The reported incidence of amphotericin B–induced AKI varies widely in the literature, from about 30% to as high as 80% of patients treated with the conventional desoxycholate formulation.[29] Nephrotoxicity is due to renal arterial vasoconstriction and distal renal tubule cell damage. Risk factors for development of AKI include high daily dosage, large cumulative dose (greater than 2 to 3 g), preexisting kidney dysfunction, dehydration, and concomitant use of other nephrotoxic drugs. Tubular abnormalities manifesting as hypomagnesemia and hypokalemia often occur within the first 2 weeks of treatment, followed by the overt development of AKI.

Three lipid-based formulations of amphotericin B have been developed in an attempt to improve efficacy and limit toxicity, particularly nephrotoxicity: amphotericin B lipid complex, amphotericin B colloidal dispersion, and liposomal amphotericin B. The range of nephrotoxicity reported is 15% to 25% for

these formulations. The mechanism for decreased nephrotoxicity has not been completely elucidated, but it is thought to be due to preferential delivery of amphotericin B to the site of infection, with less affinity for the kidney.[31] Costs for liposomal formulations are significantly higher than for the conventional formulation; thus, lipid-based formulations are typically recommended for individuals with risk factors for AKI. Administration of IV normal saline may also attenuate nephrotoxicity associated with amphotericin B.

Whether there are significant differences in nephrotoxicity between the three lipid-based formulations remains unclear. In a recent meta-analysis of eight studies evaluating the nephrotoxicity of liposomal amphotericin B compared with amphotericin B lipid complex, nephrotoxicity was generally similar.[32] However, large prospective studies comparing the incidence of nephrotoxicity among liposomal formulations are needed to definitively ascertain differences in nephrotoxicity.

### ▶ Radiocontrast Agents

Radiocontrast agents are administered during radiologic studies and are associated with a well-documented risk of contrast-induced AKI (CI-AKI). Although definitions have been variable in the literature, CI-AKI is frequently defined as a rise in SCr of at least 0.5 mg/dL (44 µmol/L) or a 25% increase in Scr within 48 hours of contrast administration. Patients at risk for developing CI-AKI include patients with a GFR less than 60 mL/min (1.0 mL/s), diabetes, dehydration, age more than 65 years, concomitant nephrotoxic drug administration, and higher dose of contrast dye.[33] The risk increases as GFR decreases and patients with CKD and another comorbidity (eg, diabetes or dehydration) are at a significantly higher risk.

Contrast agents are water soluble, triiodinated, benzoic acid salts. The mechanism of nephrotoxicity is not fully understood; however, direct tubular toxicity, renal ischemia, and tubular obstruction have been implicated.[34] Diatrizoate and metrizoate are ionic, high osmolar contrast agents. Iohexol, iopamidol, ioversol, and iopromide are nonionic, low osmolar agents. The incidence of nephrotoxicity with ionic and nonionic agents is similar in patients at low risk for developing AKI; however, in high-risk patients, nephrotoxicity is significantly greater when high ionic, high osmolar contrast agents are used. The cost of nonionic agents is approximately 10-fold higher, which may limit their routine use to high risk patients.

Therapeutic measures to decrease the incidence of CI-AKI include extracellular volume expansion, limiting the amount of contrast administered, and use of nonionic contrast agents. Treatment with oral acetylcysteine has produced mixed results. Theophylline, fenoldopam, loop diuretics, mannitol, dopamine, and calcium antagonists have no effect or may worsen AKI. The antioxidant ascorbic acid has produced variable results and is not likely to have a beneficial effect.[35]

The most effective therapeutic maneuver to decrease the incidence of CI-AKI is extracellular volume expansion.[36] Either isotonic sodium chloride or sodium bicarbonate may attenuate the intrarenal and direct tubulotoxic effects, and dilute the contrast agent in the kidney tubules. Sodium bicarbonate may have the added benefit of alkalinizing renal tubule fluid, which is thought to reduce the formation of oxygen-free radicals. There is no standard dosage regimen for either fluid. A common regimen is IV isotonic sodium chloride (1 mL/kg of body weight/hour) administered for 12 hours before and 12 hours after the procedure. Urine output of more than 150 mL/hour has been associated

with a reduced incidence of AKI.[37] Sodium bicarbonate at a rate of 3 mL/kg/hour (154 mEq/L [154 mmol/L]) for 1 hour before the procedure, and 1 mL/kg/hour for 6 hours postcontrast has been administered.[38] Although some studies comparing sodium chloride to sodium bicarbonate have demonstrated a lower incidence of CI-AKI with sodium bicarbonate,[39] others have not.[40] The recommendation of the KDIGO Clinical Practice Guidelines workgroup is that either agent can be selected until more consistent benefits are realized.[2] Fluid should be administered cautiously to patients with CHF, left ventricular dysfunction, and significant renal dysfunction.

Because production of reactive oxygen species has been implicated in the pathophysiology of CI-AKI, prophylactic administration of the antioxidant acetylcysteine has been investigated. A plethora of studies evaluating the efficacy of oral acetylcysteine have been conducted with mixed results; 7 of 11 meta-analyses indicates a benefit of acetylcysteine in CI-AKI.[41] The studies were varied in terms of study population, sample size, definition of contrast nephropathy, type of contrast agent used, hydration, and formulation and dosage of acetylcysteine administered, thus making collective interpretation of the results difficult. Acetylcysteine is routinely used in many hospitals due to its low cost and safe side-effect profile at low oral doses, although data are not conclusive that it prevents development of AKI or alters patient outcomes such as mortality, need for dialysis, and length of hospitalization.

Doses of acetylcysteine in clinical studies ranged from 600 to 1200 mg orally every 12 hours for 2 days, with the first one or two doses administered prior to the contrast procedure. The KDIGO Clinical Practice Guidelines suggest that oral acetylcysteine can be used in combination with IV fluids in patients at risk for CI-AKI.[5(2)] It is not considered a replacement for adequate hydration, which remains the standard of care for prevention of CI-AKI.

### ▶ Cyclosporine and Tacrolimus

The calcineurin inhibitors cyclosporine and tacrolimus are administered as part of immunosuppressive regimens in kidney, liver, heart, lung, and bone marrow transplant recipients. They are also used in autoimmune disorders such as psoriasis and multiple sclerosis. The pathophysiologic mechanism for AKI is renal vascular vasoconstriction.[42] It often occurs within the first 6 to 12 months of treatment and can be reversible with dose reduction or drug discontinuation. Risk factors include high dose, elevated trough blood concentrations, increased age, and concomitant therapy with other nephrotoxic drugs.[42] Cyclosporine and tacrolimus are extensively metabolized by the liver through the cytochrome P450 3A4 pathway; drugs that inhibit their metabolism (eg, erythromycin, clarithromycin, fluconazole, ketoconazole, verapamil, diltiazem, nicardipine) can increase plasma concentrations of cyclosporine and tacrolimus and precipitate AKI.

Because AKI is dose dependent, careful monitoring of cyclosporine or tacrolimus trough concentrations can minimize its occurrence; however, AKI can still occur with normal or low blood concentrations. In addition, there is some evidence that calcium channel blockers have a renoprotective effect through dilation of the afferent arterioles and are often used preferentially as antihypertensive agents in kidney transplant recipients. However, the dosage of calcineurin inhibitors would need to be reduced to avoid high plasma concentrations.

It is often difficult to differentiate AKI from acute rejection in the kidney transplant recipient because both conditions may present with similar symptoms and physical examination findings. However, fever and graft tenderness are more likely to occur with rejection, whereas neurotoxicity is more likely to occur with cyclosporine or tacrolimus toxicity. Kidney biopsy is often needed to confirm the diagnosis of rejection.

#### ▶ ACE Inhibitors and ARBs

In instances of decreased renal blood flow (eg, kidney disease, renal artery stenosis), production of angiotensin II increases, resulting in efferent arteriole vasoconstriction and maintenance of glomerular capillary pressure and GFR. ACE inhibitors and ARBs decrease angiotensin II synthesis, thereby dilating efferent arterioles and decreasing glomerular capillary pressure and GFR.[30]

When initiating therapy with an ACE inhibitor or ARB, a modest increase in SCr should be anticipated within the first week of starting therapy.[32(30)] However, large increases (greater than 30% increase in SCr above baseline) that do not plateau after several weeks of therapy suggest AKI, and the drug should be discontinued.[30] Risk factors for developing AKI are preexisting renal dysfunction, severe atherosclerotic renal artery stenosis, volume depletion, and severe CHF. Discontinuation of the drug usually results in the return of renal function to baseline. Initiating therapy with low doses of a short-acting agent such as captopril is recommended for patients at risk of developing AKI. If tolerated, patients can later be converted to a longer-acting agent.

#### ▶ Nonsteroidal Anti-Inflammatory Drugs

NSAIDs (eg, ibuprofen, naproxen, sulindac) can cause prerenal AKI through inhibition of prostaglandin-mediated renal vasodilation. Risk factors are similar to those of ACE inhibitors and ARBs. Additional risk factors include hepatic disease with ascites, systemic lupus erythematosus, and advanced age. Concurrent use of NSAIDS in patients on diuretics and ACE inhibitors or ARBs result in an increased risk of AKI, particularly within the first 30 days of coadministration.[43]

The onset of AKI is often within days of initiating therapy, and patients typically present with oliguria. It is usually reversible with drug discontinuation. Agents that preferentially inhibit cyclooxygenase-2 pose a similar risk as traditional nonselective NSAIDs.[30]

#### ▶ Other Drugs

Other drugs commonly implicated in causing AKI include acyclovir, adefovir, carboplatin, cidofovir, cisplatin, foscarnet, ganciclovir, indinavir, methotrexate, pentamidine, ritonavir, sulfinpyrazone, and tenofovir.[44]

## OUTCOME EVALUATION

Goals of therapy are to maintain a state of euvolemia with good urine output (at least 1 mL/kg/hour), to return SCr to baseline, and to correct electrolyte and acid-base abnormalities. In addition, appropriate drug dosages based on kidney function and avoidance of nephrotoxic drugs are goals of therapy. Assess vital signs, weight, fluid intake, urine output, BUN, creatinine, and electrolytes daily in unstable patients.

## DRUG DOSING CONSIDERATIONS IN AKI

The most accurate reflection of overall kidney function is GFR. Defined as the volume of plasma filtered across the glomerulus per unit time, GFR correlates with the excretory, endocrine and metabolic functions of the kidney. Creatinine clearance (CrCl) is routinely used as an estimate of GFR in patients with normal kidney function or with CKD for purposes of drug dosing; however, equations to estimate CrCl (eg, Cockcroft and Gault) and GFR (eg, Modification of Diet in Renal Disease [MDRD]) are not accurate or reliable in AKI, particularly in critically ill patients.[45] They tend to overestimate CrCl and GFR when kidney function is worsening.[46] Use of Cockcroft–Gault equation should be limited to instances when SCr is at steady state, with no more than a 10 to 15% change in SCr within 24 hours.

In instances where kidney function is fluctuating, several equations (Jelliffe, Brater, Chiou) have been developed to assess unstable kidney function. These equations estimate CrCl by considering the change in SCr over a specified time period (Table 25–2, Jelliffe equation.)[47] Although they are more mathematically difficult to calculate, they take into consideration a change in SCr compared with an equation that only includes a single creatinine concentration. It should be noted that these methods have not been validated, and drug dosage adjustments based on CrCl estimates from these formulas in patients with AKI have not been evaluated.

Determining the optimal dose of drugs in AKI is challenging. A variety of factors influence drug dosing, such as (1) alterations in drug pharmacokinetics that occur during AKI, (2) difficulties in accurately quantifying kidney function in AKI, (3) the influence of intermittent or continuous RRT on drug clearance, and (4) challenges in interpreting information from the literature and applying it to a specific patient. Table 25–3 provides a more complete list of different considerations when dosing medications in patients with AKI.

For drugs with a narrow therapeutic window, serum drug concentration monitoring may be available to guide drug dosing. If therapeutic drug monitoring is not available, dosing based on an estimated CrCl is recommended, with frequent reassessment of kidney function and evaluation of the patient's status to assess efficacy and adverse effects of therapy. Selection of a drug with hepatic elimination rather than renal excretion is a reasonable alternative, if possible.

In critically ill septic patients, interpatient variability in pharmacokinetics renders dosing of antibiotics difficult. Underdosing a critically ill patient may be a greater risk than potential adverse effects attributed to higher plasma concentrations, particularly with antibiotics such as β-lactams, quinolones, and carbepenems, where therapeutic drug monitoring is not available.[48] Thus, the risk of undertreatment of the infection needs to be balanced with the risk of adverse effects from the antibiotic.

### Patient Encounter, Part 3

The patient is admitted to the hospital for treatment of AKI. Based on the information available, create a care plan for this patient's AKI and provide overall recommendations for her drug therapy. The plan should include (a) a statement of the drug related needs and/or problems, (b) a patient-specific detailed therapeutic plan, and (c) monitoring parameters to assess efficacy and safety.

CrCl, creatinine clearance. For conversion of mg/dL to µmol/L creatinine multiply by 88.4.

## DRUG DOSING CONSIDERATIONS IN DIALYSIS

Dialysis membranes are classified as low flux or high flux. Low flux membranes are typically made from cellulose or cuprophane and have a relatively small pore size, whereas high flux membranes, made of synthetic substances such as polysulfone and polyamide, have a pore size that is considerably larger. Pore size of the dialysis membrane governs drug removal. For low flux membranes, drugs with a molecular weight less than 1000 Da are removed. With high flux membranes that have larger pore sizes, drugs in the range of 10,000 to 20,000 Da can be removed by diffusion of the molecules from the blood and into the dialysis solution. With hemofiltration, larger molecules are removed up to the molecular weight cutoff of the hemofilters, usually about 40,000 Da.

