measurements for uranium and plutonium. Silicon-pin photo diodes can serve as detectors for X-ray and gamma ray photons. They are used as gamma monitors in high-radiation fields. CdZnTe and CdTe detectors are ideal for field measurements and for the design of small detection probes that can be operated in close proximity to the items to be verified, even if there are space restrictions. They have become the most versatile room temperature gamma detectors, complementing the classical NaI and liquid nitrogen-cooled germanium detectors, by providing a medium resolution and a reasonable efficiency. In many cases, the use of these detectors has helped to increase both the efficiency and effectiveness of NDA methods applied in the nuclear safeguards field.

Scintillation detectors consist of a scintillator (usually inorganic crystals such as NaI) and a photomultiplier tube. The scintillator emits light upon the absorption of radiation. This light

is collected and converted into an electronic signal by a photomultiplier tube. Scintillation detectors operate at room temperature and are cheaper and more robust than germanium detectors. Scintillation counters have a low energy resolution, but high detection efficiency. However, they experience a distinct shift with temperature changes and need to be stabilized frequently. Improving detection capability, specifically resolution and sensitivity, is a continuous challenge. Recently, LaCl_3 and LaBr_3 scintillation detectors have been introduced (Synthfeld et al. 2006). This type of detector combines an improved detector sensitivity relative to CdZnTe detectors with a reasonable resolution (2% at 122 keV), in comparison with $\text{NaI}(\text{Tl})$ detectors of the same size. LaBr_3 detectors are already commercially available and implemented for isotope identification and are employed in uranium enrichment applications that profit from their superior resolution and sensitivity.

Gas-filled detectors record ionization of the gas in the chamber caused by the gamma interaction. The ion current is proportional to the amount of energy deposited by the gamma ray. Gas detectors feature long-term stability that cannot be matched by scintillator or solid-state detectors because the charge transport properties of the gas are not significantly affected by changes in temperature and the effects of radiation. This high stability is very important for detectors in unattended monitoring applications, where background temperature and radiation varies significantly. High-pressure xenon ionization chambers have emerged recently as gamma-ray spectrometers.

63.3.3.2 Low-Resolution Gamma Spectroscopy (LRGS)

Low-resolution gamma spectroscopy (LRGS) is simple to use and easy to implement under field conditions. LRGS applications in safeguards range from performing the quantitative verification of enrichment levels to the purely qualitative detection of spent fuel attributes and the presence of nuclear material.

Mini multichannel analyzers connected to NaI detectors (MMCN) are routinely used to verify the enrichment of uranium in powders and pellets (Arlt et al. 1997). The basic measurement procedure involves viewing a uranium sample through a collimator with a NaI detector. The enrichment is deduced from the intensity of gamma rays attributed to ^{235}U (e.g., gamma ray at 186 keV). Under a well-defined geometry, the measured count rate of the 186 keV photons is proportional to the ^{235}U abundance. Because of the strong attenuating properties of uranium compounds, infinite thickness for the 186 keV gamma rays is required and achieved with rather thin samples (3 mm for uranium metal, 15 mm for UF_6). The standardized procedure controls the geometry and utilizes specially designed support stands with collimators to provide a quantitative assessment of enrichment within minutes. The technique works very well for pure and homogeneous uranium materials.

Mini multichannel analyzers connected to CdZnTe detectors (MMCC) are the preferred instruments for fresh fuel verification giving more credible results than NaI -based systems (Arlt et al. 1993, 1997). The probe of the CdZnTe based system is less than 1 cm in diameter and can be inserted into the water tube or control rod guide tube of fuel assemblies and can therefore be implemented entirely in situ without any problems arising from interference resulting from radiation emitted by adjacent fuel assemblies.

In many instances, qualitative results are sufficient to characterize the nuclear material (e.g., Spent Fuel Attribute Tester (SFAT) to confirm the presence of the ^{137}Cs peak at 662 keV as

an attribute for spent fuel). In some cases, the absence of specific gamma rays confirms the absence of a particular nuclear material or distinguishes between nuclear and nonnuclear material (e.g., irradiation attribute tester (IRAT) used to confirm absence of nuclear material in closed containers stored in spent fuel ponds).

The handheld monitor (HM-5, Fieldspec) is a battery-powered, digital, low-resolution, gamma spectrometer (Jung et al. 2007). The HM-5 is a lightweight, easy to operate and very frequently used instrument for safeguards purposes. This device combines various functions such as dose rate measurement, source search, isotope identification, enrichment measurement. It uses a small scintillation NaI detector and energy selective electronics with a digital display. The HM-5 is a typical instrument for attribute measurements (if background permits) and capable of detecting different energy ranges of gamma rays, allowing qualitative verification of the presence of either plutonium or uranium in unirradiated nuclear material. The HM-5 is used to measure the active length of light water reactor (LWR) fuel assemblies. The measured length combined with data on uranium mass per unit of length, obtained from a neutron coincidence collar, enables the inspector to determine the total uranium mass in the fuel assembly. Recently, enhancement of the HM-5 has enabled it to measure the enrichment of unirradiated uranium materials. The instrument is also widely used as a key tool during complementary access (CA) activities to confirm the absence of undeclared nuclear materials (► Fig. 63.1).

The Fresh MOX Attribute Tester (FMAT) consists of a stainless steel cylinder housing shielding and collimation, a CdZnTe detector and a preamplifier (Aparo et al. 1999). A multiwire cable connects the waterproof measurement cylinder with a data acquisition/control unit (operated above water). The FMAT is used to verify fresh mixed oxide (MOX) fuel stored in spent fuel ponds awaiting loading to the reactor core. It clearly distinguishes between

► Fig. 63.1

Hand-held low-resolution gamma spectrometer (HM-5, Fieldspec)

the gamma rays of ^{235}U (186 keV) and ^{241}Pu (208 keV) and measures key plutonium gamma rays to evidence that an interrogated item exhibits the unique characteristics of fresh MOX.

The Uranium Bottle Verification System (UBVS) is an integrated system combining a weighing scale and NaI detector for ^{235}U enrichment measurement of reprocessed UO_3 in large storage bottles. An inspector determines the weight of the bottle ($\sim 1,300$ kg for full bottles) utilizing a dedicated scale. The weighing scale platform is sealed in a tamper-proof enclosure and is connected via a tamper-proof conduit to the measurement cabinet where the weighing terminal is stored. An ultrasonic gauge (ULTG) is used to measure the thickness of the bottle wall to allow for the attenuation correction of the subsequent enrichment measurement. The enrichment level is measured using either a calibrated HM-5 or a calibrated NaI detector connected to a multichannel analyzer. The acquired spectra are evaluated using a special computer code (NaIGEM). The code calculates the ^{235}U enrichment by a peak-fitting technique and allows for wall thickness and matrix corrections. A simple evaluation of the 186 keV peak by regions of interest alone would fail due to the strong interference of ^{228}Th stemming from the ^{232}U decay. Therefore, the masses for ^{235}U and U total composition are derived from a combined evaluation of the weighing results, the enrichment and the uranium concentration in UO_3 .

63.3.3.3 High-Resolution Gamma Spectroscopy (HRGS)

High resolution gamma spectroscopy (HRGS) is widely used in safeguards to verify the isotopic composition of plutonium or uranium in unirradiated nuclear material. The isotopic information for plutonium (^{238}Pu , ^{239}Pu , ^{240}Pu , ^{241}Pu , ^{242}Pu and ^{241}Am) is needed for neutron assays to convert measured neutron responses stemming from a limited number of Pu-isotopes (including Am) to total plutonium mass. Similarly, the heat output measured by calorimetry is correlated with the Pu-isotopics to obtain the total mass of Pu. Plutonium emits a complex spectrum of X- and γ -rays that are interpreted using dedicated software (Multi-Group Analysis (MGA)) (Gunnink 1990) either embedded in the multichannel analyzer software or as a stand-alone application. MGA mainly exploits the complex 94–104 keV region. MGA calculates the abundances of ^{238}Pu , ^{239}Pu , ^{240}Pu , and ^{241}Pu (^{242}Pu has indistinct gamma rays and is estimated from isotopic correlation). The abundances of ^{241}Am and, if present in the Pu sample, ^{235}U and ^{237}Np , and their respective element ratios are determined simultaneously.

The TARGA software contains an upgraded version of MGA as an engine, and provides a comparison tool for operator-declared and inspector-measured values. An alternative method – fixed energy response function analysis with multiple efficiencies (FRAM) – considers the higher energies, requiring specific hardware settings (Sampson et al. 2003). This allows for measurements in containers with steel wall thickness of greater than 10 mm.

The measurement of uranium samples usually involves only two main isotopes – ^{235}U and ^{238}U – providing the uranium enrichment of the sample. The spectral analysis of the γ -spectra is performed using a modified MGA code – MGAU (Gunnink et al. 1994). HRGS is used to determine the ^{235}U enrichment of uranium hexafluoride (UF_6) in shipping cylinders. In this case, low-resolution gamma ray systems would fail to provide accurate assays due to the complexity of the gamma spectra caused by the presence of additional radionuclides (e.g., ^{228}Th) stemming from natural decay chains plated on the container walls. In addition, for feed (Natural Uranium) and tails (Depleted Uranium) cylinders, the signal-to-noise ratio for the 186 keV peak with LRGS exceeds measurement tolerances and, therefore, HRGS is needed.

High Purity Germanium (HPGe) detectors cooled by liquid nitrogen are the backbone of HRGS applied by Safeguards. The Pu-sample is placed, in its original packaging, on a planar HPGe detector, acquiring a spectrum in the energy range 0–614 keV within 300–1,000 s. The spectrum is then analyzed using MGA code. Typical precisions and accuracies range between 0.5% and 2% reliability for all isotope abundances except ^{242}Pu .

The content of nuclear material in waste drums is usually very low and not homogeneously distributed. However, bulk-handling facilities such as reprocessing and fuel fabrication plants often accumulate a huge number of waste containers that together contain significant amounts of nuclear material. Representative sampling for DA is not feasible and NDA is the only means of determining the content of nuclear material in the waste. This is also true for the determination of holdup in bulk facilities. Although several NDA methods exist to tackle the problem of holdup accounting in bulk facilities, the related measurement uncertainties often exceed the specified goal.

The Segmented Gamma Scanner (SGS-IQ3) is a commercially available gamma assay system and uses transmission-corrected passive assay techniques to determine isotopics and to quantify individual isotopes (usually ^{239}Pu or ^{235}U) within items of scrap and waste (Booth et al. 1997; Mayer et al. 2004). The SIQ3 system utilizes a 15 cm, 4π low background, steel shield with three collimated HPGe detectors (coaxial) to perform quantitative gamma assay measurements in combination with three additional HPGe detectors (planar, optimized for low energy and high resolution) to measure the plutonium isotopics. Three transmission sources are mounted opposite the coaxial detectors to perform the transmission measurements. The quantities are determined both by summing the transmission-corrected result for each detector, and by summing the spectra and performing a quantitative assay based on the average density of the drum.

The in situ object counting system (ISOCS) is an intrinsically, numerically calibrated gamma spectrometry system incorporating a well-characterized HPGe detector (Bronson and Young 1997). The system is commercially available and is used to verify nuclear materials, in particular uranium, contained in holdup and waste. The calculation of the efficiency versus energy function is based on user-defined models that take into account all physical parameters describing geometry and sample matrix. The acquired gamma spectrum is analyzed using calibration information. The ISOCS calibration method is a powerful tool enabling calibration of the detector for a wide variety of source geometries and activity distributions.

The cascade header enrichment meter (CHEM) is another application that uses HPGe detection to qualitatively confirm the absence of HEU in centrifuge cascade header pipes of enrichment plants (Close et al. 1998). The technique uses an external radiation source (^{57}Co) and a special collimated HRGS with specific software to control, perform, and evaluate X-ray fluorescence (XRF) and passive measurements. The XRF measurement provides the amount of total uranium in the UF_6 gas. The deposit on the inside surface of a header pipe requires two measurements of the ^{235}U gamma ray at 186 keV with different geometries to determine the amount of ^{235}U in the gas alone. The level of enrichment of uranium in the gas of the header pipe can then be determined independently of the gas pressure.

Gamma/X-Ray/Weighing (GXW) method can simultaneously determine plutonium element concentration and isotopic composition both in solid and liquid samples from a single HRGS measurement (Dragnev et al. 1997; Parise et al. 2003). It exploits the full spectroscopic information contained in a gamma spectrum from a plutonium sample using several gamma-spectrometric analysis techniques such as enrichment-meter-type measurements and passive X-ray fluorescence analysis (XRF). In combination with weighing, this method determines the total Pu content in a sample.

63.3.4 Neutron Counting Techniques

NDA based on neutron measurements plays an important role in the qualitative and quantitative analysis of nuclear material, in particular plutonium in bulk and item form. Plutonium samples have a high rate of spontaneous fission neutrons, while uranium samples are typically interrogated using an induced fission neutron signature.

Neutrons are primarily emitted from nuclear material in three ways:

1. Spontaneous fission of uranium, plutonium (in particular involving even isotopes of plutonium), and curium (in spent fuel).
2. Induced fission from fissile isotopes of uranium and plutonium, typically by means of a low-energy neutron source.
3. α -particle induced reactions, involving light elements such as oxygen and fluorine.

Contamination of the plutonium-bearing materials with other spontaneous fission nuclides (e.g., ^{244}Cm) will strongly interfere with the neutron assay. ^{244}Cm is the strongest neutron emitter and accounts for more than 95% of the neutrons in spent fuel although the share of curium is only about 0.5% of the plutonium content.

A few ppm of ^{244}Cm will lead to a significant overestimation of the result. However, ^{244}Cm is an important “tagging” nuclide that could be used for neutron measurements in combination with known concentration ratios of curium, plutonium and uranium (Rinard and Menlove 1997). This technique can be applied only if chemical processes do not change the element ratio, i.e., there is no separation. This is the case for determining plutonium and uranium composition in selected process wastes, e.g., the leaching process of spent fuel or vitrification process.

Falsification of the neutron count by adding a neutron source (such as ^{252}Cf) could fool the neutron assay equipment. However, the subsequent presence of ^{252}Cf in the product would be a serious problem and a very strong indicator of attempted spoofing.

Main attributes of various neutron detector systems are listed in [Table 63.5](#).

63.3.4.1 Neutron Detectors

Neutrons can only be detected by indirect methods, e.g., via nuclear reactions producing charged particles. The electrical signal produced by the resulting charged particles can then be processed by the detection system.

^3He gas detectors are the most commonly used neutron detectors in safeguards. The detection principle is based on the $^3\text{He} (n, p) ^3\text{H}$ reaction. This reaction produces a proton with recoil energy of 732 keV that ionizes the surrounding gas and generates an electronic signal. Thermal neutrons have a high absorption cross section for the $^3\text{He}(n, p)^3\text{H}$ reaction. The neutron absorption cross section decreases with orders of magnitude as the neutron energy increases, hence moderation of neutrons is essential to achieving a reasonable detection efficiency of the counting system. ^3He gas detectors have been proven robust and effective. They are commercially available with various diameters, lengths, and gas pressures.

BF_3 detectors are occasionally used based on the $^{10}\text{B}(n, \alpha)^7\text{Li}$ reaction. BF_3 detectors are less sensitive to gamma radiation fields but are less efficient. Recently, solid-state neutron radiation devices with boron carbide diodes have been developed, which demonstrate very promising potential for future applications such as miniaturized handheld neutron detection devices.

■ Table 63.5

Neutron systems

System	Detector	Measurement task	Typical performance values (%) ^a
HLNC	³ He	Pu in PuO ₂	0.5(pure)-3(scrap)
		Pu in MOX	3–5
		Pu in pins/assemblies	1
INVS		Pu in small samples (powder, pellets, liquids)	1.5
		Pu in MOX scrap	2.5
FPAS		Pu in fresh MOX pins	2
GBAS		Pu in in-process materials	5–10
BNCN		Pu in fast critical assembly fuel plates	5
DRNC		Pu in fast critical assembly fuel drawers	3
UFBC		Pu in Powders, MOX pins and fresh FBR fuel	1–2
UWCC		Pu in fresh MOX fuel assemblies (underwater)	2–3
SFCC		Pu in spent fast breeder reactor fuel (underwater)	8
WCAS		Pu in large waste container	11
WDAS		Pu in waste drums	8
PNCC		Pu under various field conditions	
PSMC		Pu in impure samples (MOX)	2
ENMC		Pu in pure samples (MOX)	0.5
		Pu in impure samples (MOX scrap)	2–3
UNCL		²³⁵ U in LWR fresh fuel	2–4
AWCC		²³⁵ U in HEU, bulk UO ₂ and pellets	3–5
		²³⁵ U in LWR fuel	1–5(burnable poison)
AEFC		²³⁵ U in spent fuel from research reactors	10
SFNC	Fission chamber	Presence of spent fuel	Attribute

^aAverage measurement time ~300 s.

Fission chambers have a thin layer of ²³⁵U plated on the inner wall of a gas-filled chamber. Neutrons will cause fission of ²³⁵U producing high-energy fission fragments (~90 MeV). The fission fragments cause ionization in the stopping gas, which could then be transformed to an electronic signal. The fission chambers have the highest tolerance versus gamma dose rates (up to roughly 10⁴ Gy/h) of any of the available neutron detectors because the short ranging fission fragments deposit a much larger quantity of energy in the stopping gas in comparison to the gamma rays. They are the only neutron detectors capable of measuring highly active spent fuel. The inherently low efficiency of fission chambers is compensated for by the large number of neutrons available for counting.

^3He and BF_3 detectors are sensitive to high gamma radiation fields, which produce a high pile-up and mask the neutron signal. Under such conditions, fission chambers are used.

Plastic and liquid (organic) scintillators are often used for fast-neutron detection because of their fast response and modest cost. Their function is based on the elastic scattering of the neutron on light elements (mostly carbon and hydrogen). The proton absorbs the kinetic energy from the neutron, producing heat and visible light. The visible light is collected in a photomultiplier tube coupled to the scintillator and converted to an electronic pulse. However, gamma radiation also produces visible light while interacting with the scintillator. This sensitivity to gamma radiation severely limits the application of scintillators in the selective neutron detection process.

Europium-activated lithium iodide (enriched in ^6Li) as a scintillator can detect neutrons and gammas simultaneously (Mukhopadhyaya and Mchugh 2004; Syntfeld et al. 2005). Neutrons are detected via the reaction $^6\text{Li}(n, t)\alpha + 4.78 \text{ MeV}$. The high-energy pulses from the neutron events can be well discriminated from the pulses stemming from the interactions with the gamma radiation.

63.3.4.2 Gross Neutron Counting

Gross neutron counting for safeguards purposes is applied in searching for undeclared nuclear material and activities, process monitoring, measuring holdup in glove boxes, and in the assay of spent fuel.

The handheld neutron monitor (HHNM) is a portable ($\sim 4 \text{ kg}$) neutron detection device with three ^3He proportional neutron counters, a GM counter and integrated electronics, which provide a means of searching for and localizing neutron radiation sources. A measurement sequence consists of background and verification measurements. When a predetermined threshold is exceeded, the detector triggers an alarm and records the relevant information.

The DG-5 is a portable device for gamma and neutron detection using a liquid scintillator. The presence of neutrons is a strong indicator of nuclear material and activities. Neutrons are difficult to shield by heavy metals in contrast to gamma radiation. They need lightweight elements to lose their energy and be absorbed while gamma radiation would penetrate this neutron shield to a large extent. Therefore, safeguards inspectors use the DG-5 to scan for undeclared nuclear material and activities.

The spent fuel plutonium canister counter (SPCC) is designed to operate underwater and to count neutrons emitted from natural uranium spent fuel rods stored in dry stainless steel canisters (Menlove et al. 2002). The counter uses three ^3He detectors located inside watertight and Pb-shielded pipes spaced 120° apart and surrounding a cylindrical cavity. SPCC determines ^{240}Pu mass from total neutron counts corrected for background, ^{238}U spontaneous fission and multiplication.

The portable neutron uranium holdup (PNUH) monitor system is a neutron counting system to determine the quantity of uranium holdup within the cascade halls of an enrichment plant (Beddingfield and Menlove 2002). PNUH is custom built and the detector head is a polyethylene-moderated assembly with 25 ^3He neutron proportional tubes. PNUH measures the total neutron signals at various prescribed locations. Measurement data are acquired with standard INCC software and evaluated with specialized PNUH software using distributed source term analysis (DSTA).

63.3.4.3 Neutron Coincidence Counting

During fission, multiple neutrons (multiplicity $\sim 2\text{--}3$ for plutonium) are emitted contemporaneously from the splitting nucleus. Because they arrive in the detector simultaneously, these neutrons can be distinguished from all other neutrons (e.g., those produced by (α, n) reactions or by neutron generators), which are not correlated in time. The fission neutrons are referred to as coincident neutrons. The neutrons emitted by a plutonium-bearing sample consist of spontaneous fission neutrons from even-even plutonium isotopes ($^{238,240,242}\text{Pu}$), from the interaction of α -particles with low- Z elements (e.g., O, C, F, Al, etc.) and induced fissions from $^{239,241}\text{Pu}$ ("multiplication effect") caused by thermalized spontaneous fission neutrons and (α, n) neutrons. The spontaneous fission rates are sufficiently high to permit direct measurement of the fission neutrons (passive neutron counting). Emitted neutrons are moderated and then detected with ^3He tubes. Amptek circuits amplify the output pulses from the ^3He tubes and convert the pulses above a discriminator threshold to digital pulses.

The ^3He neutron counters detect all neutrons arising from both (α, n) and fission reactions. Sophisticated pulse processing electronics, called neutron coincidence counting circuits (shift register), measure the number of neutrons that are detected within a predefined time interval (gate width), and differentiate between time correlated (coincidence) neutrons emitted from the fission events and single neutrons created as a result of α -particle interactions. The measured coincident neutrons (doubles) are proportional to the mass of the even-even Pu isotopes ($^{240}\text{Pu}_{\text{effective}} = 2.43\ ^{238}\text{Pu} + ^{240}\text{Pu} + 1.69\ ^{242}\text{Pu}$).

The absolute plutonium mass is determined from the mass of ^{240}Pu effective and the isotopic abundances. Induced fissions exhibit higher neutron multiplicity than the spontaneous fission events; hence, they contribute to the enhancement of coincidence response and introduce nonlinearity in the response for higher amounts. The plutonium content of samples in this type of measurement can typically range from the gram level up to several kilograms. Standard methods have been developed for multiplication corrections.

The main parameters characterizing neutron coincidence are the average neutron lifetime (die-away time τ , typically $\sim 50\ \mu\text{s}$) and the neutron detection efficiency (ε) in terms of their magnitude and uniformity. High detection efficiency is important for coincidence counting because the probabilities of detecting dual and triple coincidences are proportional to ε^2 and ε^3 , respectively. A flat spatial efficiency profile is needed to obtain comparable results for different sample positions, dimensions, and filling heights. A short die-away time is important as it minimizes the accidental coincidence count rate from any high background of random neutrons. Both parameters are influenced by the moderator. Reducing the moderator may decrease detection efficiency and die-away time. Less-moderated counter assemblies detect neutrons before thermalization (epithermal counters) and therefore have a significantly reduced die-away time ($\tau \approx 22\ \mu\text{s}$).

The detector system is calibrated using known standards that are subject to DA sampling. Two calibrations are normally used:

- (a) "Passive" calibration curve (using measured doubles versus ^{240}Pu -effective mass). This calibration curve provides the most accurate results for measurement situations where the singles neutron background has a significant uncertainty. This is especially true for small samples where the neutron multiplication is small. For this mode of calibration, a well-matched set of standards is required and the multiplication is built into the calibration curve.

- (b) “Known-Alpha” multiplication calibration curve can be used when the material is pure. Then the α -factor (ratio of the uncorrelated to spontaneous fission neutron events) is accurately predicted by the isotopic ratios. Impurities, e.g., fluorine, moisture, significantly change the calculated neutron response. This mode of measurement always has the best statistical precision and the calibration curve is a straight line.

Interactive software (e.g., IAEA neutron coincidence counting (INCC)) functions as a hardware interface, controlling setup for the coincidence counting electronics. The software supports the inspector in setting calibration and measurement parameters and inputting sample data (e.g., Pu isotopics, declared mass of plutonium, etc.) based on the operator’s declaration or inspector’s own analysis. The code updates the input to the date of measurement providing decay-corrected values for the operator–inspector data comparison. The actual assay cycle is preceded by a sequence of normalization and background measurement cycles. Each sequence must pass all built-in quality control criteria for acceptable results. When the measurements are completed, the Pu mass is calculated based on the selected calibration parameters and the measured neutron count rates (singles, doubles, and triples) and an operator–inspector difference for the plutonium mass along with propagated errors is recorded. The computer routine facilitates the re-evaluation of results using different measurement parameters, e.g., change of calibration curve or using different data sets of isotopics.

The neutron measurements are influenced by a number of physical and environmental factors such as filling heights, changes in density, presence of nearby reflectors and additional neutron sources. These factors could change the number of neutrons available to induce fission and hence lead to false coincident events.

The same coincidence measurement technique is used for “active neutron counting techniques” whereby the fissile isotopes are irradiated by neutrons from an external source to induce fission. The resulting multiple induced fission neutrons are then measured using standard coincidence counting methods to separate the signals from induced fission neutrons from the signals caused by single neutrons. The active neutron counting technique measures the fissile isotopes of uranium (^{235}U) and plutonium (^{239}Pu , ^{241}Pu).

The high-level neutron coincidence counter (HLNC) has a detector head composed of a polyethylene cylinder with an embedded array of 18 ^3He tubes (Krick and Menlove 1979). The moderator slows down the energetic neutrons to thermal velocities. The words “high-level” are included in the name because the counting and sorting electronics can perform at a high rate, such as 100,000 cps of single neutrons. The HLNC is specifically designed to measure high spontaneous fission neutron rates from samples containing up to several kilograms of plutonium.

The HLNC is the basic model – a whole “family” of instruments exists with various measurement configurations to fit shape and size of the item being measured (Menlove 1983; Menlove et al. 1994). In most instances, these systems are facility resident or integrated into the facility process and can be operated either in attended or unattended mode. The counter is used to measure plutonium in bulk material (e.g., PuO_2 , mixed $\text{PuO}_2 - \text{UO}_2$ (MOX)) or plutonium in unirradiated MOX fuel assemblies and pins (► Fig. 63.2).

The inventory sample counter (INVS) is a small counter within the HLNC family (Miller et al. 1991; Sprinkle et al. 1993) with a high neutron counting efficiency (35%), designed to minimize perturbation from moisture, bagging, or other matrix materials in the sample. It is used to perform high-precision measurements of small plutonium samples, such as process samples, e.g., Pu pellets, powders, and solutions in vials. The samples are weighed with high accuracy ($\sim \pm 0.1$ mg) and the plutonium result is then extrapolated to the total item quantity.

■ Fig. 63.2

High-level neutron coincidence counter (HLNC)

The Universal Fast Breeder Counter (UFBC) is a thermal neutron coincidence counter designed to assay FBR fuel assemblies and other types of plutonium fuel (Menlove et al. 1984). UFBC has 7.0% efficiency using 12 ^3He tubes surrounded by polyethylene and a thin cadmium sleeve. The uniform counting (flat response) region in the detector head (141 cm high and 30.5 cm in diameter) is 105 cm. UFBC can measure assemblies with plutonium loadings of up to 16 kg (24% Pu).

The fuel pin assay system (FPAS) is used to determine the Pu-content of fresh MOX fuel pins stored on trays with results that correspond to greater than 2% with the declared data (Cowder and Menlove 1982; Miller et al. 1989). FPAS has a relatively flat response for 1.2 m. The system primarily operates in attended mode by the inspector identifying and checking the positioning of the pin tray in the counter. The system could be transformed to an unattended system using a robotic conveyor for the tray delivery/removal in combination with a radiation-triggered ID camera to record the tray identification.

The glove box assay system (GBAS) measures the in-process material of plutonium in a specific process glove box (Miller et al. 1989). This system is a very large coincident neutron counting system (160 cm high, 100 cm long, and 7.6 cm wide) that can be positioned and raised to cover the front and back sides of very tall MOX process glove boxes. Six slabs were originally installed in pairs on either side of a glove box. Each slab contains twenty 152 cm ^3He tubes. Monte Carlo calculations were used to design the detector and study its response before installation. GBAS can be moved into place around randomly selected glove boxes containing large amounts of MOX materials in process. Experience has shown a measurement uncertainty of $\sim 5\%$ for neutron assay.

The birdcage neutron coincidence counter (BCNC) verifies plutonium content in fast critical assembly fuel plates stored in containers called birdcages (Krick et al. 1985a).

A birdcage can store up to 2 kg of plutonium. Neutron coincidence measurements are performed without removing the fuel plates from the birdcages. The custom-designed detector body consists of 20 ^3He proportional counter tubes embedded in polyethylene, providing an efficiency of about 5%.

The drawer neutron counter (DRNC) has been designed to perform the assay of plutonium in fast critical assembly fuel drawers (Krick and Menlove 1980). Eight tubes (2.5 cm diameter by 91 cm active length) were used in the system. The principal feature of the neutron coincidence detector is a 7 cm by 7 cm by 97 cm detector channel, which provides a uniform neutron detection efficiency of 16% along the central 40 cm of the channel.

The underwater coincidence counter (UWCC) is a transportable system for measuring fresh MOX fuel stored under water (Eccleston et al. 1998). It is a modified version of a standard Fork detector (FDET) whereby the ionization and fission chambers have been replaced with sensitive ^3He tubes embedded in a high-density polyethylene measurement head. The UWCC measures neutrons coming from a segment of the MOX fuel in “multiplication corrected” coincidence mode and provides total Pu, once the isotopics and the active fuel length are known.

The waste crate assay system (WCAS) measures plutonium content of large waste containers for high- and low-activity waste (Menlove et al. 2001). WCAS is a passive neutron coincidence counter operating in 4π geometry and can work in high radiation fields up to 110 R/h. The system employs a combination of shielded and unshielded ^3He detectors (98 ^3He tubes in total) embedded in a polyethylene matrix and has a detection efficiency of $\sim 10\%$. For the low active waste, all tubes are used to determine ^{240}Pu effective by the coincidence rates. The high active waste measurement utilizes only the shielded tubes (78 mm steel) to obtain ^{244}Cm contents by the singles rates. The amount of plutonium and ^{235}U in the wastes are calculated with Cm/Pu ratio and Cm/ ^{235}U ratios, known from the stream average ratios at the waste generating sites. WCAS has a small ^{252}Cf source of known source strength that can be positioned in an automated sequence at a fixed number of locations adjacent to the waste container wall. The measurement with and without source provides a matrix correction factor for a given configuration. WCAS can measure a wide range of plutonium masses from a few milligrams to tens of kilograms within a matrix of 4,000 kg of mixed metal waste.

The waste drum assay system (WDAS) measures the residual small plutonium amounts of in-process wastes in 200 liter drums. The system uses a modified neutron coincidence counter with a counter comprising 60 ^3He tubes ($\sim 20\%$ efficiency) with low background. WDAS applies the add-a-source correction technique that corrects for the effects of the waste matrix on neutrons (Menlove et al. 1993, Menlove 1995). A small ^{252}Cf source is placed in various positions near the external surface of the sample drum. The changes in the ^{252}Cf coincidence counting rate provide a matrix correction for the plutonium inside the drum.