In additional to molecular weight, three additional characteristics of a drug govern removal during dialysis: percentage of drug eliminated by the kidney, volume of distribution, and protein binding. For example, removal during CRRT is greater when renal clearance accounts for 30% or more of total body clearance of the drug, volume of distribution is less than 1 L/kg, and protein binding is less than 50% because dialysis cannot remove protein-bound drugs.[49] Other factors that affect drug clearance include type of RRT (ie, IHD, CVVH, CVVHD); characteristics of the dialysis membrane; and blood, ultrafiltrate, and dialysis flow rates. In general, drug removal is greatest with CVVHDF, followed by CVVH and then IHD.[50]

Drug information references provide drug dosing recommendations in IHD and CRRT; however, they must be interpreted cautiously due to the variability in dialysis techniques used.

---

**Table 25–3**

**Drug Dosing Considerations in AKI**

| | |
|---|---|
| Alteration in drug pharmacokinetics | • Increase in volume of distribution due to fluid retention may occur.<br>• Reduction in excretion of both drugs and metabolites eliminated by the kidney.<br>• Nonrenal clearance of some drugs may be reduced. |
| Difficulty in quantifying an accurate assessment of kidney function in AKI | • Cockcroft-Gault and MDRD equations are not meant for AKI population; equations are based on a single SCr.<br>• SCr as a marker for kidney function is influenced by nonrenal factors (such as nutritional status and liver function).<br>• Equations to estimate kidney function in cases of changing kidney function have not been well studied. |
| AKI patients undergoing dialysis | • Different types of dialysis modalities results in differences in drug removal (eg, IHD vs. CRRT).<br>• Differences in intensity of dialysis dose may affect drug removal (eg, length of dialysis treatment, blood and dialysate flow rate).<br>• Populations studied in the literature are likely to be different than the specific patient being treated (eg, different types of dialysis, length of treatment). |
| Textbook dosing and literature recommendations | • Studies in patients with AKI are sparse.<br>• Many drug information recommendations on dosing are based on the manufacturer's original pharmacokinetics information, often in patients with chronic kidney disease.<br>• Most drug dosing guidelines were developed prior to standardization of SCr measurements between laboratory tests; thus today's SCr measurements are 5% to 10% higher than those reported prior to 2010.[49]<br>• There is growing support for incorporation of the MDRD equation in future pharmacokinetic studies and to guide drug dosing, although use of this equation is limited to chronic kidney disease. |

MDRD, Modification of Diet in Renal Disease equation; SCr, serum creatinine.

## The Patient Care Process

### Patient Assessment

- Assess kidney function by evaluating a patient's signs and symptoms, laboratory test results, and urinary indices.
- Obtain a thorough and accurate drug history including the use of nonprescription drugs such as NSAIDs.

### Therapy Evaluation

- Determine if drug therapy may be contributing to AKI. Consider not only drugs that can directly cause AKI (eg, aminoglycosides, amphotericin B, NSAIDs, cyclosporine, tacrolimus, ACE inhibitors, and ARBs) but also drugs that can predispose a patient to nephrotoxicity or prerenal AKI (ie, diuretics and antihypertensive agents).
- Determine if any drugs need to be discontinued, or alternative drugs selected, to prevent worsening of kidney function.
- Determine if any drugs undergo significant kidney elimination or if drugs require specific monitoring in patients with kidney disease.

### Care Plan Development

- Adjust drug dosages based on estimated kidney function or evidence of adverse drug reactions or interactions.
- Provide supportive therapy, including adequate nutrition, correction of electrolyte and acid–base abnormalities (particularly hyperkalemia and metabolic acidosis), fluid management, and correction of any hematologic abnormalities.
- Implement preventative strategies to decrease the risk of AKI, such as administration of saline with contrast dye.

### Follow-Up Evaluation

- Monitor the patient's weight, urine output, electrolytes (such as potassium), and blood pressure to assess efficacy of the diuretic regimen.
- Monitor SCr to evaluate whether kidney function is worsening or improving.

## Abbreviations Introduced In This Chapter

| | |
|---|---|
| ACE | Angiotensin-converting enzyme |
| AKI | Acute kidney injury |
| AKIN | Acute Kidney Injury Network |
| ARB | Angiotensin receptor blocker |
| ARF | Acute renal failure |
| ATN | Acute tubular necrosis |
| BUN | Blood urea nitrogen |
| CHF | Congestive heart failure |
| CI-AKI | Contrast-induced acute kidney injury |
| CKD | Chronic kidney disease |
| CrCl | Creatinine clearance |
| CRRT | Continuous renal replacement therapy |
| CVVH | Continuous venovenous hemofiltration |
| CVVHD | Continuous venovenous hemodialysis |
| CVVHDF | Continuous venovenous hemodiafiltration |
| FENa | Fractional excretion of sodium |

| | |
|---|---|
| GFR | Glomerular filtration rate |
| IHD | Intermittent hemodialysis |
| KDIGO | Kidney Disease: Improving Global Outcomes |
| JVD | Jugular venous distention |
| LDD | Low-dose dopamine |
| MDRD | Modification of Diet in Renal Disease |
| NSAIDs | Nonsteroidal anti-inflammatory drugs |
| RIFLE | Risk, Injury, Failure, Loss, End stage |
| RRT | Renal replacement therapy |
| SCr | Serum creatinine |

# 26 Chronic and End-Stage Renal Disease

Kristine S. Schonder

## LEARNING OBJECTIVES

● **Upon completion of the chapter, the reader will be able to:**

1. List the risk factors for development and progression of chronic kidney disease (CKD).

2. Explain the mechanisms associated with progression of CKD.

3. Outline the desired outcomes for treatment of CKD.

4. Develop a therapeutic approach to slow progression of CKD, including lifestyle modifications and pharmacologic therapies.

5. Identify specific consequences associated with CKD.

6. Design an appropriate therapeutic approach for specific consequences associated with CKD.

7. Recommend an appropriate monitoring plan to assess the effectiveness of pharmacotherapy for CKD and specific consequences.

8. Educate patients with CKD about the disease state, the specific consequences, lifestyle modifications, and pharmacologic therapies used for treatment of CKD.

## INTRODUCTION

The kidney is made up of approximately 2 million **nephrons** that are responsible for filtering, reabsorbing, and excreting solutes and water. The kidney has three primary functions: excretory (excrete fluid, electrolytes, and solutes); metabolic (metabolize vitamin D and some drugs, such as insulin and some β-lactams); and endocrine (produce erythropoietin). As the number of functioning nephrons declines, the primary functions of the kidney that are affected include:

- Production and secretion of **erythropoietin**
- Activation of vitamin D
- Regulation of fluid and electrolyte balance
- Regulation of acid–base balance

**Chronic kidney disease** (CKD) is defined as abnormalities in the structure or function of the kidney, present for 3 months or more, with implications for health.[1] Markers of structural abnormalities include **albuminuria** (30 mg/24 hours or more or an albumin: **creatinine** ratio (ACR) of more than 30 mg/g [or 3.5 mg/mmol for female and 2.5 mg/mmol for male but varies between different guidelines and location]); hematuria or casts in urine sediment; electrolyte and other abnormalities caused by renal tubular disorders; abnormalities detected by histology or imaging; or history of kidney transplantation. Functional abnormalities are indicated by a decline in **glomerular filtration rate** (GFR) less than 60 mL/min/1.73m² (0.58 mL/s/m²). Generally, CKD is a progressive decline in kidney function (number of functioning nephrons) that occurs over several months to years. A rapid decline in kidney function over days to weeks is known as acute kidney injury (AKI), which is discussed in Chapter 25.

Because the decline in kidney function in CKD is often irreversible, treatment of CKD is aimed at slowing the progression to end-stage kidney disease (ESKD).

## EPIDEMIOLOGY AND ETIOLOGY

**KEY CONCEPT** *The Kidney Disease: Improving Global Outcomes (KDIGO) CKD Work Group developed a classification system for CKD.[1] The staging system defines the stages of CKD based on cause, GFR category and albumin category, as outlined in Tables 26–1 and 26–2.* The previous classification system for CKD was developed by the National Kidney Foundation's Kidney Disease Outcomes Quality Initiative (KDOQI), which used only the GFR to determine the stage of CKD.[3] Most of the literature and guidelines refer to the KDOQI staging system. Table 26–1 correlates the KDIGO and KDOQI systems and both will be referred to throughout the chapter.

The United States Renal Data System (USRDS), using data from the National Health and Nutrition Examination Survey (NHANES), estimates the prevalence of CKD in the United States is 13.6%, corresponding to nearly 44 million people.[3] CKD is more common in people older than 60 years and African Americans. Diabetes increases the risk of developing CKD by more than 3-fold and hypertension increases the risk more than twice than those who do not have either disease.[3]

**KEY CONCEPT** *CKD is a progressive disease that eventually leads to ESKD.* The prevalence of ESKD has increased nearly 11-fold since 1980 to almost 634,000 people in 2012 with over 114,000 new cases of ESKD diagnosed in 2014.[3] The prevalence of ESKD is related to ethnicity, affecting 3.5 times more African Americans, 1.6 times more Native Americans, and 1.5 more Hispanics as whites.[3]

**Table 26–1**

**GFR Categories in CKD**

| GFR Category | GFR (mL/min/1.73 m²)[1] | Terms | KDOQI Category[2] |
|---|---|---|---|
| G1 | ≥ 90 | Normal or high (with kidney damage) | Stage 1 |
| G2 | 60–89 | Mildly decreased (with kidney damage) | Stage 2 |
| G3a | 45–59 | Mildly to moderately decreased | Stage 3 |
| G3b | 30–44 | Moderately to severely decreased | Stage 3 |
| G4 | 15–29 | Severely decreased | Stage 4 |
| G5 | < 15 | Kidney failure | Stage 5 (ESRD, if requiring dialysis) |

[1]Multiply by 0.00963 to convert to units of mL/s/m².

CKD, chronic kidney disease; GFR, glomerular filtration rate.

Adapted from Table 29–1 in Chapter 29: Chronic Kidney Disease. In Pharmacotherapy: A Pathophysiologic Approach, 9th Ed. 2014. McGraw-Hill.

Identifying risk factors for CKD is difficult because CKD progresses slowly and is often not diagnosed until late in the disease. Risk factors identified for CKD are classified into three categories (see Table 26–3):

- **Susceptibility factors** are associated with an increased risk of developing CKD but are not directly proven to cause CKD. These factors are generally not modifiable by pharmacologic therapy or lifestyle modifications.
- **Initiation factors** directly cause CKD. These factors are modifiable by pharmacologic therapy.
- **Progression factors** result in a faster decline in kidney function and cause worsening of CKD. These factors may also be modified by pharmacologic therapy or lifestyle modifications to slow the progression of CKD.

## Susceptibility Factors

Susceptibility factors can be used to identify targets for CKD screening programs. For example, older patients, those with low kidney mass or birth weight, and those with a family history of kidney disease should be routinely screened for CKD. Minority and low socioeconomic communities may be targets for more widespread CKD screening programs. Other factors, such as hyperlipidemia, are not directly proven to cause CKD but can be modified by drug therapies.

### ▶ Hyperlipidemia

Patients with CKD have a higher prevalence of dyslipidemia compared with the general population. More than 81% of patients with a GFR less than 60 mL/min/1.73 m² (0.58 mL/s/m²) had hyperlipidemia.[3] The dyslipidemia in CKD is manifested primarily as elevated triglycerides and lipoprotein(a) levels, and decreased high-density lipoprotein cholesterol (HDL-C) levels. Total cholesterol and low-density lipoprotein cholesterol (LDL-C) levels generally remain within normal limits.[4] Kidney disease alters lipid metabolism, allowing lipoproteins to remain in circulation longer.[4] In contrast, patients with nephrotic syndrome, characterized by urine protein rates that exceed 3 g/24 hours, often have elevated total cholesterol and LDL-C. Nephrotic syndrome may be associated with increased hepatic lipid production and decreased LDL-receptor activity.[5] Dyslipidemia can promote kidney injury and subsequent progression of CKD. Endothelial dysfunction results from inflammation and monocyte activation, whereas deposition of lipids results in glomerulosclerosis and glomerular mesangium dysfunction.[4]

## Initiation Factors

The three most common causes of CKD in the United States are diabetes mellitus (DM), hypertension, and **glomerulonephritis**. Together these account for more than 75% of CKD cases (37% for diabetes, 25% for hypertension, and 14% for glomerulonephritis).[3] These are discussed in further detail in the following sections. Other causes of CKD include polycystic kidney disease, Wegener granulomatosis, vascular diseases, human immunodeficiency virus (HIV) nephropathy, and AKI.

### ▶ Diabetes

DM is the most common cause of CKD, causing 37% of all ESKD, which is an increase from 15% in 1995.[3] The risk of developing diabetic kidney disease (DKD) associated with DM

**Table 26–2**

**Albumin Categories in CKD**

| Category | AER (mg/24 hours) | ACR (Approximate Equivalent) (mg/mmol)[a] | (mg/g) | Terms |
|---|---|---|---|---|
| A1 | < 30 | < 3.4 | < 30 | Normal to mildly decreased |
| A2 | 30–300 | 3.4–34 | 30–300 | Moderately increased |
| A3 | > 300 | > 34 | > 300 | Severely increased[b] |

ACR, albumin-to-creatinine ratio; AER, albumin excretion rate; CKD, chronic kidney disease.

[a]Actual cutoffs vary between different guidelines and locations. Sex-specific cutoffs are often used with lower cutoffs for males compared with females.

[b]Including nephrotic syndrome (albumin excretion usually > 2200 mg/24 hours [ACR > 2200 mg/g; > 250 mg/mmol]).

| Table 26–3 |
| --- |

**Risk Factors Associated with CKD**

**Susceptibility**
- Advanced age
- Reduced kidney mass
- Low birth weight
- Racial/ethnic minority
- Family history of kidney disease
- Low income or education
- Systemic inflammation
- Dyslipidemia

**Initiation**
- Diabetes mellitus
- Hypertension
- Autoimmune disease
- Polycystic kidney disease
- Drug toxicity
- Urinary tract abnormalities (infections, obstruction, stones)

**Progression**
- Hyperglycemia: Poor blood glucose control (in patients with diabetes)
- Hypertension: Elevated blood pressure
- Proteinuria
- Tobacco smoking

is closely linked to hyperglycemia and is similar for both type 1 and type 2. The prevalence of albuminuria is 25% to 40% in patients with type 1 DM after 15 to 25 years[6] and 43% in patients with type 2 DM.[7]

#### ▶ Hypertension

The second most common cause of CKD is hypertension.[3] It is more difficult to determine the true risk of developing CKD in patients with hypertension because the two are so closely linked, with CKD also being a cause of hypertension. The prevalence of hypertension is correlated with the degree of kidney dysfunction (decreased GFR) with 36% of patients with CKD Stage 1, 48% of patients with CKD Stage 2, and 85% of patients with CKD Stage 3 presenting with hypertension.[8] The risk of developing ESKD increases with the degree of hypertension and is linked to both systolic and diastolic blood pressure.[8]

#### ▶ Glomerulonephritis

The term *glomerulonephritis* includes many specific diseases that can affect glomerular function. These include such diseases as IgA nephropathy and glomerulonephritis associated with systemic lupus erythematosus and streptococcal disease, among many others. The etiologic and pathophysiologic features of glomerular diseases vary with the specific disease, making it difficult to extrapolate the risk for progression of CKD in patients affected by glomerular diseases. Certain glomerular diseases are known to rapidly progress to ESKD; others progress more slowly or may be reversible.

### Progression Factors

Progression factors can be used as predictors of CKD. The most important predictors of CKD include proteinuria, elevated blood pressure, hyperglycemia, and AKI. Tobacco smoking also plays a role in progression of CKD.

#### ▶ Proteinuria

The presence of protein in the urine is a marker of glomerular dysfunction and some tubulointerstitial diseases. The degree of proteinuria correlates with the risk for progression of CKD.[9] The effects of proteinuria appear to be worse with milder stages of CKD. Compared with patients with no proteinuria, proteinuric patients with Stage 3 CKD are 15 times more likely to double serum creatinine; patients with Stage 4 CKD are 8 times more likely to double serum creatinine.[9] The mechanisms by which proteinuria potentiates CKD are discussed later. Albuminuria (greater than 30 mg albumin excreted per day) is also linked with vascular injury and increased cardiovascular mortality.[7]

#### ▶ Elevated Blood Pressure

Systemic blood pressure correlates with glomerular pressure, and elevations in both systemic blood pressure and glomerular pressure contribute to glomerular damage. The rate of GFR decline is related to elevated systolic blood pressure and mean arterial pressure. The decline in GFR is estimated to be 14 mL/min/year (0.23 mL/s/year) in patients with diabetes with a sustained systolic blood pressure of 180 mm Hg. Conversely, the decline in GFR decreases to 2 mL/min/y (0.03 mL/s/year) with a systolic blood pressure of 135 mm Hg.[10]

#### ▶ Elevated Blood Glucose

The reaction between glucose and protein in the blood produces advanced glycation end products (AGEs), which are metabolized in the proximal tubules. Hyperglycemia increases the synthesis of AGEs, which affects glomerular, tubular, and vascular function in the kidney. AGEs are known to affect podocyte activity, the epithelial cells responsible for filtering blood in the glomerulus, which contributes to proteinuria, and, in turn, damages tubules.[11]

#### ▶ Acute Kidney Injury

Nephron damage that results from AKI increases the risk of developing CKD, even if renal function recovers.[12] The most predictive risk factor of whether patients will develop CKD is the severity of AKI. Severe AKI is associated with a 28-fold increased risk of developing CKD, but even mild AKI is associated with a 2-fold increased risk. Older age also increases the risk of developing CKD after AKI. The cause of AKI may also affect the risk of CKD.[12]

### PATHOPHYSIOLOGY

A number of factors can cause initial damage to the kidney. The resulting sequelae, however, follow a common pathway that promotes progression of CKD and results in irreversible damage leading to ESKD (Figure 26–1).

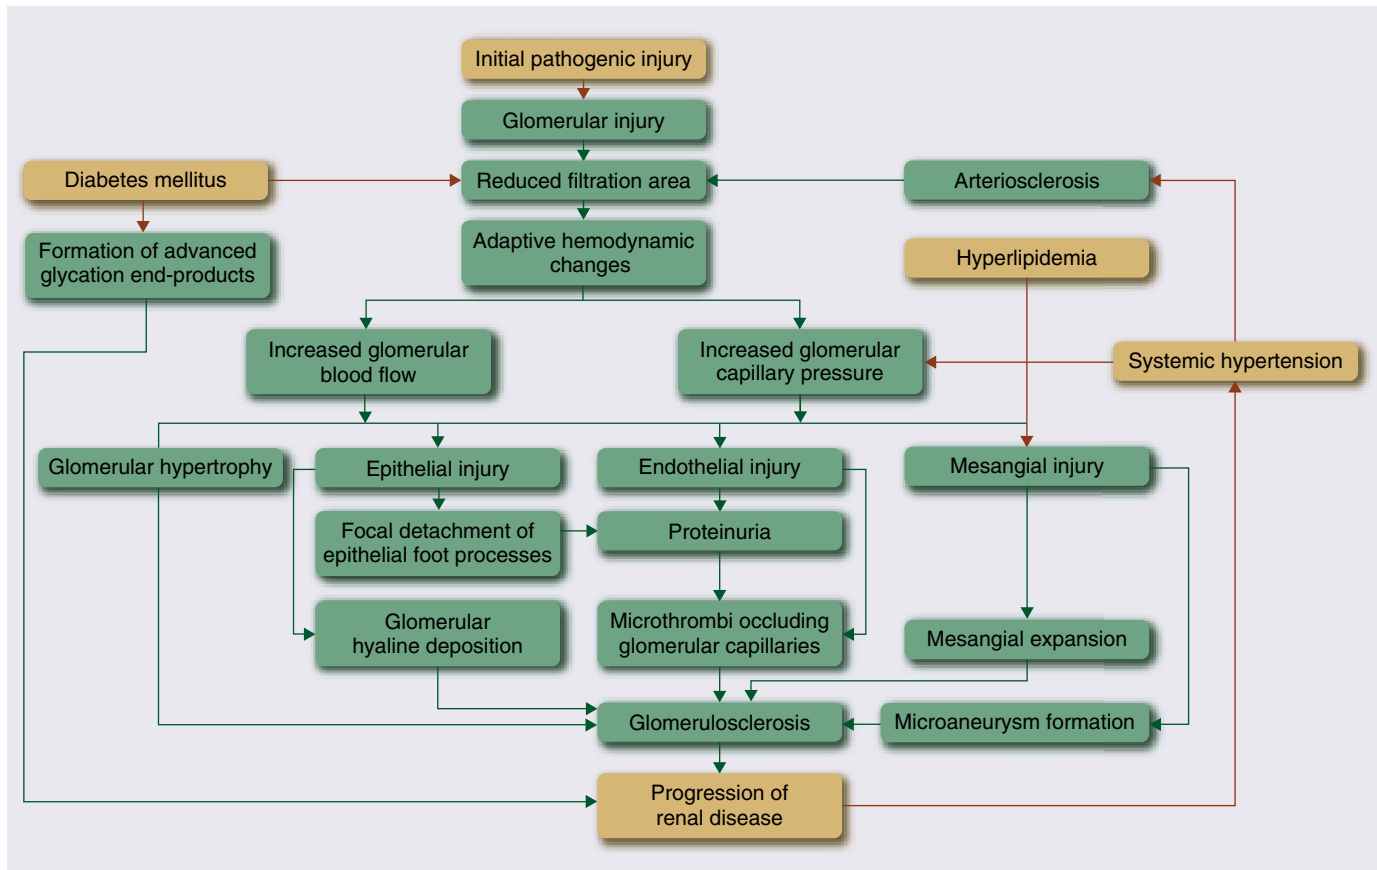
Regardless of the initial cause of kidney damage, the result is a decrease in the number of functioning nephrons. The remaining nephrons hypertrophy to increase glomerular filtration and tubular function, both reabsorption and secretion, in an attempt to compensate for the loss of kidney function. Initially, these adaptive changes preserve many of the clinical parameters of kidney function, including creatinine and electrolyte excretion. However, as time progresses, angiotensin II is required to maintain the hyperfiltration state of the functioning nephrons. Angiotensin II is a potent vasoconstrictor of both the afferent and efferent arterioles but has a preferential effect to constrict the efferent arteriole, thereby increasing the pressure in the glomerular capillaries. Increased glomerular capillary pressure expands the pores in the glomerular basement membrane, altering the


**FIGURE 26-1.** Proposed mechanisms for progression of kidney disease. (From Hudson JQ, Wazny LD. Chronic kidney disease. In: DiPiro JT, Talbert RL, Yee GC, et al., eds. Pharmacotherapy: A Pathophysiologic Approach, 9th ed. New York, NY: McGraw-Hill Education, 2014:636, with permission.)

size-selective barrier and allowing proteins to be filtered through the glomerulus.[13]

Proteinuria increases nephron loss through various complex mechanisms. Filtered proteins are reabsorbed in the renal tubules, which activates the tubular cells to produce inflammatory and vasoactive cytokines and triggers complement activation. These cytokines cause interstitial damage and scarring in the renal tubules, leading to damage and loss of more nephrons. Ultimately, the process leads to progressive loss of nephrons to the point where the number of remaining functioning nephrons is too small to maintain clinical stability, and kidney function declines.

## ASSESSMENT

Because CKD often presents without symptoms, assessment for CKD relies on appropriate screening strategies in all patients with risk factors for developing CKD. Evaluation for CKD and the subsequent treatment strategies depend on the diagnosis, comorbid conditions, severity and complications of disease, and risk factors for the progression of CKD. **KEY CONCEPT** *Early treatment of CKD and the associated complications of CKD are the most important factors to decrease morbidity and mortality associated with CKD.* Screening for CKD should be performed in all people with an increased risk for developing CKD, including patients with DM, hypertension, genitourinary abnormalities, autoimmune disease, increased age, a family history of kidney disease, or following

AKI. Assessment for CKD includes measurement of SCr, urinalysis, blood pressure, serum electrolytes, and/or imaging studies.

A key part of CKD assessment is analysis for proteinuria, which is the primary marker of structural kidney damage, even in patients with normal GFR. Protein excretion can be assessed by measuring urine albumin-to-creatinine ration (ACR), urine protein-to-creatinine ratio, or urinalysis with a reagent strip test.[3] A urinary protein excretion of 30 mg/day or more or an ACR or 30mg/g (or 3.5 mg/mmol for female and 2.5 mg/mmol for male but varies between different guidelines and locations) or more on a random untimed urine sample is considered to be significant in the context of CKD.[1] Albuminuria should be assessed with GFR at least annually in people with CKD. Assessment of protein excretion is particularly important in patients with DM, even without CKD. Screening for albumin excretion should be performed 5 years after the diagnosis of type 1 DM and at the time of diagnosis of type 2 DM.[14]

## Complications

**KEY CONCEPT** *The decline in kidney function is associated with a number of complications, which are discussed later in the chapter, including:*

- *Hypertension*
- *Fluid and electrolyte disorders*
- *Anemia*
- *Metabolic bone disease*

## TREATMENT

### Desired Outcomes

The primary goal is to slow and prevent the progression of CKD to prevent a cardiovascular event, CKD complications and the need for kidney replacement therapy. This requires early identification of patients at risk for CKD to initiate interventions early in the course of the disease.