The portable neutron coincidence counter (PNCC) consists of four individual slab detectors with four ^3He tubes each that can operate in multiple modes and configurations (Thornton et al. 2006). The detector is lightweight and portable (~ 15 kg) to address flexibility of measurement requirements for various field environments. PNCC has about 12% detection efficiency.

63.3.4.4 Multiplicity Coincidence Counting

Normal coincidence counting techniques rely on the detection of two coincident neutrons (doubles) and making an assumption based either on the multiplication or on the (α , n) neutron rate. These two analysis methods – passive calibration and known-alpha – require

traceable calibration standards and the results can be subject to bias due to changes in sample multiplication or composition; however, they are useful for identifying these changes in the material.

Multiplicity counting uses the additional information from events when three coincident neutrons are emitted per fission (triples) (Ensslin et al. 1998). This additional information is obtained from the measurable multiplicity distribution and allows solving all three unknowns, namely, ^{240}Pu -effective mass, multiplication, and the (α, n) neutron rate. Therefore, the mass of plutonium in the sample can be calculated directly without making any assumptions about its chemical and physical composition. Multiplicity counting can be applied to all plutonium samples, but is beneficial primarily in measuring impure samples. For some material categories (e.g., small Pu samples, process residues with high (α, n) neutron rate) multiplicity counting may not be helpful because of the limited precision of the triple coincidences. Multiplicity counting requires high efficiency as the detected triples rate is proportional to the efficiency cubed. The counters are designed to minimize die-away time and deadtime. Conventional coincidence counters can be used for multiplicity analysis, but their lower efficiencies and longer die-away times lead to very long counting times.

The plutonium scrap multiplicity counter (PSMC) is a high-efficiency neutron multiplicity counter with cadmium lining designed for measuring impure samples such as MOX scrap materials (Nakajima et al. 1997). The PSMC contains 80 ^3He -filled tubes (at 4-atmosphere fill pressure) arranged in four rings embedded in polyethylene and has an efficiency of $\sim 55\%$.

Epithermal-neutron multiplicity counters (ENMCs) use ~ 120 high-pressure ^3He tubes (10 atm) in closely packed rings with less moderator material (Langner et al. 2006; Asano et al. 2006). The higher pressure and the large number of tubes capture more of the thermalized and epithermal neutrons resulting in an efficiency of about 65%. The reduced thickness of high-density polyethylene shortens the neutron die-away time to only 22 μs . This combination improves the statistical precision by a factor of 5–20 compared with traditional thermal-neutron counters depending on the characteristics of the samples (Stewart et al. 2000). Sufficient counting statistics are important for unfolding the multiplicity distribution to determine the triples. In addition, the singles background rate must be accurately measured and shielding used on the outside of the neutron detector to reduce the singles neutron background. The background for doubles and triples is very small and relatively constant. Although designed for multiplicity counting, ENMC is a very powerful “normal” neutron coincidence counter due to its high efficiency and optimized design parameters. In some cases, statistical errors for small samples have been reduced to less than 0.15% using an ENMC; in impure samples, the statistical error dominates the systematic error and can be as high as 3% (over 100 min measurement time).

63.3.4.5 Active Neutron Coincidence Counting

The fissile isotopes of uranium (^{235}U) and plutonium (^{239}Pu , ^{241}Pu) can be measured using “active neutron counting techniques.” This technique uses an external neutron source to induce fission in the fissile plutonium and uranium content of the sample. The multiple induced fission neutrons are then measured using standard coincidence counting methods. The technique is mainly applied to determine the mass of ^{235}U in uranium-bearing samples (from LEU to HEU) in powder, metal, pellets, fresh fuel elements, and waste drums. It can be operated either with or without a cadmium liner (fast or thermal mode).

The uranium neutron coincidence coLLar (UNCL) can be operated in either an active or a passive mode to measure the ^{235}U and the ^{238}U mass per unit length of LWR fuel assemblies (Menlove 1981). UNCL has four polyethylene slabs that surround a central cavity where a fuel assembly is placed for measurement. ^3He tubes are embedded in three of the four slabs. The fourth polyethylene slab contains a cylindrical well for the AmLi neutron source. The active mode uses neutrons from a low-intensity (5×10^4 n/s) AmLi neutron source to cause fission of ^{235}U in the fuel and the neutrons from induced fission in ^{235}U are counted using coincidence electronics. When no interrogation source is present, the passive neutron-coincidence count rate from spontaneous fission gives a measure of ^{238}U linear mass density (g/cm). The UNCL measures only one section of the fuel, approximately 40 cm long. The measured coincidence neutron rate is proportional to the ^{235}U mass per unit length. Together with a measurement of the active length of fuel (e.g., using an HM-5), the UNCL can verify the operator-declared total ^{235}U content of a fuel assembly. Measurements on pressurized water reactor (PWR) and boiling water reactor (BWR) assemblies have demonstrated that, for measurements of similar fuel assemblies used for calibration, the overall accuracy for assay of ^{235}U linear density is 1–2%. For absolute measurements, using calibration parameters from other facilities and fuel assemblies, the accuracy is in the range of 2–4%, depending on how closely the standards match the assemblies assayed and how precisely calibration has been performed. When operated in passive mode, the UNCL can be used to confirm ^{238}U linear density to within 10%. The ^{235}U sensitivity enables detection of a removal or substitution of three to four rods in a PWR assembly and a single rod in a BWR assembly. Assemblies containing Gd as a neutron poison need to be analyzed using a poison correction factor calculated by Monte Carlo simulations (Menlove and Pieper 1987).

The active well coincidence counter (AWCC) is designed to measure ^{235}U in HEU metals, bulk UO_2 materials and light water reactor (LWR) fuel pellets (Krick et al. 1985b; Menlove et al. 1996). The AWCC has 42 ^3He tubes in two rings, achieving an efficiency of about 36%. The system uses two AmLi neutron sources, each mounted in one of the end plugs of the assay chamber of the coincidence counter body. The neutron sources induce fissions in isotopes not having significant spontaneous fission activity, e.g., ^{235}U . The induced-fission neutrons of the sample are quantified with standard coincidence counting techniques. The use of the AWCC to verify total ^{235}U content provides an important advantage over gamma-ray techniques for some applications (e.g., for large and/or heterogeneous samples). The high neutron penetrability permits the AWCC to measure the entire ^{235}U content of a sample rather than just the surface layer that would be measured using gamma-ray techniques. The AWCC can be operated either with or without a cadmium liner (thermal or fast mode). Although designed for active neutron assay, it is also a good passive neutron counter if the AmLi sources are removed.

63.3.5 Spent Fuel Measurement

NDA methods are presently the only feasible means of verifying spent fuel. Several instruments are available for measuring spent fuel assemblies stored underwater. Direct measurement of plutonium and uranium in spent fuel is normally impossible because the primary neutron and gamma signals come from higher actinides (e.g., spontaneous fission neutrons from the ^{242}Cm and ^{244}Cm isotopes) and fission products. The measurement of gamma and neutron radiation from spent fuel assemblies can be used to confirm various attributes and to estimate burnup, which can be correlated to the quantity of plutonium in the assembly. The variability of the fuel

designs is a challenge for the adaptation of these techniques, particular in the area of the quantitative verification of irradiated fuel from research reactors that might contain HEU.

The most powerful verification tools for spent fuel in wet storage are the improved Cherenkov viewing device (ICVD), safeguards MOX python (SMOPY) device and the FORK detector (FDET). The ICVD is a nonintrusive instrument based on the detection of Cherenkov light specific to high irradiation effects in water caused by spent fuel. SMOPY and FDET measure total neutron and gamma radiation simultaneously. A passive gamma emission tomograph is currently being tested to be able to detect defects at a pin level.

63.3.5.1 Gamma Methods

The spectrometric performances of CdZnTe detectors, their robustness, and simplicity are key to their wide application for the verification of irradiated materials in spent fuel (Lebrun et al. 2000; Lebrun and Carchon 2003).

High-resolution gamma spectrometric measurements from fission products have also been used to estimate burnup. The fission product nuclide must be long-lived in comparison to the fuel irradiation time. The measured gamma-ray intensity must be corrected for cooling time decay; if the cooling time is not known, it can be estimated from the relative activities of various fission products. Errors can be greatly reduced by measuring the ratio of the activities of two nuclides having a known dependence on burnup. Although capable of giving good estimates of burnup, this method is time consuming, because of the need to place detector systems underwater and to move each fuel assembly to the detector position for verification to be performed.

The spent fuel attribute tester (SFAT) is a routine inspection instrument for gross defect detection. It provides a qualitative verification of the presence of spent fuel through the detection of particular fission product gamma rays – either from ^{137}Cs (662 keV) for fuel which has cooled for longer than 4 years or from ^{144}Pr (2,182 keV) for fuel with shorter cooling time (Carrasco et al. 1997). The equipment comprises a stainless steel watertight housing containing a collimated NaI, CdTe, or CdZnTe detector that can be submerged in a storage pond. SFAT takes measurements from the top of a fuel assembly as it sits on top of the underwater storage rack and does not require movement of the fuel. The SFAT is applied where Cherenkov viewing cannot provide conclusive verification (e.g., for low burnup or long cooling time, where the Cherenkov radiation is too weak or where the water in the storage pond is not clear enough).

The irradiated item attribute tester (IRAT) differentiates irradiated nonfuel items from irradiated fuel items that are stored in spent fuel storage ponds (Aparo et al. 1999). It consists of a stainless steel cylinder housing shielding and collimation, a miniature CdZnTe detector, and a preamplifier. A multiwire cable connects the measurement cylinder (watertight) and data acquisition/control unit (operated above water). The IRAT detects gamma radiation characteristic of either fission products contained in spent fuel or activation products contained in irradiated structural materials. The IRAT uses the detection of key fission product gamma rays as evidence that an item being measured has the characteristics of spent fuel. A statistical test compares the measured gamma ray spectrum to a background measurement in order to determine if a certain gamma emitter is present. The presence of such fission/activation products serves as evidence that an item once underwent fission (^{137}Cs for cooling time > 4 years; ^{144}Pr , ^{137}Cs , ^{134}Cs , or $^{95}\text{Zr/Nb}$ cooling time < 4 years) or, in the case of a structural item, was once exposed to a significant neutron flux (^{60}Co). The measurement with

Fig. 63.3**The irradiated item attribute tester (IRAT)**

IRAT requires movement of the spent fuel as the detector approaches the item from the side. IRAT is very similar to FMAT with differences in the collimator part and the type of CdZnTe detector (► Fig. 63.3).

The high-sensitivity gamma monitor (HSGM) is an enhanced underwater survey meter, consisting of a Geiger–Mueller probe and a microprocessor unit. It measures gamma and X-rays in the 60 keV to 3 MeV range over a total dose rate range of 1 mSv/h (0.1 mR/h) to 300 Sv/h (30,000 R/h). The HSGM is powered by an internal chargeable battery (or by facility power if the battery is discharged beyond a certain level). The technique provides a qualitative confirmation of irradiated items. The method cannot readily distinguish between irradiated nonfuel items and genuine spent fuel items, as it only detects the radioactivity of each item. It does not provide any information on burnup, cooling time, plutonium content, or any other quantitative property. In contrast to ICVD or SFAT, each item to be verified must be isolated from neighboring items. Thus, movement of items is a requisite unless a sufficient separation already exists.

The CANDU (CANada Deuterium Uranium) spent fuel bundle verifier for baskets (CBVB) employs a highly collimated and shielded CdTe, suspended on an automatic winch whose speed can be set for scanning either storage baskets or stacks. It verifies the presence of irradiated CANDU fuel bundles stacked in baskets under water.

The CANDU bundle verifier for stacks (CBVS) moves vertically along the space between columns of trays (10 cm gap) of spent fuel and uses a CdZnTe detector for bundle identification (Ahmed et al. 2001). It employs thick lead shielding to protect the electronics and detector. The CBVS is unable to verify the spent fuel at the bottom layer of a stack due to limited accessibility of a large-size detector part through the funnel structure. During inspection, the tray must be moved. In addition, the large size of the scanning part is both heavy and difficult to handle.

63.3.5.2 Neutron Methods

The advanced experimental fuel counter (AEFC) is used for the characterization of spent fuel from research reactors stored underwater (Menlove et al. 2007). The AEFC can be operated in

either passive neutron mode or active neutron mode, using an AmLi neutron source to generate fissions in the fuel item. The counter is transportable (~ 70 kg) and consists of a polyethylene moderator containing six boron-lined ^3He tubes with a lead shield surrounding the measurement cavity (117 mm in diameter) to reduce the gamma dose to acceptable levels. The radiation tolerant ^3He tubes are embedded in the moderator forming two different measurement sets. One set (inner row) measures neutron coincidences to distinguish fission neutrons from background. The second set (outer row) is placed further back within the polyethylene moderator and is therefore much less sensitive to AmLi neutrons than to fission neutrons, so that the signal is approximately proportional to the fission rate in the fuel item. The detector also contains a collimated ionization chamber to record the gamma emission profile correlated with the relative burnup of the measured item.

The spent fuel coincident counter (SFCC) is an underwater neutron coincident counter for the verification of operator-declared plutonium content in canned fast breeder reactor spent fuel (Bytchkov et al. 2001; Lestone et al. 2002). The SFCC is hermetically sealed; it operates ~ 5 m below water level in a fixed position in a spent fuel storage pond. SFCC has a ring of 20 ^3He tubes embedded in polyethylene ($\sim 15\%$ detection efficiency) and shielded from fission product gamma rays by a 7 cm thick lead ring. A single ionization chamber measures the gamma-ray dose from the spent fuel to determine the appropriate operational parameters to avoid gamma-ray pile effects in the ^3He tubes. The plutonium isotopics are calculated based upon validated burnup chains code and specially developed iterative software in combination with MCNP modeling converts the measured single and double neutron count rates to plutonium mass. An inspector is guided by the software through all measurement, evaluation and decision making (accepted/rejected) processes. The SFCC easily distinguishes irradiated fuel from nonfuel items, which are loaded to the reactor to replace discharged assemblies.

The spent fuel neutron counter (SFNC) is a prototype neutron-detector system that verifies closely packed spent fuel assemblies stored in a spent fuel pond (Ham et al. 2002). The system contains a fission chamber moderated by a polyethylene cylinder housed in a watertight stainless steel enclosure. The SFNC measures total neutron signals from long-cooled spent fuel assemblies while in their storage position, without requiring them to be moved. The technique can detect a missing fuel assembly. These measurements are performed underwater in a gap between four assemblies.

63.3.5.3 Combined Gamma/Neutron Methods

The ratio of neutron to gamma ray data, when combined with other complementary information, is used to characterize a particular type of fuel. To simplify the verification of spent fuel, a technique involving gross gamma ray and neutron measurements can be used.

The Fork DETector (FDET) measures gross gamma and neutrons from a spent fuel assembly, which can be correlated with the operator's declared data on burnup and cooling time (Halbig et al. 1985). Separate detector heads are used to measure BWR- fuel and PWR-type fuel. The system is operated in the spent fuel pond and consists of a microprocessor-controlled, battery-operated electronics unit, a preamplifier, 5–6 meter long pipes to support the detector underwater, and a special watertight measuring head. This head has two pairs of fission chambers for neutron counting and a single pair of ionization chambers for the total gamma flux, which form a fork-type measurement cavity. The pairing of detectors on two sides of an assembly minimizes the sensitivity to assembly-detector geometry and burnup

asymmetries. The operator has to move the fuel assembly to the measurement cavity. Interactive software prompts the user through the measurement procedure and simultaneously collects neutron and gamma data. The software can also support unattended measurements.

The safeguards MOX Python (SMOPY) device combines gross neutron counting with low-resolution gamma spectroscopy to characterize any kind of spent fuel (Lebrun et al. 2001). The SMOPY uses online interpretation tools for the evaluation of measurement data. The system contains a well-shielded and collimated CdZnTe gamma detector and a fission chamber. It is placed over the storage hole of the spent fuel assembly. The assembly is lifted through the open measurement cavity and it can either be scanned or selective parts measured. The SMOPY can verify and distinguish irradiated MOX fuel from LEU fuel and can confirm the burnup of a spent fuel assembly.

The SMOPY device can also be operated in active mode using an AmLi source. This has been successfully demonstrated for the underwater verification of canisters containing residues of irradiated HEU. This application is based on total neutron counting and detects the difference between active background and active background plus induced fissions.

The cask radiation profiling system (CRPS) records radiation profiles (“fingerprints”) from spent fuel storage containers at the time of positioning casks in the dry silo and compares them with a fingerprint taken at the time of subsequent verification (Thevenon et al. 2008). A collimated and calibrated CdZnTe detects gamma spectra in scanning mode while ascending down the verification tube at constant speed. The verification tube is adjacent to the silo and ranges from the top to the bottom. The position information of the detector is provided by a pulser, which emits a signal for every constant interval rotation of the motor’s winch wheel that drives the detector within the verification tube. All raw data are acquired and processed with dedicated software on the inspector’s laptop.

The CRPS provides a tool to reverify a dry storage cask in its storage position to demonstrate that the cask content has not changed (in the event of loss of continuity of knowledge) or as a part of periodic routine requirements for reverification. The maintenance and/or restoration of continuity of knowledge of a spent fuel dry storage container by a reproducible fingerprint require a systematic management of fingerprints over a long period. A database has been developed for the storage and evaluation of fingerprints to secure and effectively compare fingerprints while taking into account decay and changes in the measurement hardware configuration. Automatic unfolding of the radiation profiles to count the number of baskets loaded in the storages is also possible. The CRPS could be run with a pair of detectors to perform neutron (fission chamber) and gamma profiling.

63.3.5.4 Optical Methods

The improved Cherenkov viewing device (ICVD) is the instrument most commonly used by safeguards inspectors to verify spent fuel (Trepte et al. 1996). Observation of the Cherenkov radiation from irradiated reactor fuel assemblies is used to obtain qualitative confirmation of the presence of spent fuel in storage pools. Cherenkov radiation, which results from the interaction of the intense beta radiation from spent fuel with the water in the storage pool, varies in intensity and – for highly active fuel – can be seen in darkness with the naked eye. For fuel with low burnup and/or long cooling times, the Cherenkov intensity is very low, but can be seen using a light-amplifying capability in the night vision device. The ICVD employs light filtering techniques (e.g., ultraviolet filters). Special photo cathodes have been developed with

appropriate spectral sensitivity for Cherenkov light to minimize background light interference and even permit use of the ICVD under normal facility lighting.

Observation of the Cherenkov radiation from irradiated reactor fuel assemblies is used to obtain qualitative confirmation (attribute testing) of the presence of spent fuel in storage by scanning rows of assemblies from the pool bridge. Characteristic patterns formed by the arrangements of rods and holes in fuel assemblies have to be observed to ensure a valid verification. A well-trained inspector can easily detect the presence of an inactive “dummy assembly” surrounded by highly active neighbors.

ICVD cannot be used when fuel is stored in canisters. Furthermore, absorption and reflection of the Cherenkov light caused by additives or particles in the water and its turbulence in spent fuel ponds may result in failure to verify the spent fuel. It is also difficult to see fuel assemblies that are double-stacked in the storage pool.

The digital Cherenkov viewing device (DCVD) is used to verify assemblies with long cooling times and/or low burnups, which have weak Cherenkov signals that cannot be seen with a standard ICVD (Chen et al. 2006a). Apart from its higher sensitivity, the DCVD can record and document individual scans for subsequent reanalysis. It has the potential to quantify the Cherenkov glow from spent fuel assemblies as a function of irradiation history and cooling time. Further development efforts to enable partial defect detection are promising (Chen et al. 2006b).

The optical fiber radiation probe system (OFPS) is used to verify irradiated bundles in the spent fuel bay of CANDU stations (Kim et al. 2006). The OFPS consists of a scanning actuator, an optical fiber scintillator coupled to a flexible optical fiber, data acquisition electronics, and a PC.

The use of an optical fiber scintillator for CANDU spent fuel verification has the benefit of detecting gross gamma rays in storage ponds without being hindered by the funnel structure. Gamma rays from the spent fuel interact with the optical fiber scintillation media to produce ionization, which subsequently leads to the emission of fluorescent light (~ 400 nm) of the doped Ce^{3+} in the optical fiber. Since the optical fiber scintillator is both highly resistant to radiation and able to withstand high temperature and humidity, more precise and safe measurement is possible in between bundles of a tray. In high radiation fields, the optical fiber cable itself emits light from radiation interactions. Therefore, the signal from the cable has to be compensated by a second optical fiber cable (without scintillation media). The detector can be placed between bundles (1.5 cm gap). The verification system performs gross gamma measurements supporting the re-verification of CANDU spent fuel bundles stored in ponds without requiring movement of the horizontal storage trays.

63.3.6 Unattended NDA Systems

Modern nuclear facilities are increasingly automated with the aim of decreasing both personnel exposure and production costs. Owing to automation, direct access to nuclear material may be limited for both the operator and the inspectorate. Unattended NDA systems generate measurement data without requiring the presence of an inspector. The data acquired are routinely collected from measurement cabinets after a certain period or are transmitted remotely to an external location (such as an inspector's office). Main attributes of various unattended NDA systems are listed in [Table 63.6](#).

A combination of containment and surveillance (C/S) data with synchronized NDA data is a very powerful tool to monitor nuclear processes while C/S or NDA data in isolation have less

■ Table 63.6

Unattended NDA systems

System	Detector	Main measurement task	Typical performance values (%) ^a
VIFM	VIFB: solid state Si	Counts SF bundles (fuelling machine → SF pond)	Attribute
	VIFC: solid-state Si & FC	Counts SF bundles from core to fuelling machine	Attribute
SEGM	Si-Pin	Monitors cask loading into dry storage silo	Attribute
ISVS	Xe-IC + ³ He	CoK spent fuel receipts to spent fuel pond	Attribute
IHVS	IC + ³ He	CoK of spent fuel from pond to dissolver	Attribute
PCAS	³ He	Pu in PuO ₂ , MOX in canister	1–2
IPCA	³ He	Pu in MOX in canister	0.85
	3 HPGe	²⁴⁰ Pu-effective (%), U/Pu ratio	
(A)MAGB	³ He	Pu powder/pellets/scrap in process container	4.5
	HPGe	²⁴⁰ Pu-effective (%), U/Pu ratio	
FAAS	³ He	Pu in final fresh MOX assemblies	1.8
VWCC	³ He	U, Pu in vitrified highly active waste via ²⁴⁴ Cm	5–25
VCAS	FC + IC	U, Pu in vitrified highly active waste via ²⁴⁴ Cm	5–25
ENGM	24 ³ He	Pu in fresh MOX (receipt)	Attribute
CCRM	³ He + NaI	CoK of fresh MOX fuel between ENGM and EVRM	Attribute
EVRM	³ He + NaI	CoK of MOX fuel between EVRM and core	Attribute
EXGM	¹⁰ B + 2 IC	CoK of spent MOX fuel to and from spent fuel pond	Attribute
PIMS	142 ³ He	Pu in powder process area	6
RHMS	3 ³ He	Pu, U in leached hulls via ²⁴⁴ Cm	5–25
TCVS	³ He	Pu in MOX canisters temporary stored in process	<6
HMMS	³ He	Pu, U in hulls via ²⁴⁴ Cm	5–25
DCPD	³ He	CoK of Pu canister movements	Attribute
DSNC	³ He	Pu, U in high active, dry reprocessing material via ²⁴⁴ Cm	5
DSNM	³ He	CoK of rear access ports of glove boxes	Attribute
ATPM	Temperature/flow	Power monitoring of research reactors	Attribute
MUND	³ He	Monitoring of fuel transfer casks	Attribute
SMMS	Pressure/temperature	Volume determination/balancing of solutions	0.05

^aAverage measurement time ~300 s.

value. These systems help to decrease overall inspection effort and are capable of monitoring routine activities involving nuclear material, such as the complete process of loading, transferring, and storing spent fuel in dry storage silos.

The main drawback of these automated systems is their predictability. In most safeguards approaches, this drawback is compensated for by unannounced or short-notice inspections on a random basis. Most unattended NDA systems are part of the HLNC family. Other systems use low-resolution gamma detectors either in combination or as a stand-alone application.

Recently, a large reprocessing facility has been commissioned and the safeguards instrumentation in place has set a new technological standard in terms of the networking and integration of different unattended verification systems and C/S systems covering the complete process and storage areas (Johnson et al. 2001, 2004).

63.3.6.1 Unattended Gamma-Based NDA Systems

The VXI integrated fuel monitor (VIFM) is used at CANDU stations to monitor and count fuel bundles discharged from the reactor (Bot et al. 1997; Truong et al. 2001). The system employs radiation hardened solid-state gamma detectors with self-authenticating/tamper-indicating circuitry. The VIFM uses an autonomous data acquisition module (ADAM) to acquire data from the radiation sensors. High operational reliability, great dynamic detection sensitivity (to include all operational possibilities), and insensitivity to power outages are some of the important features of the system. The VIFM has three subsystems:

- A VIFM core discharge monitor (VIFC) detects discharges of spent fuel from a reactor core into the fuelling machine. Both neutron (normal on-power discharge signal) and gamma ray intensities are continuously monitored by solid-state silicon gamma detectors and an array of fission chambers for neutron counting. High dose (~ 2 Mrad) tolerant electronics are employed to withstand the strong radiation fields. An inspector, evaluating the monitoring data, is able to identify in a straightforward, unambiguous manner the abrupt but characteristic changes in count rate associated with fuel bundle discharges, regardless of the operational status of the reactor. Because of the linear increase in background signal, the system can also track the operating power level of the reactor.
- A VIFM bundle counter (VIFB) counts irradiated fuel bundles as they are transferred between the fuelling machine and the spent fuel bay(s). Collimated gross gamma counters detect each fuel bundle as it passes. The proper placement of detectors and the use of the appropriate evaluation algorithm for the facility enable the device to count the bundles as they pass and, to record the direction in which the bundles are moving.
- A VIFM Yes/No monitor (VIFD) determines if any irradiated fuel has been discharged through access ports that are not part of the normal discharge path.

The silo entry gamma monitor (SEGM) monitors the final loading of dry storage containers into a final silo storage location (Zendel et al. 2006). The SEGM consists of a pair of pin-diode gamma silicon detectors, which are inserted at different levels into the verification tubes available for each silo, thereby providing direction-sensitive verification of the silo loading. The detectors are installed before the start of the transfer campaign in all of the silos that will be used for that campaign. The cables from several silos (up to 8) are routed to a common electronics cabinet, where the resulting data is logged. The maximum length of the signal cables connecting the electronic cabinet to the detectors is 200 m. The data can be extracted either

locally or remotely via a standard Ethernet link. The detectors are removed by inspectors and replaced by seals after each silo has been completely filled and the top cover welded.

The integrated spent fuel verification system (ISVS) consists of time synchronized CCTV cameras and radiation detectors, which verify the receipt of spent fuel assemblies received into a facility, unloaded from the transport cask and transferred into storage ponds (Yokota et al. 1998). The radiation detectors, a high-pressure Xe ionization chamber for gammas and a ^3He tube for neutrons, are assembled with preamplifiers and shielding inside a watertight tube. Each channel is equipped with two tubes at each side to provide redundancy for improved system reliability and to enable verification of the direction of spent fuel moving into the temporary storage pit or returning to the unloading pit.

The integrated head-end verification system (IHVS) is intended to maintain continuity of knowledge on spent fuel assemblies moving from the spent fuel storage area to the shearing machine, as well as the removal of hulls drums to waste storage (Yoshida et al. 2005). The system employs radiation-tolerant camera(s) and radiation detectors (CRD) contained in a cylindrical body, which is installed into the shielding wall itself and also contains internal shielding to reduce the dose rate to meet requirements at the exterior of the cell. Each CRD has one ^3He neutron detector and two ion chambers to detect the radiation of a spent fuel assembly in a respective cell. The cameras provide identification and monitoring of transfer routes. The IHVS comprises 14 CRD devices covering the feeding, sharing, and hulls drumming cells.

The continuous enrichment monitor (CEMO) monitors the absence of HEU production in selected gaseous centrifuge facilities and delivers qualitative Go-No-Go information to the inspectorate (Packer 1991; Packer et al. 1997). The CEMO determines the content of U-235 from the intensity of the 186 keV peak using NaI detectors fixed on the product header pipes and correlating the pressure of the gaseous UF_6 with a transmission measurement (radioactive X-ray transmission source: ^{109}Cd (~20–50 keV)). The enrichment is then calculated based on these two parameters. The system operates continuously and transmits remotely (twice a day) state of health and alarm messages in the event that LEU is not confirmed or when a system fault occurs.

63.3.6.2 Unattended Neutron-Based NDA Systems

Continuously operating, unattended and custom-designed NDA systems are being implemented at plutonium handling facilities (e.g., reprocessing, conversion, and fabrication plants) to monitor and determine the plutonium content in various process stages. The main components of these systems are modified HLNC counters tailored to the specification of the material container and process environment. In general, the detectors operate in continuous mode with data dumps every minute. Radiation triggered ID cameras generate time stamped video records, which the inspector can correlate with the raw measurement data.

The plutonium canister assay system (PCAS) determines the content of plutonium in MOX and pure oxide powders in cans contained in a specific transport container (four cans per canister) (Menlove et al. 1986). The system can be integrated into an operator's material handling system and continuous measurement cycles are performed, which are evaluated at the end of a given collection period. Thereby, continuous verification of the flow of canisters can be performed without inspectorate intervention. For inventory verification, an inspector provides an electronic list of canisters to be verified and the operator transfers the selected

canister to the PCAS during shift work without an inspector being present. At the end of a verification campaign, the inspector collects the verification data for evaluation.

The improved plutonium canister assay system (IPCA) is a neutron coincidence detector with provision for the simultaneous measurement of Pu isotopics by HRGS (Abhold et al. 2001). The neutron detector uses a double ring of ^3He tubes for the determination of ^{240}Pu effective mass contained in MOX canisters. The HRGS includes three Ge detectors that determine isotopic composition including the U/Pu ratio. A digital camera, automatically triggered by neutrons, records the canister ID during these measurements. The IPCA is designed to determine the mass of plutonium and uranium in MOX canisters with an uncertainty better than 0.85% for a range of 5–16 kg of plutonium. This performance significantly reduces the random sample size for destructive analysis.

The material accountancy glove box counter (MAGB) provides the plutonium content in specific process containers, handled in the glove boxes of the automated process (Menlove et al. 1993). The system consists of two slab detectors viewing the load cell of a process glove box, where the container filled with either feed powder, pellets, or scrap is placed. A radiation-triggered camera identifies the process container and creates a time stamped video ID record. An upgraded version (AMAGB) employs an HPGe system for the determination of isotopics and U/Pu ratio.

The MOX fuel assembly capsule assay system (FAAS) determines plutonium content in the final assembly contained in a storage capsule. Coupled to the automated capsule transfer system, it provides information about the movements of fuel into and out of the product storage (Menlove et al. 1993). It is designed to assay the complete active zone of the assembly with plutonium loadings up to 10 kg and can accommodate 5 m long capsules that contain the fuel assemblies. The unshielded detector body has 12 ^3He tubes and an efficiency of $\sim 16\%$. In addition, the continuous mode gives a time history of movements of neutron source material in the vicinity. The FAAS is augmented with a surveillance system to meet verification requirements.