### Nonpharmacologic Therapy

#### ▶ Nutritional Management

Reduction in dietary protein intake has been shown to slow the progression of kidney disease.[15] Protein intake should be lowered to 0.8 g/kg/day in adults with diabetes or people with a GFR less than 30 ml/min/1.73 m$^2$ (0.29 mL/s/m$^2$) who are not on **dialysis**. Protein intake should not exceed 1.3 mg/kg/day in any adult with CKD.[1] However, protein restriction must be balanced with the risk of malnutrition in patients with CKD. In particular, patients on **dialysis** are at risk for nutritional abnormalities, which can lead to increased rates of hospitalization and death.[16] Malnutrition is common in patients with ESKD for various reasons, including decreased appetite, protein catabolism due to protein losses in the urine, and nutrient losses through dialysis. For this reason, patients receiving dialysis should maintain protein intake of 1.2 g/kg/day and maintain a caloric intake of 30 to 35 kcal/kg (125–147 kJ/kg) of ideal body weight.[16]

Limiting salt intake to less than 2 g (90 mmol) of sodium per day (equivalent to 5 g sodium chloride) will help to control blood pressure and reduce water retention in CKD. Patients with CKD should be encouraged to increase physical activity, with a goal of at least 30 minutes five times per week, to achieve a healthy weight, with a goal BMI of 20 to 25.[1]

### Pharmacologic Therapy

#### ▶ CKD with Diabetes

**Figure 26–2** outlines the management of patients with CKD and DM. The target glycated hemoglobin level (HbA1c) should be less than 7.0% (0.07; 53 mmol/mol Hgb) for patients with DM to decrease the incidence of albuminuria in patients with and without documented DKD.[1,14] This generally involves intensive insulin therapy for type 1 DM or insulin-dependent type 2 DM or optimizing doses of oral hypoglycemic agents in patients with non-insulin-dependent type 2 DM. However, glycemic control should be balanced with the risk of hypoglycemia, especially in patients with CKD and DM with comorbidities.[1]

KEY CONCEPT *Angiotensin-converting enzyme inhibitors (ACEI) and angiotensin receptor blockers (ARBs) are the antihypertensive agents of choice in patients with CKD with an albumin excretion rate (AER) of 30 mg/day or more because of their greater effect on lowering proteinuria, compared with other antihypertensive agents.* ACEIs and ARBs should be started at a low dose and

---

## Clinical Presentation and Diagnosis of CKD

### General

The development of CKD is usually subtle in onset, often with no noticeable symptoms.

### Symptoms

Stages 1 and 2 CKD are generally asymptomatic.

Stages 3 and 4 CKD may be associated with minimal symptoms.

Stage 5 CKD can be associated with pruritus, dysgeusia, nausea, vomiting, constipation, muscle pain, fatigue, and bleeding abnormalities.

### Signs

Cardiovascular: Worsening hypertension, edema, dyslipidemia, left ventricular hypertrophy, electrocardiographic changes, and chronic heart failure.

Musculoskeletal: Cramping.

Neuropsychiatric: Depression, anxiety, impaired mental cognition.

Gastrointestinal (GI): Gastroesophageal reflux disease, GI bleeding, and abdominal distention.

Genitourinary: Changes in urine volume and consistency, "foaming" of urine (indicative of proteinuria), and sexual dysfunction.

### Laboratory Tests

Stages 1 and 2 CKD: **Blood urea nitrogen** (BUN) and serum creatinine (SCr) are generally within normal limits, despite mildly decreased GFR.

Stages 3, 4, and 5 CKD: Increased BUN and SCr; decreased GFR.

Advanced stages: Increased potassium, phosphorus, and magnesium; decreased bicarbonate (metabolic acidosis); calcium levels are generally low in earlier stages of CKD and may be elevated in Stage 5 CKD, secondary to the use of calcium-containing phosphate binders.

Decreased albumin, if inadequate nutrition intake in advanced stages.

Decreased red blood cell (RBC) count, hemoglobin (Hgb), and hematocrit (Hct); Decreased iron stores (iron level, total iron binding capacity [TIBC], serum ferritin level, and transferrin saturation [TSat]). Erythropoietin levels are not routinely monitored and are generally normal to low. Urine positive for albumin or protein.

Increased parathyroid hormone (PTH) level; decreased vitamin D levels (Stages 4 or 5 CKD).

Stool may be Hemoccult-positive if GI bleeding occurs from uremia.

### Other Diagnostic Tests

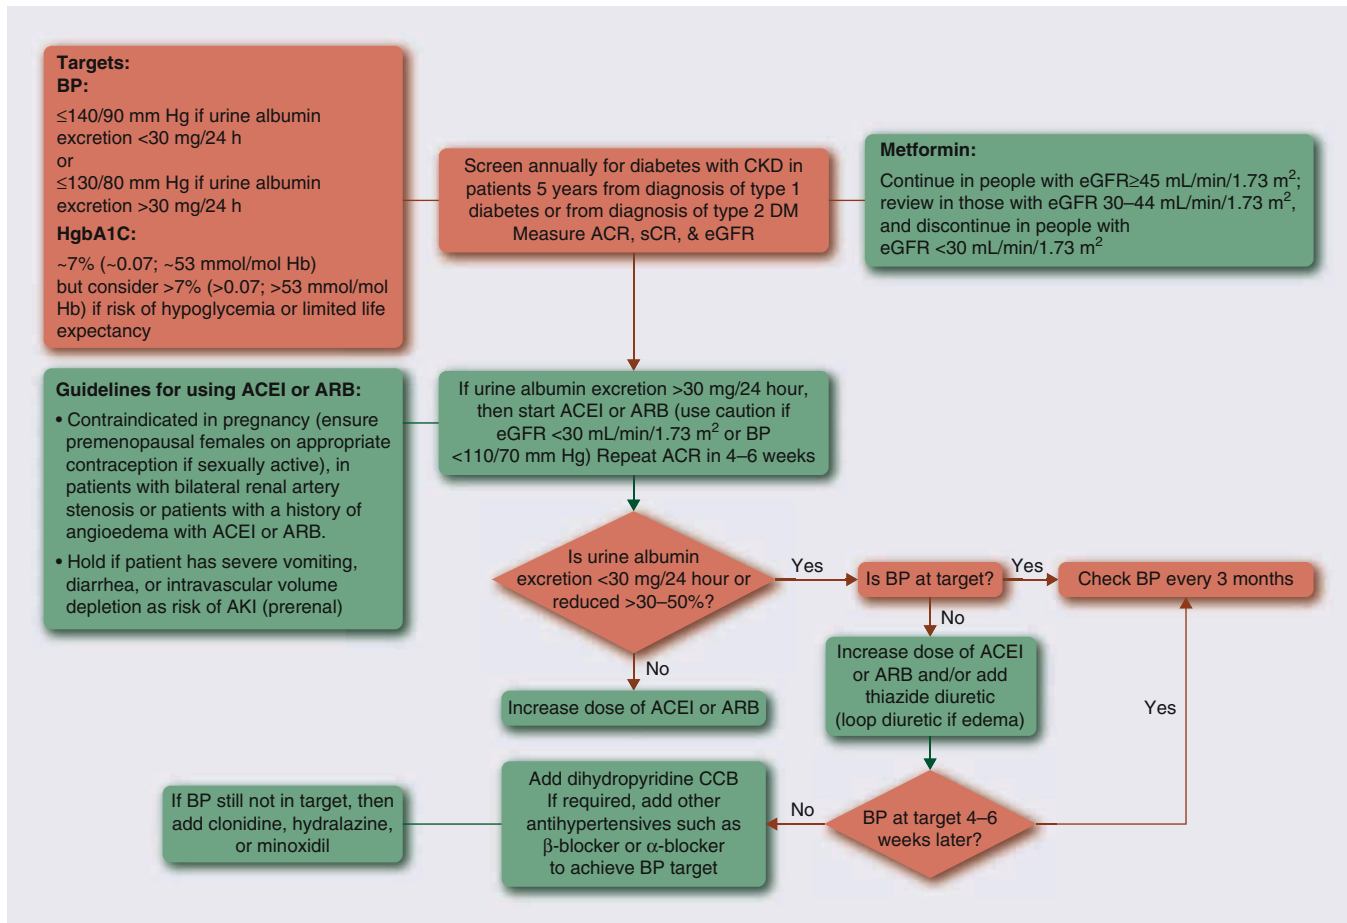
Structural abnormalities of kidney may be present on diagnostic examinations.


**FIGURE 26–2.** Algorithm for management of CKD with DM. Management is based on urine albumin excretion, target blood pressure, and GFR. (ACE-I, angiotensin-converting enzyme inhibitor; ACR, albumin-to-creatinine ratio; ARB, angiotensin receptor blocker; BP, blood pressure; CCB, calcium channel blocker; eGFR, estimated glomerular filtration rate; HgbA$_{1C}$, hemogloblin A$_{1C}$; sCR, serum creatinine.) (From Hudson JQ, Wazny LD. Chronic kidney disease. In: DiPiro JT, Talbert RL, Yee GC, et al., eds. Pharmacotherapy: A Pathophysiologic Approach, 9th ed. New York, NY: McGraw-Hill Education, 2014:642, with permission.)

the dose should be titrated upward slowly to minimize the risk of AKI (see Chapter 25). Ideally, the dose of ACEIs and ARBs should be increased to achieve a 30% to 50% reduction in urinary albumin excretion, but this may be limited by side effects, such as hyperkalemia, in patients with CKD.

▶ *Optimal Blood Pressure Control*

Reductions in blood pressure are associated with a decrease in proteinuria, leading to a decrease in the rate of progression of kidney disease. Figure 26–3 outlines the management of blood pressure in patients with CKD. Blood pressure goals for patients with CKD are dependent on the degree of urinary albumin excretion. The KDIGO guidelines recommend that patients with CKD who have an AER less than 30 mg/day should achieve a blood pressure target of less than or equal to 140/90 mm Hg. If AER is 30 mg/day or greater, the blood pressure goal is less than or equal to 130/80 mm Hg.[17] The first-line antihypertensive agents for patients with an AER of 30 mg/day or more are ACEIs or ARBs, because of their ability to also lower protein excretion.

In patients with Stage 5 CKD who are receiving hemodialysis, cardiovascular mortality is affected by blood pressure both before and after hemodialysis.[18] A systolic blood pressure

greater than 160 mm Hg and diastolic blood pressure greater than 90 mm Hg after hemodialysis are independently associated with an increased risk of cardiovascular mortality (hazard ratio [HR]: 1.2 for each).[18] Similarly, a systolic blood pressure less than 120 mm Hg or diastolic blood pressure less than 60 mm Hg before hemodialysis is associated with a higher risk of cardiovascular mortality (HR: 1.1 and 1.3, respectively [p less than 0.05 for each]); the same systolic or diastolic blood pressure at the end of hemodialysis is associated with a comparable risk (HR 1.1 and 1.2, respectively [p less than 0.05 for each]).[18] However, there are no consensus guidelines on the optimal blood pressure goals before or after hemodialysis. Newer evidence suggests that blood pressure on nonhemodialysis days may be a more appropriate measure, and correlates better with cardiovascular outcomes.[19]

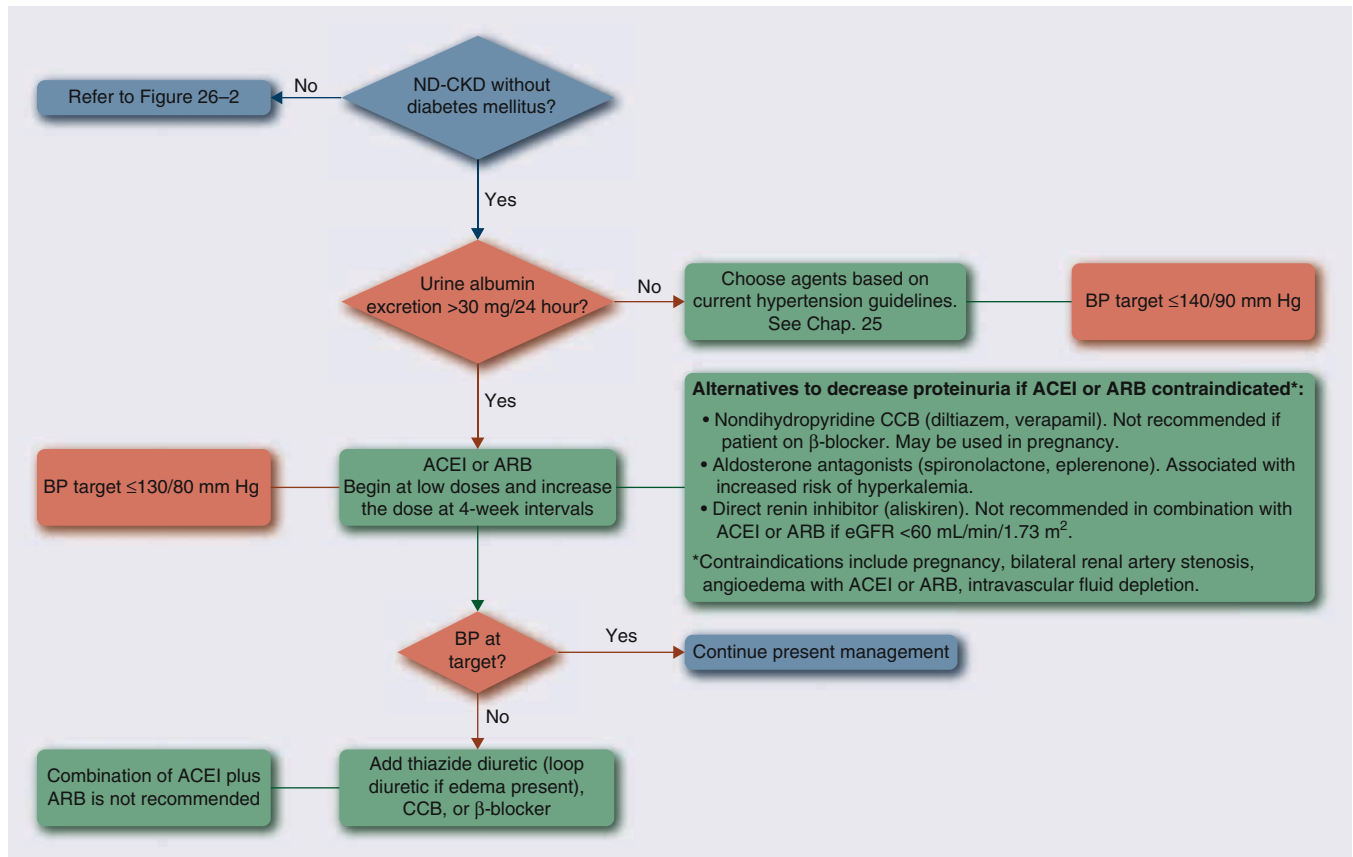
Because hypertension and kidney dysfunction are linked, blood pressure control can be more difficult to attain in patients with CKD compared with patients with normal kidney function. All antihypertensive agents have similar effects on reducing blood pressure. However, two or more agents are generally required to achieve the blood pressure goal of less than 140/90 mm Hg or 130/80 mm Hg in CKD patients.[17] Timing of blood pressure medications may also be important. One study suggests


**FIGURE 26–3.** Algorithm for management of hypertension in CKD. Management is based on urine albumin excretion and target blood pressure. (ACE-I, angiotensin-converting enzyme inhibitor; ARB, angiotensin receptor blocker; BP, blood pressure; CCB, calcium channel blocker; eGFR, estimated glomerular filtration rate; ND-CKD, non-dialysis chronic kidney disease.) (From Hudson JQ, Wazny LD. Chronic kidney disease. In: DiPiro JT, Talbert RL, Yee GC, et al., eds. Pharmacotherapy: A Pathophysiologic Approach, 9th ed. New York, NY: McGraw-Hill Education, 2014:643, with permission.)

that administration of at least one antihypertensive medication at bedtime decreased cardiovascular risk by 14% in patients with CKD compared with taking all antihypertensive medications in the morning.[20]

### ▶ Reduction in Proteinuria

Reduction of proteinuria within the first year of therapy predicts long-term renal and cardiovascular prognosis.[21] The ability of antihypertensive agents to reduce protein excretion differs. ACEIs and ARBs decrease glomerular capillary pressure and volume because of their effects on angiotensin II. This, in turn, reduces the amount of protein filtered through the glomerulus, independent of the reduction in blood pressure,[21] which ultimately decreases the progression of CKD. The ability of ACEIs and ARBs to reduce proteinuria is greater than that of other antihypertensives, up to 35% to 40%,[21] making ACEIs and ARBs the antihypertensive agents of choice for all patients with CKD with an AER of 30 mg/day or more, unless contraindicated. Combining ACEIs and ARBs should be done with caution. Although it has been demonstrated that combination therapy leads to greater reductions in protein excretion,[22] this also leads to faster progression of CKD.[23]

The nondihydropyridine calcium channel blockers (CCBs) have been shown to also decrease protein excretion in patients with and without diabetes,[24] but the reduction in proteinuria appears to be related to the reductions in blood pressure. The maximal effect of nondihydropyridine CCBs on proteinuria is seen with a blood pressure reduction to less than 130/80 mm Hg, and no additional benefit is seen with increased doses. Dihydropyridine CCBs, however, do not have the same effects on protein excretion. In fact, dihydropyridine CCBs may worsen protein excretion, despite similar reductions in blood pressure as nondihydropyridine CCBs.[24]

### ▶ Hyperlipidemia Treatment

Hyperlipidemia plays a role in the development of cardiovascular disease (CVD) in patients with CKD. The primary goal of treatment of dyslipidemias is to decrease the risk of atherosclerotic CVD. A secondary goal in patients with CKD is to reduce proteinuria and decline in kidney function. Treatment of hyperlipidemia in patients with CKD has been demonstrated to increase GFR by 1 mL/min/year (0.016 mL/s/year) of treatment with antihyperlipidemic agents.[7]

Because data do not support the use of LDL-C levels to guide treatment of hyperlipidemia, the KDIGO guidelines recommend starting statins for all patients with non-dialysis-dependent CKD aged 50 years and older, regardless of GFR

category.[25] Ezetimibe should be considered when GFR is less than 60 ml/min/1.73 m² (0.58 mL/s/m²). Statins should also be used for patients aged 18 to 49 years who have known coronary artery disease, DM, prior ischemic stroke, or more than a 10% estimated 10-year incidence of coronary death or nonfatal myocardial infarction.[25] However, because of the lack of efficacy in reducing cardiovascular events and the risk of adverse effects associated with statins in patients with ESKD, statins should not be initiated in patients on dialysis, unless they were receiving statins prior to starting dialysis.[25]

## Outcome Evaluation

Monitor SCr and potassium levels and blood pressure within 1 week after initiating ACEI or ARB therapy. Discontinue the medication and switch to another agent if a sudden increase in SCr greater than 30% occurs, hyperkalemia develops, or the patient becomes hypotensive. Titrate the dose of the ACEI or ARB every 1 to 3 months to effect using the maximum tolerable dose. If blood pressure is not reduced to goal, add another agent to the regimen. Refer the patient to a nephrologist to manage complications associated with CKD. As CKD progresses to Stage 4 (GFR category 4), begin discussion to prepare the patient for renal replacement therapy (RRT).

## CONSEQUENCES OF CKD AND ESKD
### Anemia of CKD

The progenitor cells of the kidney produce 90% of the hormone erythropoietin (EPO), which stimulates red blood cell (RBC) production. **KEY CONCEPT** *Reduction in the number of functioning nephrons decreases renal production of EPO, which is the primary cause of anemia in patients with CKD. The development of anemia of CKD results in decreased oxygen delivery and utilization, leading to increased cardiac output and left ventricular hypertrophy*

*(LVH), which increase the cardiovascular risk and mortality in patients with CKD.* Each 1 g/dL (10 g/L; 0.62 mmol/L) decrease in hemoglobin (Hgb) below 12 g/dL (120 g/L; 7.45 mmol/L) is associated with a 5% increase in the relative risk (RR) of mortality.[26]

### ▶ *Epidemiology and Etiology*

Current KDIGO guidelines define anemia as a Hgb level less than 13 g/dL (130 g/L or 8.07 mmol/L) in males and less than 12 g/dL (120 g/L or 7.45 mmol/L) in females.[27] A number of factors contribute to the development of anemia, including deficiencies in vitamin B$_{12}$ or folate, hemolysis, bleeding, or bone marrow resistance to EPO. Many of these can be detected by alterations in RBC indices, which should be included in the evaluation for anemia (see Chapter 66). A complete blood cell count is also helpful in evaluating anemia to determine overall bone marrow function. The prevalence of anemia correlates with the degree of kidney dysfunction. Only 8.4% of patients with Stage 1 (GFR category 1) have anemia, whereas the number increases to 53.4% with Stage 5 (GFR category 5).[28]

### ▶ *Pathophysiology*

The primary cause of anemia in patients with CKD is a decrease in EPO production. With normal kidney function, as Hgb, hematocrit (Hct), and tissue oxygenation decrease, the plasma concentration of EPO increases exponentially. As the number of functioning nephrons decrease, EPO production also decreases. Thus, as Hgb, Hct, and tissue oxygenation decrease in patients with CKD, plasma EPO levels remain constant within the normal range but low relative to the degree of hypoxia present. The result is a normochromic, normocytic anemia.

Several other factors contribute to the development of anemia in patients with CKD. Uremia, the accumulation of toxins that results from declining kidney function, decreases the lifespan of

## Patient Encounter 1

A 52-year-old Caucasian man presents to the clinic for a routine checkup. He has no complaints today, but needs a refill for his insulin.

**PMH:** Diabetes mellitus, diagnosed 3 years ago; hypothyroidism; hypertension

**SH:** He is unemployed; he smokes 2 ppd; stopped drinking alcohol 5 years ago after a bout of pancreatitis; reports a remote history of marijuana use in the past in his 20s

**Meds:** Insulin glargine 30 units SC daily; levothyroxine 75 mcg orally daily; omeprazole 20 mg orally twice daily; metoprolol succinate 25 mg orally daily

**ROS:** Unremarkable

**PE:**

**VS:** BP 152/99 mm Hg, P 85 beats/min, T 98.8°F (37.1°C), Ht 6′ (183 cm), Wt 167 lb (75.8 kg)

**CV:** RRR, normal S$_1$, S$_2$; no murmurs, rubs or gallops; lungs clear

**Abd:** No organomegaly, bruits or tenderness, (+) bowel sounds; heme (–) stool

**Exts:** Trace pedal edema bilaterally; decreased sensation in feet to light touch; no lesions

Labs (Fasting): Sodium 141 mEq/L (141 mmol/L); potassium 4.0 mEq/L (4.0 mmol/L); chloride 99 mEq/L (99 mmol/L); carbon dioxide 26 mEq/L (26 mmol/L); blood urea nitrogen (BUN) 26 mg/dL (9.3 mmol/L); serum creatinine (SCr) 1.6 mg/dL (141 µmol/L); glucose 148 mg/dL (8.2 mmol/L); total cholesterol 254 mg/dL (6.57 mmol/L); low-density lipoprotein cholesterol (LDL-C) 164 mg/dL (4.24 mmol/L); high-density lipoprotein cholesterol (HDL-C) 30 mg/dL (0.78 mmol/L); triglycerides 300 mg/dL (3.39 mmol/L); hemoglobin$_{A1c}$ (Hb$_{A1c}$) 8.4% (0.084; 68 mmol/mol Hgb); urine albumin: creatinine 45 mg/g creatinine (5.1 mg/mmol creatinine)

## Clinical Presentation and Diagnosis of Anemia of CKD

### General

Anemia of CKD generally presents with fatigue and decreased quality of life.

### Symptoms

Anemia of CKD is associated with symptoms of cold intolerance, shortness of breath, and decreased exercise capacity.

### Signs

Cardiovascular: Left ventricular hypertrophy, ECG changes, congestive heart failure.

Neurologic: Impaired mental cognition.

Genitourinary: Sexual dysfunction.

### Laboratory Tests

Decreased RBC count, Hgb, and Hct.

Decreased serum iron level, TSat and serum ferritin, and increased TIBC.

</div>

RBCs from a normal of 120 days to as low as 60 days in patients with Stage 5 CKD. Iron deficiency and blood loss from regular laboratory testing and hemodialysis also contribute to the development of anemia in patients with CKD.

▶ *Treatment*

Patients with CKD should be evaluated for anemia when the GFR falls below 60 mL/min (1.0 mL/s) or if the SCr rises above 2 mg/dL (177 μmol/L). An anemia workup should be performed if the Hgb is less than 13 g/dL (130 g/L or 8.07 mmol/L) in males or less than 12 g/dL (120 g/L or 7.45 mmol/L) in females. The workup for anemia should rule out other potential causes for anemia (see Chapter 66). Abnormalities found during the anemia workup should be corrected before initiating erythropoiesis-stimulating agents (ESAs), particularly iron deficiency, because iron is an essential component of RBC production. If Hgb is below 10 g/dL (100 g/L or 6.21 mmol/L) when all other causes of anemia have been corrected, EPO deficiency should be assumed. EPO levels are not routinely measured and have little clinical significance in monitoring progression and treatment of anemia in patients with CKD.

**Nonpharmacologic Therapy**  Approximately 1 to 2 mg of iron is absorbed daily from the diet. This small amount is generally not adequate to preserve adequate iron stores to promote RBC production in patients with CKD-related anemia. RBC transfusions have been used in the past as the primary means to maintain Hgb and Hct levels in patients with anemia of CKD. This treatment is still utilized today in patients with severe anemia or contraindications to ESAs, but it is considered a third-line therapy for chronic anemia of CKD.

**Pharmacologic Therapy**  The first-line treatment for anemia of CKD involves replacement of iron stores with iron supplements. When iron supplementation alone is not sufficient to increase Hgb levels, ESAs are necessary to replace erythropoietin. ESAs are synthetic formulations of EPO produced by recombinant human DNA technology. Use of ESAs increases the iron demand for RBC production and iron deficiency is common, requiring iron supplementation to correct and maintain adequate iron stores to promote RBC production. The approach to the management of anemia of CKD with iron supplementation and ESAs is illustrated in Figure 26–4.

*Iron Supplementation.*  Use of ESAs can lead to iron deficiency if iron stores are not adequately maintained. Iron supplementation should be considered when:

- Serum ferritin levels greater than 500 ng/mL (500 mcg/L; 1124 pmol/L)
- Transferrin saturation (TSat): greater than 30% (0.30).[27]

Serum ferritin is an acute phase reactant that may become elevated with inflammation and infection. Thus when serum ferritin

## Patient Encounter 2, Part 1

A 42-year-old Caucasian woman with a history of lupus nephritis presents to your clinic for a routine checkup. She complains of getting fatigued easily at work. She works as a secretary at a busy law office and notes that she is not able to keep up with her work. She notes that she feels winded when she walks even short distances.