The vitrified waste coincidence counter (VWCC) is used at a vitrification facility to quantify plutonium and uranium present in canisters of vitrified highly active nuclear waste that is not suitable for further nuclear use (Beddingfield et al. 1998). The system contains five ^3He tubes shielded by 100 mm of lead. The efficiency is 0.5–1.0% depending on the distance between the detector and the canister. The VWCC calibration is based upon Monte Carlo computer modeling. The upper limit for Pu as a measured discard in vitrified waste is in the order of 5 g in a 10 kg matrix, which can be easily measured by the VWCC. The individual components are all radiation hardened to allow for proper operation in this strong radiation environment. The coincidence counting rates are used to determine the amount of ^{244}Cm , which is the dominating neutron contributor. The inspector will then apply the Pu/Cm and U/Cm mass ratios that have been analytically determined for each batch from an aliquot taken from the input tank of the melter. These ratios do not change during the vitrification process and hence Cm can be used as a tag for the mass of plutonium and uranium. The total rates will be used to verify sample-to-sample uniformity.

The vitrified waste canister assay system (VCAS) is intended to determine the residual uranium and plutonium content in canisters of vitrified high-level spent-fuel reprocessing waste prior to the termination of safeguards on this material. It consists of five neutron detectors (two ^{235}U fission chambers, two ^{238}U chambers and a bare ^{235}U chamber sensitive to thermal neutrons) and one gamma detector (ionization chamber, meant to authenticate the presence of gamma radiation). In contrast to the VWCC, the VCAS uses ^{235}U fission chambers

to determine the ^{244}Cm content by singles (totals) neutron counting. The plutonium and uranium contents are calculated from Pu/Cm and U/Cm ratios (determined in the feed solution to the melter). In addition, vitrification of the waste solution is verified by measurement of the neutron spectrum (using the ratio of counting rates in ^{235}U and ^{238}U fission chambers). The fill level of the canister is determined by a comparison of count rates from top and bottom ^{235}U fission chambers. The neutron radiation data will be integrated with cameras that monitor the measurement station and verify the canister ID.

The entrance gate monitor (ENGM) is a passive neutron coincidence collar detector permanently installed at the entrance to the fresh fuel transfer route of a fast breeder reactor (Hashimoto et al. 1994; Iwamoto et al. 1997). The detector head has four groups of ^3He with six tubes each. Fresh fuel assemblies entering the reactor facility must pass through the ENGM so that their Pu content can be verified. Therefore, the ENGM is the system that verifies the amount of fresh fissile fuel in an assembly and serves as the first detector in a sequence of detector systems that follow the movement of fuel assemblies within the reactor facility.

The cask car radiation monitor (CCRM) consists of a ^3He detector and NaI detector installed close to the surface of the cask car. By measuring neutron and gamma doses, the monitor is able to distinguish between fresh fuel and spent fuel as well as between other items (e.g., irradiated reflectors and control rods). The monitor controls the flow of fresh fuel between ENGM and the ex-vessel transfer machine radiation monitor (EVRM) and the flow of spent fuel from the EVRM to the spent fuel storage via the exit gate monitor (EXGM). It further monitors any movements of spent fuel retrieved from the spent fuel pond via the EXGM.

The EVRM has the same detection features as the CCRM. It controls the flow of assemblies to and from the core.

The EXGM is a watertight detector assembly including a lead shielded ^{10}B detector and two ionization chambers located underwater, close to the spent fuel transfer equipment, where spent fuel is taken to the storage racks. The direction of the transfer is monitored by two gamma detectors, placed above and below the neutron detector.

The plutonium inventory monitoring system (PIMS) is a network of 142 ^3He neutron detectors in moderating enclosures, which are installed in a plutonium-powder process area at fixed positions outside of process glove boxes and the ventilation system (Simpson et al. 1998; Parvin 2007; Whitehouse et al. 2004). The collected neutron counts are processed in a matrix approach to image the neutron field of the process area. Any change to the in-process inventory will be detected and can be accounted for on a near real-time basis. The PIMS will also be used to verify the clean out and to measure any residual material. The PIMS is operator-owned equipment used jointly with the inspectorate. Appropriate authentication measures are therefore in place to validate the measurement results.

The Rokkasho hull monitor system (RHMS) consists of three ^3He detectors embedded in the operator's hull monitor system and determines uranium and plutonium content in canisters of leached hulls at the Rokkasho Reprocessing Plant. The operator uses a sophisticated system with both passive and active interrogation. The safeguards detectors are operated independently of the operator's system, using the passive phase of the measurement cycle to register total neutrons (singles) from ^{244}Cm . The plutonium and uranium content can then be calculated from the Pu/Cm and U/Cm ratios derived from the associated dissolver solution.

The temporary canister verification system (TCVS) verifies the inventory of plutonium in MOX canisters in temporary storage positions located in glove boxes. It consists of NDA measurement stations on both sides of the storage glove boxes using an array of ^3He tubes. The TCVS is capable of quantifying 0.1–30 kg Pu in MOX powder and continuously records

data to monitor the movement of canisters (e.g., actual storage position and whether a full canister is coming from a different process step). Quantitative results are needed at specific inventory times achieving measurement uncertainties for partial defect testing (i.e., better than 6% at 1 sigma).

The hulls monitoring and measurement system (HMMS) measures the neutron emitted from spontaneous fission of ^{244}Cm in the hull drum, and calculates the amount of Pu and U contained in the hull drum using the ratios of $^{244}\text{Cm}/\text{Pu}$ and $^{244}\text{Cm}/\text{U}$ arrived at by applying a calculation code.

The directional canister passage detector (DCPD) is intended to verify the movement of MOX canisters. Each monitor comprises a double neutron ^3He tube in a polyethylene moderator supported by surveillance. The system determines whether a canister follows the normal process route (e.g., when and where the MOX canister came from and when the canister left the process area). All other possible movement combinations should be flagged by the system.

The Direct Use of PWR spent fuel in CANDU (DUPIC) safeguards neutron counter (DSNC) is a well-type neutron coincidence counter with 18 ^3He detectors configured with appropriate shielding, which measures all types of highly active materials from the dry reprocessing process for CANDU bundles (Menlove et al. 1997). It derives plutonium and uranium contents from the measured ^{244}Cm contents. Plutonium- and uranium-curiu ratios are determined from burnup calculations (Origen code) validated by HRGS scanning. The DSNC is operated remotely in a hot cell.

The DUPIC safeguards neutron monitor (DSNM) monitors the rear access ports of the process glove boxes through total neutron monitoring using ^3He detectors (Kim 2007).

The mobile unit for neutron detection (MUND) is an all-in-one neutron detection system for data collection and storage capable of running on battery power (Zendel et al. 2006). The unit is based on a ^3He detector mounted inside a polyethylene moderator slab. The preamplifier, HV supply, discriminator, recording electronics, and battery are all integrated inside a single, sealable enclosure. Two redundant data loggers record the data produced by the detector. The MUND collects data for more than 8 weeks without service. For servicing purposes, the device is removed from its measurement location, data are downloaded from the internal electronics, and batteries are recharged. The system has been specifically designed to perform the unattended monitoring of fuel transfer flasks. It is not intended for use in high-radiation environments. Once installed, an MUND is usually serviced by replacing the unit with a fully recharged one.

The mobile monitoring system for container transport (MMCT) consists of radiation monitoring, video surveillance, GPS location equipment, and smart power management to monitor the transfer of spent fuel via railcar (Lucero et al. 2004). The radiation sensors detect the spent fuel assembly during the loading, transfer and unloading process. The detector enclosure contains the detector assembly, which comprises six ^3He neutron tubes and two ionization chambers. The system is capable of acquiring safeguards data continuously for more than 1 week under harsh environmental, outdoor conditions (e.g., -20°C) without requiring recharging of the batteries.

63.3.6.3 Other Unattended NDA Systems

The advanced thermo-hydraulic power monitor (ATPM) is a monitoring system that can measure the actual thermal power produced by a reactor to confirm the declared operation in

nuclear research reactors (Araujo et al. 2001). The ATPM is a complete system comprising ultrasonic flow and temperature sensors mounted on primary cooling loop elements, together with a data collection and evaluation system housed in a tamper-indicating 19" industrial cabinet, which can be located up to 300 meters from the sensor location. The ATPM measures the reactor-coolant inlet and outlet temperatures and the coolant flow through the reactor core. These parameters are used to calculate the energy flow rate and the total energy produced in the reactor. The result of this calculation is then used to determine if substantial amounts of fissile material might have been generated in the reactor or, to confirm its declared operation.

The solution measurement and monitoring system (SMMS) uses high-accuracy and authenticated pressure and temperature measurement devices installed on selected process tanks to determine the volume, density, and temperature of the respective solution (Ehinger et al. 2004). The instruments are connected directly to the pneumatic dip-tube measurement lines of the tanks. The monitoring data exhibits temporal changes caused, for example, by filling, holding, sparging, sampling, and transferring activities. The system evaluation software discriminates between these characteristic changes and other disturbances and alerts the inspector to any unexpected operations. SMMS provides continuity of knowledge for plutonium-bearing materials in the solution process and supports the verification of nuclear material inventory, inventory changes, and other transfers. The SMMS software automatically decides whether a process follows its declared operation based upon the observed volume, density, and temperature data.

The IPCA Load Cell (IPLC) is an unattended load cell system intended to measure independently, the weight of MOX powder canisters with a relative accuracy of greater than 0.05%. The IPLC includes three load cells located on top of the IPCA system – raw data is collected and processed through an amplifier and dedicated software. The typical weights to be measured are between 200–300 kg.

63.3.7 Other NDA Techniques

This category of instrument comprises systems that measure physical properties such as weight, volume, absorption of light, sound velocity and heat. Weighing is performed to determine the net weight of an item or batch that is selected as a sample for verification. It is normally applied in conjunction with other accountancy verification methods in order to determine the quantity of nuclear material within the sample. Volume and concentration measurements, in conjunction with other verification methods, are carried out extensively in reprocessing plants to derive amounts of materials contained in solutions. An ultrasonic thickness gauge determines the thickness of container walls and is needed to correct for gamma ray attenuation. Measurement of decay heat can indicate the presence of spent fuel or, when measured in a calorimeter, can quantify pure plutonium samples. Laser-based technologies are becoming increasingly important, providing new and novel verification and detection tools for current and future safeguards activities (Zendel et al. 2007).

Main attributes of various further measurement systems are listed in [Table 63.7](#).

63.3.7.1 Physical Property Measurement

The load cell-based weighing system (LCBS) is used for weighing large uranium hexafluoride (UF₆) product cylinders (Dermendjiev et al. 1983). Cylinders are weighed with the LCBS

■ Table 63.7

Other measurement systems

System	Detector	Verification task	Typical performance values (%)
ICVD	Light amplifier for Cherenkov light	Spent fuel (cooling time <10 years)	Attribute
DCVD	Digital light amplifier for Cherenkov light	Spent fuel (low burnup, long cooling time >10 years)	Attribute
OFPS	⁶ Li-doped fibers	CANDU spent fuel bundles	Attribute
LCBS	Strain gauge	Weighing of UF ₆ cylinders	0.1
ULTG	Ultrasonic sensor	Measurement of wall thicknesses	0.3
PPMD	Pressure sensor	Volume in tanks	0.01
CALO	Temperature sensitive resistance sensor	Pu in nuclear material	0.4
XRFA	Si detector	Characterization of metals, alloys, minor and trace elements	Attribute
KEDG	HPGE transmission measurement	Pu, U concentration in solutions (>50 g/l)	0.2
HKED	XRF + KEDG	Pu, U in input solutions (IAT)	0.6 (U), 1.0 (Pu)
		Pu, U in product solutions (OAT)	0.3 (U), 0.9 (Pu)
COMPUCEA	LaBr ₃ + Si	U in unirradiated solutions	0.2
HFLS	Tunable laser + spectrophotometer	Detection of nuclear activities involving UF ₆	Sensitivity > 0.1 ppm
UFLS	Tunable laser + spectrophotometer	²³⁵ U-Enrichment in UF ₆	[0.15 (LEU)-0.7 (DU)] ^a
LIBS	Laser + spectrophotometer	Confirming past nuclear activities and absence of undeclared activities by trace analysis	Attribute
LIDAR	Laser + spectrophotometer	Detecting signatures of nuclear activities	Attribute
XRFS	X-ray detector	U, Pu, Np, Th, Am concentrations	1
OSAS	Alpha spectrometer	Pu in diluted solutions (<10 mg/l)	
OSCA	³ He + HKED	Cm/Pu/U ratio in input/HALW solutions	
OSDM	Frequency oscillator	Density of solutions	0.04

^aTarget accuracy.

attached to a crane. The load cell senses the weight of the suspended product cylinder and results are indicated on a display unit. After assembly and setup (requiring 20–30 minutes), weighing time is typically 3–5 minutes per cylinder with an accuracy of greater than 0.1%.

The ultrasonic thickness gauge (ULTG) is a small and simple instrument designed for measuring metal thickness. The measurement principle is based on measuring the time interval

from sound emission to reception of the echo and then multiplying this interval by the material-specific sound velocity. Silicone grease is used as couplant to eliminate any air between the sensor and measurement surfaces. The ULTG is required to measure the wall thickness of containers to allow correction for variations in the attenuation of the 186 keV gamma peak. The ULTG cannot determine multiple layers and measures only the outer layer.

Portable pressure measurement device (PPMD) is a lightweight carry-on type instrument comprising digital pressure modules (DPM) packed together with a power supply in a tamper-indicating enclosure (Landat et al. 1997). The PPMD can be connected to the level, density, and reference probes of a tank in parallel to an operator's own equipment. The sensor data are used to independently verify the volume of solutions in various storage and process tanks.

The 3D laser range finder (3D-LRF) is in routine use for design information verification (DIV) activities involving the largest reprocessing plant under safeguards (Agboraw et al. 2006). The system is capable of confirming within an accuracy of millimeters that no structural changes have occurred since the previous scanning and, of highlighting changes that may have occurred, in particular, to maintain continuity of knowledge (CoK) of the interiors of hot cells especially on various piping arrangements. For this purpose, baseline scans – called reference scans – are performed during the plant construction; subsequent verification scans taken during periodic inspection activities are compared to the original references.

The ground penetrating radar technology (GPRT) is based on the transmission and reflection of electromagnetic pulses. It represents a nonintrusive means of surveying sites for the identification and/or verification of structural elements. GPRT uses pulses of electromagnetic radiation in the microwave band (UHF/VHF frequencies) of the radio spectrum, and reads the reflected signal to detect subsurface structures and objects without drilling, probing, or otherwise breaking the ground surface. Applications include the detection of hidden objects and structures (Carchon et al. 2006).

63.3.7.2 Calorimetric Techniques

Calorimeters measure the heat produced by a sample of nuclear material, whereby the heat originates primarily from the α -decay of the isotopes making up the nuclear material. Calorimeters have traditionally been fabricated using a sensor of nickel wire wound around a measurement chamber (Bracken et al. 2002). The nickel wire provides a temperature-sensitive resistance leading to highly accurate and precise electrical measurements of the power produced by a sample. Calorimeters are calibrated with ^{238}Pu heat sources or plutonium samples with known mass and isotopic composition. Calorimetric assay is the most precise and accurate NDA measurement method for plutonium products (>100 grams).

Plutonium samples always contain a mixture of isotopes: ^{238}Pu , ^{239}Pu , ^{240}Pu , ^{241}Pu , and ^{242}Pu . The nuclide ^{241}Am is also present in most plutonium-bearing items. The amount of heat produced per gram of each nuclide is a known physical quantity ("specific power") based on the decay rate and decay energy of the isotope. The major contributors to the heat produced are ^{238}Pu and ^{241}Am . The measurement of the total heat in a calorimeter coupled with the measurement of the relative abundance of the individual nuclides in the sample (nuclidic/isotopic composition) provides the elemental mass in the sample. Calorimetry and neutron coincidence counting are complementary assay techniques that provide high assurance of correct and valid measurements. The calorimeter has the advantage being insensitive to geometry, matrix and humidity. However, measurements using calorimeters are very time

consuming in contrast to neutron measurements. Therefore, calorimetry is barely used by international safeguards but widely used in domestic safeguards to quantify plutonium and americium in plutonium bearing items.

63.3.7.3 X-Ray Measurements

X-ray emission is characteristic of the element while gamma-ray emission is characteristic of the isotope. Plutonium and uranium, as atoms with high atomic numbers, absorb energy at distinctive energies (e.g., the K-edge for Pu is at 121.8 keV as discussed below), associated with the energies needed to dislodge electrons from their innermost electron shells.

The X-ray fluorescence analyzer (XRFA) is a light, portable, and commercially available instrument (1.4 kg) for the characterization of metals, alloys, and possible dual-use materials by means of X-ray fluorescence (XRF). It is used by safeguards inspectors to verify the correctness and completeness of the presence of declared materials and the absence of undeclared ones. The measurement principle is based on irradiating the sample material by an X-ray photon field generated by an X-ray tube (no radioactive source!) and then measuring the characteristic X-ray fluorescence spectrum emitted by the sample using a high-performance Peltier-cooled Si-PiN detector. XRF can determine semi-quantitatively the relative concentrations of major, minor, and trace elements with atomic masses from 9 (fluorine) through 89–103 (the actinide elements) in various types of samples without requiring any sample preparation (► Fig. 63.4).

K-EDGE X-ray densitometry (KEDG) measures the photon transmission through a liquid sample at two energies that bracket as closely as possible the K-absorption edge energy of the element of interest. The K-absorption edge energy represents an element-specific signature. The logarithmic ratio of the photon transmission measured below and above the absorption edge is directly proportional to the volume concentration of the measured element for a well-defined sample cell. For plutonium, radioactive sources from ^{75}Se ($E_\gamma = 121.1$ keV) and ^{57}Co ($E_\gamma = 122.2$ keV) are used as transmission sources. These γ -ray energies very closely bracket the 121.8 keV electron-binding energy of the K shell of plutonium. The majority of the K-edge

■ Fig. 63.4

X-ray fluorescence analyzer (XRFA)

densitometers used for safeguards are now equipped with an X-ray generator that acts as a photon source for the transmission measurement. The high photon strength provided by an X-ray tube allows measurements to be performed on highly radioactive samples. The method is very selective and is one of the most accurate NDA techniques, but the determination of Pu may be biased by the presence of a minor actinide element of lower atomic number, such as U. It is therefore best used for relatively concentrated solutions (>50 g/l) of plutonium in product solutions, input solutions, and process solutions (in-line measurements).

Hybrid K-edge (HKED) is a technique used for measuring the concentration of U and Pu in mixed solutions by combining X-ray fluorescence and K-edge densitometry. Depending on the concentration of plutonium and uranium, the higher element concentration is identified by K-edge measurement and the lower concentration from the ratio of Pu/U of the XRF. HKED has become a standard technique to analyze solutions samples containing U and/or Pu over a concentration range from 0.5 to 400 g/l in reprocessing plants. In addition, HKED is also used to determine Np in the presence of fission products.

The X-Ray beam in KEDG-mode passes through a sample cell with a known path length and an HPGe detector measures the absorption at the K-edge to determine the concentration, based on the calibration of the system with solution standards. Located at a backward angle of 150° relative to the beam, a second HPGe detector can measure the X-Ray spectrum generated by the elements in the sample. K-edge densitometers equipped with an X-ray generator are usually resident and attached to shielded or unshielded glove boxes for sample handling (► Fig. 63.5).

Combined procedure for uranium concentration and enrichment assay (COMPUCEA) is a transportable system used to perform accurate on-site analytical measurements of elemental

► Fig. 63.5

The hybrid K-edge densitometer

assay and enrichment of liquid, unirradiated uranium samples (Ottmar et al. 2007). Solid uranium samples require preparation by quantitative dissolution of the sample. The system is portable and can be used at room temperature. The technique combines absorption edge spectrometry to establish the uranium concentration (L-edge for uranium: 17.17 keV) and a ^{235}U -enrichment spectrometer based on LaBr_3 . The L-edge technique uses a small X-ray generator of low energy and an ultrahigh-resolution Si gamma detector operated under modest Peltier cooling.

63.3.7.4 Analytical NDA Techniques at Laboratories

Some of the NDA verification techniques on samples of nuclear material taken during a safeguards inspection are carried out at specialized analytical laboratories, for example, the Safeguards Analytical Laboratory (SAL) at Seibersdorf in Austria or the On-Site Laboratory (OSL) at the Rokkasho Reprocessing Plant in Japan. Commercially available and customer-specific equipment is used to determine amounts and isotopic compositions of plutonium and uranium in inspection samples, having various chemical and physical forms, to supplement or replace destructive analysis. A parallel analysis of one and the same sample by NDA and DA serves the quality assurance of the analytical methods and control of the results.

High-resolution gamma spectrometry (HRGS) determines enrichment in uranium bulk samples by relating the gamma results to the total U content of the sample that has been assayed by titration or other methods such as IDMS or KEDG. In the absence of radioisotope interferences, the results have a precision and accuracy ranging between 0.5% rel. for natural and 0.2% rel. for enriched U. At OSL, HRGS is applied to Pu sampled from the output accountancy tank (OAT) to determine the isotopic composition, if the sample is not subjected to mass spectrometry. Additionally, Np in U and in Pu product samples can be determined. HRGS is used at SAL to screen all Pu samples as they are received.

X-Ray fluorescence spectrometry (XRF) is a non-portable XRF diagnostics tool, measuring well-characterized emissions from various elements (ranging from sodium to the highest elements on the periodic chart) when they are stimulated by x-rays. It provides the amounts of each element present (but not individual isotopes) within microgram detection limits. XRF is used to simultaneously determine concentrations of Th, U, Np, Pu, and Am. The XRF technique is applied if the element concentration to be determined falls below the useful range for K-edge measurements ($<40\text{g/l}$). It provides quantitative concentration measurements down to concentration levels of about 0.5 g/l. The quantitative evaluation of XRF measurements for concentrations is not as straightforward as for KEDG, e.g., matrix effects, but the technique is very accurate in performing element ratio measurements to determine the concentration of a minor element relative to the concentration of a major element known from a K-edge measurement.

The hybrid K-edge densitometry (HKED) at OSL is the main instrument to analyze solutions samples from the input accountability tank (IAT) and output accountability tank (OAT) containing U and/or Pu over a concentration range from 0.5 to 400 g/l. The KEDG-mode is applied down to 40 g/l and the XRF-mode down to 0.5 g/l U or Pu. Thus, the evaluation of KEDG and XRF spectra of a sample from the IAT yields the concentration of U (KEDG alone), the U/Pu ratio (XRF alone), and the Pu concentration (KEDG and XRF combined).

The OSL Alpha Spectrometer (OSAS) estimates plutonium in diluted solutions containing less than 10 mg/l of plutonium. An α -source can be made from the sample through a simplified

drop deposition method, followed by combustion. Spectra with higher resolution are obtained by electro-deposition, a method that is also preferred due to safety reasons (namely, using a furnace in a glove box is avoided). The sum activity of $^{239}\text{Pu} + ^{240}\text{Pu}$ is measured with an α -detector and the Pu concentration of the sample is estimated by comparing the α -count rate of the unknown sample with the count rate of a known standard reference source.

The OSL-curium neutron analyzer (OSCA) is a neutron coincidence counter that measures ^{244}Cm in solutions. At OSL, the system is integrated within a Hybrid-K-Edge (HKED) enclosure. The OSCA associated with HKED or isotope dilution mass spectrometry (IDMS) will provide analytical data to establish the $^{244}\text{Cm}/\text{Pu}$ and $^{244}\text{Cm}/\text{U}$ ratios in IAT solutions or in high active liquid waste solutions.

The OSL-density meter (OSDM) measures the density of solutions to estimate accurately the mass of a solution contained in a sampled vessel/container. OSDM measures the frequency of an oscillating tube filled with the solution sample. The instrument is calibrated by measuring the frequency of oscillation using air, water, or liquid density standards. A sample solution is injected, or drawn, into the temperature-stabilized tube and a built-in computer automatically converts the frequency measurement into a density reading.

63.3.8 New and Novel Technologies

Emerging and future needs for safeguards verification require state-of-the-art equipment and innovative technological solutions to meet current and future verification challenges (Khlebnikov et al. 2006a; Annese et al. 2009; Tolk et al. 2007). The early detection of undeclared facilities, activities and materials has become a major safeguards task. It plays a primary role in providing independent safeguards conclusions on the completeness and correctness of a state's nuclear program. The increasing complexity and automation of nuclear facilities as well as new facility types require new approaches and advanced instrumentation. The verification system has to be further developed taking full account of advances in present safeguards verification techniques ("new technologies") and through the exploration of innovative technologies that are either already available or investigated in other branches of science and technology fields not traditionally related to safeguards ("novel technologies"). In particular, capabilities to detect nuclear activities (e.g., reprocessing or enrichment) from a distance are of prime interest and require a new toolbox for the inspectorate. In many cases, safeguards implementation involves unannounced inspections and complementary access (CA) requiring detection devices to search for nontraditional elements/nuclides (such as americium, neptunium, beryllium, and tritium) that could indicate the presence of a clandestine nuclear weapons program. Instruments for these specific types of verification activities often need to be made available to inspectors at very short notice. Such equipment must be multipurpose, robust, portable, and easy to operate to allow the inspector to readily perform numerous tasks within the short time span of each particular verification activity, including the search for indicators of undeclared nuclear materials and activities.

63.3.8.1 New Technologies

New technologies for safeguards purposes could address missing capabilities in routine verification tools and could enhance the effectiveness and efficiency of present verification systems. Instrumentation based on new technologies might be in its final development stage

but not yet available for routine safeguards implementation. Such equipment will be authorized for routine use subject only to a careful assessment of aspects (including its expected performance, usability, and affordability) and the completion of a successful field test. New sensors for nuclear material detection and characterization, process monitoring equipment/techniques and analytical equipment are the main new technology drivers. Various efforts are underway to develop techniques for the direct verification of plutonium in spent fuel (Tobin et al. 2008, 2009).

The *superconducting gamma spectrometer* is a cryogenic, ultrahigh energy resolution γ -ray spectrometer, operated at temperatures of $T \approx 0.1$ K (Ali et al. 2006, 2008). It can be characterized as a cryogenic gamma-ray micro-calorimeter, which measures the energy of radiation from increase in temperature upon absorption of a γ -ray. The detector consists of a highly sensitive, cryogenic transition-edge sensor (TES) coupled to a tin γ -ray absorber. The TES is a Mo/Cu multilayer sensor capable of determining the energy of a single γ -photon with extremely high precision – it operates in the narrow temperature range of the transition from superconducting to normal state. An individual sensor element is 1.5×1.5 mm by 0.25 mm thick. To achieve reasonable counting statistics, detector arrays with many sensors are used (Hoover et al. 2009). The system offers an order of magnitude improvement in energy resolution over conventional high-purity Ge (HPGe) detectors. It could be used for accurate enrichment measurements and Pu-isotopics.

The *differential die-away self-interrogation (DDSI) technique* is a recently conceived NDA technique for quantifying the total fissile and fertile content in spent fuel (Menlove et al. 2009) using a modified ^3He coincidence counter. In DDSI, the spontaneous fission neutrons from ^{244}Cm that are present in the assembly act as the interrogating source. After each spontaneous fission event, the neutron time distribution is analyzed to determine the fast and slow neutron distributions from the spontaneous and induced fissions in the sample, respectively. Fissile mass is determined from the fissions induced by reflected thermal neutrons originating from the spontaneous fission reaction. The sensitivity of the fissile mass measurement is enhanced by measuring the sample with and without a cadmium liner between the sample and the surrounding moderator (“passive-neutron albedo reactivity (PNAR)”). The fertile mass is determined from the multiplicity analysis of the neutrons detected soon after the initial triggering neutron is detected.

Self-interrogation neutron resonance densitometry (SINRD) uses the unique neutron-resonance cross-sectional structure for fissionable nuclides such as ^{235}U , ^{233}U , ^{239}Pu , and ^{241}Pu . Its sensitivity is based on using the same fissile materials in the sample and in the fission chamber because the effect of resonance absorption lines in the transmitted flux is amplified by the corresponding (n,f) reaction peaks in the fission chamber (LaFleur et al. 2008, 2009). The amount of resonance absorption of these neutrons in the spent fuel can be measured using ^{235}U and ^{239}Pu fission chambers placed adjacent to the assembly.

^{252}Cf interrogation with prompt neutron detection (CIPN) is a lightweight, active interrogation instrument/detector, similar in size and shape to the FORK detector (Scheer et al. 2009). The main difference between CIPN and a FORK detector is the introduction of an interrogating ^{252}Cf source adjacent to the fuel and opposite to the fission-chamber detector region. Two gross-neutron measurements are performed: a background measurement (without ^{252}Cf) and an active assay with the ^{252}Cf source next to the fuel. Fissile content is quantified using the measured neutron multiplication in the assembly.

The *delayed neutron technique* quantifies the fissile content in a spent fuel assembly by measuring the delayed neutrons emitted by fission fragments after active interrogation by

a neutron burst (~ 1 s) from a neutron generator (Scheer et al. 2009). The generator stops after 1 s and starts again after another second. In between, the delayed neutrons are being measured and multiple interrogation/measurement cycles are performed to gain sufficient counting statistics.

Self-induced X-ray fluorescence (XRF) can be used to quantify the Pu content in spent fuel (Charlton et al. 2009). The radioactive decay in the spent fuel leads to self-induced XRF of uranium and plutonium atoms in the fuel and resulting X-rays are then emitted by the fuel. It has been demonstrated by measurements and simulations that the Pu/U atom ratio at the surface of a fuel pin can be measured in an appropriately designed and implemented instrument using the 103.7 keV K X-ray from Pu.

Lead slowing-down spectroscopy (LSDS) is an active interrogation technique that has been used for several decades in cross-sectional measurements. It can provide independent Pu isotopic mass without operator-declared information about the spent fuel (Gavron et al. 2009). In typical operation, a neutron source provides a pulse of neutrons close to the center of a large block of lead. The neutrons are moderated slowing down gradually. The incoming neutrons from the slowing down process will induce fission in the fuel placed in the center of the lead block and high-energy fission- neutrons are emitted. An annular ring of fission chambers selectively measures the higher-energy fission neutrons as a function of the time after the neutron pulse. Potential threshold fission chamber types include those lined with ultra pure ^{238}U (to minimize the contributions from ^{235}U) and those based on ^{232}Th . New time-spectra analysis methods are applied to determine the fissile mass of $^{239,241}\text{Pu}$ and ^{235}U .

A new on-line monitoring system featuring Raman and ultraviolet-visible-near infrared (UV-vis-NIR) spectroscopy methods combined with a Coriolis and conductivity probes provides immediate chemical data and flow parameters of high-level radioactive waste streams (Bryan et al. 2009). This allows real time monitoring of the solvent extraction flow sheets for quick detection of undeclared activities with fissile isotopes present in the radiochemical streams during reprocessing activities. The proof-of-principle has been successfully demonstrated for on-line monitoring of U (VI), nitrate, and HNO_3 by using Raman spectroscopy and on-line monitoring of Np, Pu, Nd, for both aqueous and organic phases, using Vis/NIR.

The multi-isotope process (MIP) monitors spent nuclear fuel reprocessing facilities on-line, nondestructively, and in near real time (Orton et al. 2009). The method is based upon the measurement of distribution patterns of a suite of indicator (radioactive) isotopes present within particular process streams. Distribution patterns, monitored on-line by gamma spectrometry, are compared in near real time to patterns representing “normal” process conditions using multivariate pattern recognition software. The MIP monitor is sensitive to minor alterations in major process variables including acid and organic ligand concentration. Therefore, it might be used to confirm the declared operation of a reprocessing plant, providing additional information on reactor type, burnup, and cooling time.