**PMH:** systemic lupus erythematosus; seizure disorder

**Current Meds:** Lisinopril 20 mg orally daily; furosemide 20 mg orally daily; levetiracetam 250 mg orally twice daily

**ROS:** Skin pale in color; fatigue daily throughout the day with minimal exertion; otherwise unremarkable

**PE:**

**VS:** BP 97/62 mm Hg, P 94 beats/min, T 97.5°F (36.4°C), Ht 5′ (152 cm), Wt 110 lb (49.9 kg)

**CV:** RRR, normal $S_1$, $S_2$

**Abd:** No organomegaly, bruits or tenderness; (+) bowel sounds; heme (–) stool

**Ext:** 2+ pedal edema bilaterally

**Labs:** Sodium 136 mEq/L (136 mmol/L); potassium 3.9 mEq/L (3.9 mmol/L); chloride 104 mEq/L (104 mmol/L); carbon dioxide 23 mEq/L (23 mmol/L); BUN 34 mg/dL (12.1 mmol/L); SCr 3 mg/dL (265 μmol/L); glucose 70 mg/dL (3.9 mmol/L); white blood cell (WBC) count $5.3 \times 10^3$ cells/mm$^3$ ($5.3 \times 10^9$/L); red blood cell (RBC) count $3.1 \times 10^6$ cells/mm$^3$ ($3.1 \times 10^{12}$/L); hemoglobin (Hgb) 9.1 g/dL (91 g/L; 5.65 mmol/L); hematocrit 27% (0.27); platelets $428 \times 10^3$ cells/mm$^3$ ($428 \times 10^9$/L)

*What signs and symptoms are consistent with anemia of CKD?*

*What additional information could you request to determine other causes of anemia in this patient?*

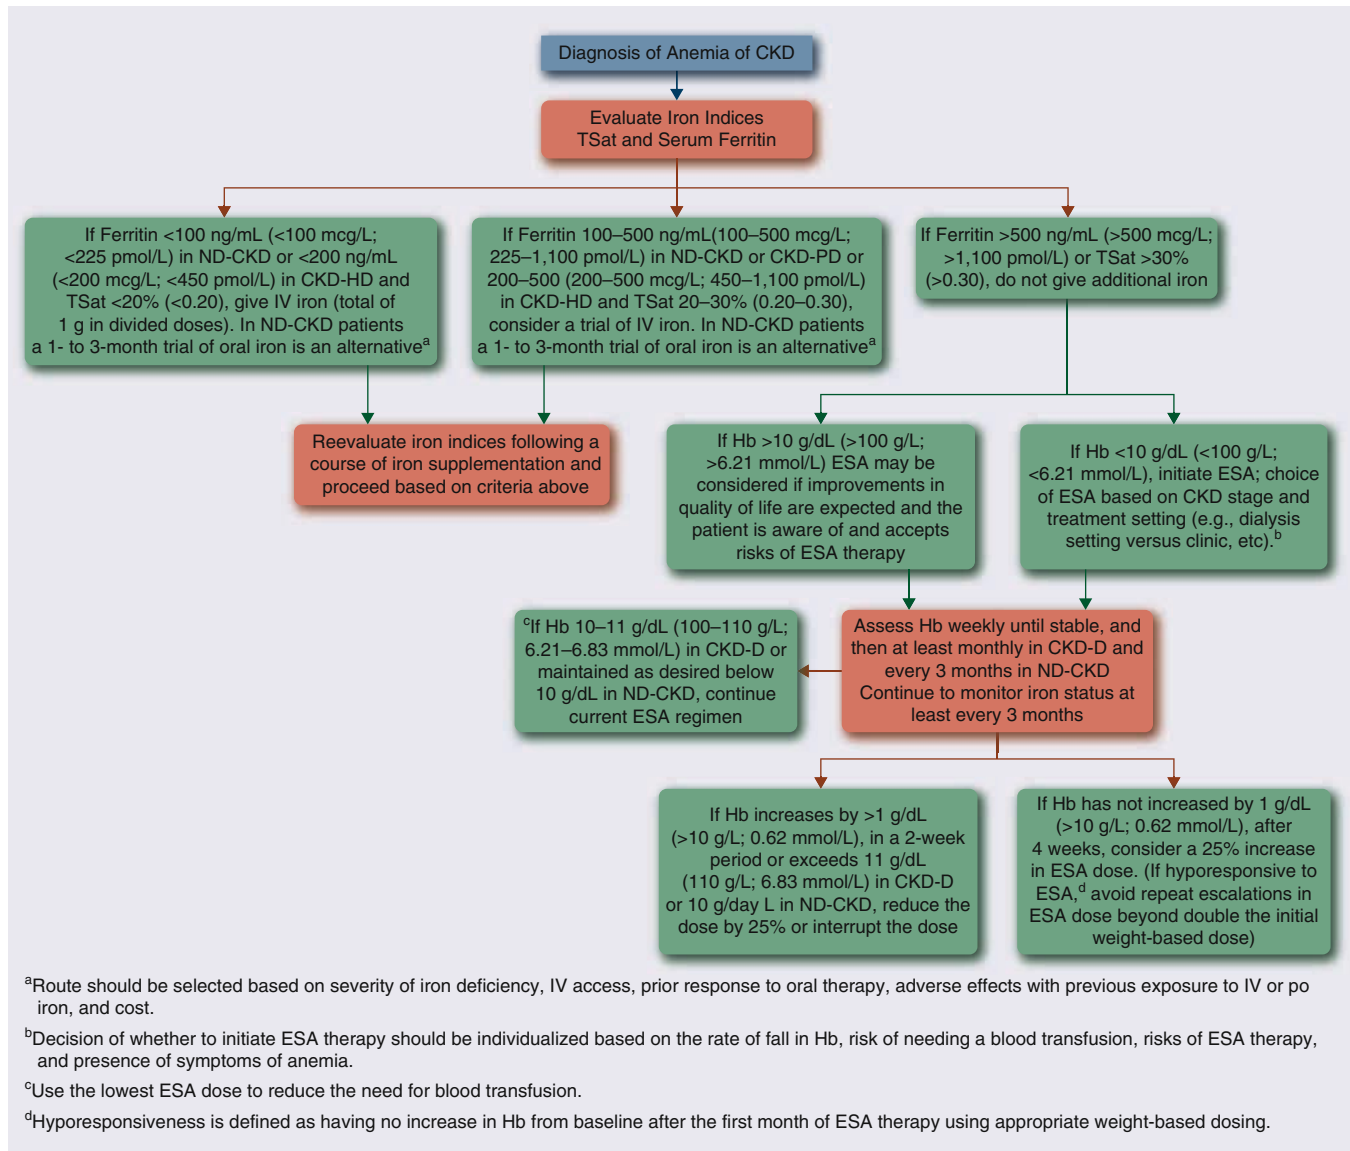
</div>


**FIGURE 26–4.** Algorithm for management of anemia of CKD. (CKD-HD, chronic kidney disease receiving hemodialysis; ESA, erythropoiesis-stimulating agent; Hgb, hemoglobin; ND-CKD, chronic kidney disease not receiving dialysis; SC, subcutaneous; TSat, transferrin saturation.) (From Hudson JQ, Wazny LD. Chronic kidney disease. In: DiPiro JT, Talbert RL, Yee GC, et al., eds. Pharmacotherapy: A Pathophysiologic Approach, 9th ed. New York, NY: McGraw-Hill Education, 2014:651, with permission.)

is normal or elevated in conjunction with TSat levels less than 30% (0.30), treatment should be based on the clinical picture of the patient. Iron supplementation may be indicated if Hgb levels are below the goal level, but avoided if the patient is infected.

Oral iron supplements are generally less costly than IV supplements and are generally the first-line treatment for iron supplementation for patients with CKD not receiving hemodialysis. When administering iron by the oral route, 200 mg of elemental iron should be delivered daily in divided doses to increase or maintain adequate iron stores.[27]

When oral iron is not effective to increase iron stores or for patients receiving hemodialysis, IV iron should be administered. Table 26–4 lists the FDA-approved doses of the currently available IV iron products. Patients receiving hemodialysis have ongoing blood losses with each hemodialysis session, which can lead to iron losses of 1 to 2 g/year. For hemodialysis, IV iron

may be administered episodically based on routine surveillance of iron stores as a total of 1 g of IV iron, administered in small sequential doses to replete iron stores. An alternative method to administer IV iron is to give smaller maintenance doses of iron weekly or with each dialysis session (eg, iron dextran or iron sucrose 20 to 100 mg/week; sodium ferric gluconate 62.5 to 125 mg/week). The latter approach of giving smaller maintenance doses may result in lower cumulative doses of iron and lower doses of ESAs.[27] Ferric carboxymaltose is a new IV iron replacement product approved for two doses separated by 7 days of 750 mg each for patients weighing at least 50 kg or 15 mg/kg/dose for patients under 50 kg.

IV iron preparations are equally effective in increasing iron stores. Anaphylaxis may occur with all IV preparations, but most notably with iron dextran, which can also cause delayed reactions, such as arthralgias and myalgias. A test dose of 25-mg

| Ferumoxytol (Feraheme) | Adults with iron-deficiency anemia associated with CKD | IV: 510 mg (17 mL) as a single dose, followed by a second 510-mg dose 3–8 days after the initial dose (rate of 1 mL or 30 mg/s) | General | 1020 mg (two doses of 510 mg separated by 3–8 days) | 17-mL vials containing 510 mg (30 mg/mL) |
| Ferric carboxymaltose (Injectafer) | Adults with non-dialysis dependent CKD | IV push: 750 mg over 10 minutes<br>IV infusion: 750 mg in 100–250 mL of 0.9% NaCl over at least 15 minutes | General | 1500 mg (two doses of 750 mg separated by at least 7 days) | 15-mL vials containing 750-mg elemental iron |

CKD, chronic kidney disease; ESA, erythropoietin-stimulating agent; HD, hemodialysis; PD, peritoneal dialysis.

[a]Small dosing ranges (eg, 25–100 mg/week) generally used for maintenance regimens. Larger doses (eg, 1 g) should be administered in divided doses.

iron dextran should be administered 30 minutes before the full dose to monitor for potential anaphylactic reactions, although anaphylactic reactions can occur in patients who safely received prior doses of iron dextran. A test dose is not require for the newer iron preparations, sodium ferric gluconate, iron sucrose, ferumoxytol, and ferric carboxymaltose because they are associated with fewer severe reactions and a much lower risk of anaphylaxis, making them the first-line agents in CKD. The most common side effects seen with these preparations include hypotension, flushing, nausea, and injection site reactions.

After administering a 1-g course of IV iron, iron status should be monitored to determine the effectiveness of the treatment. Serum ferritin and TSat should be monitored no sooner than 1 week after the last dose of IV iron. If Hgb does not increase after a course of IV iron or serum ferritin is not greater than 500 ng/mL (500 mcg/L; 1124 pmol/L) and TSat greater than 30% (0.30), an additional 1 g of IV iron may be administered, based on the clinical situation.

***Erythropoiesis-Stimulating Agents.*** ESAs may be considered if Hgb levels remain persistently low to improve symptoms of anemia. In patients not receiving dialysis, the decision to initiate ESAs should be based on the rate of Hgb decline, prior response to anemia treatment, risks associated with ESAs and the patient's symptoms. The KDIGO guidelines recommend considering initiating ESAs when Hgb is less than 10 g/dL (100 g/L or 6.21 mmol/L).[27]

However, the target for Hgb is unclear because use of ESAs to increase Hgb levels beyond 12 g/dL (120 g/L or 7.45 mmol/L) is associated with increased mortality.[29,30] The ESAs currently available in the United States are as follows:

- Epoetin alfa (distributed as Epogen and Procrit)
- Darbepoetin alfa (Aranesp)

Epoetin α and epoetin β, which is available outside the United States, have the same biological activity as endogenous EPO. Darbepoetin alfa differs from epoetin alfa by the addition of carbohydrate side chains that increase the half-life of darbepoetin alfa compared with epoetin alfa and endogenous EPO, allowing for less frequent dosing than that of epoetin alfa. All ESAs are equivalent in their efficacy and have a similar adverse-effect profile.

The most common adverse effect seen with ESAs is increased blood pressure, which may require antihypertensive agents to control blood pressure. Caution should be used when initiating an ESA in patients with very high blood pressures (greater than 180/100 mm Hg). If blood pressures are refractory to antihypertensive agents, ESAs may need to be withheld. Seizures and pure red cell aplasia have also been reported in patients initiating ESA therapy.

Subcutaneous (SC) administration of ESA produces a more predictable and sustained response than IV administration, and it is therefore the preferred route of administration for both agents. IV administration is often utilized in patients who have established IV access or are receiving hemodialysis. Starting doses of ESAs depend on the Hgb level, the target Hgb level, the rate of Hgb increase, and clinical circumstances.[27] The initial increase in Hgb should be 1 to 2 g/dL (10–20 g/L or 0.62–1.24 mmol/L) per month. The recommended starting dose of epoetin alfa is 50 to 100 units/kg/dose administered SC or IV two to three times weekly; the starting dose of darbepoetin alfa is 0.45 mcg/kg administered SC or IV once weekly (Table 26–5).

When prescribing ESAs, clinicians should not attempt to target "normal" Hgb levels (ie, greater than 13 g/dL [130 g/L or 8.07 mmol/L] in males; greater than 12 g/dL [120 g/L or 7.45 mmol/L] in females). Several clinical trials have demonstrated that targeting Hgb levels greater than 13 g/dL (130 g/L or 8.07 mmol/L) resulted in more cardiovascular complications or death, compared with target Hgb levels less than 11 g/dL (110 g/L or 6.83 mmol/L), with little or no benefit on the quality of life.[29,30] Although not completely understood, the increased mortality is postulated to result from increased blood viscosity, which can trigger platelet activity,

and hemoconcentration, which occurs when large amounts of fluid are removed during hemodialysis.[30] A third mechanism may relate to relative unphysiological concentrations of EPO that are achieved with intermittent dosing of ESAs, which may promote inflammation or thrombosis.[30]

Further studies are needed to evaluate the appropriate target level for Hgb. Nonetheless, based on these findings, the US FDA recommended addition of a black box warning to the product information for all ESAs indicating the maximum target Hgb should not exceed 11 g/dL (110 g/L or 6.83 mmol/L) and requires a medication guide be given to patients who are receiving ESAs.