The laser-based optical and chemical imager (LOCI) is a unique instrument that combines accurate isotope ratio analyses obtained both by laser desorption Fourier transform ion cyclotron resonance mass spectrometry (FTICR-MS) and by LIBS without any sample preparation (Scott and McJunkin 2009). A single photon ionization (SPI) process is implemented allowing near 100% ionization efficiency for elements and compounds with ionization energies less than 10.5 eV. The FTICR-MS and LIBS isotope capability coupled with LOCI's wide mass range, mapping capability, high resolution, and automated data collection as well as data interpretation offers an alternative to the labor-intensive bulk analysis of traditional methods,

such as TIMS. This capability will be very useful for environmental samples and for determining the burnup rates within fuel elements.

Electrochemically modulated separations (EMS) is a technique that relies on electrochemical redox adjustment and surface chemistry to effect isolation and accumulation of Pu at a target electrode (Clark et al. 2006; Duckworth et al. 2009). EMS may be a rapid and cost-effective means of performing Pu separations that has implications for DA and NDA, simplifying laboratory separations and allowing NDA for input accountancy tanks.

Automated radioanalytical chemistry can provide near real time monitoring of reprocessing plant operations (O'Hara et al. 2009). A sequential injection chromatography system for the separation and analysis of Am, Pu, and Np isotopes is integrated in a modular system that automates the complete sample analysis process, from initial sample preparation to final data reporting.

The laser item identification system (L2IS) is capable of monitoring all transfers of UF₆ cylinders between process areas (Poirier et al. 2009). L2IS uniquely identifies each cylinder through exploring the unique microstructure of each cylinder's surface with different lasers. It has been demonstrated that every cylinder has a unique "fingerprint" that remains intact even under extreme environmental conditions. The L2IS system is composed of a portable unit, operated in attended mode, and a fixed installed unit, operated without inspector presence. The portable unit acquires the fingerprints of a given set of feed cylinders intended to be used over the coming months and the fixed system monitors the flow of previously identified cylinders in a transfer corridor.

63.3.8.2 Novel Technologies

Novel Technologies aim to provide access to a wider range of methods and instruments in support of safeguards implementation by adapting technologies already available or being developed in other branches of science and technology fields but not used for safeguards. Such technologies could significantly contribute to the early detection of undeclared nuclear activities and material. Typical examples include the determination of an undeclared location previously used for storing radioactive material, forensics of materials found on-site and evidence of nuclear fuel-cycle process activities at suspected locations. In contrast to new technologies, safeguards equipment based on novel technologies is in its early stage of development and may not be readily available within a short time frame. Several promising technologies based on laser spectrometry and optically stimulated luminescence (OSL), anti neutrino detection, nuclear magnetic resonance (NMR), atmospheric gas sampling, and analysis and various electromagnetic systems have been identified (Khlebnikov et al. 2006b; Whichello et al. 2009). Nanotechnology in its various forms such as nano-electronics, nano-electromechanical systems, ultra-small, highly sensitive, and selective sensors (Morrison et al. 2007) could significantly contribute to novel technologies. A novel suite of smart safeguards verification systems can be expected with unique detection features allowing at the same time further miniaturization of the equipment. The most impressive advance allowed for by nanotechnology development is the possibility of autonomous smart sensor networks. These networks could support safeguards monitoring functions by capturing data, processing and transmitting information, and communicating with other sensors in potentially hostile environments.

Optically stimulated luminescence (OSL) is capable of de-trapping radiation-induced excitation energy accumulated during the irradiation of a surface (Kosierb 2007). The release

of this energy could be stimulated by various types of lasers in the visible and infrared frequency ranges. The intensity of the resulting photon emission is proportional to the radiation dose absorbed by the material, unveiling information on the former presence of a radioactive source. The detection system uses a charge-coupled device (CCD) camera attached to a photomultiplier. The optical part of the detector has to be optimized to decouple the larger signal, emanating from the optical pump, from the smaller signal emitted by the sample. Samples collected by the inspectors are analyzed by OSL, indicating the previous presence of stored nuclear materials and thereby presenting the potential to disclose undeclared activities.

OSL could also be used for container verification. Luminescent phosphor additives, ionized by radiation, are mixed with paints or clear coats and are applied to the surface of a container (Miller et al. 2009). The OSL phosphors luminesce in proportion to the ionization radiation dose and the intensity of excitation light. The OSL coatings/additives will be invisible to the naked eye, but could be seen using an InGaAs infrared detector. The OSL additives would tag the container and reveal an attempt to tamper with the container and therefore increase the confidence that its integrity had not been compromised.

Tunable diode laser spectroscopy (TDLS) systems are tuned to access specific regions of the mid-infrared spectrum where most gases of interest such as UF_6 have strong absorption while common gases, such as oxygen and nitrogen, do not. TDLS systems have the potential to determine ^{235}U enrichment in UF_6 gas and to indicate the presence of HF gas, a by-product of enrichment activities.

The HF detector laser system (HFLS) is a portable instrument for HF gas detection, designed for easy operation in airborne and ground-based mobile searches for enrichment activities. The HFLS is built as a backpack unit allowing continuous air monitoring while leaving the inspector's hands free. A tunable diode laser shines through a multipass cell, which is continuously collecting air gas. The detector then analyzes the unique absorption lines caused by the HF gas in the cell. The instrument is very sensitive and can measure HF concentrations of >0.1 ppb. The system provides a very quick measurement and identification with high spectral resolution in the infrared range.

The UF_6 detector based on laser spectrometry (UFLS) is an on-site analytical instrument based on TDLS. It measures the enrichment of UF_6 samples (Lebrun et al. 2008). The system has passed feasibility study and is now under development for field use. It determines the concentration of ^{235}U and ^{238}U in UF_6 on-site with an accuracy of greater than 1% for ^{235}U enrichment. The precise measurement of the isotopically broadened absorption peaks of ^{235}U and ^{238}U requires a mid-IR laser with wide single-mode tuning ranges, better than 4 cm^{-1} of continuous tuning at $1,290\text{ cm}^{-1}$ and less tuning at 852 cm^{-1} . In comparison with mass spectrometry, UFLS does not require a highly trained specialist to perform measurements. It is hoped that the instrument will partly replace the need for DA and thereby will improve verification timeliness and reduce inspection resources.

Laser-induced breakdown spectroscopy (LIBS) is being applied for a novel complementary access instrument based on the detection of gaseous and solid signatures and indicators of nuclear fuel cycle processes (Kosierb 2007; IAEA 2009b). LIBS is an atomic emission spectroscopy technique that utilizes a pulsed, well-focused laser to create a micro-plasma on the sample surface (Salmon et al. 2008). The resulting light emission spectrum of the decaying vapor plume has well-known specific emission lines that are analyzed by an integrated spectrometer. The spectroscopic profile is compared to those in its library to determine the composition of the material. LIBS can perform the analysis of elemental composition and trace analysis of solid

■ Fig. 63.6

Laser-induced breakdown spectroscopy (LIBS)

materials to confirm past nuclear activities and the absence of undeclared activities, and is therefore considered as a possible screening device to reduce the number of environmental samples (► Fig. 63.6).

The light detection and ranging (LIDAR) system may remotely sense the presence of characteristic gaseous compounds emanating from nuclear fuel cycle (NFC) processes into the atmosphere (IAEA 2006b). LIDAR might be capable of analyzing emissions and detecting fingerprints of undeclared nuclear activities from a distance of some kilometers of a suspected site by using a mobile LIDAR laboratory in its vicinity. A laser, tunable to precise wavelengths, selectively stimulates such airborne molecules. A light-sensitive telescope scans the atmosphere, detecting the presence of the stimulated molecules. For safeguards purposes, differential absorption LIDAR (DIAL) is particularly interesting. This technology sends laser pulses tuned on two different wavelengths to the atmosphere – one specific to the strongly absorbing molecule, the other less absorptive as a reference – and then analyzes the intensity of light scattered back over time. The signals are processed providing the transmission both on and off a molecular absorption feature to give a measure of the concentration.

The *antineutrino detector* can measure the plutonium content of an online nuclear reactor core, may provide effective power and burn-up to confirm that reactors are operating as declared (Bernstein et al. 2003; Bowden et al. 2007; IAEA 2009c). Antineutrinos are produced in nuclear reactors when uranium and plutonium atoms fission into neutron-rich fragments that undergo successive beta decays. A common detection scheme uses the inverse beta decay reaction producing a closely timed coincident neutron and positron – these are detectable in a scintillator that is shielded from background radiation. Despite the small cross section, the abundant antineutrino production of the core allows for high statistical detection with modestly sized detectors (1 m^3) at practical standoff distances (tens of meters). When an antineutrino collides with a proton, it produces a positron and a neutron. The interaction of these two particles creates the antineutrino signature – two relatively intense flashes of light that occur so close in time to one another that they appear to be almost simultaneous (► Fig. 63.7).

■ Fig. 63.7

The antineutrino detector

The Fourier-transform infrared system (FTIR) is a well-known spectroscopic technique based on the absorption of infrared photons that excite vibrations of molecular bonds. Molecules such as U_3O_8 , UO_2 , UO_3 , ThO_2 , have characteristic absorption bands in the infrared region that can be used like a fingerprint to detect their respective presence. FTIR radiometry has become a relatively mature and reliable method for the identification and measurement of chemicals emitted from stacks and its potential for passive standoff detection of nuclear material is under investigation (Puckrin and Thériault 2006).

Electromagnetic wave gradiometer technology can be used to detect underground electrically conductive structures or paths such as clandestine tunnels (Matter 2003). Primary low-frequency electromagnetic (EM) waves induce electrical current flow in conductive paths located underground. Conductive paths are abundant in underground operating structures, such as electrical power cables or air ventilation pipes, or conductive paths such as the moist conductive soil layer that commonly surrounds tunnels with high humidity and condensation. The transmitter can be located above ground (either in a fixed location or carried by an inspector) or underground in a borehole. The induced current flow generates a secondary magnetic wave that is retransmitted through the ground and measurable on the surface above the underground structure using a gradiometer antenna array with a narrow band synchronous receiver. The signal is scanned on the surface and a plot of its magnitude yields a profile showing the structure's centerline and depth information.

Nuclear magnetic resonance (NMR) could measure the $^{235}\text{U}/^{238}\text{U}$ ratio accurately and therefore it could be used to detect clandestine enrichment at a declared facility, applying mature NMR technology (Pepper et al. 2007; Magnelind et al. 2009). NMR provides

a quantitative measure of the number of nuclei of a given isotope in a given sample. The NMR signature of materials is measured in ultralow magnetic fields and at ultralow frequencies. The method has the potential of quickly and accurately (possibly at the fraction of a percent level) measuring the amounts of ^{238}U and ^{235}U in each and every cylinder containing feed, tails, and product, as well as monitoring the flow of UF_6 in the cascade area. The benefits of NMR include that it is nonintrusive and no source is required.

Acoustic wave analysis technology may provide a viable containment verification tool (Goldfarb 2007). Acoustic waves are disturbances in mechanical vibrations in solids, liquids, or gases. The interpretation of acoustic waves can unveil subtle structural changes in materials, including cracks, pits, voids, gaps, bends, and changes in density and elasticity. A monitoring system with a network of acoustic sensors may be useful to detect abnormal process operations.

The *speckle laser interferometric application* could detect hidden underground structures or other non-visible items (Mersch 2007; Nothdurft and Yao 2005). The system uses subtle differences in surface response to coherent light and requires significant interpretive analysis. It subtracts a picture taken from a surface illuminated by laser light (background picture) from subsequent pictures taken after “disturbing the surface,” e.g., by a small underground detonation. The effect of the observed subsurface disturbance on the surface is a function of the hidden subsurface features.

Remote sensing in satellite imagery and “stereo mapping” could be further developed to enhance interpretation of site activities using the broad potential of satellite imagery data ranging from panchromatic, multispectral, hyperspectral to radar for site description and change detection (Niemayer 2009). A satellite could view the earth in different spectral bands covering the visible and infrared band. It could measure local ground and water temperatures to an absolute accuracy of 1 K. By further investigating other portions of the electromagnetic spectrum, it may be possible to detect and identify the location of an undeclared nuclear activity, e.g., to detect the waste heat from a clandestine plutonium production reactor. Hyperspectral data allow for a quantitative estimation of geophysical and geochemical characteristics of the earth’s surface and is therefore useful for assessing, e.g., surface cover changes due to drilling, mining, and milling activities.

Atmospheric gases sampling and analysis can provide useful information about the existence and nature of ongoing nuclear activities. ^{85}Kr could be indicative of reprocessing activities (Kalinowski et al. 2006; IAEA 2006a). For each kilogram of plutonium reprocessed, some 10–35 TBq of ^{85}Kr are typically released into the atmosphere. This evidence can be detected from a distance, varying from hundreds of meters to some kilometers, depending on meteorological conditions. The technique uses air sampling with a cryo-absorption device to concentrate the fraction of noble gases. The amount of ^{85}Kr is determined either by low-level counting of the β -radiation, by accelerator driven mass spectrometry or by atom-trap trace analysis (ATTA).

Micro seismic monitoring can detect any abnormal underground activities that could indicate unauthorized design changes and containment breaches in final nuclear depositories (Saari and Lakio 2008). It consists of several seismic sensors grouped in a network to monitor remotely excavation-induced micro-earthquakes and explosions occurring inside the local geology of nuclear repositories. The system can also detect early the drilling activity of a tunnel-boring machine trying to excavate an access tunnel to the depository from outside (Saari and Lakio 2009).

Microelectromechanical systems (MEMS) have the potential for creating miniature bench-top laboratories on a chip (Janssens-Maenhout and Nucifora 2007). Such miniaturized

chemical laboratories could provide real-time chemical detection of trace elements in vapor and they could be tailored to detect many classes of chemicals, providing a quick indication of the presence of a class of selected chemicals in the field. MEMS would work with sensors that would use polymer or gel-coated silicon devices to trap targeted chemicals, and then send the agents through fluidic channels to on-chip arrays of surface-acoustic-wave detectors (SAWs). The sensors can be “pre-tuned” to targets of interest, during fabrication, by careful selection of absorption layer and can perform spectroscopic measurements. A follow-on device would integrate the fluidics, sensors, and support electronics on a single device.

Detectors, sensitive to hydrogen fluoride and other fluorine-containing gases (Moritz et al. 1999; Filippov et al. 2007) are of safeguards interest for indicating possible enrichment activities. These types of sensors are based on the Pd-LaF₃-SiO₂-Si structure that generates a signal resulting from the electrochemical reaction with the fluoride on the surface of the sensor. The lower detection limit offered by this technology has been estimated at around 0.05 ppm of HF. It can be assumed that a device based on this semiconductor sensor is able to register directly both UF₆ and further products resulting from its degradation.

Other sensors are composed of nanostructured materials such as carbon nanotubes and metal oxide nanowires. These materials have a controlled pore size and an increased adsorptive capacity due to the large surface area enabling the selective uptake of gaseous species. The absorption can lead to a measurable change in some specific properties, e.g., conductance, capacitance, etc. (Li et al. 2003).

Nanocomposite scintillators utilizing nanocrystals of known scintillator and detector materials will allow for the production of large composites of the nanocrystals with an expanded variety of attainable shapes and sizes (Del Sesto et al. 2007; McKigney et al. 2007). These nanocomposite materials are expected to have improved properties with respect to the properties of the bulk single crystal scintillators from which they are derived. Preliminary measurements show that nanophosphor materials have a significantly higher light output (by a factor of 3) than single-crystal materials of the same weight. This translates to greater scintillation efficiency. In addition, a shift toward longer wavelengths is observed in both the photoluminescence excitation and emission of the nanomaterial with a smaller overlap of the excitation and emission spectra, enhancing the energy resolution of the nanocrystal material.

Nanocomposite semiconductors such as nanowires arrays of CdZnTe can be used for detecting low-energy gamma rays (Gandhi et al. 2008). The CdZnTe compound semiconductor is electrodeposited in the form of nanowires onto a TiO₂ nanotubular template. The preliminary results indicate that the CZT nanowire arrays can be used as radiation detector materials at room temperature with a much lower bias potential (0.7–2.3 V) as compared to the 300–500 V applied to bulk detector materials.

Solid-state neutron detectors using silicon nanopillars (Cheung et al. 2006) are being developed. The space between the silicon nanopillars is completely filled with ¹⁰B-enriched material using chemical vapor deposition (CVD). The incident neutrons are converted by the nuclear reaction ¹⁰B(n, α)⁷Li to α-particles, which are collected and detected by the silicon (Nikolic et al. 2007). The coin-sized detector has achieved a thermal neutron detection efficiency of 20% and neutron/gamma discrimination of 10⁵, which are comparable to the parameters of a ³He-based detector. Such detectors could be arranged in flexible arrays and could be directly attached to a moderator. They could also replace ³He tubes. Another attractive application combines recent advancements in ultrawide band radio frequency identification (RFID) technology with such neutron detectors (Nekoogar et al. 2009). The RFID neutron tags can be used for neutron monitoring. They are totally passive and will operate indefinitely

without battery power. The tag is compact; it can be directly mounted on metal, and has high performance in dense and cluttered environments.

Miniaturized wireless semiconductor devices can form sensor networks – also known as smart dust (Sailor and Link 2005). These devices are millimeter- to micrometer-sized multifunctional packages, combining a sensor (e.g., optical, chemical, vibration, or radiation) with computing and communication capabilities. A large number of these packages can be integrated to form an “Internet-like” network. The devices could be inexpensively mass-produced using conventional silicon fabrication techniques coupled with nanotechnology. Potential applications for safeguards may include the monitoring of facilities and inventories, measuring temperature profiles and detecting undeclared process activities via chemical signatures.

63.4 Laboratory Analysis for Nuclear Material Accountability Verifications

63.4.1 Introduction

One diversion scenario is the removal of small amounts of material over a longer period, masking under the measurement uncertainties the slow accumulation of “significant quantities” of material in a “protracted diversion.” This can involve small underestimates in the declaration of inputs, small overestimates of the outputs, or inflated estimates of measurement uncertainties by the operator. *Destructive analysis* (DA) remains the basic tool to detect such potential actions by analyzing independent samples obtained by the inspectors during physical inventory or material flow verifications, based on a random sampling plan. The inspection samples are most often shipped for analysis to specialized laboratories operated by or on behalf of the inspectorate. In the case of some large bulk-handling facilities, inspectorate specialists will analyze the inspection samples locally or on the plant site at a dedicated laboratory. Inspectors may perform additional inspections and request other samples for the purpose of verifying the quality of the measurement systems and providing independent estimates of the measurement uncertainties. The inspectorate laboratories supply also certified materials, which are submitted to the operator laboratory as part of external analytical quality control measures. They also prepare and/or certify spikes for isotope dilution assays and physical or chemical standards for the calibration of portable or installed instruments used for on-site verification measurements.

The accountability measurements of the facility operators and the verification measurements by the inspectorate are expected to meet internationally accepted standards of precision and accuracy (IAEA 2001), which were defined by an international panel of analytical chemists and data evaluation specialists and are reviewed at regular intervals.

63.4.2 Bulk Measurement, Sampling, Conditioning, and Shipment of Safeguards Inspection Samples

A prerequisite for accurate destructive analysis is a strict representativity of the sample, when it is taken, and its proper conservation during its handling at the plant and its shipment to the analytical laboratory. If the purpose of the sampling is to verify material accountability, the

weight or volume of the material to be sampled must be measured just before sampling and recorded. Operator's installations and procedures are normally used for bulk measurements of weights or volumes and sampling for verifications.

A validation of operator sampling installations and procedures is therefore done during the initial design information verifications and associate inspectors, sampling specialists, and analysts of the inspectorate laboratory. The sampling installations and procedures should comply with internationally accepted standards and technical norms. Inspector's samples of plutonium and spent fuel samples must frequently be pretreated, diluted, conditioned, and packaged so that the amount of radioactive material per package complies with international air transport regulations (IATA 2003). Because of their small size, the composition of inspection samples is prone to be affected by humidity, air oxidation or evaporation. The inspectorates select and qualify, therefore, carefully the vessels in which inspection samples are taken, conditioned, and shipped in a way to ensure their integrity until they reach the laboratory. The vessels should be chemically inert and should not break during transport. Their tare should be stable over time and varying atmospheric conditions, and it must be possible to close or cap them hermetically, so that a weight control may detect potential changes in the composition of the sample between its taking and its analysis and permit their correction, when necessary. Plastic vessels are used for samples of solutions or sintered pellets and dense metal. Glass vessels are chosen for powder and most other samples. The sampling vessels, the sample vials and their handling must always remain under inspectors' supervision and control. Document STR69 (IAEA 2004) describes the precautions and procedures adopted for obtaining reliable DA inspection samples from most types of materials subject to nuclear safeguards.

Sampling is not recommended in the case of finished or intermediate products from which analytical samples cannot be taken without destroying a valuable manufactured item (e.g., rods, bundles, assemblies). It is also undesirable on very heterogeneous materials in small quantities from which representative samples cannot be taken without unreasonably great effort and expense, and therefore sampling may not lead to meaningful results. Verifications of the accountability of the above materials will rely on NDA methods, combined with C/S measures. However, when the weight or volume of the material cannot be measured, the taking and analysis of a sample may still be justified for verifying the operator's measurement system.

The procedures are designed to yield at least duplicate results, which allow estimating the uncertainties resulting from subsampling and conditioning steps. Four examples are outlined below.

63.4.2.1 Spent Fuel Solutions

In spent fuel reprocessing plants, inspection samples of spent fuel (SF) solutions are taken from tanks equipped with means to homogenize the solution, by air sparging or mechanical stirring, and to measure the weight of the solution, using strain gauges, or its level and volume, usually with dip tube systems and differential manometers (ISO 1996a). During normal plant operation, this is done solely at the input accountability tank for material flow verification. Inventory verifications are scheduled when the plant is idle and most fuel material is removed from the process areas. Only storage tanks may need then to be measured and sampled.

The norm ISO18213 gives detailed recommendations concerning accountability tank installations and procedures for volume calibration and measurement (ISO 2007b). It reflects the results of extensive experience collected at a number of spent fuel reprocessing plants

(CETAMA 1997; Hunt et al. 1994; Janin 2006). For accurate bulk measurements and representative sampling, the “dead volumes” of ancillary pipes should be negligible compared to the volume of the bulk solution, and the heel remaining at the bottom of the tank after it is emptied should be minimized. Such tanks are subject to initial calibration before the start of plant operation and typically verified once a year (Janin 2006).

Primary samples of 3–5 ml are withdrawn from a sampling pot through which an airlift circulates the bulk solution, while the tank is stirred (ISO 1995a). The operator collects a sequence of primary samples in evacuated 5–10 ml vials, capped with a synthetic rubber septum. The inspector selects one of the primary sampling vials and witnesses its subsequent subsampling and conditioning. Occasionally, the inspector may request replicate primary samples to check their representativity. This can be done on the spot by witnessing a measurement of their density and comparing the results with the density of the bulk solution measured with the dip tubes in the tank, after referring all values to the same temperature (ISO 1995b).

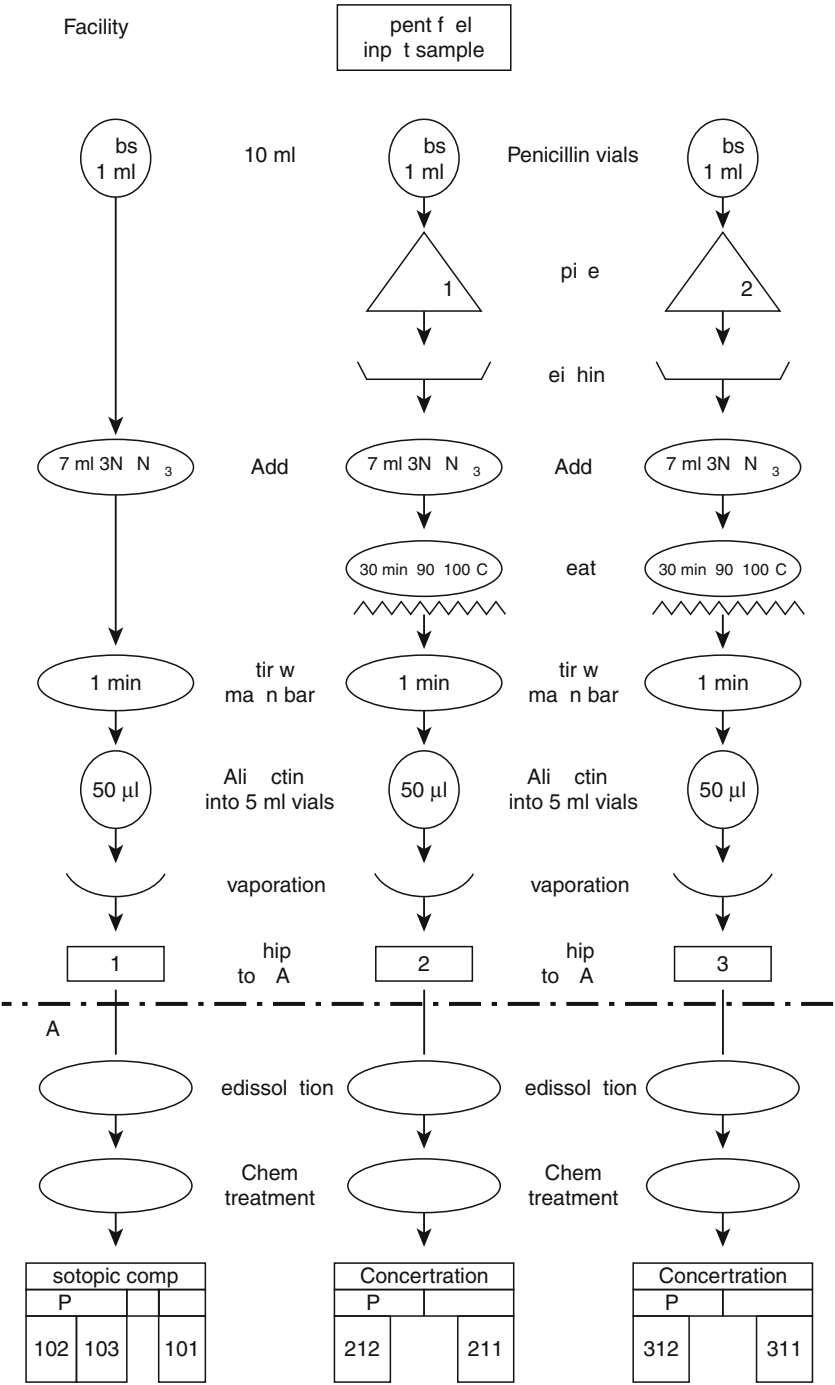

The large-size-dried (LSD) spike procedure is the standard IAEA procedure for the preparation and analysis (see section “Isotope Dilution Mass Spectrometry”) of high burnup spent fuel samples with a ^{239}Pu abundance lower than 80% by isotope dilution mass spectrometry (IDMS). The procedure for sample conditioning at the facility and the measurement scheme followed in the laboratory are outlined in [Fig. 63.8](#). The first of the three subsamples is intended for isotopic analysis and is transferred into an empty 10 ml penicillin vial. The second and third subsamples, intended for elemental assay, are transferred into separate 10 ml penicillin vials, which contain certified amounts of a mixed U/Pu tracer. The latter two subsamples are weighed to an accuracy of ± 0.0005 g or better. The tracers are re-dissolved with nitric acid; the subsamples are diluted to about 7 ml and homogenized. An aliquot of about 50 μl of each diluted subsample is transferred into a clean and empty penicillin vial of 5 ml and dried carefully. The penicillin vials are capped and inserted in a small lead pot. The lead pots are bagged out and packed in a tin can. Several tin cans may be packaged in a single Type A container, which is air flown to the inspectorate laboratory.

63.4.2.2 Uranium Hexafluoride in Pressurized Cylinders

Bulk measurement of UF_6 in isolated UF_6 cylinders consists of determining the gross weight of the cylinder on a suitable scale just before sampling and then subtracting the known tare. To obtain a representative sample suitable for elemental uranium assay, the cylinder is placed in an autoclave, connected to a stainless steel vacuum rig ([Fig. 63.9](#)), heated and kept at 93–113°C throughout a prescribed period and during sampling. After complete homogenization, a measured portion of UF_6 is withdrawn from the liquid phase via a “pigtail” and transferred into a large primary sample bottle. The convection currents in the liquid UF_6 readily achieve isotopic homogeneity. However, chemical homogeneity is more difficult to reach in the presence of insoluble particles or volatile impurities. Excessive volatile impurities are vented to the process before weighing and sampling the cylinder.

The primary sample bottle is transferred to the operator’s laboratory and mounted on a subsampling station ([Fig. 63.10](#)). The UF_6 is liquefied and a subsample of 1 to 5 g is collected again from the liquid phase (ANSI 1972; ISO 1996b) into a finger tube ([Fig. 63.11](#)), which is weighed and shipped to the inspectorate laboratory. If the subsample is not issued from homogeneous liquid phases, only the uranium isotopic analysis will provide a meaningful result. In such a case, it is recommended to skip the elemental uranium assay.

63.4.2.3 Plutonium Oxide Powders

PuO₂ powders readily exchange atmospheric moisture and carbon dioxide, particularly on their surface. With the precautions described below, the shipper's and the receiver's data were in

■ Fig. 63.11

UF₆ subsampling tubes (IAEA 2004)

excellent agreement, with uncertainties of the order of 0.07% over a large number of shipments of plutonium oxide between the plants of La Hague in France and Sellafield in the United Kingdom (Swinburn and McGowan 1976). The operator's sampling and subsampling procedures must conform to internationally accepted standards (ISO 1993). Special care is further required in the conditioning of inspector's subsamples to minimize the atmospheric effects and to allow a correction for changes in the chemical composition before the sample reaches the inspectorate laboratory.

The selected can of powder is weighed just before sampling. A large primary sample is collected in a tared and gas-tight flask, under a dry controlled atmosphere in the glove box where the material is processed or stored. The primary sample flask should be transferred immediately to a subsampling glove box where its gross weight is measured on an analytical balance and recorded. Just prior to subsampling, the sample flask is shaken vigorously; the gross weight is checked and recorded. Duplicate subsamples of about 1 g are weighed to ± 0.5 mg or less into tared vessels.

These vessels can be small glass tubes, like the inserts of the BC4 and BC5 brass containers (► Fig. 63.12), whenever one can use a Type B package carrying several grams of plutonium to ship a load of samples. These containers were actually designed and qualified for use with the PAT2 container, which had received approval for the shipment of Type B quantities of Pu samples to or from the USA (Kuhn et al. 1982). Their compact size make them very attractive for shipments of gram size Pu samples in any Type B container.

■ Fig. 63.12

BC5 and BC4 brass vials with glass tube insert (IAEA 2004)

In other cases, the subsamples are dissolved in nitric acid in the operator's analytical laboratory. An aliquant of each subsample, carrying about 4 mg of plutonium, is taken into a 5 ml penicillin vial and dried carefully to form an adherent film of nitrate salt on the bottom of the vial. The two aliquants are intended for elemental assays. Another fraction of at least one subsample is usually prepared for isotopic analysis and dried as above. With current products issued from high burnup spent fuel, some 20 penicillin vials could be packed together into a single Type A container and flown to SAL.