▶ *Outcome Evaluation*

Evaluate Hgb monthly when ESA therapy is initiated or the dose is adjusted to ensure Hgb does not exceed 11.5 g/dL (115 g/L or 7.14 mmol/L).[27] The ESA dose can increase monthly if Hgb is below goal. Once a stable Hgb is attained, evaluate Hgb every 3 months thereafter. While the patient is receiving ESA therapy, monitor iron stores at least every 3 months or more frequently when initiating or increasing the dose of ESAs, when monitoring response to a course of IV therapy, or when blood loss or other circumstances that may lead to depletion of iron stores occur.[28] When the goal Hgb is reached, monitor iron stores every 3 months. Serum ferritin and TSat should be monitored no sooner than 1 week after the last dose of IV iron is administered.

## CKD-Mineral and Bone Disorder and Secondary Hyperparathyroidism

▶ *Epidemiology and Etiology*

Increases in parathyroid hormone (PTH) occur early as kidney function begins to decline. The actions of PTH on bone turnover lead to CKD-mineral and bone disorders (CKD-MBD). The majority of patients with GFR categories 3–5 have CKD-MBD.[31] The type of bone disease can vary based on the degree of bone turnover. High bone turnover, known as osteitis fibrosa cystica, is generally mediated by high levels of PTH. Adynamic bone disease, characterized by low bone turnover, is now the most common form of bone disease, which may be related to excessive

**Patient Encounter 2, Part 2**

The patient returns to your clinic in 1 week and states that her symptoms have not changed. She is asking about the results of her laboratory studies.

**Labs:** WBC 5.9 × 10³ cells/mm³ (5.9 × 10⁹/L); RBC 2.9 × 10⁶ cells/mm³ (2.9 × 10¹²/L); Hgb 8.9 g/dL (89 g/L; 5.52 mmol/L); hematocrit 26% (0.26); mean corpuscular volume (MCV) 84 fL; mean corpuscular hemoglobin concentration (MCHC) 29 g/dL (290 g/L); platelets 415 × 10³ cells/mm³ (415 × 10⁹/L); iron 31 mcg/dL (5.5 μmol/L); total iron binding capacity (TIBC) 490 mcg/dL (87.7 μmol/L); ferritin 42 ng/mL (42 mcg/L; 94 pmol/L); transferrin saturation (TSat) 14% (0.14); stool guaiac negative × 3

*What treatment would you recommend for this patient for treatment of anemia?*

*How would you evaluate the effectiveness of treatment of anemia?*

suppression of PTH.[32] The development of CKD-MBD can dramatically affect morbidity in patients with CKD.

### ► Pathophysiology

As kidney function declines in patients with CKD, decreased phosphorus excretion disrupts the balance of calcium and phosphorus homeostasis. Decreased vitamin D activation in the kidney also decreases calcium absorption from the gastrointestinal (GI) tract. Fibroblast growth factor 23 (FGF-23) is a hormone produced by osteocytes and osteoblasts that is stimulated by increased phosphate and calcitriol. In CKD, elevated phosphate concentrations increase expression of FGF-23, which promotes phosphorus excretion and downregulates vitamin D activation in the kidney.[32] Each of these stimulates the parathyroid glands. **KEY CONCEPT** *The parathyroid glands release PTH in response to decreased serum calcium and increased serum phosphorus levels. The actions of PTH include the following*:

- Increasing calcium resorption from bone
- Increasing calcium reabsorption from the proximal tubules in the kidney
- Decreasing phosphorus reabsorption in the proximal tubules in the kidney
- Stimulating activation of vitamin D by 1-$\alpha$-hydroxylase to calcitriol (1,25-dihydroxyvitmin $D_3$) to promote calcium absorption in the GI tract and increased calcium mobilization from bone

All these actions are directed at increasing serum calcium levels and decreasing serum phosphorus levels, although the activity of calcitriol also increases phosphorus absorption in the GI tract

and mobilization from the bone, which can worsen hyperphosphatemia. Calcitriol also decreases PTH levels through a negative feedback loop. These measures are sufficient to correct serum calcium levels in the earlier stages of CKD.

As kidney function continues to decline and the GFR falls less than 30 mL/min/1.73 m² (0.29 mL/s/m²), phosphorus excretion continues to decrease and calcitriol production decreases,[32] causing PTH levels to begin to rise significantly, leading to **secondary hyperparathyroidism** (sHPT). The excessive production of PTH leads to hyperplasia of the parathyroid glands, which decreases the sensitivity of the parathyroid glands to serum calcium levels and calcitriol feedback, further promoting sHPT.

The most dramatic consequence of sHPT is alterations in bone turnover and the development of **renal osteodystrophy** (ROD). Other complications of CKD can also promote ROD. Metabolic acidosis decreases bone formation by reducing hydroxyapatite solubility, inhibiting osteoblast activity, stimulating osteoclast activity, and reducing the sensitivity of the parathyroid gland to serum calcium levels.[33] Excessive aluminum levels cause aluminum uptake into bone in place of calcium, weakening the bone structure. The pathogenesis of sHPT and CKD-MBD are depicted in **Figure 26–5**.

### ► Treatment

**General Approach** **KEY CONCEPT** Diagnosis and management of bone disease in CKD is based on corrected serum levels of calcium and phosphorus, and intact PTH levels (iPTH).[31] In general, calcium, phosphorus, and PTH levels should be maintained in the normal range for all stages of CKD. For patients receiving dialysis, it is often difficult to achieve normal serum levels for these parameters. Attempts should be made to

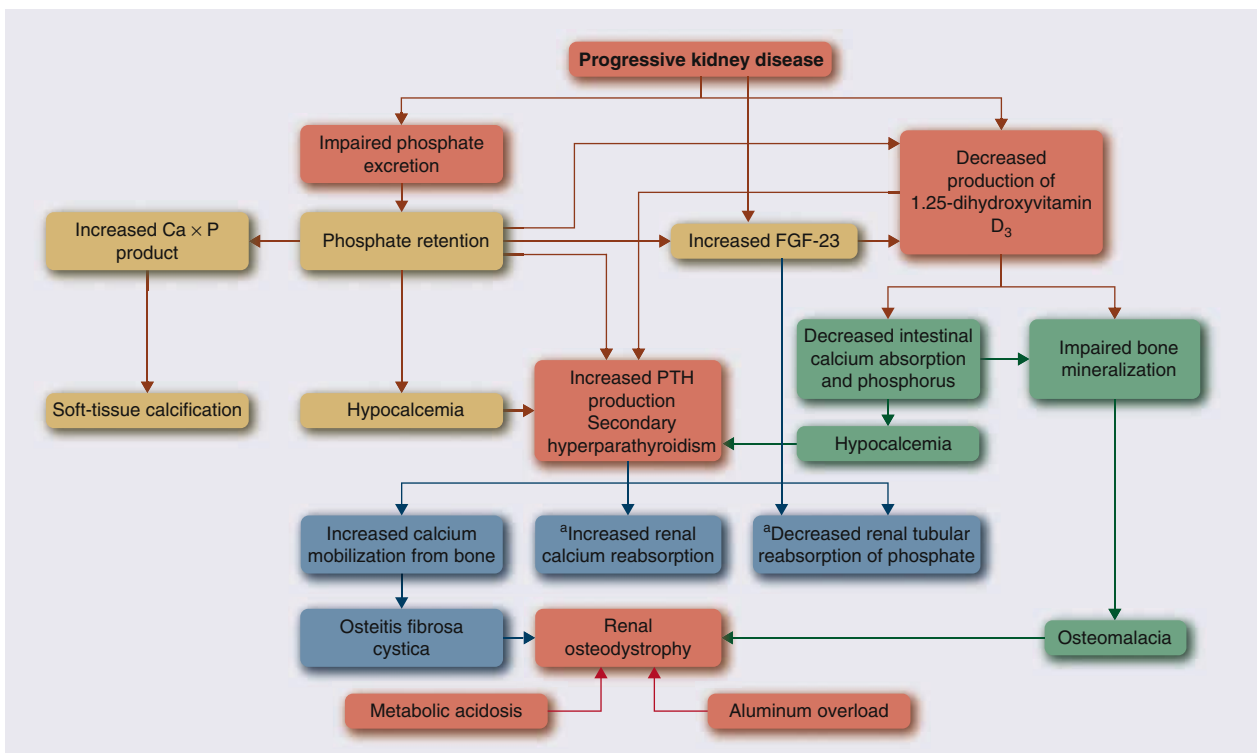

**FIGURE 26–5.** Pathogenesis of CKD-MBD and renal osteodystrophy.ªThese adaptations are lost as kidney failure progresses. (From Hudson JQ, Wazny LD. Chronic kidney disease. **Table 26–6**

**Target Levels for Calcium, Phosphorus, and Intact PTH**

| Parameter | GFR Categories 3a and 3b (Stage 3) | GFR Category 4 (Stage 4) | GFR Category 5 (Stage 5) |
|---|---|---|---|
| Corrected Calcium | "Normal range" | "Normal range" | 8.4–9.5 mg/dL (2.10–2.38 mmol/L)[a,b] |
| Phosphorus | "Normal range" | "Normal range" | 3.5–5 mg/dL (1.13–1.62 mmol/L)[a,b] |
| Intact PTH[a,c] | 35–70 pg/mL[d] (3.7–7.5 pmol/L) | 70–100 pg/mL (7.5–10.7 pmol/L) | 150–300 pg/mL (16.0–32.1 pmol/L) |

Ca–P, calcium–phosphorus product; GFR, glomerular filtration rate; PTH, parathyroid hormone.

[a]Based on KDOQI guidelines (Nigwekar SU, Bhan I, Thadhani R. Ergocalciferol and cholecalciferol in CKD. Am J Kidney Dis. 2011;60[1]:139–156).

[b] KDIGO guidelines recommend "normal range."

[c]KDIGO guidelines recommend two to nine times normal.

[d]Units of pg/mL are equivalent to ng/L.

maintain calcium and phosphorus levels as close to normal as possible, but levels slightly above the normal range are acceptable in most cases. Target ranges for the various parameters are listed in Table 26–6.

The primary target for treatment is control of serum phosphorus levels because this is the initial parameter that disrupts homeostasis. However, serum phosphorus can be difficult to control, particularly in the latter stages of CKD. Management of sHPT often requires supplemental treatment with vitamin D analogs or cinacalcet in addition to phosphorus management.

**Nonpharmacologic Therapy** The first-line treatment for the management of hyperphosphatemia is dietary phosphorus restriction to 800 to 1000 mg/day in patients with Stage 3 CKD or higher who have phosphorus levels at the upper limit of the normal range or elevated iPTH levels.[31,34] Many foods high in phosphorus are also high in protein, which can make it difficult to restrict phosphorus intake while maintaining adequate protein intake to avoid malnutrition. Hemodialysis and peritoneal dialysis can remove up to 2 to 3 g of phosphorus per week. However, this is insufficient to control hyperphosphatemia, and pharmacologic therapy is necessary in addition to dialysis treatment.

Other nonpharmacologic strategies to manage sHPT and CKD-MBD include restriction of aluminum exposure and parathyroidectomy. Chronic ingestion of aluminum-containing antacids and other aluminum-containing products should be avoided in patients with GFR categories 4 and 5 (GFR less than 30 mL/min/1.73 m² [0.29 mL/s/m²]) because of the risk of aluminum toxicity and potential uptake into the bone. Purification techniques for dialysate solutions also minimize the risk of exposure to aluminum.

Parathyroidectomy is a treatment of last resort for sHPT, but should be considered in patients with persistently elevated iPTH levels above 800 pg/mL (800 ng/L; 85.6 pmol/L) that is refractory to medical therapy to lower serum calcium and/or phosphorus levels.[31] A portion or all of the parathyroid tissue may be removed, and in some cases a portion of the parathyroid tissue may be transplanted into another site, usually the forearm for easy surgical access. After parathyroidectomy, serum calcium levels can decrease dramatically due to the low levels of PTH after the parathyroid tissue is removed, which decreases intestinal calcium absorption and bone resorption. Therefore, serum ionized calcium levels should be monitored frequently

(every 4–6 hours for the first 48–72 hours) in patients receiving a parathyroidectomy. Calcium supplementation is usually necessary, administered IV initially, then orally (with vitamin D supplementation) once normal calcium levels are attained for several weeks to months after the procedure.

## Clinical Presentation and Diagnosis of sHPT and ROD

**General**

Onset of sHPT and ROD is subtle and may not be associated with symptoms.

**Symptoms**

sHPT and ROD are usually asymptomatic in early disease. Calcification in the joints can be associated with decreased range of motion.

Conjunctival calcifications are associated with a gritty sensation in the eyes, redness, and inflammation.

**Signs**

Cardiovascular: Increased stroke index, heart rate, and diastolic and mean arterial pressures.

Musculoskeletal: Bone pain, muscle weakness.

Dermatologic: Pruritus.

**Laboratory Tests**

Increased serum phosphorus levels.

Low to normal serum calcium levels.

Increased PTH levels.

Decreased vitamin D levels.

**Diagnostic Tests**

Radiographic studies show calcium–phosphate deposits in joints and/or cardiovascular system.
Bone biopsy of the iliac crest (not routinely performed).

### Pharmacologic Therapy

*Phosphate-Binding Agents.* When serum phosphorus levels cannot be controlled by restriction of dietary intake, phosphate-binding agents are used to bind dietary phosphate in the GI tract to form an insoluble complex that is excreted in the feces. Phosphorus absorption is decreased, thereby decreasing serum phosphorus levels. The drugs used for binding dietary phosphate are listed in Table 26–7. These agents should be administered with each meal and can be tailored to the amount of phosphorus that is typically ingested during each meal. For example, patients can take a smaller dose with smaller meals or snacks, and a larger dose with larger meals. Although phosphate binders are not FDA approved for patients with CKD who are not receiving dialysis, they are used clinically when phosphorus levels are elevated, regardless of the GFR category.