63.4.2.4 Uranium Dirty Scrap Materials

Uranium scrap materials in cans or hoppers are expected to be heterogeneous in element concentration and isotopic composition, and tend to change in composition upon exposure to atmosphere. As far as possible, the content of the container to be verified should be carefully mixed just before sampling. The item is weighed on a suitable scale immediately before duplicate samples of relatively large size are taken by collecting material from various spots in the bulk of the material.

Each sample of about 30 g is introduced into a tared glass bottle, which is immediately capped tightly and weighed. Metal-capped bottles used in the pharmaceutical industry (► Fig. 63.13) are ideal for this purpose as their tare is very stable and the cap inner PE lining insures a very tight closure. The same bottles are used to take and ship gram size samples of uranium compounds in powder form, like UO_2 products or yellow cake. The samples are packed without further handling in an "Excepted" or "Type A" package and flown to the inspectorate laboratory.

■ Fig. 63.13

Glass bottle for samples of uranium oxide powders and scrap (IAEA 2004)

63.4.3 Safeguards Analytical Laboratories

63.4.3.1 Off-Site Laboratories

The concept of IAEA's safeguards analytical services (Lopez-Menchero et al. 1976) foresaw that the agency would establish and operate a fully equipped safeguards analytical laboratory (SAL). The analytical capability of SAL was to be such that samples taken from any key measurement point of the fuel cycle could be analyzed and that the results of these analyses would meet the requirements of safeguards accounting verification.

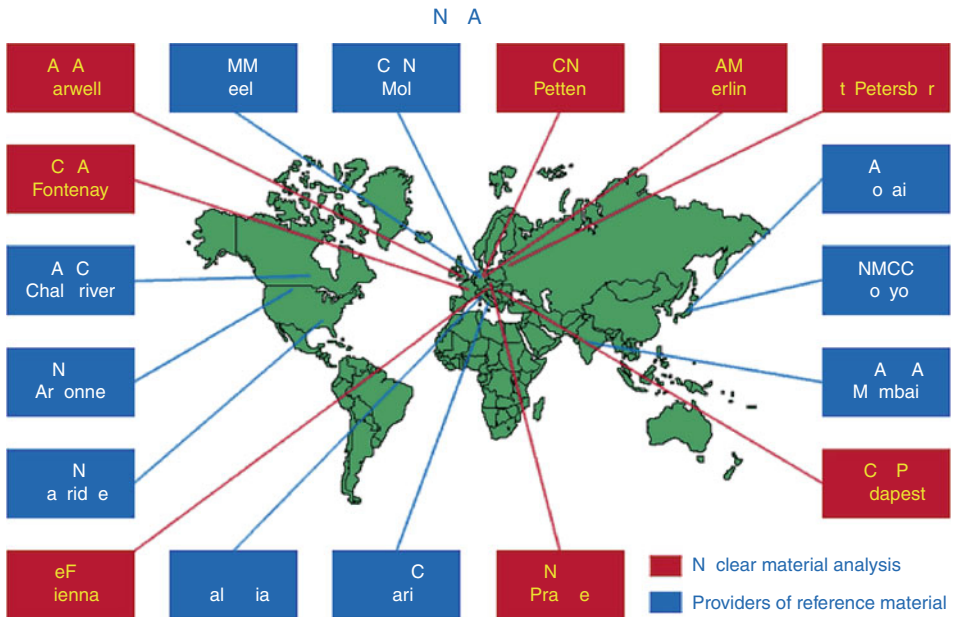

To accommodate the 5,000 samples that were anticipated annually, SAL was to become part of a network of analytical laboratories (NWAL), along with existing laboratories nominated by member states for this purpose at the request of the IAEA. This approach was selected for reasons of economy and flexibility of services, but also because it provided the possibility of checking the accuracy of the analyses of actual inspection samples by comparing results obtained by different verification laboratories. Such an intercomparison was to become an important feature of the quality control program that the IAEA maintains to ensure the quality of measurements made by SAL and the network. Other safeguards systems operate in a similar way, which indeed strengthen the credibility of the verification measurements. After the successful completion of the PAFEX-1 and PAFEX-2 tests, IAEA NWAL became operational in 1975 (● Fig. 63.14).

In order to preserve the confidentiality of their origin, all IAEA inspection samples are sent first to the IAEA Laboratories in Seibersdorf (Austria), from where a number of them are redispached to NWAL, in accordance with instructions of the inspectorate. In 1975, about 480 samples, mostly uranium products but also a few of plutonium dioxide, were analyzed. A maximum was reached in 1990 with 1,600 samples, including uranium, plutonium, and spent fuel samples received and analyzed (Deron et al. 1994).

Safeguards analytical laboratories use essentially the same sorts of techniques and equipment as research and plant laboratories for nuclear material isotopic and elemental assay and

■ Fig. 63.14

The IAEA Network of Analytical Laboratories in the 1980s

material accountability. DA has the advantage that the sample is treated in a way to optimize the conditions of its final measurement. However, advances made in NDA measurements have found many applications in laboratories too, as can be seen in ▶ Sects. 63.4.3, ▶ 63.4.4, and ▶ 63.5.

63.4.3.2 On-Site Laboratories

With the planning and construction of large spent fuel reprocessing or mixed U/Pu oxide fuel fabrication plants with annual throughputs close to 1,000 “Significant Quantities,” the safeguards inspectorates planned minimal laboratory facilities directly on site. Their justification is to reduce strongly the number of samples of sensitive materials, which need to be shipped to distant laboratories, and to obtain analytical results faster, by eliminating long shipment times. Much research went into developing and testing robotized equipment to perform DA treatment and measurements automatically (Brandalise et al. 1994; Takahashi et al. 1994; Zahradnik and Swietly 1996) for their eventual installation at on-site laboratories.

EURATOM set up on-site laboratories in La Hague in France (Regnier et al. 1994) and in Sellafield in the UK (Schneider et al. 1999). The Japanese state system and the IAEA operate jointly an On-Site Safeguards Analytical Laboratory (OSL) at the Rokkasho-Mura Reprocessing Plant (RRP) in Japan (Zahradnik-Gueizelar et al. 2007; Iwamoto et al. 2006). The latter includes (Matsuo 2008) a high activity laboratory handling spent fuel and high active waste samples in hot cells, a medium activity laboratory equipped with shielded glove boxes where plutonium and uranium products are measured and subsampled (▶ Fig. 63.15), a low

activity laboratory for chemical separations and alpha spectrometry, and a mass spectrometry laboratory (🔗 [Table 63.8](#)).

The pneumatic *sample transfer system* within OSL/RRP is connected to the operator's automatic sampling and sample transfer systems. Inspection sampling jugs are fed into the

■ **Fig. 63.15**

OSL facilities at RRP. (a) Hot cells; (b) Glove Boxes (Matsuo 2008)

■ **Table 63.8**

OSL/RRP analytical equipment (Midorikawa et al. 2006)

		HRGS	Pu isotopics	14.3.1
Low activity	Glove boxes	Separation robot	U, Pu separation	
		Alpha spectrometer	$^{238}\text{Pu}/(^{239}\text{Pu} + ^{240}\text{Pu})$ and Pu concentration < 10 mg/l	14.4.4.2
Mass spectrometry	Glove boxes	TIMS	U, Pu isotopics and content by IDMS	14.4.4.1, 14.E4.5.5.2

system from a jug-feeding machine installed in OSL/RRP. Authentication of inspectors' jugs is further ensured by *inspector passage detectors* tracking the inspectors' jugs between their departure from OSL, their arrival at the automatic sampling bench, and their return to OSL. Correlation with information from the operator-declared data and the *automatic sampling authentication system* confirm the authenticity of the inspector samples (Duhamel et al. 2004).

63.4.4 Isotopic Analysis

63.4.4.1 Isotopic Analysis by Mass Spectrometry

A *mass spectrometer* consists of three main components, which are kept under high vacuum: an ionization source, a mass analyzer, and a detector assembly (➤ Fig. 63.16). Ionization of the analyte may be produced by thermal ionization, inductively coupled plasma, or other means. The mass analyzer separates the ions according to their electrical charge and kinetic energy. It can be a time-of-flight system, a quadrupole, an electromagnetic sector, an accelerator, or another kind of mass filter. Electromagnetic sectors offer better mass resolutions and isotope abundance sensitivities than cheaper quadrupole analyzers and are therefore preferred to obtain the accuracies required for safeguards isotopic DA measurements.

Isotopic Analysis by Thermal Ionization Mass Spectrometry

Thermal ionization mass spectrometers (TIMS) with magnetic sector are thus the basic instruments for Pu and U isotopic analysis in safeguards inspection samples. The performance of commercial instruments has improved tremendously, particularly in the last 30 years, in terms of vacuum capability, design of the ionization source and detector assembly, stability of electrical supplies, sensitivity and linearity of ion current amplifiers, and includes full automatization of the measurement and data reduction.

In modern instruments, the *ionization source* is equipped with a turret, which may hold 13 to MS filament assemblies (Tuttas et al. 1998). Each assembly carries one or two side filaments, usually in platinum or tungsten, and a center rhenium ionization filament. A 1 µl or less of sample solution containing 0.05 to 1 µg of uranium or 5–100 ng of plutonium is loaded onto a side filament, and dried electrically under controlled conditions to obtain a reproducible

■ Fig. 63.16

Main components of a mass spectrometer

oxide deposit. The loaded turret is mounted inside the ionization source and the ionization source cavity is evacuated to 10^{-4} Pa or less. The samples are degassed in sequence before starting a cycle of measurements as follows.

The temperature of the center ionization filament is raised to about $2,500^{\circ}\text{C}$ and maintained at a constant value within 10°C , preferably under optical pyrometer control. The temperature of the sample is raised stepwise; molecular species volatilize and break down partially to produce U or Pu atoms. Impacts with electrons emitted by the center filament produce positive ions, which are extracted by a set of electrostatic focusing lenses under high voltage, and injected into the mass analyzer. The magnetic field of the analyzer is adjusted to collect the major analyte isotope ions in the center of the selected ion current detector. Focusing of the ion beam is adjusted to obtain a maximum intensity of the major isotope ion current. The instrument and its tuning are optimized to obtain a very flat top with sharp edges when scanning across an isotope ion peak (🔗 Fig. 63.17).

Various approaches have been devised to increase the *thermoionization efficiency*, such as electro-codeposition of actinides and platinum on the sample filament (Rokop et al. 1982), the resin bead loading technique (Walker and Smith 1979), or carburization (Jakopic et al. 2008). All these methods are said to facilitate the reduction of the sample species into atoms and enhance their ionization. An electrically heated cavity as sample holder installed in the source turret of a commercial mass spectrometer (Riciputi et al. 2002) yields also amazing increases of the ionization efficiency up to 5 and 7%.

Ions captured in a *faraday cup* detector produce very low electrical currents, typically below 1 pA, which flow across a very large resistor to yield voltage signals in the range of 0.1–100 mV. The linearity of the response of faraday cups, the stability of the signal and the signal-to-noise ratio were greatly increased with the introduction and improvements of digital voltage amplifiers, the use of 10^6 M Ω voltage drop resistors, instead of the 10^5 M Ω resistors used earlier (Tuttas et al. 1998). In standard designs, the image of the exit slit of the ionization source, focused on the ion detector entry slit, has the same size than the source slit. Operating

🔗 Fig. 63.17

Typical scan over isotope ion peaks measured with compact discrete-dynode detectors

■ Fig. 63.18

Increased magnification reduces losses of secondary ions within faraday cups

with a magnification of $\times 2$ instead of $\times 1$, and installing deeper faraday cups (Thermo Fisher Scientific: Triton 2005) provide greater space to install multidetectors and decrease the loss of secondary ions, minimizing thereby between-cup differences (► Fig. 63.18).

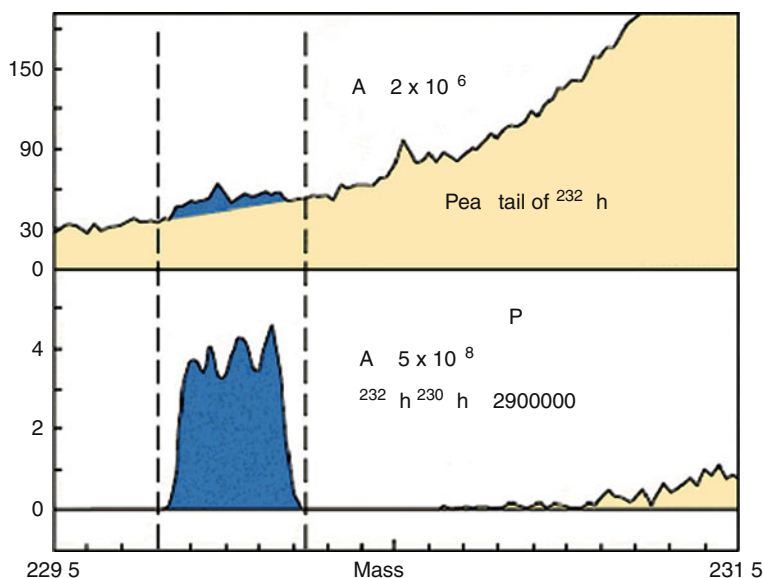

Minor isotopes or samples of very small size, typically in ng range or below, are measured with *ion multipliers* rather than with faraday cups. Three types of ion multipliers may be used: Daly scintillation detectors (Daly 1960), discrete-dynode multipliers (DNM), or continuous electron multipliers (“channeltrons”), with amplifications of 10^4 – 10^8 . Channeltrons are very compact but have a narrower dynamic range than DNMs. The output signal of the ion multiplier can be used to measure the instantaneous intensity of the ion beam as it is done with the faraday cup signal. Alternatively it serves to count the number of ions hitting the detector, using pulse counting technology. Channeltrons with a diameter of 2 mm, faraday cups, 3.5 mm in diameter, or 7 mm wide discrete-dynode detectors exist now. *Multidetector assemblies* with 8–12 detectors can be built with such devices (Tuttas et al. 2005). The individual detectors are spaced in a way to allow a simultaneous collection of the ion currents of isotopes of interest, namely ^{233}U , ^{234}U , ^{235}U , ^{236}U , ^{238}U and/or ^{238}Pu , ^{239}Pu , ^{240}Pu , ^{241}Pu , ^{242}Pu and ^{244}Pu . The ion synchronous collection eliminates the effects of changes in thermionic emission and time drift of the ion currents. This improves the reproducibility of the results and shortens the duration of a measurement, but raises the question of checking the relative ion sensitivity of the various detectors when using a multi-ion-detector thermal ionization mass spectrometer (MIC/TIMS).

Highest *isotope abundance sensitivity* is needed to measure well very minor isotopes, e.g., to determine the age of a uranium sample (Wallenius et al. 2001). Use of tandem magnetic sectors or addition of an energy filter (Thermo Fisher Scientific, Patent 1993) like a retarding potential quadrupole lens (RPQ) (► Fig. 63.19) would do the job.

All processes in the course of the loading of the sample and its TIMS measurement may entail small *isotopic fractionation* effects, which bias isotope ratio measurements. This is particularly the case during sample evaporation and ionization within the ionization source, which favor the lighter isotopes. These effects are globally corrected via a *mass discrimination factor* determined by measuring U and Pu isotopic standards, such as the ones listed in ► Table 63.9, under exactly the same conditions than actual samples are.

■ Fig. 63.19

Isotope abundance sensitivity with and without a retarding potential quadrupole

Note (a): The figures in parentheses represent the expanded standard uncertainties on the last decimal figures of the certified values, with $k = 2$.

In the standard *data collection scheme*, the isotopic ion beams are collected sequentially on a *single detector* by changing the magnetic field of the mass analyzer or the accelerating voltage of the ionization source. The mass spectrum of interest is scanned repeatedly in a way that allows to account for the changes in the rate of ion emission with time. *Peak jumping* is the preferred scanning scheme when the measurement is done in automatic mode. With *multidetector* the magnetic field and accelerating voltage are kept constant and the various isotope ions are collected simultaneously but in separate detectors. Ion current changes with time no longer perturb the measurement. However, as said above, it is necessary to verify that all detectors have the same response, or ion sensitivity, or otherwise to correct for differences (Ramakumar and Fiedler 1999).

Total evaporation is very effective in minimizing the isotope discrimination effect. In this scheme, the sample is heated progressively and the isotope ion currents are collected as early as possible after the beginning of the ion emission. Data are collected until the sample has been totally exhausted. Total evaporation is readily applied in multi-detection mode (Callis and Cappis 1996; Aggarwal et al. 1999), but can also be used in single detection mode (Fiedler 1995). The method permits the analysis of samples much smaller than required for conventional techniques using Faraday collectors. Reproducibilities of 0.02% RSD and less have been obtained for U and Pu isotope ratios (Callis and Abernathy 1991).

The value of the isotope ratio is derived from the ratio of the measured ion currents, or their integral, corrected for the isotope discrimination effects as shown in the example below:

$$n(^{236}\text{U})/n(^{238}\text{U}) = (1 - 2k)I(^{236}\text{U})/I(^{238}\text{U}) \quad (63.1)$$

where $n(^{236}\text{U})/n(^{238}\text{U})$ is the ratio of ^{236}U and ^{238}U isotopes to be determined, $I(^{236}\text{U})/I(^{238}\text{U})$ is the ratio of the measured ion currents, or their integral, k is the mass discrimination factor per mass unit.

As said above, the factor k is obtained by measuring for example an isotopic reference material with certified $^{235}\text{U}/^{238}\text{U}$ ratio

$$k = (R/R(I) - 1)/3 \quad (63.2)$$

where R is the certified value of the isotope ratio $n(^{235}\text{U})/n(^{238}\text{U})$ of the reference material $R(I)$ is the ratio $I(^{235}\text{U})/I(^{238}\text{U})$ of the measured ion currents.

Ion fractionation can be very effectively corrected by an *internal calibration* after spiking a uranium sample with a mixture of isotopes of certified ratio, like IRMM-3636 (Richter et al. 2008) or CETAMA-MIRF-02, or spiking a plutonium sample with a certified mixture of ^{242}Pu and ^{244}Pu isotopes. Several batches of mixtures of ^{236}U , ^{233}U , ^{242}Pu , and ^{244}Pu isotopes were prepared for isotopic and IDMS assays of spent fuel solution samples using the method of internal calibration (Stepanov et al. 1990b). Calibration of such spikes could now be done to an accuracy of $\pm 0.05\%$ (1s) against isotopic standards certified to $\pm 0.03\%$ or less, like the $^{233}\text{U}/^{235}\text{U}/^{238}\text{U}$ reference materials IRMM-74/7-10 with low ^{233}U abundance. Unfortunately, there exists yet no mixture of ^{239}Pu and ^{240}Pu isotopes certified on a purely gravimetric basis.

The results reported in Stepanov et al. (1990b) led to suspect that some small differences between laboratories may be due to uncorrected differences in detector sensitivities or errors therein, at the laboratories using MIC/TIMS instruments. On commercial MIC/TIMS, a program measures the relative gains of the various amplifier chains. A program connecting a given amplifier chain sequentially with the various ion detectors, called *virtual amplifier*, corrects for differences between amplifier chains. Yet it is also necessary to measure the ratios of the *ion capture efficiencies* of the various cups or ion multipliers. This may be done by

producing a very steady ion beam, often the rhenium ion beam emitted by the ionization filament, and programming the instrument to peak jump from one collector to the next. More convincing but more tricky is to load a very accurately characterized mixture of three or more isotopes of the element of concern (Fiedler and Donohue 1988). The isotope ratios are measured in multidetection mode while the isotope ion spectrum is shifted by one detector in successive steps. ➤ **Table 63.10** describes a sequence of steps which may be used with a mixture of ^{239}Pu , ^{240}Pu , ^{242}Pu and ^{244}Pu isotopes, available with reference material UK Pu5/92138 issued by AERE, Harwell (Hamilton et al. 1989). The isotope fractionation at each step is corrected by reference to the certified isotope ratios. The idea was further developed by Dubois et al. into a *dynamic multidetection* measurement mode (Dubois et al. 1989), which practically eliminates mass fractionation effects and possible mismatches of cup efficiencies with a 2-isotope internal standard and MIC/TIMS. According to the results presented, precisions and accuracies of 0.01% are achievable with this procedure. An ultimate refinement has been introduced by performing total evaporation measurements with peak tailing correction in dynamic multicollection mode, using a MIC/TIMS with magnetic sector equipped with a dispersion quadrupole (Goldberg et al. 2002; Richter and Goldberg 2003).

High-accuracy measurements require very sophisticated instruments and measurement procedures, but *isobaric interference* of ^{238}U on ^{238}Pu measurement, and that of ^{241}Am on ^{241}Pu also deserve great attention. These can be minimized by taking advantage of different atomization kinetics. Actually in resin bead measurements the ^{238}U interference is corrected by collecting ^{235}U isotopes during the Pu measurement (Walker and Smith 1979). It is now becoming practical to do so with commercial MIC/TIMS (Aggarwal and Alamelu 2005). Yet in order to achieve best results it is customary to perform a careful chemical separation and to eliminate uranium contaminations. Chemical treatment is unavoidable in IDA to ensure a *complete isotope exchange* (see section “Isotope Dilution Mass Spectrometry”). A *chemical separation* follows to provide U and Pu fractions in a clean and controlled matrix. When analyzing spent fuel samples the separation serves also to yield samples free from fission products, which do not need to be handled in a high activity laboratory (see ➤ Sect. 63.4.2.2).

■ **Table 63.10**

Example of a sequence of measurements of a 4-Pu isotope mixture for the determination of relative ion efficiencies of the 7 faraday cups of a MAT 261 mass spectrometer

Step	Faraday cup number						
	8	7	6	5	4	3	2
1			239	240		242	244
2		239	240		242		
3	239	240		242		244	
4				239	240		
5					239	240	242
6					239	240	242
7				239	240		
8	239	240		242		244	
9		239	240		242		
10			239	240		242	244

Proven valency adjustment and separation procedures are outlined below.

- (a) *ISO 8299 procedure* (ISO 2005b): Reduce plutonium to Pu(III) and Pu(IV) in 7 M nitric acid with Fe(II), reoxidize to Pu(IV) with nitrite, then adsorb U and Pu in 7 M nitric acid on a quaternary ammonium anion exchange column, elute fission products, Am and other potential interferences with 7 M nitric acid before collecting the uranium fraction; finally reduce Pu on the column to Pu(III) with hydroxylamine and elute it with the same reagent.
- (b) *ISO 15366 procedure* (ISO 1999): Reduce and reoxidize Pu in 3 M nitric acid as in the previous procedure, adsorb Pu and U on a TOPO impregnated silicagel column, wash out fission products, Am and other potential interfering species with 3 M nitric acid, then condition the column with 1.7 M nitric acid before reducing Pu on the column with a freshly prepared solution of 0.1 M HI/1.7 M HNO₃; elute Pu with the HI/HNO₃ reagent, and finally wash out U with water.
- (c) *LANL procedure* (Marsh et al. 1974): Oxidize Pu to Pu(VI) by fuming the sample with HClO₄, re-dissolve the sample in 12 M HCl and adsorb U and Pu on a quaternary ammonium anion exchange column, elute fission products, Am and other interfering species with 12 M HCl; then reduce Pu on the column and elute it with a reducing solution of 0.1 M HI/12 M HCl; finally wash out U with dilute 0.1 M HCl.
- (d) *UTEVA procedure* (Morgenstern et al. 2002): In 6 M HNO₃/0.3% H₂O₂ a sample of spent nuclear fuel is expected to contain Am(III), Pu(IV) with 13% Pu(III), Np(IV), and U(VI) along with the fission products. In this medium Pu, Np and U are adsorbed on a liquid ion exchanger column (UTEVA), while the fission product and Am are not retained. Pu is fully reduced to Pu(III) and eluted with 2 M HNO₃/0.002 M ascorbic acid. Then Np is recovered with a 2 M HNO₃/0.1 M oxalic acid eluent. Finally, U is eluted with 0.007 M ammonium oxalate.
- (e) *The resin bead procedure* (Marsh et al. 1981): An aliquot of sample containing about 1 mg of U and/or 10 µg of Pu is adjusted to 8 M HNO₃ and subjected to a redox valency adjustment with Fe(II) and nitrite as in procedures (a) and (b). The sample is equilibrated with about 10 anion exchange resin beads of around 300 µm diameter. Each bead collects about 10 ng of U and/or Pu and is mounted on a mass spectrometer filament for a sequential measurement of the Pu and U isotopic compositions.

Isotopic Analysis by Inductively Coupled Plasma Mass Spectrometry

While the ionization filament in a TIMS may be heated to a maximum temperature of 2,500°C, inductively coupled plasma reach temperatures of 15,000–20,000°C and have much higher ionization efficiency. A pneumatic nebulizer serves to inject sample solutions directly into the plasma. Inductively coupled plasma mass spectrometers (ICP-MS) have thus become powerful tools in trace and ultra-trace analyses with detection limits down to 1 ppq or less. ➤ [Section 63.4.5.8](#) refers to ICP-MS applications in measuring alternative nuclear materials, Am, Np, and Cm, and ➤ [Sects. 63.5.2](#) and [63.5.5.4](#) dwell upon their use in environmental analyses for safeguards.

Commercial ICP-MS equipped with magnetic sectors and multidetection could meet the requirements of safeguards accountancy verifications (Pereira de Olivera et al. 2008). Prior chemical separations of the nuclear elements are, however, of benefit to reduce isobaric interferences by the numerous polyatomic ions generated by the plasma source. An elegant solution is to attach a liquid chromatography unit in line with the ICP source (Guenther-Leopold et al. 2005). Double focusing mass filters or diverse energy filter components

■ Fig. 63.20

The Varian 90° deflector (Elliott et al. 2005)

overcome some of the interferences. Collision reaction cells (Varian 2009) are also common accessories to segregate polyatomic ions and might improve the isotopic analysis of actinides too. Ion multiplier detectors should be protected against impacts from high-energy photons and neutral particles, as done with the 90° deflector of Varian (Elliott et al. 2005) (► Fig. 63.20).

Active research in safeguards applications of ICP-MIC-SFMS is thus to be expected in DA of nuclear fuels as well as in environmental analyses.

63.4.4.2 ^{238}Pu Abundance by Alpha Spectrometry

Isobar ^{238}U can be a source of positive bias in the determination of ^{238}Pu isotopic abundance by mass spectrometry despite prior chemical separation of the two elements. In this respect, eluting Pu before U is advantageous (see section “Isotopic Analysis by Thermal Ionization Mass Spectrometry,” procedures (b)–(d)). Great attention must be placed anyway to minimize sources of blanks due to low levels of natural uranium in most chemical reagents and mass spectrometry filaments. It is therefore still customary to perform ^{238}Pu measurement by alpha spectrometry in parallel with mass spectrometry.

^{238}Pu abundance in safeguards samples varies between 0.001% in so called weapon grade plutonium to over 1.5% in plutonium from high burnup spent fuel. A typical alpha spectrum (Bagliano et al. 1991) obtained with an ion-impact detector with a resolution of 12 keV is shown in ► Fig. 63.21. The presence of Am-241 with alpha rays in the range of 5.39–5.49 keV will yield high results. ► Table 63.11 lists the relevant nuclear data. The accuracy of the alpha spectrometry of plutonium depends strongly upon the chemical preparation of the sample, the production of carrier-free alpha sources, the counting geometry, the detector resolution, and the method used to correct for the tailing of the ^{239}Pu and ^{240}Pu alpha peaks.

Fig. 63.21

Typical plutonium alpha spectrum (Bagliano et al. 1991)

Table 63.11

Relevant nuclear data (Nichols et al. 2008)

Nuclide	Half-life [year]	Radiation	Energy [keV]	Emission probability [%]
^{238}Pu	87.74	α	5,456.3	28.29
	± 0.03		5,499.03	69.3
^{239}Pu	24,110	α	5,105.5	11.94
	± 30		5,144.3	17.11
			5,156.6	70.77
^{240}Pu	6,561	α	5,123.68	27.16
	± 7		5,168.17	72.74
		β^-	20.78	100.00
^{241}Pu	14.290	α	4,853.0	0.0003
	± 0.006		4,896.3	0.002
^{242}Pu	373,000	α	4,858.1	23.49
	$\pm 3,000$		4,902.2	76.48
^{244}Pu	8.00×10^7	α	4,546	19.4
			4,589	80.5
^{241}Am	432.6 ± 0.6	α	5,388.2	1.660
			5,442.8	13.1
			5,485.56	84.45
		γ	59.54	35.9
			26.34	2.27

The separation of ^{241}Am deserves particular attention, when the ^{241}Pu abundance is high and when a long time has elapsed since the plutonium fuel material was produced. This is the case with samples of high burn-up spent fuel. The standard anion exchange method described in section “Isotopic Analysis by Thermal Ionization Mass Spectrometry,” para. (a) is well suited for the purpose, as Pu is eluted long after Am, fission products and U are. It is a good practice, nevertheless, to measure the ^{241}Am gamma emission at 60 keV in the separated Pu fraction to verify that it will not bias the results.

The aim of the source preparation is to obtain very thin, smooth, and uniform deposit to minimize the effects of self-absorption and retrodiffusion, which alter the resolution of the alpha spectrum. Some of the methods are listed below:

Electrodeposition on polished platinum or stainless steel disks, with a variety of supporting electrolytes (ISO 2007d; Ingelbrecht et al. 1997; Amoudry and Silly 1984; Hallstadius 1984; Lally and Glover 1984).

Vacuum sublimation on glass (Amoudry and Eloy 1984).

Drop deposition, usually with addition of spreading agents such as tetraethyleneglycol (ISO 2005c; Miguel et al. 1984).

Deposition on a mass spectrometry filament to perform alpha and mass spectrometry measurement on the same filament (Strebin and Robertson 1977).

The deposit should not carry more than 10–20 $\mu\text{g}/\text{cm}^2$ of matter to minimize self-absorption (Amoudry and Silly 1981). The support material must have a finely polished surface and be inert to corrosion. Support material of high atomic weight reduces retrodiffusion of alpha rays. Gold-plated copper or steel support produces sources of resolution down to 12 keV. Several publications report comparisons of different methods of source preparation (Aggarwal et al. 1985; Lally and Glover 1984).

The spectrum of alpha radiation may be measured in a gas proportional counter or a gridded ionization chamber (Bortels et al. 1985), but semiconductor detectors are more commonly utilized in nuclear fuel analyses. The properties of Si detectors for alpha spectrometry have been studied extensively (Bortels et al. 1994, 1993; Bortels 1991; Bortels and Bauer 1990a, 1990b; Aggarwal et al. 1988). Particle implanted passivated silicon (PIPS) detectors nowadays present resolutions down to 9 keV (► Fig. 63.22), which permit, with a favorable geometry (Amoudry and Silly 1981), a deconvolution of the ^{239}Pu and ^{240}Pu alpha peaks in the range of 5.0–5.2 keV (Amoudry and Burger 1984). The counting chamber is kept under reduced pressure of 0.5 Pa or less during measurement.

A number of elaborate peak fitting algorithms have been proposed to correct for the tailings and deconvolute overlapping peaks (Raab and Parus 1994; Babeliowsky and Bortels 1993; Garcia-Torano 1990; Amoudry 1983). *Deconvolution* of the ^{239}Pu and ^{240}Pu peaks is not normally done to measure the ^{238}Pu abundance in safeguards samples, as more precise results are obtained by combining the alpha activity ratio $^{238}\text{Pu}/(^{239}\text{Pu} + ^{240}\text{Pu})$ with the $^{240}\text{Pu}/^{239}\text{Pu}$ isotope ratio measured by mass spectrometry. The $^{238}\text{Pu}/^{239}\text{Pu}$ isotope ratio is calculated according to ► Eq. (63.3):

$$R_8 = R_\alpha T_8 (T_9^{-1} + R_0 / T_0) \quad (63.3)$$

where R_8 is the $^{238}\text{Pu}/^{239}\text{Pu}$ isotope ratio, R_α the $^{238}\text{Pu}/(^{239}\text{Pu} + ^{240}\text{Pu})$ alpha activity ratio, R_0 the $^{240}\text{Pu}/^{239}\text{Pu}$ isotope ratio measured by mass spectrometry, T_8 , T_9 , T_0 are the half-lives of isotopes ^{238}Pu , ^{239}Pu , ^{240}Pu , respectively.

■ Fig. 63.22

Alpha spectrum of a $^{239}\text{Pu}/^{240}\text{Pu}$ mixture obtained with a PIPS detector of 9 keV resolution

A simple algorithm is sufficient to correct the ($^{239}\text{Pu} + ^{240}\text{Pu}$) alpha activity for the tailing of the ^{238}Pu peaks, such as a “linear decrease,” an “exponential decrease” (ED), or a GP (geometric progression) tail correction. Results obtained using the GPRANL code (Gunnink et al. 1984), the ED or GP correction methods agree within 0.3% of the mass spectrometry results, as long as the $^{238}\text{Pu}/(^{239}\text{Pu} + ^{240}\text{Pu})$ alpha activity ratio stays below 5 (Bagliano et al. 1991; Aggarwal et al. 1980; Ramaniah et al. 1980). In these cases, and with sources of suitable quality, the counts around 5.17 MeV, at the ^{239}Pu and ^{240}Pu peaks, should be at least 300 to 500 times larger than the counts in the valley around 5.25 MeV. Then tailing corrections will not exceed 0.2 to 0.5%.

At present, IAEA SAL estimates at 0.4% the total uncertainty (1s) of its determinations of ^{238}Pu abundance in safeguards samples by a combination of alpha and mass spectrometry taking into account the contributions of short and long term measurement reproducibility, calibration, and nuclear data uncertainties.

63.4.4.3 Gamma Spectrometry of Nuclear Material Samples

Gamma ray spectrometry is widely used in safeguards laboratories to measure the isotopic abundance of various U and Pu isotopes but also their concentration, as well as the concentration of “alternative nuclear elements” (see Sect. 14.4.4.8) fission and decay isotopes (Parus and Raab 1996; Parus et al. 1987). Laboratory applications make use of the developments of NDA technology mentioned in ► Sect. 63.3.1, but are usually part of DA procedures.

The ^{235}U abundance of LEU products is determined with a total uncertainty of 0.13% (1s) by measuring the 186 keV gamma rays with a NaI or GeLi well detector on 5 ml solutions containing a well-known amount of uranium, close to 0.5 g. The volume of the sample and synthetic calibration test solutions, their acid and U concentrations are kept in a very narrow range so that the self-absorption and counting geometry be constant factors or minor variations be accurately

corrected. The technique is a good back up to mass spectrometry in case of a pile up of samples. Alternatively, the procedure can be used to measure U concentration of samples with known ^{235}U abundance, when the accuracy of a titration is not required.

High-resolution gamma spectrometry (HRGS) is routinely used as screening and quality control tool in processing nuclear material as well as environmental samples (see ▶ Sect. 63.5.3.1). In IAEA/SAL vials of Pu product samples are all subject to gamma spectrometry before any wet chemical treatment is undertaken. Estimates of elemental and isotopic composition of U, Pu, Am, or other relevant radioisotopes serve to orient further processing and are recorded for later use. The gamma spectrometry data help to select the optimal spike for IDMS or IDAS, when spiking is to be done in the laboratory. On the whole, U and Pu isotopic gamma results will be matched with the mass spectrometric assays to exclude any gross error in the analytical process. Gamma rays at 60 keV will detect ^{241}Am , which may remain in the separated Pu fractions, before alpha and mass spectrometry (see ▶ Sects. 63.4.4.1 and ▶ 63.4.4.2). Fission products are also measured in spent fuel samples when inspectors want to verify burn-up data.

The MGA (Wang et al. 1999; Buckley et al. 2000) and MGAU (Gunnink et al. 1994) gamma spectroscopy softwares, designed for the low-energy region, are used commonly for measurements of Pu and U in product or scrap samples, while general surveys of fission products require measurement over the entire energy range and call usually upon commercial softwares (Canberra 2009a, 2009b).

63.4.5 Elemental Assay

63.4.5.1 Ignition Gravimetry of U, Pu, Th

Ignition gravimetry remains the most reliable and accurate analytical method for elemental assay, especially if gram size samples are available. It is most easily applied for the analysis of nuclear grade oxides of uranium, plutonium or thorium, or to samples that can be readily transformed into an oxide, such as powders and solutions of nitrate salts (Rodden 1953; ISO 1987a, 1987b, 2003, 2004b, 2007). The sample in oxide form is ignited, usually in a platinum crucible, to a temperature between 870 and 1,250°C, depending on the element, for 1 hr periods to reach a constant weight and the formation of a stoichiometric oxide. The average relative atomic mass of uranium or plutonium, W , must be derived from their measured or known isotopic composition. The total mass fraction of nonvolatile impurities, ε , remaining in the ignited oxide must also be measured or known with a suitable precision and accuracy. The mass fraction, C , of the analyte, M , ($M = \text{U, Pu or Th}$), is derived from ▶ Eq. (63.4):

$$C = m_o(1 - \varepsilon)G/m_s \quad (63.4)$$

where m_o is the mass of ignited oxide, m_s the mass of the sample, G the gravimetric factor calculated with ▶ Eq. (63.5):

$$G = xW/(xW + yW_o) \quad (63.5)$$

where $W_o = 15.9994$ is the relative atomic mass of oxygen, and M_xO_y is the stoichiometric molecular formula of the ignited oxide, with $M = \text{U, Pu or Th}$.

A precision of 0.05% or less is expected if the sample contains less than 0.05% nonvolatile impurities. Random uncertainties may increase to 0.15% if the impurity content reaches 0.5%.

Deviations of the ignited oxide from stoichiometry lead to systematic errors, which should not exceed 0.1%. Systematic errors may also come from calibration errors in the impurity analyses and from systematic errors due, e.g., to uncertainties in their chemical form. The result carries a positive bias, if an impurity, although present, is not measured or detected.

Less pure materials may be analyzed by ignition gravimetry after a suitable chemical purification. For example, thorium in ores, alloys or other materials may be separated by precipitation as oxalate (Scott 1939; Ewing and Banks 1948; Willard and Gordon 1948; Kall and Gordon 1953), which is then ignited to ThO_2 at 95°C. However, the extra steps bring additional random as well as systematic errors.

63.4.5.2 Uranium Titration

Most uranium titration procedures rely on the redox properties of the U(VI)/U(IV) couple. In early redox titration methods, U(VI) was reduced with Ti(III), Cr(II), Pb, Cd amalgam or a Jones reductor. Most of these procedures are not very selective, require a prior removal of nitrate, or operate at elevated temperatures and under inert atmosphere. Samples of nitric solutions, adjusted to 1N HNO_3 and 2N H_2SO_4 , can be titrated directly by Ce(IV) with o-phenanthroline as colorimetric end point indicator, after Ti(III) reduction (Corpel and Regnaud 1962). The method was adapted to a gravimetric titration by Cr(VI) with amperometric end point (Nair et al. 1996) and applied to diluted dissolver solutions, containing 100–300 µg of uranium, with burnup of up to 10,000 MWd/t. Uranium can be titrated potentiometrically with Fe(II) from strong phosphoric acid medium (Rao and Sagi 1962). Fe(II) and W(VI) do not interfere, but V(V), Mo(VI), and Cr(II) do. A fast and very selective procedure was derived from the latter, based on the reduction of U(VI) by an excess Fe(II) in a phosphoric acid medium, the catalytic destruction of the excess Fe(II) by nitric acid in the presence of molybdate, followed by a dilution and a titration with a standardized solution of dichromate with a colorimetric end point detection (Davies and Gray 1964). Out of 23 species, only Ag(I), V(IV), or V(V) appear to interfere appreciably. In the Davies & Gray/NBL-modified procedure a potentiometric titration with vanadyl ion as electrochemical indicator replaced the colorimetric titration (Eberle et al. 1970). This procedure is widely used for accountability and safeguards verification measurements. ISO 7097-1 describes its application to a gravimetric titration of aliquants of samples of uranium nitrate solutions, metal, oxides and hexafluoride of nuclear grade, containing about 50 mg of uranium (ISO 2004a). The overall process is equivalent to a titration of U(IV) with dichromate according to

Eq. (63.6) below:

The mass fraction of uranium in the sample, C_U , in g/g, is equal to:

$$C_U = WT(m_c/2m_a) \quad (63.7)$$

where W is the relative atomic mass of the uranium in the sample, T the titer of the dichromate solution in equivalent/gram, m_c the mass of dichromate solution used to reach the end point, in gram, m_a the mass of sample aliquant used in the titration, in gram.

The final titration is usually performed with a commercial automatic volumetric titrator. Gravimetrically calibrated burettes yield coefficients of variation of 0.05% or less for the overall uncertainties of random or systematic nature in the assays of samples of uranium and mixed

■ Fig. 63.23

IAEA-SAL robotized system for the treatment and titration of uranium samples by the NBL modified Davies & Gray method (Aigner and Aigner 1994)

uranium/plutonium products. Robot systems (● Fig. 63.23) automatize the entire process, including the redox steps preceding the titration, and run reliably unattended overnight with the same precision and accuracy than with the semi automatic procedure (Aigner and Aigner 1994). A scaled down procedure processes 5–25 mg aliquants of uranium with no loss of precision (Slanina et al. 1976). The Davies & Gray procedure is sufficiently selective to be applicable to the determination of uranium in dissolver solutions from spent fuel reprocessing plants.

The dichromate titrant is particularly attractive as its solutions are very stable as long as they are stored in hermetic vessels, and can be calibrated directly versus primary standards, namely, NIST 136f dichromate (Montgomery and Sanerwein 2008) and NBL 112A (NBL 2008) or CETAMA MU2 (CETAMA 2009) uranium metal. Nonetheless, NBL felt compelled to replace dichromate by Ce(IV), which is not listed as a toxic chemical (Zebrowski et al. 1995; ISO 2007a).

63.4.5.3 Plutonium Titration

Plutonium titrations take general advantage of the properties of the Pu(III)/Pu(IV) or Pu(IV)/Pu(VI) electrochemical couples. Microvolumetric titrations of mg amounts of plutonium with potentiometric end point detection were widely used in the past (Metz 1957; Fudge et al. 1960).

Plutonium was often reduced to Pu(III) with an excess Ti(III), which was titrated colorimetrically (Corpel and Regnaud 1962) to Pu(IV) with Ce(IV), after destroying the excess Ti(III). The method was adapted to a sequential amperometric titration of U and Pu in samples of breeder reactor fuel materials (Chadwick and McGowan 1972). 500 mg samples of Pu metal

can be dissolved in 6N HCl to obtain Pu(III), which is titrated spectrophotometrically with Ce(IV) in presence of ferroin with uncertainties of $\pm 0.07\%$ (Caldwell et al. 1962). 50–140 mg samples of Pu metal, dissolved in 4N sulfuric acid and reduced to Pu(III) on a Jones reductor, may be titrated gravimetrically with Cr(VI) using two polarized gold electrodes to detect the end point, with a coefficient of variation of 0.05% and 100.01% recovery (Pietri and Baglio 1960). In a more selective method, Pu is reduced to Pu(III) with an excess Cu(I) in a solution of HCl/sulfamic acid and aluminum chloride. Fe(II) and the excess Cu(I) are reoxidized by Cr(VI) up to a potentiometric end point. Sulfuric and phosphoric acid are then added to lower the Pu(III)/Pu(IV) redox potential, so that Pu(III) can be titrated with Cr(VI) without oxidizing chloride (Davies and Townsend 1974).

Another group of methods relies on a prior oxidation of plutonium to Pu(VI) by fuming perchloric acid (Waterbury and Metz 1959), argentic oxide (Drummond and Grant 1966), sodium bismuthate (Charyulu et al. 1984), or Ce(IV) (MacDonald and Savage 1979). In the so-called AgO-method, a longtime accountability method at many bulk handling plants, the excess AgO is destroyed by sulfamic acid, an excess standardized ferrous sulfate is added to reduce Pu(VI) to Pu(IV) and the excess Fe(II) backtitrated with Ce(IV) by potentiometry with polarized electrodes (Corpel and Regnaud 1966) or by amperometry with Cr(VI) (Cherry et al. 1968). However, Ag^+ , coming from the destruction of AgO, oxidizes a fraction of the excess Fe(II) and introduce a very reproducible bias of 0.2%. The titrant therefore must be standardized against a Pu standard solution treated in the same way than the samples (Cauchetier et al. 1975). ^{241}Am gives also a positive bias for Am/Pu ratios above 0.02 because of a partial oxidation of Am or the presence of radiolytic H_2O_2 (Spevackova et al. 1978). Unfortunately, Cr interferes, yielding high results in case of corrosion of process tanks.

A method, free from Fe or Cr interference, (MacDonald and Savage 1979) involves a prior oxidation of plutonium to Pu(VI) with an excess of Ce(IV). Sulfamic acid is added to avoid side reactions with nitrites. Fluoride residues from the dissolution of solid samples are complexed by addition of Al(III). The excess Ce(IV) is then reduced by a slight excess of arsenite in the presence of Os(VIII) as catalyst. Excess As(III) is oxidized by permanganate, also in a very quantity. Finally, oxalic acid is added to reduce the excess Mn(VII). Pu(VI) is then reduced quantitatively to Pu(IV) with Fe(II) and the excess Fe(II) backtitrated with Cr(VI). All steps are followed potentiometrically and carefully timed. The Pu mass fraction, C_{Pu} , in g/g, in the sample aliquant submitted to titration is calculated according to the following equation:

$$C_{\text{Pu}} = W(T_{\text{f}}m_{\text{f}} - T_{\text{c}}m_{\text{c}})/2m_{\text{a}} \quad (63.8)$$

where W is the relative atomic mass of the plutonium in the sample, T_{f} the titer of the Fe(II) solution, in equivalent/g, m_{f} the mass of Fe(II) solution, in g, T_{c} the titer of the dichromate solution in equivalent/g, m_{c} the mass of dichromate solution used to reach the end point, in g, m_{a} the mass of sample aliquant used in the titration, in g.

A scaled down procedure, applicable to the titration of 4 mg of plutonium, was set up at IAEA/SAL with the assistance of Dounreay (MacDonald and Savage 1987) and of the Nuclear Research Institute in Řež (CSSR) (Kuvik 1991). This made possible to receive and titrate samples of Pu products taken in Japanese facilities, as only mg amounts of plutonium can be air flown from Japan in Type A packages. The process including the preliminary redox steps, was automatized to achieve coefficients of variation of 0.05% (Kuvik et al. 1992; Ronesch et al. 1992). 23 species do not interfere, but vanadium does quantitatively, and Np partially. The test sample should carry less than mg-amounts of nitrite, fluorosilicate, and iodate. The effect of americium remains to be studied (ISO 2000).

63.4.5.4 Controlled Potential Coulometry of Plutonium

Before operational amplifiers became available, constant current coulometry (CCC) was used more often than controlled potential coulometry (CPC) because the instrumentation was so much simpler. CCC continued to be used for highly precise U determinations in very pure materials (Goode et al. 1967; Malinowski 1967; Merciny et al. 1981).

In CPC, the *measurement cell* (► Fig. 63.24) consists of a sample cell [1], a working electrode [4], a counter electrode compartment [5], and a reference electrode compartment [6]. A *potentiostat* supplies an electrolysis current between the working and the counter electrode in a way to maintain a chosen difference of potential between the working and the reference electrodes. Normally, a Pu assay involves two steps: first, the potential of the working electrode is set to a value leading to the reduction of Pu to Pu(III); the electrode potential is then changed to a value required to reoxidize Pu(III) to Pu(IV). The reduction and reoxidation potentials are selected to reach near quantitative electrolysis of plutonium while minimizing the electrolysis of possible interfering species. A *current integrator* measures the quantity of electricity needed to achieve the reoxidation of Pu(III) to Pu(IV) and relates it to the amount of plutonium.

Dilute sulfuric (Shults et al. 1959; Jackson et al. 1980), nitric (Holland et al. 1998), perchloric (Metz and Waterbury 1962), hydrochloric (Shults 1963), or phosphoric acid (Bärring and Jönsson 1970) have been used as *supporting electrolyte*. The choice of the supporting electrolyte determines the magnitude of interferences from potential impurities (Milner and Phillips 1974): iron interferes stronger in nitric acid than in sulfuric acid, but little or not in hydrochloric acid, as indicated by the Pu(III)/Pu(IV) and Fe(II)/Fe(III) formal potentials (► Table 63.12). Oxygen removal is also a greater challenge with sulfuric acid than with nitric acid.

■ Fig. 63.24

CPC cell

■ **Table 63.12**

Formal potentials of Fe(II)/Fe(III) and Pu(III)/Pu(IV) redox couples, volt versus standard calomel electrode (SCE)

Electrolyte	Concentration	Potential Fe(II)/Fe(III)	Potential Pu(III)/Pu(IV)	Difference
H ₂ SO ₄	0.5M		0.492	
HNO ₃	0.9M	0.66	0.668	0.01
HClO ₄	1M	0.53	0.73	0.20
HCl	2.5M	0.446	0.705	0.259
	5.5M	0.372	0.686	0.315
	7.4M	0.323	0.640	0.317

Chemistry may be combined with CPC to improve selectivity. For example (Jackson et al. 1980) applying the chemistry of the Davies and Townsend titration (see ▶ Sect. 63.4.4.3), Pu is first reduced electrolytically to Pu(III) in an hydrochloric/sulfamic acid mixture along with iron and other potential interfering species. Iron and a number of the other impurities are reoxidized next without reoxidizing Pu(III). Finally, phosphate is added to lower the redox potential of the Pu(III)/Pu(IV) couple to permit a quantitative electrooxidation of Pu(III) to Pu(IV), without oxidizing chloride ions. The procedure is very selective and is applicable to Pu determinations in the presence of uranium in 10:1 U/Pu molar ratio.

CPC at a solid electrode has also been applied to determine uranium (Davies et al. 1970; Phillips and Crossley 1978), which is reduced from U(VI) to U(IV) with electrogenerated Fe(II). The approach has been used for sequential coulometry of U and Pu (Angeletti et al. 1969; Davies et al. 1970; Fardon and McGowan 1972; Phillips and Crossley 1978).

Controlled potential reduction of Pu(VI) to Pu(IV) has also been used to avoid iron interference, but plutonium must be oxidized chemically by AgO, Ce(IV) or fuming HClO₄ prior to its coulometric determination (Shults 1963).

The characteristics of a coulometric method depend also upon the *choice of the working electrode*. Electrode double-layer charging, surface oxide formation, hydrogen evolution at low potential, and electrode or electrolyte oxidation at higher potentials contribute to the background current and depend upon the electrode material and the electrolyte. Mercury pool electrodes have been used for uranium coulometry, but efficient stirring of the solution/electrode interface is difficult to achieve. Long electrolysis times lead to uncertainties in the background current correction. Faster electrolysis is achieved with solid working electrodes such as a Pt gauze electrode (Shults et al. 1959; Shults 1960; Jackson et al. 1980), or a gold mesh electrode (Holland et al. 1998). Glassy carbon was used as indicating electrode in Pu titrations and CPC of iron, chromium, uranium, and neptunium was done with a glassy carbon crucible as working electrode (Plock and Vasquez 1969). Electrochemical reactions at solid electrodes may be slowed down considerably by adsorption or deposition of trace species in solution. Pretreatment and storage of the electrode must be subject to well-validated procedures in order to maintain or restore the electroactive properties of the working electrode. Samples having undergone an ion exchange purification carry resin degradation species, which accelerate electrode “poisoning.” This effect is overcome by fuming the purified sample in concentrated sulfuric acid before performing the CPC measurement.

The *design of the electrolysis cell* is a critical parameter. The objective is to achieve a fast and rigorous removal of dissolved oxygen, to maintain accurate control of the potential of the

working electrode, to achieve near-quantitative electrolysis in the shortest possible time, and to minimize diffusion and leakages between the working electrode compartment and the counter electrode and reference electrode compartments. The working electrode compartment being usually a small cylindrical glass vessel, ideal control of the electrode potential would require a perfect cylindrical symmetry of the working electrode, the counterelectrode, and the mechanical stirrer. Full symmetry never exists in practice, as either the counterelectrode (Holland et al. 1998) or the stirrer is off center (Jackson et al. 1980). It is essential to locate the tip of the reference electrode compartment in a region of highest current density and as close as possible to the surface of the working electrode, in order to best control the electrochemical reactions occurring there (Harrar 1968; Harrar 1987; Harrar and Shain 1996). The larger the ratio of the area of the working electrode to the volume of the test solution, the faster is the electrolysis. Wrapping several layers of platinum or gold gauze as the working electrode is probably not so much increasing the effective area of the electrode but decreases the volume of the test solution. Yet the benefit is partially offset by the increase of the capacitive component of the background current. Analysts deploy much ingenuity in devising special designs of the mechanical stirrer to reach the fastest stirring rate without solution splashing.

Modern electronics will meet the following essential *instrumental requirements* (Holland et al. 1998). For assays of up to 15 mg of plutonium, the potentiostat should be able to supply a current output of 250 mA or more, in order to observe an exponential decay of the coulometric current at the outset of the electrolysis. The potential control circuitry should be fast enough to raise the control potential by 1 V within a millisecond with less than 1 mV overshoot. The selected potential should remain stable to ± 1 mV during measurements. The meter measuring the difference of potential between the working and reference electrodes should have an input impedance of $10^{11} \Omega$ or more. The current integrator should cover a range of 50 μA to 100 mA with a linearity of 0.005% or less. It is recommended to include in the equipment an adjustable constant current supply with a stability of 0.002% to perform an electrical calibration of the current integrator with an accuracy of 0.01%. If room temperature varies excessively, the instrument should be located in a temperature-controlled cabinet to limit electronic drift to the above values.

The norm ISO 12183 incorporates the latest technological experience (ISO 2005d). It describes the coulometric assay of 4 to 15 mg aliquants of plutonium in 0.9M nitric acid, using a gold working electrode. The current integrator is calibrated electrically. A blank is measured first under conditions similar to those used for a plutonium sample. The plutonium test aliquant is weighed into a coulometric cell, fumed to dryness with sulfuric acid and re-dissolved with the blank solution. The test solution is degassed and about 99.9% of the plutonium reduced to Pu(III). The rest potential of the working electrode is measured. The potential of the working electrode is raised to oxidize Pu(III) to Pu(IV). The electrooxidation current is integrated until about 99.9% of the electrolysis is completed. The quantity of electricity used in the oxidation and the rest potential of the working electrode at the end of the oxidation are recorded. The fraction, f , of plutonium electrolyzed is calculated according to the Nernst equation. Stopping the electrolyses before their completion shortens the process and reduces the background current correction and its uncertainty. With automatic coulometers, like the ones described by Jackson et al. (1980) and Phillips et al. (1977), uncomplete electrolysis is not usually corrected mathematically but via a chemical calibration against plutonium reference materials. The Harwell instrument (Phillips et al. 1977) was equipped with an automatic sample changer.

Pd, Ir, Pt, Au interfere but are normally not of concern in nuclear fuel materials. Interference of Fe or Np can be corrected if their content is measured or known and their atom ratio to

plutonium does not exceed 0.005. A confidence interval of 0.1 to 0.2% is achievable for a single determination of plutonium at a confidence level of 0.95. This includes the contribution of uncertainties of systematic character, which should not exceed 0.03%. The uncertainties will increase if the sample must be purified by a suitable chemical separation before applying the coulometric measurement (Pietri et al. 1981; Mitchell et al. 1990). The accuracy of the procedure is verified by measuring aliquants of standard plutonium solutions.

With increasing concerns about the treatment of radioactive wastes, CPC of plutonium or uranium in sulfuric or nitric acid is becoming more attractive, as titration procedures like the Davies&Gray or the McDonald&Savage methods yield complex liquid wastes, which are difficult to condition.

63.4.5.5 Isotope Dilution Assays

Isotope dilution analysis (IDA) involves mixing an aliquant of the sample with an aliquant of an artificially enriched isotope of the element to be analyzed. The content of the latter in the original sample is derived from the results of the isotopic analysis of the mixture compared to the isotopic compositions of the sample and of the enriched isotope. The term “spiking” is often used to refer to the mixing step. The aliquant of enriched isotope added to the sample is also commonly called a “spike.” IDA is used in particular for the determination of uranium, plutonium, or thorium in solutions of irradiated nuclear fuels. It has also been used for an independent measurement of the total volume or mass of solution in accountability tanks of chemical processing plants.

Radiometric Isotope Dilution Assay Techniques

Gamma spectrometry could readily be used to determine uranium with good accuracy by spiking the sample with a uranium spike of sufficiently different ^{235}U abundance, and measuring the 185 keV gamma ray emission of the ^{235}U isotope before and after spiking with enriched ^{235}U . Alpha and gamma spectrometry were shown to be applicable to the IDA of plutonium (Mayer et al. 1995; Parus and Raab 1996) measuring the ratio of the ^{238}Pu activity to the sum of the ^{239}Pu and ^{240}Pu activities. The $^{238}\text{Pu}/(^{239}\text{Pu} + ^{240}\text{Pu})$ alpha activity ratios should not exceed 5 in the spiked and unspiked samples (Ramaniah et al. 1980; Parus et al. 1992), when determining Pu concentrations by isotope dilution alpha spectrometry (IDAS). A plutonium containing 95% of ^{239}Pu or more and less than 0.01% of ^{238}Pu is a convenient spike for IDAS of high burnup plutonium samples holding, e.g., 1% of ^{238}Pu and 50% of ^{239}Pu , just as it is too for isotope dilution mass spectrometry (IDMS). Use of a ^{238}Pu spike is recommended only when the ^{238}Pu isotope abundance does not exceed 0.1% in the unspiked sample. Precautions required to reach accuracies of a few percent by IDAS were described in ► Sect. 63.4.4.2.

Isotope Dilution Mass Spectrometry

Although the technique is more expensive than radiometry, mass spectrometry is, however, the preferred method for IDA of samples of nuclear materials taken for accountability verifications. Traditionally, separated or highly enriched isotopes, absent from the samples or only present as minor isotopes, such as ^{233}U , ^{242}Pu , ^{244}Pu or ^{230}Th were used as spike material in isotope dilution mass spectrometry. IDMS is the standard operator method for the accountability of nuclear materials in input solutions of irradiated nuclear fuels. The method involves taking a representative sample from the input accountability tank and diluting it accurately 100–1,000-fold in a heavily shielded cell. A portion of the diluted solution is transferred to

a medium activity laboratory where it is subsampled and mixed with an accurately measured aliquot of a calibrated dilute spike solution.

IDMS is also the basic technique for safeguards verification measurements on spent fuel solutions and active liquid wastes from reprocessing plants, although it may be used too for the verification of the composition of any sample taken in the nuclear fuel cycle. At first, the IAEA used ^{233}U and ^{242}Pu spikes in the form of a dried nitrate carrying about 1 mg of uranium and 10 μg of plutonium in a sealed penicillin vial. The inspector witnessed the taking of the primary sample, its dilution and requested the weighing of a milliliter of the diluted input solution into duplicate dried spike vials. The inspector witnessed further the heating of the subsamples with nitric acid to re-dissolve the mixed spike, their drying, the capping of the penicillin vials, their bagging out and packaging in Type A containers, which were air flown to Seibersdorf.

- (a) *The resin bead method.* In the resin bead method (Carter et al. 1976) a few beads of anion exchange resin are used to retrieve minute amounts of the unspiked and spiked samples, and transferred to the safeguards laboratory. At the analytical laboratory, a single bead of each sample is mounted on the filament of a thermal ionization mass spectrometer to measure plutonium and uranium sequentially. It was hoped that such resin bead samples may be air mailed to SAL in Seibersdorf in accordance with the regulations of the international air transport association (IATA) and the universal postal union (UPU) valid in 1985. It is essential to achieve full chemical equilibrium between the sample and the spike before adsorbing plutonium on resin beads. According to (Marsh et al. 1981) ferrous sulfamate and nitrite are the most effective reagents to do this. The optimized procedure was tested successfully at La Hague (Cesario et al. 1987) and at the reprocessing plant in Tokai Mura in the frame of the TASTEX program (Walker et al. 1981); the test samples having been sent by registered air-mail or shipped as “excepted” air cargo. Current international air mailing of radioisotopes (UPU 2009) have become more restrictive but shipping resin bead samples of irradiated fuel samples as “excepted” air cargo remains possible (IATA 2010). Yet, this attractive approach has not been implemented further, mainly because the preparation of the samples, although simple, requires more handling by the plant operator and therefore more efforts from the inspector for witnessing or authenticating these operations.
- (b) *Spiking undiluted spent solution samples.* Actually, enriched ^{235}U and low burnup plutonium with a ^{239}Pu abundance of 95% or higher are very suitable spikes for the assay of samples of industrial nuclear materials. Alloy chips containing about 50 mg of 20–90% enriched ^{235}U and 2 to 4 mg of plutonium with a high ^{239}Pu abundance, known as *UPu metal spikes*, were used by EURATOM inspectors to spike samples of concentrated input solutions directly (Debievre and Van Audenhove 1976). The homogeneity of the alloys is considered a limiting factor in the accuracy of their certification. A similar method based on the use of *Al capsules* holding a dried mixture of uranyl and plutonium nitrate suitable for spiking a sample of the concentrated input solution (Koch et al. 1976). Both techniques avoid the need for an accurately measured dilution and its independent verification. It is also claimed that an effective valency cycling and isotopic equilibration of the plutonium is achieved during the re-dissolution of the metal alloy or the aluminum capsule. A small fraction of the spiked solutions containing 1–10 μg of plutonium are taken, dried, and shipped to the safeguards laboratory.
- (c) *The large size dried spike method.* In the large-size dried spike (LSD) procedure, selected by the Nuclear Material Control Centre Laboratory (NMCC) in Tokai Mura and the

IAEA (Kuno et al. 1989), the spike is a mixture of uranylene and plutonium nitrate carefully dried in a 10 ml penicillin vial. For the assay of spent fuel solutions and MOX products with U/Pu ratios around 100:1, each vial contains about 50 mg of uranium-enriched just below 20% in ^{235}U and 2 mg of plutonium with a ^{239}Pu abundance of 95% or more. Calculations (Laszlo et al. 1991) and experience show that these amounts are appropriate to reach relative uncertainties around 0.1% in a single measurement of samples carrying about 100 mg of depleted uranium and 1 mg of high burn plutonium with a ^{239}Pu abundance of 50%.

The mass of uranium or plutonium, m , in the sample aliquant, in g, is derived from \bullet Eq. (63.9) below:

$$m = S(I_s/I)(R_s - R_m)/(R_m - R) \quad (63.9)$$

where S is the mass of spike plutonium added to the sample aliquant, in g, I_s is the ^{235}U or ^{239}Pu isotopic abundance in the spike, in weight %, I is the ^{235}U or ^{239}Pu isotopic abundance in the sample, in weight %, R , R_s , R_m are the $^{235}\text{U}/^{238}\text{U}$ or $^{240}\text{Pu}/^{239}\text{Pu}$ isotope ratios, respectively in the sample, spike, and their mixture.

The diagrams in \bullet Fig. 63.25 assume that the $^{240}\text{Pu}/^{239}\text{Pu}$ atom ratios in the unspiked and spiked samples can be measured with a relative uncertainty of 0.05%. The uranium enrichment should not exceed 20% so that the spike does not come in the category of high enriched uranium (HEU), subject to stricter safeguards controls, and will not be allowed in facilities, which are not licensed for the processing of HEU materials.

- (d) *Preparation and certification of LSD spikes.* NMCC and IAEA SAL jointly prepare a stock solution by dissolving metal standards of natural or depleted uranium (NBL112A, EC101, CEA-MU2 or JAERI-U4), HEU (NBL-NRM116) and plutonium with high ^{239}Pu abundance (NBL 126, EC 201, CEA-MP2 or NBS 949) and mixing them to obtain a concentration of about 2 mg/g of plutonium and 50 mg/g of uranium with a ^{235}U abundance just below 20%. The titers are calculated from the “make-up” data and the certificates of the source

\bullet Fig. 63.25

Random measurement uncertainty of the plutonium assay using the LSD spike, as a function of the ratio of mass of ^{239}Pu spike and mass of Pu in sample

metals. The titers are verified (Doubek et al. 1991) by mass spectrometric analyses of the isotopic compositions, potentiometric titration of uranium and potentiometric titration, or controlled potential coulometry of plutonium in accordance to ISO 10980 (ISO 2005b).

The advantage of the LSD spikes is that they can be prepared from primary reference materials more easily than UPu alloy spikes. On the other hand, the dissolution of the LSD spike with the spiked sample does not bring the benefit of a redox equilibration of the sample and spike plutonium, as the dissolution of metallic spikes does. It is therefore essential to avoid losses of LSD spiked samples after their drying in the plant laboratory and until their chemical treatment at the safeguards laboratory. As a quality assurance measure, a number of LSD spikes shipped to a plant under safeguards are returned unused to the verification laboratory in order to check that the spikes are not damaged during shipments or storage.

LSD spikes of certified isotopic and element compositions are available from IRMM since the 1970s (IRMM 2008; Verbruggen et al. 2008a). Automatic equipment (Verbruggen et al. 2008b) was installed to boost the production, also starting from certified metal reference materials.

- (e) *Analytical measurement procedures.* At the safeguards laboratory, the unspiked and spiked samples are re-dissolved in nitric acid and undergo a chemical valency adjustment to achieve isotopic equilibration between the sample and the spike. Uranium and plutonium are separated from each other and from interfering isobares or species altering the ionization and/or fractionation pattern of uranium or plutonium during their measurement by thermal ionization mass spectrometry. Alternative chemical treatments were described in Sect. 63.4.3.1 about isotopic analysis by mass spectrometry. The procedure follows essentially the international standard ISO 8299 (ISO 2005a) with an expected precision and accuracy of 0.1% or better. The calculations are also in line with the mathematical model described by (Kipphardt et al. 2004).
- (f) *Verifications of tank volumes.* For an independent verification of the total mass or volume of solution of nuclear material in accountability tanks of chemical processing plants a known amount, Σ , of a tracer element is added to the nuclear fuel solution in the tank. Only elements which do not disturb the plant process can be used as tracers. They should also be absent or present only in low concentrations in the nuclear material solution. Natural lithium (Bokelund 1970), magnesium (Mathew et al. 1976), and lutetium (Bokelund et al. 1996) have been used as tracers in demonstration exercises. The tank is carefully mixed after the addition of the tracer, the solution is sampled, the sample is diluted by a factor K , and aliquants of the diluted sample are then spiked with ^6Li , ^{26}Mg or ^{176}Lu enriched isotope. Li, Mg, or Lu is separated after a chemical equilibration step. A blank sample, taken prior to the addition of the tracer in the tank, is treated in the same way to determine the isotopic composition and the concentration of Li, Mg, or Lu, which may be present initially in the tank solution. The concentration of added tracer, T , observed in the tank solution, is derived from the dilution factor, K , TIMS measurements of the isotope ratios $^6\text{Li}/^7\text{Li}$, $^{26}\text{Mg}/^{24}\text{Mg}$ or $^{175}\text{Lu}/^{176}\text{Lu}$ in the blank sample, in the tracer and in the sample collected after the addition of the tracer in the tank, and the isotopic compositions of the blank and the tracer. The mass of the solution, M , in the tank is equal to:

$$M = \Sigma / T \quad (63.10)$$

The diluted sample can also be spiked with an enriched isotope of uranium, plutonium, or thorium to determine by IDMS its concentration in nuclear fuel element, C_d ,

along with its concentration in added tracer, T_d . The total mass of nuclear fuel element present in the tank, NF , is readily calculated according to ▶ Eq. (63.11):

$$NF = \Sigma \times C_d / T_d \quad (63.11)$$

This estimate is independent of the dilution factor, K , which does not need to be measured.

Risks of sample contamination are high with Li or Mg tracers and isotopic fractionation is large during lithium TIMS measurements.

Neodymium has been considered as an alternative tracer (Debievre 1997), as it is a fission product present in measurable concentrations in spent fuel solutions and can serve as in situ spike. The accuracy of TIMS measurements is now so good that it could be practical to use enriched ^{235}U or ^{233}U as a tracer for the direct measurement of the total content of fissile material in a tank, skipping altogether the verification of the volume or mass of solution in the tank (Debievre and Perrin 1991).

Nonetheless, the efficiency of the mixing of the tracer and the fuel solution, the impact of solution trapped in ancillary tubes and a number of other points remain to be investigated, so that the procedure has rarely been implemented in safeguards verifications up to now.

63.4.5.6 Spectrophotometric Determination of Hexavalent Plutonium

The absorption peak by PuO_2^{2+} ions at 831 nm is the basis of selective Pu determinations (ISO 2009; Cauchetier 1981). Pu in nitric acid solutions is quantitatively oxidized to Pu(VI) with ceric nitrate or argentic oxide AgO . A recording double-beam spectrophotometer is used to scan the absorption spectrum between 800 and 860 nm (Schmieder et al. 1970). The absorption peak at 831 nm is very sharp with a half height width of 26 Å (▶ Fig. 63.26). The peak height is proportional to the concentration of plutonium in the sample up to 0.55 g/l, provided that the spectrophotometer has a resolution of 4 Å or less and the scanning speed is slow enough to allow the recorder to complete a full scale excursion while scanning across the absorption peak.

■ Fig. 63.26

Pu(VI) absorption peak at 831 nm (Schmieder et al. 1970)

The method is calibrated against Pu standard solutions treated in the same way than the unknown samples.

Acidity, anions and temperature affect the oxidation of plutonium and the Pu(VI) extinction coefficient (Savage et al. 1986). Oxidation by Ce(IV) is less prone to anion interferences than AgO oxidation. The acidity should preferably not exceed 2 N when using Ce(IV) as the oxidant, except in the presence of phosphates. Yet for a long time AgO was the preferred oxidizing agent at La Hague, particularly in the assay of dissolver solutions containing always a significant fraction of fine solids (Patigny 1982). The extinction coefficient of Pu(VI) decreases by 0.7% with an increase of 0.1 M in nitrate concentration. It decreases too with temperature by 0.5% per °C. All these parameters must be carefully controlled and be the same for the treatment and measurement of the samples and calibration standards.

Pu(VI) spectrophotometry is actually used in many instances at spent reprocessing plants, including in their accountability programs (Grison 1980; Holland and Dorsett 1986). Fiber optics has eased its applications to analyses in glove boxes and hot cells (Schott 1984). Diode-array spectrophotometers should find applications in process control and safeguards (Cauchetier et al. 1985), as the optical spectra give abundant information on the species present in process solutions. Pu and U spectrophotometry is amenable to automation (Jackson et al. 1976). Use of Nd(III) as internal standard and authentication tag was validated for on-site safeguards measurements of plutonium in highly active waste solutions in spent fuel reprocessing plants by Pu(VI) spectrophotometry (Surugaya et al. 2008). A reproducibility of 10% should be achievable for plutonium concentrations around 10 mg/l. The limit of detection varies between 0.1 mg/l and 2mg/l depending upon the authors.

Higher reproducibilities and accuracies of 0.06–0.1% were obtained (Nikitina et al. 2007) with a two-channel photometer for the characterization of ^{240}Pu , ^{242}Pu or ^{244}Pu spikes or their mixtures. The two channels are centered on the Pu(VI) absorption peak at 831nm and in a region of low absorbance at 720 nm. The ratio of the light intensities in the two channels is taken as a measure of the plutonium light absorption. The technique was proposed for the determination of U, Pu, and fission products such as Nd and Rh in dissolver solutions (Stepanov et al. 2002) with expected reproducibilities of 0.1 to 0.25%. LSD spikes containing around 50 mg of 20% enriched uranium and 2 mg of plutonium have been verified with the same technique and precision. With such a capability, the technique would qualify as a bias defect detection method.

63.4.5.7 X-ray Absorption and Fluorescence Spectrometry

In the 1970s (Pella and von Baeckman 1969; von Baeckman 1971), an instrument was developed for the automatic dilution and L-X-ray fluorescence analysis (XRFA) of U and Pu in spent fuel solutions with a precision and accuracy of about 1%.

The *hybrid K-edge densitometer* (HKED) turned out to find quicker applications for safeguards verifications (Ottmar et al. 1986; Ottmar and Eberle 1991) at the input of spent fuel reprocessing plants, as the sample needs neither a dilution nor any treatment before measurement. The technique, considered as an NDA method and described in ▶ Sect. 63.3.1, is installed in particular in on-site analytical laboratories and operated by analytical chemists on duty there. Operators have found the instrument so practical and reliable that they use it in their nuclear material accountability program (Brousse et al. 1993). The HKED fluorescence channel is also used for DA of Th or mg-size Pu samples,

measuring the Th/U or Pu/U ratios against a uranium “internal standard” (Ottmar et al. 1991; Doubek et al. 1994).

L X-ray fluorimetry with commercial XRF analyzers has been applied to determine U, Th and Pu in oxides and mixed oxides dissolved in borax or polyphosphate glass beads with 0.3% reproducibility. Average relative differences of $\pm 0.2\%$ were observed with results of titrations or gravimetric assays with standard deviations of 0.5% on the differences (Bagliano et al. 1991). The technique has the advantage of yielding only solid wastes and no liquid waste. These instruments are also powerful tools to determine the overall chemical composition of mixed fuels, alloys, nuclear scrap, sludges, fuel cladding, and structural components, etc. Analyses of impurities in ignited oxides are an important component of U, Th, and Pu gravimetric determinations (Sect. 63.4.4.1). Checks of the chemical purity of reagents and samples at key analytical steps are another application of X-ray fluorimetry to the control of the quality of DA procedures.

63.4.5.8 Assay of Alternative Nuclear Materials

The irradiation of nuclear fuels in the reactors produce important amounts of fissile isotopes such as ^{237}Np , ^{241}Am , and ^{243}Cm , besides Pu. Since 1993, the IAEA is called to take these isotopes into consideration in its safeguards duties, as a category of “alternate nuclear materials” (ANM), which might be used to fabricate nuclear explosives (Charlton and Stanbro 2001; Bathke et al. 2009). To guard against such misuses, it was agreed at present to verify that undeclared production of these isotopes does not remain concealed. This is done through an evaluation of the flow sheet of the chemical processing plants (Koch et al. 1997; Rance et al. 2007) and the verification that the process is not modified to allow a separation of ANMs. To perform such “flow sheet verifications” the inspectors must be able to use at least some qualitative or semiquantitative tools to confirm that ANMs are not present in unexpected steps or amounts in the processes. Safeguards focuses particularly on ^{237}Np , which is a long-lived nuclide, as it is expected to be easier to use to produce alternate nuclear fuels or nuclear explosives.

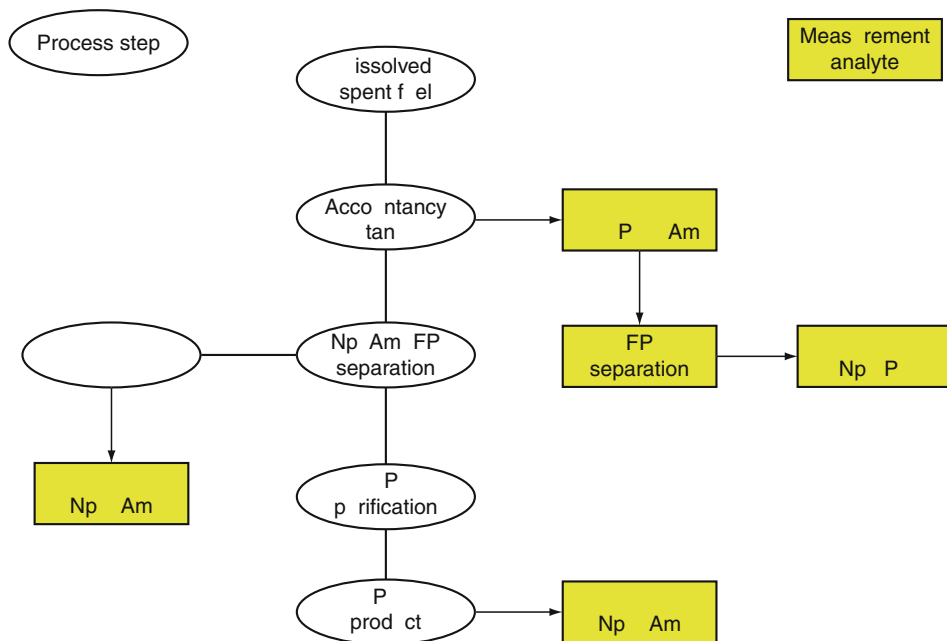

An attractive proposal is to combine U, Pu, Am verifications by HKED with a simple DA measurement of Np/Pu ratios (Ottmar et al. 2001) at spent fuel reprocessing and Pu fuel fabrication plants (Fig. 63.27).

A large arsenal of “conventional” methods exists for measurements that are more elaborate whenever this would be needed. Separated ANMs can be assayed by gravimetry, titration, or coulometry (Crossley 1988). Smaller or more dilute materials may be analyzed by spectrophotometry (ISO 1997; Kageyma et al. 2001), L X-ray fluorimetry (Benony et al. 1994), IDMS (Efurd et al. 1986), IDAS (Aggarwal et al. 2005) or isotope dilution gamma spectrometry (IDGS) (Sus et al. 1996). Gamma (Ludwig et al. 2008) or alpha spectrometry (ISO 2007c; Sus et al. 1998), differential pulse polarography (Cauchetier 1978), laser-induced fluorimetry (Stepanov et al. 1990a; Aleksandruk et al. 1991) are applicable to very dilute materials. The sensitivity of laser-induced photoacoustic spectrophotometry (LIPAS), developed to investigate actinide chemistry in dilute solutions, would allow to determine Am down to 10^{-8} M and Np down to 10^{-7} M (Ewart et al. 1987), with careful control of the oxidation state and chemical forms.

A review of “nonconventional” methods (Rosenberg 1992) concludes that ICPMS can be the most attractive and versatile instrument as it already is in environmental analyses (Varga et al. 2006), when combined with modern chromatographic separations (Vajda et al. 2009).

Proposed scheme for the control of alternative nuclear materials at a spent fuel reprocessing plant with the HKED (Ottmar et al. 2001)

63.5 Environmental Sampling and Analysis to Verify the Completeness of State Declarations

63.5.1 Introduction

Starting from the inception of international safeguards under INFCIRC-66 and -153 type agreements, the main emphasis of IAEA safeguards inspections was to verify that declared nuclear material placed under safeguards was accounted for and had not been diverted for non-peaceful purposes. Concerns about the existence of undeclared nuclear materials or activities in states subject to comprehensive safeguards agreements were not directly addressed by the IAEA, with the assumption being that any such activities would be detected by other means. The IAEA's involvement in such investigations began with the implementation of United Nations Security Council Resolution 687 (United Nations Security Council 1991) following the expulsion of Iraqi armed forces from the territory of Kuwait in early 1991. UNSCR 687 entered into force on April 3, 1991, and specified that the IAEA, in conjunction with a UN Special Commission (UNSCOM), would carry out inspections inside Iraq for the destruction, removal, or rendering harmless of all "nuclear weapons or nuclear-weapons-usable material or any subsystems or components or any research, development, support or manufacturing facilities related to the above." The IAEA, in turn, set up an Action Team consisting of safeguards inspectors and experts, supplemented by experts supplied by its member states, to carry out these inspections aimed at understanding all aspects of the Iraqi nuclear activities carried out prior to 1991 in breach of their safeguards undertakings under the NPT.

The IAEA Action Team inspections in Iraq began in May, 1991, and continued until December 1998 during which time a number of previously unknown nuclear facilities and processes came to light, including the uranium recovery from phosphate ores at Al Jesira and Al Qaim, the electromagnetic isotope separation facilities at Al Tarmiya and Ash Sharqat, the centrifuge facility at Al Furat and the nuclear weapon design and explosive test facility at Al Atheer (Dillon 2002). The details of this undeclared nuclear development program were painstakingly pieced together from physical evidence (buildings and equipment), interviews with Iraqi scientists, documents seized by the inspectors and, last but not least, by measuring small traces of nuclear material in so-called “environmental samples” taken at known and suspected nuclear facilities in Iraq (Donohue and Zeissler 1993; Zeissler and Donohue 1995). The collection and analysis of such environmental samples were a completely new activity for the IAEA. It exposed the agency to a number of developments that had been carried out in the member states prior to that time. Among these were methods for sampling radioactive effluents in waterways, for taking swipe samples of dust in buildings and from equipment as well as the analysis of such samples by highly selective and sensitive methods such as the fission-track method combined with thermal ionization mass spectrometry (FT-TIMS).

The uncovering of the Iraqi undeclared nuclear program starting in 1991 demonstrated that the traditional nuclear accountancy-based safeguard system applied up to that time needed to be strengthened. Addressing the *correctness* of the states’ declarations was not a protection against a state that was determined to carry out undeclared nuclear activities for the production of special nuclear materials and with the intention of hiding this from IAEA safeguards inspectors. This revelation convinced the IAEA and its member states of the need to develop new approaches and tools to provide additional assurances about the *completeness* of the states’ declarations and the absence of undeclared materials and activities. The efforts to strengthen agency safeguards in light of these events was embodied in the Program 93+2, which was initiated in 1993 and was planned to finish in time to provide input to the NPT Review and Extension Conference planned for 1995 (IAEA 1994, 1995, 1996). Program 93+2 studied a number of strengthening measures such as the use of third-party or open-source information, use of satellite imagery and import-export information, as well as the logistics and optimized use of environmental sampling and analysis.

The environmental sampling activities under Program 93+2 focused on 12 field trials in which a wide variety of environmental samples were taken around known nuclear facilities in 11 member states (see ► Table 63.13).

The main conclusions from these field trials were that nuclear activities, especially those involving large amounts of nuclear or radioactive materials were detectable in the environment at distances of 10–20 kilometers by use of water, sediment, biota, and vegetation samples. However, the dilution effects were found to be large and the signatures were often mixed with global fallout or releases from other facilities. These effects tend to reduce the usefulness of such sampling for safeguards purposes and to raise the question of the cost-effectiveness of such sampling on a regular basis to detect undeclared activities in a wide-area approach (i.e., where the exact source of effluents is not known a priori). However, the field trials did demonstrate the utility and cost-effectiveness of swipe sampling inside facilities; the complete details of declared activities could be revealed by sensitive and selective analysis of such samples (see ► Sects. 63.5.5 and ► 63.5.6).

In parallel with the 93+2 field trials, the IAEA designed and constructed a special Clean Laboratory for Safeguards in Seibersdorf, Austria (see ► Sect. 63.5.3.1), which went into full operation in 1996. In the years since 1996, the environmental sampling for safeguards program

■ Table 63.13

Field trials of environmental sampling for safeguards under Program 93+2

Country	Facility	Date	Conclusions
Sweden	Power reactors, Research center	Sept 1993	Fission and activation products were seen in effluent water released in a coastal area
Hungary	Power reactor	Oct 1993	Elevated fission and activation products in a river were possibly due to Chernobyl accident
USA	Enrichment plant	Mar 1994	Enriched uranium could be seen in vegetation, water and sediment at a distance of several km
Japan	Reprocessing plant	Apr 1994	No clear indication of reprocessing could be seen in water released in a coastal area
South Africa	Enrichment plant	Apr 1994	Enriched uranium particles were seen in vegetation and swipes from vegetation as well as in swipes from inside buildings
Australia	Research center	Apr 1994	Enriched uranium used as targets for medical isotope production could be seen in swipe samples as well as depleted uranium used in research activities
Argentina	Enrichment plant	May 1994	Swipe sampling in buildings showed depleted and enriched uranium particles typical of enrichment operations
Indonesia	Research center	May 1994	Low levels of fission and activation products were seen in water and vegetation. Swipe samples taken in buildings showed low and high-enriched uranium particles from research and medical isotope production activities
Republic of Korea	Research center	June 1994	Water samples showed both depleted and enriched uranium associated with research and fuel fabrication activities. Swipe samples from buildings showed depleted and low-enriched uranium particles
UK	Reprocessing	Sept 1994	Fission products associated with fuel reprocessing were seen in water and vegetation; uranium particles found in swipe samples from process buildings were diagnostic of the processes carried out
Netherlands	Enrichment Plant	Dec 1994	No signatures of enrichment could be found in water, sediment, biota, or vegetation, but swipe samples from inside buildings showed depleted and enriched uranium particles representative of enrichment operations.
Japan	Enrichment	Mar 1995	No signatures of enrichment were found outside the facility, but swipe samples from inside buildings showed clear signatures of enrichment operations

has grown in terms of the number of samples taken and the number of facilities that have been sampled. Protocols have been implemented for all aspects of the program, including sample kit production, sample taking and shipment, screening, analysis at SAL/CL or in the network of analytical laboratories (NWAL) in the agency's member states, as well as the evaluation of the data and drawing of safeguards conclusions (IAEA 2005). Between 300 and 700 swipe samples

are taken each year by agency inspectors and each sample is subjected to screening and detailed analysis at two separate laboratories in order to obtain cross confirmation about the presence of any unexpected or undeclared nuclear materials present. The following sections give a detailed picture of the environmental sampling process.

63.5.2 Sampling, Conditioning, and Shipment of IAEA Safeguards Environmental Inspection Samples

63.5.2.1 Cotton Swipe and Other Swipe Materials

The basic IAEA swipe sampling kit (see [Fig. 63.28](#)) consists of six cotton wipers, which are 10 × 10 cm in size. Mini-grip bags of two different sizes are included to individually bag and double-bag the swipes after sampling; this double-bagging is the principle means to stop cross-contamination of the sample from that point onward. Each sampling kit also contains two pairs of clean-room latex gloves, a sample data sheet, pen, and extra labels. The kits are prepared in a Class 100/ISO Class 5 work area that is monitored before and after each batch

Fig. 63.28
Standard cotton swipe sampling kit

of kits is prepared to ensure that the cleanliness class is not exceeded. In addition, swipes are taken of the workbench before and after sample kit preparation and these swipes are analyzed by bulk and particle methods to detect unusually high levels of U or Pu or the presence of particles containing these elements. A certain number of unused kits from each production batch are also archived in case of future questions about their cleanliness. Finally, the cotton wipers used in making the kits are subjected to destructive (bulk) analysis whenever a new batch is received; typical levels of U in the wipers are from 1–3 ng whereas Pu is below the detection limits of the most sensitive techniques available (less than approximately 1 fg).

A second type of swipe material (designated Type-J) consists of cellulose material similar to filter paper with a circular center part of 2.5 cm diameter. These cellulose wipers are used to take swipe samples inside hot cells. Four wipers, attached to a plastic holder, are introduced into the hot cell of interest and used by the remote manipulators to take a swipe sample. Upon exiting the bank of hot cells, usually through a glove box, one of the wipers is detached and given to the facility operator for making radioactivity measurements that will determine the shipment conditions for the remaining three wipers that are sent back to the IAEA in Austria. Each of the three hot cell swipes is packaged in a plastic bottle that is bagged in a polyethylene mini-grip bag or heat-sealed in plastic (so-called bag-out) before being placed in a Pb or stainless steel container to provide a minimum of shielding for energetic beta or gamma radiation. The three shielded samples are then placed in a special sealable aluminum can and eventually in a steel drum or other container that is licensed for transport of excepted or type-A quantities of radioactive materials.

The Type-J wipers are also used to take samples in a certain enrichment facility under safeguards in a nuclear weapons state. The wiper is inserted in a special metal fitting (a so-called Koshelev fitting) that is part of the pipe-work connected to the enrichment cascade. Therefore, this sample comes into contact with the UF_6 gas in the pipe-work and can be used to detect the presence of material with higher ^{235}U enrichment than declared.

63.5.2.2 Air Filters

During the IAEA Action Team inspections in Iraq (see [Sect. 63.5.1](#)), a variety of sampling media were tested, in the context of non-site-specific or wide-area environmental sampling. In addition, various field trials of wide-area environmental sampling were carried out in which high-volume air samplers were employed. One such sampler is shown in [Fig. 63.29](#). It consists of a high-volume air blower system pulling ambient air through a 20×30 cm paper filter. Typical air volumes sampled by such devices are in the range 40–900 m³ per hour. Deployment of air filter samplers in a safeguards role presents the following challenges:

Each sampler must be supplied with electrical power and is subject to interruptions if used in an unattended mode.

Cameras or other systems would be needed to ensure that the sampler is not tampered with. Clogging of the filter medium with sand or high dust loading would limit the duty cycle between filter changes.

Analysis of the resulting filter samples would be possible by nondestructive methods such as gamma spectrometry or X-ray fluorescence but these do not represent the most sensitive methods. Bulk analysis would be affected by the high dust loading of the filter and perhaps by the filter material itself, e.g., glass-fiber filters would be difficult to destroy chemically

■ Fig. 63.29

High-volume air sampler

and would add unwanted elements. Particle analysis would present similar difficulties as with soil sampling.

Use of high-volume air samplers in a wide-area sampling scheme would be prohibitively expensive because a “grid” of samplers would be needed with samples collected every week, representing many hundreds or thousands of samples per year for a medium-sized area (for example, Iraq has an area of 438,000 km²).

For the reasons listed above, as well as owing to the large dilution effects that can be expected as a plume of effluent leaves a nuclear facility and travels down-wind, high-volume air sampling was not chosen as a routine sampling method for IAEA safeguards. The IAEA reserves the right to implement such wide-area sampling under the additional protocol (IAEA 1997) in those cases where it is both feasible and cost-effective.

63.5.2.3 Water, Soil, Vegetation, and Biota Samples

Samples of the true “environment” such as water from rivers and lakes, sediment, biota, vegetation, and soil, were taken in Iraq by the IAEA Action Team in the period 1991–1998 and during the field trials carried out under Program 93+2. Protocols and sampling equipment were developed and tested for these different sample types. One such device was a high-volume water sampling system based on a sample collection cartridge connected to a water pump powered by a 12 V battery, as shown in ▶ Fig. 63.30. The cartridge contains a paper filter to trap particulates and radionuclides adsorbed on particles and a mixed ion exchange bed to remove dissolved species such as ¹³⁷Cs. The flow rate through such a sampler is in the range of 200–300 liters per hour.

Fig. 63.30**High-volume water sampler and cartridge**

Sampling of soil, vegetation, and water-borne biota for safeguards purposes was performed during the 93+2 field trials using ad hoc methods developed at the time. Plastic mini-grip bags were used for soil and vegetation and 1 liter wide-mouth plastic bottles were used for biota sampling. A more systematic study of such sampling methods was carried out and special protocols were developed (Rose et al. 1997). Since that time, these types of samples have rarely been taken by IAEA inspectors and, therefore, will not be covered here in detail.

63.5.2.4 Process and Structural Materials

There is no limit to the types of materials that might be taken as safeguards samples in the search for undeclared activities. Elemental impurities can be used to trace the origin of nuclear materials through various stages of a technological process such as mining of uranium ore, concentration of the uranium in the form of yellowcake, conversion of yellowcake to UO_2 , further conversion to UF_6 for enrichment, etc. Elemental impurities are removed at each stage, until nuclear grade purity is achieved, but certain elements may be reintroduced coming from the reagents or vessels used. Although such information may be used to match two or more known materials, the sampling uncertainties and batch-to-batch nonreproducibility will make absolute source attribution much more difficult.

63.5.3 Safeguards Analytical Laboratories

63.5.3.1 Clean Laboratory for Safeguards

The role of the clean laboratory (CL) for safeguards as well as the structure of IAEA's environmental sampling for safeguards (ESS) program are described elsewhere

(Deron et al. 1996; Donohue 1998, 2002; IAEA 2003). The clean laboratory (CL) consists of two zones; the first zone of approximately 100 m² is maintained at a cleanliness level of “Class-100,000” according to the US Federal Standard 209E or ISO Class 8 according to the ISO Standard 14644-1. The CL is equipped for the measurement of samples using instrumental methods such as thermal ionization mass spectrometry (TIMS), inductively coupled plasma mass spectrometry (ICP-MS), scanning electron microscopy (SEM) in combination with X-ray spectrometry (XRS) and high-resolution gamma spectrometry (HRGS). A higher class of cleanliness is maintained in the second zone of the CL, also of approximately 100 m² area, where work surfaces are kept at US Class 100/ISO Class 5 for the chemical treatment of swipe samples and the production of certified clean sampling kits.

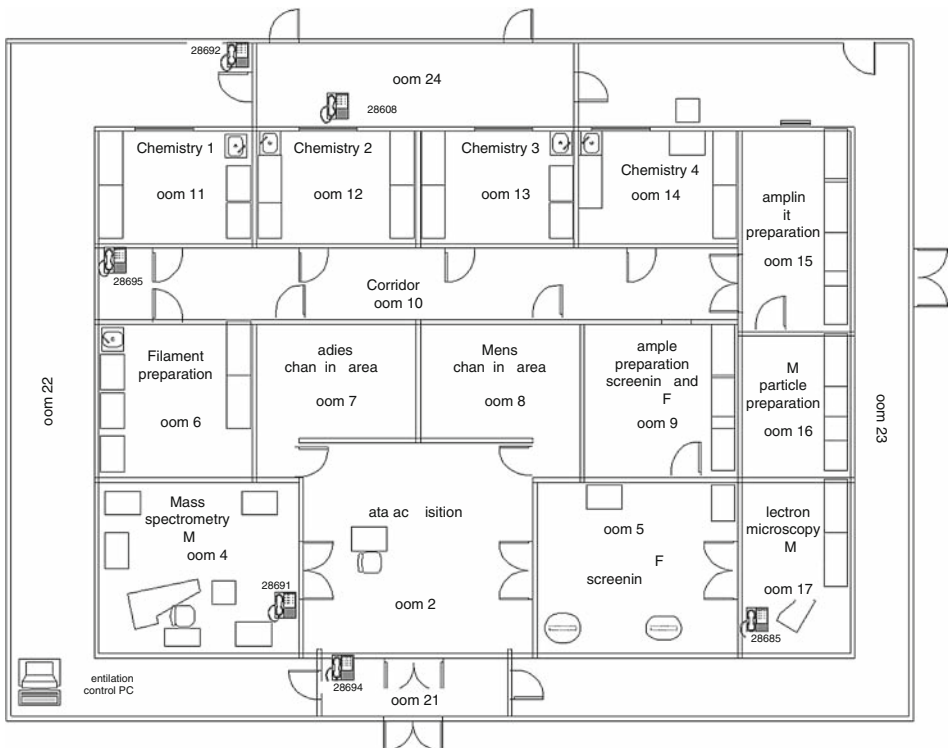

The CL was constructed in 1995 and entered into full operation in 1996 at the same time that the agency began to implement environmental sampling for safeguards (ESS) as a routine tool under existing legal authority. A floor plan of the CL is shown in [Fig. 63.31](#).

The CL was designed to support the following activities:

1. Preparation and certification of clean sampling kits and supplies for taking environmental samples. The number of sampling kits produced per year is approximately 1,000.
2. The receipt, book-in and recoding of up to 1,000 environmental samples per year. After initial cleaning of the outer sample bags and screening by high-resolution gamma

Fig. 63.31

Floor plan of the IAEA Clean Laboratory for Safeguards

spectrometry (HRGS) and X-ray fluorescence spectrometry, the samples are kept in archival storage until a detailed analytical request is received. It is IAEA policy to retain in the archive at least one subsample of every environmental sample received for an indefinite period. For this reason as well as others, it is sometimes necessary to split subsamples; this is done in a glove bag inside a Class-100 clean-air bench in order to avoid cross contamination.

3. Detailed bulk analysis of environmental samples according to an analytical request. Bulk analysis (see [Sect. 63.5.5](#)) refers to the complete dissolution of the subsample (usually a cotton or cellulose swipe), chemical treatment and measurement of U and Pu by thermal ionization mass spectrometry (TIMS, see [Sect. 63.5.5.3](#)) or inductively coupled plasma mass spectrometry (ICP-MS, see [Sect. 63.5.5.4](#)). Element concentrations are measured using the isotope dilution mass spectrometry (IDMS) method. In addition to U and Pu, the element Am is sometimes measured using either ICP-MS or alpha spectrometry.
4. Particle analysis of environmental samples by secondary ion mass spectrometry (SIMS, see [Sect. 63.5.6.3](#)) or scanning electron microscopy in combination with X-ray spectrometry (SEM-XRS, see [Sect. 63.5.6.4](#)). The SEM-XRS instrument and its sample-preparation area are located in the clean laboratory, but the SIMS instrument is not. Sample preparation for SIMS can be carried out in the CL, but a small dedicated clean-room at US Class-100/ISO-Class 5 cleanliness level is colocated with the instrument to avoid potential cross contamination when transporting the prepared sample planchets to the instrument. The SEM-XRS method is also supported in the CL by an array of optical microscopes equipped with micromanipulation systems for picking up particles of interest prior to further treatment such as chemical analysis and isotopic measurement by TIMS or ICP-MS.

In general, the CL is operated as a mixed-flow clean-room facility, meaning that the Class-100/ISO Class 5 areas are the workbenches and fume cupboards in the various rooms, rather than the entire room. A laminar flow of clean air falls from high-performance particulate (HEPA) filters in the suspended ceiling of the room and is directed to the work area by plastic curtains. Certain clean laboratories in the network employ full laminar flow in the rooms at US Class 10/ISO Class 4 cleanliness conditions. The most sensitive measure of effectiveness is the blank levels of U and Pu that can be achieved, rather than the chosen cleanliness class. Blanks consist of the following types:

1. Reagents used in the chemical treatment of the samples for bulk analysis (“process blank”). These are typically ultra-pure mineral acids such as HNO_3 or HCl as well as reducing agents such as HBr or HI and highly pure water (18 M Ω).
2. Blanks of the swipe sample matrix (“swipe blank”) after each processing step. The swipe blank contains the process blank as well as any U, Pu or interfering elements contained in the swipe material. The cotton wipers chosen for swipe sampling are generally quite low in U content – 1–5 ng per wiper – and the Pu content is not measurable by bulk analysis: it is believed to be below 1 fg (the most likely source would be Pu from nuclear weapons fallout).
3. Blanks of the air in a clean-room laboratory or other working area (“room blank”). These are collected in a petri dish of approximately 100 cm² area that is left exposed on a surface for 1–2 weeks. Then, U and Pu are recovered with concentrated HNO_3 , spiked with tracers of ²³³U and ²⁴²Pu, and subjected to bulk analysis by ICP-MS. Typical values in a Class 100/ISO Class 5 working area are in the range 0.1–0.2 fg/cm² – hour for U and below the detection limit of the ICP-MS method for Pu (estimated to be 10⁴ times lower).

The IAEA Clean Laboratory for Safeguards is certified annually to meet the specified cleanliness standards by an outside organization.

63.5.3.2 The Network of Analytical Laboratories (NWAL) of the IAEA

The IAEA collaborates with a number of laboratories in the member states that form a network dedicated to the analysis of environmental samples for safeguards. ▶ [Table 63.14](#) lists the members of this network and the analytical services they offer.

63.5.4 Sample Screening Methods

Screening of incoming environmental samples is performed to obtain information that will guide the further detailed analysis and to assist in the shipment of samples to the NWAL. Samples that are known to be radioactive for the purposes of shipment from the field to the IAEA are delivered directly to the nuclear laboratory of SAL for screening and archival storage because the CL is not licensed to handle such materials. All samples known to be below the limits for radioactive shipment purposes are delivered to the CL where they are screened,

■ **Table 63.14**

Member laboratories of the IAEA NWAL for environmental sample analyses. Techniques in use by the NWAL include FT-TIMS = fission-track thermal ionization mass spectrometry, AMS = accelerator mass spectrometry, SIMS = secondary ion mass spectrometry, HRGS = high-resolution gamma spectrometry, TIMS = thermal ionization mass spectrometry, ICP-MS = inductively coupled plasma mass spectrometry, SEM = scanning electron microscopy

archived, analyzed, or transferred to the NWAL. The limits for declaring a sample as radioactive for the purposes of shipment are described in the International Air Transport Authority (IATA 2010) regulations, which are based on the IAEA Regulations for the Safe Transport of Radioactive Materials (IAEA 2009a). So-called “cold” or non-radioactive environmental samples can actually contain a measurable amount of alpha, beta, or gamma radioactivity as long as they fall below the limits given in the above regulations. This is why HRGS screening is performed on all environmental samples received, regardless of their status under the shipping regulations.

63.5.4.1 Gamma Spectrometry

Screening of all environmental samples is performed by HRGS either in the CL for “cold” samples or in the nuclear laboratory of SAL for “radioactive” samples (Parus et al. 2003; Carchon et al. 2007). Cotton swipes and cellulose (Type-J) swipes are placed in a Marinelli beaker to maximize collection efficiency. The samples are measured with a coaxial Ge detector system in the CL for a typical measurement time of 6 hours. Samples that are known to be more active are measured in SAL at greater distance from the detector or for shorter periods using gamma spectrometers with high-purity planar Ge detectors.

The range of gamma-ray energies measured with these systems is from 20 keV to 2,620 keV, which allows the measurement of most fission and activation products expected to be found in environmental samples. The nuclides of interest, their half-lives and main gamma-ray energies are shown in ▶ [Table 63.15](#). The data from HRGS screening are evaluated with commercial software using energy and efficiency calibration data from the measurement of reference material samples. The result is a report for each sample of those nuclides that were detected above the detection limit or the minimum detectable amount for all other nuclides of interest.

63.5.4.2 X-Ray Fluorescence Spectrometry

In addition to the HRGS screening that is performed on all environmental samples received by the IAEA, X-ray fluorescence (XRF) screening is performed on all “cold” samples in the CL to detect significant amounts of U. This screening is useful for the CL and network laboratories in their further processing of the samples in case the amount of U present represents an increased risk of cross contamination. The equipment for this screening consists of a 100 W X-ray generator with Rh anode and end-window configuration, a robotic arm for manipulation of the samples (usually a single cotton swipe in a plastic bag held in a metal frame), and two X-ray detectors (a high-purity Ge detector and a Si(Li) detector). The Si(Li) detector is equipped with an energy filter (Bragg filter using single-crystal graphite strips) tuned to the L-alpha energy of U (13.6 KeV). This system, referred to as “Tripod I,” has a detection capability of approximately 35 ng/cm² for U with a 4 hour measurement time and the data can be displayed as an elemental map.

63.5.5 Bulk Sample Analysis

The purpose of bulk analysis is to detect U and Pu at the lowest possible levels and to measure both their concentration and isotopic composition. This process involves destruction of the

sample matrix (usually cotton or cellulose swipes) by high-temperature ashing followed by dissolution in strong mineral acid. The resulting solution is split in two equal parts and one part is kept as an archive in case problems should occur with the other fraction. The fraction of the original solution to be measured is split again into portions that will result in U and Pu concentration determination by use of the IDMS method and fractions that will be processed for U and Pu isotopic composition measurements.

63.5.5.1 Tracers

The primary tracers used for bulk analysis are shown in ► [Table 63.16](#). They are produced by the Institute for Reference Materials and Measurements in Geel, Belgium.

■ Table 63.16

Tracers used for isotope dilution mass spectrometry

Tracer	Isotope ratio	Isotope amount ratio
IRMM-057 (^{233}U Spike)	$^{234}\text{U}/^{233}\text{U}$	0.000352 (14)
	$^{235}\text{U}/^{233}\text{U}$	0.000004124 (29)
	$^{236}\text{U}/^{233}\text{U}$	0.0000000434 (14)
	$^{238}\text{U}/^{233}\text{U}$	0.00001043 (21)
IRMM-044 (^{242}Pu Spike)	$^{238}\text{Pu}/^{242}\text{Pu}$	0.000009 (6)
	$^{239}\text{Pu}/^{242}\text{Pu}$	0.000827 (4)
	$^{240}\text{Pu}/^{242}\text{Pu}$	0.000108 (4)
	$^{241}\text{Pu}/^{242}\text{Pu}$	0.000009 (4)
	$^{244}\text{Pu}/^{242}\text{Pu}$	0.000015 (4)

Note: IRMM-057 certificate date February 2003; IRMM-044 validity date 30.06.1989.

63.5.5.2 Sample Preparations and Separations

The procedure for chemical separation of these various aliquots is based on anion exchange and solvent extraction chromatography using AG MP-2 anion exchange resin in HNO_3 medium and UTEVA (Eichrom Corp.) in HNO_3 and HCl media. The basic steps in a bulk-analysis preparation scheme are listed below (Shinonaga 2008):

1. The swipe is placed in a covered quartz tube and ashed in an oven at 600°C for 8–10 h. A blank swipe and an empty quartz tube are treated at the same time to provide the swipe and process blank values.
2. The ash is dissolved in 16 M HNO_3 and dried and re-dissolved several times. It is then treated with H_2O_2 and aqua regia to complete the oxidation and sample destruction process and a “mother” solution is re-dissolved in 8 M HNO_3 .
3. The mother solution is split into 3 parts; 20% will be used for U IDMS and ^{238}Pu analysis by TIMS, and alpha spectrometry, respectively. Forty percent will be used for U isotopic analysis, and Pu elemental and isotopic analysis by IDMS (there is no un-spiked Pu fraction and Pu isotopic composition will be estimated by isotopic stripping of the ^{242}Pu spike). The rest (40%) of the solution is kept as an archive.
4. High-purity isotopic spikes of ^{233}U (IRMM-057) and ^{242}Pu (IRMM-044) are added to the 20% and 40% fractions, respectively, and the isotopes are equilibrated by repeated drying and re-dissolution in 16 M HNO_3 and treatment with H_2O_2 .
5. Resin columns containing AG MP-2 and UTEVA are prepared in nitrate form in 8 M HNO_3 . The sample fraction is loaded on the MP-2 column in 8 M HNO_3 and rinsed further with 8 M HNO_3 with the eluate going into the UTEVA column. The MP-2 column is further processed for Pu analysis and the UTEVA column is further processed for U analysis.
6. The Pu is eluted from the MP-2 column with a mixture of 9 M HCl and 1 M HI , then the Iodine is removed by repeated fuming with 10 M HCl . This Pu fraction is further cleaned using an MP-2 column in the chloride form and elution with $\text{HCl-H}_2\text{O}_2$ and HBr . This fraction is finally taken up in 16 M HNO_3 .

7. The U on the UTEVA column is eluted with 0.05 M HCl, dried and re-dissolved in 10 M HCl. This fraction is then further purified with an MP-2 column in the chloride form at a molarity of 10 M HCl. The U is finally eluted with 0.05 M HCl, dried, and converted to the nitrate form with 16 M HNO₃.

63.5.5.3 Thermal Ionization Mass Spectrometry

The measurement of U IDMS and U isotopic fractions from the chemical separation shown above are performed on a Thermo-Fisher Triton mass spectrometer equipped with a single-ion counting detection system (Thermo Fischer Scientific: Triton 2005). Therefore, a peak-jumping measurement scheme is used along with manual sample filament heating procedure to optimize the signal intensity prior to data acquisition. Depending on signal intensity, one or two blocks of data are taken – consisting of 20 scans each. A single block takes approximately 20 minutes. The isotopes of U from 233 to 238 are symmetrically scanned to cancel out drift in signal intensity during the scan. Typical count rates for a 1–2 ng filament loading are 20,000–50,000 ion counts per second for the major isotope present.

63.5.5.4 Inductively Coupled Plasma Mass Spectrometry

In the past decade, ICP-MS instruments have become sufficiently sensitive and stable to offer an attractive alternative to the traditional TIMS measurements for bulk analysis of U and, especially, Pu. The ICP-MS method offers the advantage that samples are presented to the instrument in solution form which eliminated the filament-loading step and filament-blank considerations that are seen with TIMS. An additional advantage is the more constant sensitivity of the ICP plasma ion source and the absence of interference effects that suppress ionization of the element of interest. On the other hand, the ICP source produces a much larger number of molecular ion interferences that affect the accuracy of a Pu measurement, especially at near the detection limit (low parts per quadrillion, ppq). The best approach for these interferences is to remove all possible interfering elements during the chemical preparation of the samples. In any case, the potential interferences must be measured at some point during the analysis of a sample to ensure that they are below the threshold for significant contribution to the masses of interest (²³⁸Pu through ²⁴⁴Pu). In those cases where the interfering elements are above this threshold, a correction can be made for them, based on the “formation co-efficient” that relates the ion signal of the interfering element to the production of molecular species at the mass of a plutonium isotope. This correction procedure will naturally increase the uncertainty of the final Pu isotopic data, in some cases significantly.

The ICP-MS instrument used in the IAEA Clean Laboratory is the Thermo-Finnigan Element 2. It uses a magnetic sector double-focusing mass spectrometer with single-ion counting detector system and peak-jumping data collection. The quoted sensitivity with a concentric nebulizer is 10⁹ cps per ppm, which gives a theoretical sensitivity of 1 ppq for elements that do not suffer molecular interference effects. Special de-solvating nebulizers such as the Apex Q (Elemental Scientific Corp.) can improve the sensitivity further.

63.5.6 Particle Analysis

Early in the environmental sampling program of the IAEA it was recognized that the analysis of individual micrometer-sized particles was a source of unique information about nuclear materials and activities. ▶ [Table 63.17](#) shows the calculated composition of 1 μm diameter particles coming from various nuclear processes. Thus, it can be seen that a pure particle of natural U oxide (“NU”) contains about 10^{10} U atoms in total and that when this particle is irradiated in a reactor, approximately 5 million atoms of ^{239}Pu would be created. Furthermore, a particle of high-enriched uranium (“HEU”) would produce only small numbers of ^{231}Pa and ^{232}Th daughter atoms in 10 years of decay. To be able to “age-date” such a particle would involve measurement of these small components, something which is currently not possible with the most sensitive techniques.

The above considerations show that particles contain small amounts of material, but that the major isotopes would be easily measurable by sophisticated methods such as TIMS or ICP-MS. One of the most challenging aspects of particle analysis for safeguards is the methods used to locate the particles of interest in a “sea” of uninteresting environmental materials such as minerals and organic particles like pollen and fibers. The detection and location of particles containing fissile nuclides such as ^{235}U and ^{239}Pu can be accomplished by the fission-track technique (Fleischer et al. 1975). This method is based on creating a close contact between the particles and a polycarbonate plastic surface (Lexan) which is then irradiated in a nuclear reactor at high thermal neutron fluence (approximately $1 \times 10^{15} \text{ n/cm}^2$) for several minutes. During this irradiation, atoms of the fissile isotopes will undergo fission and the energetic fission fragments will leave damage tracks in the plastic material. After separation of the particle layer from the Lexan, it is etched in NaOH solution to make the damage tracks visible under an optical microscope. The selectivity of this method is very high because no other particles will leave such tracks and the number of tracks compared to the size of the particle gives a clue to the presence of enriched U or Pu because natural U with a ^{235}U content of 0.7% only leaves a small number of tracks in comparison. The fission-track method has been

■ **Table 63.17**

Composition of typical 1 μm diameter particles found in nuclear facilities

Nuclide	NU	Irradiated NU (700 MWD/T)	LEU (4%)	Irradiated LEU (30 GWD/T)	HEU (93%)	Decay of HEU (10 years)
U-238	9,900 M	9,900 M	9,600 M	9,310 M	600 M	
U-236	<1	1.2 M	<1	45 M	<1	
U-235	72 M	64 M	400 M	155 M	9,300 M	
U-234	550 K	530 K	3,600 K	2,500 K	100 M	
Pu-239		5.5 M		57 M		
Pa-231						92
Th-230						2,820

Note: GWD/T = gigawatt-days per ton; MWD/T = megawatt days per ton; LEU 4% = low-enriched uranium with 4% abundance of ^{235}U .

combined with thermal ionization mass spectrometry (FT-TIMS) to provide a powerful method to locate particles containing U or Pu and then to measure their isotopic composition with high sensitivity and accuracy. A calculation of the number of U atoms needed to produce one fission track in Lexan under nominal irradiation conditions is about 10^7 or 4 fg, keeping in mind that a 1 μm diameter particle would contain about 5 pg of U. Furthermore, if such a particle can be manipulated and mounted on a filament for measurement by TIMS, the efficiency of ion collection would be in the range of 0.1–1%, i.e., one ion detected for every 100–1,000 atoms loaded. A particle containing 10^{10} atoms would therefore provide a minimum of 10^7 ions at the mass spectrometer output. Thus, minor isotopes such as ^{234}U or ^{236}U could be measured with counting-statistics limited accuracy of several percent relative and the ^{235}U could be measured with less than 1% relative uncertainty. These calculations are borne out by actual measurement data from the network laboratories that perform FT-TIMS measurements (Stetzer et al. 2004; Park et al. 2006; Usuda et al. 2006).

63.5.6.1 Sample Preparation

Most particle-analysis methods (SEM, SIMS and FT-TIMS) require the removal of particles from the swipe substrate and deposition on a flat surface. In the case of FT-TIMS, the particles are removed by ultrasonic treatment in a suitable suspension medium such as ethanol or siloxane. The suspension is then mixed with collodion and dried as a thin layer on the Lexan plastic for irradiation. After irradiation, this collodion layer can be peeled off to allow chemical etching of the fission tracks in the plastic. The collodion layer can also be replaced on the Lexan after etching with a slight offset so that the particles and tracks are visible under a light microscope at magnification 250–500. Replacement of the collodion layer is not necessary if a comparator microscope is available that allows viewing two objects (i.e., the collodion layer and the Lexan with tracks) simultaneously.

For both SEM and SIMS, the only requirement is that particles should be deposited on a polished flat and conducting surface; pyrolytic graphite planchets with a diameter of 2.5 cm are frequently used. The particles are deposited from suspension or can be deposited using a vacuum extractor system in which the planchet acts as an impactor in a flow of gas with the particles entrained. The one disadvantage of the vacuum extractor is that many particles bounce off the planchet and often a type of sticking agent (polyisobutylene in nonane) is applied and later removed by heating at 250°C. In all procedures where ultrasonic removal and suspension in an organic liquid are used, care must be taken to avoid cutting the swipe material because it results in many organic fibers on the planchet that can accumulate charge and deflect the electron or ion beam of the final measurement instrument. Care is also needed in all methods of particle deposition to avoid too thick a deposit where particles are on top of each other or too close together to allow unambiguous measurements. An optimal spacing between particles is 10–20 μm .

63.5.6.2 Thermal Ionization Mass Spectrometry

The basic processes in TIMS, which apply equally to the measurement of particles, have been published elsewhere (Duckworth et al. 1986). In TIMS, the particle is deposited on a pure metal filament; typical filament materials are W, Ta, and Re which have been purified by

zone-refining to greater than 99.99% purity in order to remove possible U background. In the vacuum system of the mass spectrometer, the filament is heated by passing a current of several amperes through it until it reaches a temperature of 1,400–1,800°C. At these temperatures, the elements Pu and U tend to evaporate from the particle in contact with the filament surface and a certain fraction of these atoms will leave as positive ions. The ratio between neutral and ionic species is given by the Saha-Langmuir equation (Duckworth et al. 1986):

$$N_+ = N_0 \exp[e(\omega - \varphi)]/kT, \quad (63.12)$$

where N_+ is the number of positive ions produced, N_0 is the number of neutral atoms produced, $e\varphi$ is the ionization potential of the element, $e\omega$ is the work function of the surface, k is the Boltzmann constant, and T is the absolute temperature of the filament surface.

The main challenge of single-filament TIMS is that there is a competition between evaporation of the analyte atoms and their ionization; a higher temperature favors ionization but accelerates the loss of material from the filament. In situations where the amount of sample element is severely limited, this competition is a serious challenge. Use of separate evaporation and ionization filaments allows the analyst to better control both processes but the geometrical coupling between the two filaments separated by about 1 cm means that the overall ionization efficiency is reduced. Under the best of circumstances, the ion production efficiency of a thermal ion source is in the range 0.1 to 1% (ions collected per atom loaded). The sensitivity of TIMS for low levels of actinide elements has been demonstrated in many laboratories (Elliott et al. 2006; Buerger et al. 2009; Kraiem et al. 2010).

Modern TIMS instruments combine a single magnetic sector with multi-ion detection systems, although the use of multiple ion counters is not yet mature and many laboratories continue to use a single-ion counting detector and peak jumping. Use of multiple Faraday collectors is a mature technology with excellent methods to inter-calibrate the collectors, but the ion signals and consequent sample amounts must be high for this method and it is not commonly used with ultra-low amounts (pg-ng) as found in environmental samples. Use of a reverse polarity quadrupole filter before the ion-counting detector is also used to reduce the tailing of ions from major isotopes, thus improving the abundance sensitivity from a value of 10^6 to around 10^8 .

63.5.6.3 Secondary Ion Mass Spectrometry

A description of the basic operation of a SIMS instrument is also found elsewhere (Duckworth et al. 1986). The basic principle is the bombardment of the sample surface with energetic ions (typically O_2^+ at 10–15 keV of energy). The interaction of these ions with the sample atoms results in sputtering of material from the surface. A small fraction of the sputtered material is in the form of positive secondary ions, which can be accelerated into an ion lens and analyzed in a double-focusing mass spectrometer. Raster scanning of the primary ion beam and synchronous display of the detected ions will provide an ion image showing local concentrations of that isotope. The ion microscope produces a similar image through stigmatic imaging of the secondary ions and their detection by a position-sensitive ion detector system. In the case of particle analysis, the particles removed from a swipe sample are deposited on a flat conductive surface and illuminated by the primary ion beam. The ion image of this field (typically $150 \times 150 \mu m^2$) will show the presence of particles in the 0.5–10 μm diameter range that contain, e.g., either ^{235}U or ^{238}U . Mathematically comparing these two images will yield the

“enrichment” of the particles. Measurement of an area on the planchet of 1 cm^2 using fields of $150 \times 150 \text{ }\mu\text{m}$ in size takes approximately 6–8 hours.

The sensitivity of SIMS for U particles is limited by the secondary-ion production and extraction efficiency, which is approximately 0.1% under typical measurement conditions (Tamborini et al. 2004). Therefore, a U particle of $1 \text{ }\mu\text{m}$ diameter containing 10^{10} total U atoms would be expected to yield approximately 10^7 ions of the major isotope (^{238}U) and approximately 10^5 ions of the minor isotope (^{235}U) under ideal conditions. Practical considerations such as pre-sputtering and duty cycle would reduce these values by as much as a factor of 10. The result is that the enrichment or ratio of $^{235}\text{U}/^{238}\text{U}$ can only be measured with 1–5% uncertainty for a pure U particle that is $1 \text{ }\mu\text{m}$ in size. Realistic particles encountered in environmental samples are frequently smaller or less pure, and certain interference effects can also reduce the quality of such data. An obvious improvement is offered by a large-geometry SIMS instrument like the Cameca IMS-1280 that has significantly higher sensitivity and resolution to reduce the effects of molecular ion interferences (Ranebo et al. 2009).

63.5.6.4 Scanning Electron Microscopy with X-Ray Spectrometry

Another method to locate particles containing elements of interest is the scanning electron microscope combined with energy-dispersive X-ray spectrometry (SEM-XRS). The SEM instrument used in the clean laboratory consists of a JEOL 6490 SEM with Oxford INCA X-ray spectrometer. The software supplied with this instrument allows an automated search capability in which a specified area of the sample planchet is sequentially scanned in fields of approximately $100 \times 100 \text{ }\mu\text{m}$. The backscattered electron detector is used to detect particles containing high-Z (atomic number) elements. When such a particle is detected, the energy-dispersive X-ray spectrum of the particle is accumulated for a specified time such as 10 s, the resulting spectrum is stored and the search continues. At the end of an analysis, which may take many hours, the data can be sorted according to the element of interest and particles revisited for further analysis, either by energy-dispersive XRS or wavelength-dispersive XRS, which is capable of measuring elemental composition with reasonable accuracy down to element ratios of 1 part per thousand (0.1%). Particles identified in this way can be manipulated inside the vacuum system of the SEM or offline with an optical microscope and further analysis can be carried out by bulk, SIMS, or other mass spectrometric methods to obtain a complete elemental and isotopic analysis of a single interesting particle.

Undulator, 1742, 1744
 Unified atomic mass unit, 150, 477, 479, 487
 Unimodal distribution, 400
 Units of activity, 334
 Universal constants, 482
 Universal Linear Accelerator (UNILAC), 1011, 1012
 Unmoderated neutron, 2622–2625
 Unresolved resonance region, 1868
 UNSCEAR, 2215, 2218, 2236, 2242, 2243, 2513, 2517, 2527–2546, 2549–2555
 Uranium, 1315, 1334, 1499, 1592–1593, 1597, 1598, 1604, 1658, 1660, 1698
 Uranium-234 dating, 803
 Uranium-238 dating, 803
 Uranium enrichment and conversion, 2544, 2554
 Uranium, fission products, 1855, 1936
 Uranium hexa-fluoride (UF_6), 2377, 2381–2383, 2400–2401, 2544, 2554
 Uranium mining and milling, 2554
 Uranium production, 2405, 2408, 2422
 Uranium series, 800
 Uranium ($4n+2$) series, 344
 Uranium tetra-fluoride (UF_4), 2449, 2544
 Uranium, thorium based dating, 352
 Uranium/thorium/lead dating, 804
 Uranium/xenon, uranium/krypton dating, 813
 Urea, 1990, 1998, 2005

V

Vacancy cascade, 1341
 Van de Graaff accelerator, 2342
 van der Waals force, 232
 Van Hove correlation function, 1523, 1524
 Vapor pressure curve, 933
 Vapor pressure isotope effects, 708
 Vascular recirculation, 1955
 VASSILLISSA, 1016
 Velocity calibration, 1428, 1429
 Velocity filter SHIP, 894
 Velocity selector, 1545, 1549
 Ventricular function, 1955, 1958
 Vibrational density of states, of Fe-57 in Al, 1457
 Vitamins, 2110–2112
 Vittrification, 2802, 2813, 2814, 2824
 Voigt function, 1425
 Volatile compounds, 2430, 2439–2446, 2448–2449, 2451, 2452
 Volatility, 2378, 2440, 2446–2449, 2452, 2453
 Volcanoes, 802
 Volume energy, 232, 233
 VPIE, 708

W

¹⁷⁸W, 1944, 1955–1958
¹⁸⁸W, 1864, 1889, 1896, 1897, 1936, 1944, 1957, 1959, 1962–1964

Walden inversion, 1782
 Warman–Asmus–Schuler equation, 1277
 Water calorimeter, 2309–2312
 Water clean-up, 2425
 Water-moderated reactors, 2621, 2630, 2633, 2640, 2873
 Water radiolysis, 1306, 1310, 1321, 1326
 Water targets, 1910, 1911, 1914, 1917, 1918
 Watertightness, 1791
 Watt's equation, 2624
 Wavelength-dispersive crystal spectrometer, 1710
 WAY 100635, 1981, 1998, 2007, 2106
 Weak bosons, 465–468, 470
 Weak decoupling, 629–632
 Weak freeze-out, 630–632
 Weak interaction, 134–135, 464–470, 625–627, 633, 642
 Weak isospin, 463–466, 469, 472
 Weak plasma coupling, 323
 Weighted least squares method in nuclear spectroscopy, 451–453
 Weinberg angle, 470
 Weizsäcker formula, 51
 Westcott g-factors, 1622, 1799
 White dwarf, 639, 641, 646, 654–656
 Whole-rock dating, 768, 813
 Wideröe structure, 2354
 Wien velocity filter, 2467–2468
 Wiggler, 1742
 Wigner–Eckart theory, 1411
 Wilets–Jean model, 95
 WIMP, 621, 637
 Window method, 1427
 Windscale, 2550
 Wittig reaction, 1986, 1996, 2004
 Wittig reagents, 1986
 WKB approximation, 118, 288
 Woods–Saxon potential, 74, 239, 240, 286, 287
¹⁸⁸W/¹⁸⁸Re generator, 1944, 1957, 1959, 1962–1964
 W-values, 1275

X

X-ray absorption, 1746–1747, 1750, 1755
 X-ray absorption fine structure (XAFS), 818, 858, 861–865
 X-ray absorption near edge structure (XANES), 1742, 1744, 1750, 1756–1758
 X-ray absorption spectroscopy (XAS), 1739, 1742, 1750, 1751, 1756–1758
 X-ray burst, 655–656
 X-ray diffraction (XRD), 1739–1741, 1750, 1756, 1758
 X-ray energies, 510–515
 X-ray fluorescence analysis (XRF), 1657, 1707, 1737–1758
 X-ray fluorescence microtomography (XFCT), 1739, 1750–1758

X-ray imaging, 1755
X-ray intensities, 510–515
X-ray photoelectron spectroscopy (XPS), 1376,
1738, 1745
X-ray scattering, 1518, 1519, 1525, 1526, 1537, 1662
X-ray standards, 2566

Y

⁸⁶Y, 1905, 1919, 1924, 1928, 1931, 2145, 2149
⁹⁰Y, 1859, 1864, 1871, 1889, 1919, 1924, 1928, 1943, 1947,
1959–1962, 2144–2151, 2158, 2169, 2181, 2182, 2186,
2187, 2196–2199
Yellow cake, 2422, 2554

Yield curves, 244, 248, 250
Yield purity, 1911, 1914, 1924

Z

Zeeman effect, 241
Zeolite, 1483, 1530
Zero-point energy approximation, 710
Zevalin, 1959, 2151
Zirconium, 2419, 2423, 2442, 2548, 2639–2643, 2724,
2737, 2824
⁶²Zn, 1919, 1936, 1943, 1945, 1950, 2145
Zp-model, 266–268
z-scores, 1607