Calcium-based phosphate binders, including calcium carbonate and calcium acetate, are effective in decreasing serum phosphate levels, as well as in increasing serum calcium levels. Calcium acetate binds more phosphorus than the carbonate salt, making it a more potent agent for binding dietary phosphate. Calcium citrate is usually not used as a phosphate-binding agent because the citrate salt can increase aluminum absorption. The calcium-containing phosphate binders also aid in the correction of metabolic acidosis, another complication of kidney failure. Calcium-based phosphate binders should not be used if serum calcium levels are near the upper end of the normal range or are elevated, if arterial calcifications are present, or if the patient has adynamic bone disease.[31] The dose of calcium-based phosphate binders should not provide more than 1500 mg of elemental calcium per day, and the total elemental calcium intake per day should not exceed 2000 mg, including medication and dietary intake.[34] The most common adverse effects of calcium-containing phosphate binders are constipation and hypercalcemia.

Aluminum- and magnesium-containing phosphate-binding agents are not recommended for chronic use in patients with CKD to avoid aluminum and magnesium accumulation. Aluminum-containing agents may be used for a short course of therapy (less than 4 weeks) if phosphorus levels are significantly elevated greater than 7 mg/dL (2.26 mmol/L), but should be replaced by other phosphate-binding agents after no more than 4 weeks. Excessive aluminum levels lead to aluminum intoxication, causing neurotoxicity that can manifest as encephalopathy or dementia, bone disease, and anemia. In addition to the risk of magnesium accumulation, the use of magnesium-containing agents is also limited by the GI side effects, primarily diarrhea.

Sevelamer, lanthanum, and iron-based phosphate binders do not contain calcium, magnesium, or aluminum. These agents are particularly useful in patients with hyperphosphatemia who have elevated serum calcium levels or who have vascular or soft tissue calcifications. Sevelamer is a cationic polymer that is not systemically absorbed and binds to phosphate in the GI tract, and it prevents absorption and promotes excretion of phosphate through the GI tract via the feces. Sevelamer has an added benefit of reducing LDL-C by up to 30% and increasing HDL-C levels.[34] The most common side effects of sevelamer are GI complaints, including nausea, constipation, and diarrhea. The cost of sevelamer is significantly higher compared with calcium-containing phosphate binders, which often makes sevelamer a second-line agent for controlling phosphorus levels. However, some studies demonstrate that sevelamer may decrease mortality in patients receiving hemodialysis compared with calcium-containing phosphate binders, primarily by decreasing the occurrence of calcifications in the coronary arteries.[31] Sevelamer may lower FGF-23 levels, which can negatively impact renal phosphate excretion.[35] Sevelamer carbonate may have added benefit to aid in the correction of metabolic acidosis.

Lanthanum is a naturally occurring trivalent rare earth element (atomic number 57). Lanthanum carbonate quickly dissociates in the acidic environment of the stomach, where the lanthanum ion binds to dietary phosphorus, forming an insoluble compound that is excreted in the feces. Lanthanum has been shown to be as effective as other phosphate binders and may improve bone turnover, compared with calcium-containing products.[31] Side effects of lanthanum include nausea, peripheral edema, and myalgias.

Sucroferric oxyhydroxide and ferric citrate are iron-based phosphate binders that lower phosphate levels. Sucroferric oxyhydroxide is an insoluble form of iron that binds to phosphate in the GI tract and has been shown to be as effective as other phosphate binders with a lower pill burden.[36] Ferric citrate also lowers phosphate as effectively as other phosphate binders and can also increase serum ferritin and TSAT levels.[36] The major side effects associated with both products are GI side effects, namely diarrhea. Sucroferric oxyhydroxide cannot be taken with levothyroxine and must be taken 1 hour after doxycycline and alendronate. This product was not studied in patients on peritoneal dialysis, with significant liver or GI disease, or following major GI surgery.[36]

*Vitamin D Therapy.* Vitamin D regulates many processes in the body, including calcium and phosphorus absorption from the GI tract and kidney, PTH secretion, maintaining muscle, cardiovascular, immune and brain function, and glucose control. Vitamin D is activated in various tissues, with the liver and kidney being primary sites. In CKD, a decrease in renal metabolism of vitamin D decreases circulating concentrations of the activated form of vitamin D, calcitriol (1,25-dihydroxyvitamin D) and its precursor 25-hydroxyvitamin D. Vitamin D deficiency becomes evident as early as Stage 2 (GFR category 2).[37] PTH levels rise as early as Stage 3 (GFR category 3) as a result of low calcitriol concentrations.

Exogenous vitamin D compounds that mimic the activity of calcitriol act directly on the parathyroid gland to decrease PTH secretion by upregulation of the vitamin D receptor in the parathyroid gland, which decreases parathyroid gland hyperplasia and PTH synthesis and secretion. This is particularly useful when reduction of serum phosphorus levels does not sufficiently reduce PTH levels.

Vitamin D supplementation (Table 26–8) can be used to lower serum PTH levels in patients with CKD. Ergocalciferol and cholecalciferol have been shown to be effective in lowering PTH secretion in patients with Stage 3 CKD[31] and are useful in later stages of CKD to maintain adequate 25-hydroxyvitamin D levels for extrarenal functions. In Stages 4 and 5 (GFR categories 4 and 5), activated vitamin D analogs must be used to decrease PTH secretion. Synthetic calcitriol has the same biologic activity as endogenous calcitriol. Doxercalciferol (1-$\alpha$-hydroxyvitamin $D_2$) is another vitamin D analog that is hydroxylated in the liver to 1,25-dihydroxyvitamin $D_2$, which has the same biologic activity as calcitriol. Both calcitriol and doxercalciferol upregulate vitamin D receptors in the intestines, which increases calcium and phosphorus absorption, increasing the risk of hypercalcemia and hyperphosphatemia. It is important that serum calcium and phosphorus levels are within the normal range for the stage of CKD prior to starting either of these therapies. Paricalcitol (19-nor-1,25-dihydroxyvitamin $D_2$) is a vitamin D analog that has equal efficacy to calcitriol but may cause less

| Table 26–7 |
|---|

**Phosphate-Binding Agents Used to Treat Hyperphosphatemia in CKD**

| Compound | Trade Name | Dosage Form | Compound Content (mg) | Elemental Calcium Content (mg) | Starting Dose | Comments |
|---|---|---|---|---|---|---|
| Calcium carbonate (40% elemental calcium) | Tums | Chewable tablet | 500, 750, 1000, 1250 | 200, 300, 400, 500 | 0.5–1 g (elemental calcium) three times a day with meals | First-line agent; dissolution characteristics and phosphorus-binding effect may vary from product to product; try to limit daily intake of elemental calcium to 1500 mg/day |
| | Oscal-500 | Tablet | 1250 | 500 | | |
| | Caltrate 600 | Tablet | 1500 | 600 | | |
| | Nephro Calci | Tablet | 1500 | 600 | | |
| | LiquiCal | Liquid gelcap | 1200 | 480 | | |
| | Calci-Chew | Chewable tablet | 1250 | 500 | | Approximately 39 mg phosphorus bound per 1 g calcium carbonate |
| Calcium acetate (25% elemental calcium) | PhosLo | Capsule, Tablet | 667 | 167 | 0.5–1 g (elemental calcium) three times a day with meals | First-line agent; comparable efficacy to calcium carbonate with one-half the dose of elemental calcium; do not exceed 1500 mg elemental calcium intake per day |
| | Phoslyra | Solution | 667/5 mL | | | Approximately 45 mg phosphorus bound per 1 g calcium acetate |
| | | | | | | By prescription only |
| Sevelamer HCl | Renagel | Tablet | 400, 800 | — | 800 mg three times a day with meals | First-line agent; lowers LDL-C |
| Sevelamer carbonate | Renvela | Tablet, Powder for suspension | 800 | | | More expensive than calcium products; preferred in patients at risk for extraskeletal calcification |
| | | | | | | May require large doses to control phosphorus levels |
| Lanthanum | Fosrenol | Chewable tablet | 500, 750, 1000 | — | 750–1500 mg three times a day with meals | Second-line agent; more expensive than calcium products; preferred in patients at risk for extraskeletal calcification |
| | | | | | | Most patients require 1500–3000 mg/day to control phosphorus |
| Aluminum hydroxide | AlternaGel Amphojel | Suspension | Various | — | 300–600 mg three times a day with meals | Third-line agents; do not use concurrently with citrate-containing products |
| | | | | | | Reserve for short-term use (4 weeks) in patients with hyperphosphatemia not responding to other binders |
| Magnesium carbonate/ calcium carbonate | MagneBind 400 | Tablet | 400 mg (elemental magnesium) | 80 | 400 mg three times a day with meals | Third-line agent; Same as for calcium carbonate and magnesium carbonate |
| Sucroferric oxyhydroxide | Velphoro | Chewable tablet | 500 | — | 500 mg three times a day with meals | Do not use with levothyroxine; separate from doxycycline and alendronate by 1 hour |
| Ferric citrate | Auryxia | Tablet | 1000 | — | 2000 mg (2 tablets) three times a day with meals | Maximum dose is 12 tablets per day |
| | | | | | | Each tablet provides 210 mg elemental iron |

CKD, chronic kidney disease; LDL-C, low-density lipoprotein cholesterol.

| Table 26–8 | | | | |
|---|---|---|---|---|
| **Available Treatments for Secondary Hyperparathyroidism** | | | | |
| **Generic Name** | **Trade Name** | **Dosage Range** | **Dosage Forms** | **Frequency of Administration** |
| **Vitamin D precursor** | | | | |
| Ergocalciferol | Vitamin $D_2$ | 400–50,000 IU | By mouth | Daily (doses of 400–2000 IU) |
| Cholecalciferol | Vitamin $D_3$ | | | Weekly or monthly for higher doses (50,000 IU) |
| **Active Vitamin D** | | | | |
| Calcitriol | Calcijex | 0.5–5 mcg | Intravenous | Three times per week |
| | Rocaltrol | 0.25–5 mcg | By mouth | Daily, every other day, or three times per week |
| **Vitamin D analogs** | | | | |
| Paricalcitol | Zemplar | 1–4 mcg | By mouth | Daily or three times per week |
| | | 2.5–15 mcg | Intravenous | Three times per week |
| Doxercalciferol | Hectorol | 5–20 mcg | By mouth | Daily or three times per week |
| | | 2–8 mcg | Intravenous | Three times per week |
| **Calcimimetics** | | | | |
| Cinacalcet | Sensipar | 30–180 mg | By mouth | Daily |

hypercalcemia. Alfacalcidol ($1$-$\alpha$-hydroxyvitamin $D_3$), falecalcitriol, and 22-oxacalcitriol (maxacalcitol) are only available outside the United States.

**Calcimimetics** Cinacalcet is a calcimimetic that increases the sensitivity of receptors on the parathyroid gland to serum calcium levels to reduce PTH secretion, but has no effect on intestinal absorption of calcium or phosphorus, and may even lower serum calcium levels.[31] Thus, cinacalcet is beneficial for patients with elevated PTH levels who have increased calcium or phosphorus levels or cannot use vitamin D therapy. Cinacalcet should also be used with caution in patients with seizure disorders because low serum calcium levels can lower the seizure threshold.

▶ *Outcome Evaluation*

Monitor serum calcium and phosphorus levels regularly in patients receiving phosphate-binding agents. When initiating therapy, monitor serum levels every 1 to 4 weeks, depending on the severity of hyperphosphatemia. Titrate doses of phosphate binders to achieve the target levels of serum calcium and phosphorus and iPTH (see Table 26–6). Once target levels are achieved, monitor serum calcium and phosphorus levels every 1 to 3 months. Monitor intact PTH levels monthly while initiating vitamin D therapy, then every 3 months once stable iPTH levels are achieved. When starting or increasing the dose of cinacalcet, monitor serum calcium and phosphorus levels within 1 week; iPTH levels should be monitored within 1 to 4 weeks. Once target levels are achieved, decrease monitoring to every 3 months.

## Impaired Electrolyte and Acid–Base Homeostasis

The kidney is responsible for regulating homeostasis for sodium, potassium, water, and acid base. Reductions in the number of functioning nephrons decrease glomerular filtration regulation of electrolytes and acid secretion.

▶ *Pathophysiology*

As the number of functioning nephrons decreases, the remaining nephrons are able to increase excretion of sodium, water, potassium, and hydrogen ions. However, this is limited and as the number of functioning nephrons decreases as CKD progresses, total excretion of electrolytes and fluid eventually decreases.

Sodium and water balance is maintained by natriuretic peptides, namely atrial natriuretic peptide (ANP), which increases sodium excretion in the kidneys.[38] The relative increase in sodium excretion by a smaller number of functioning nephrons results in an osmotic diuresis that promotes water excretion,

## Patient Encounter 3

A 61-year-old African American woman with a history of hypertension presents to your clinic for a routine follow-up. He has no complaints at this time.

**PMH:** Hypertension, diagnosed 25 years ago; hyperlipidemia

**Current Meds:** Aspirin 81 mg orally daily; atorvastatin 10 mg orally daily; carvedilol 25 mg orally twice daily; hydralazine 50 mg orally daily; lisinopril 40 mg orally daily; nifedipine ER 90 mg orally daily

**ROS:** Unremarkable

**PE:**

**VS:** BP 146/94 mm Hg, P 70 beats/min, T 96.3°F (35.7°C), Ht 5'9" (175 cm), Wt 177 lb (80.3 kg)

**CV:** RRR, normal $S_1$, $S_2$

**Abd:** No organomegaly, bruits, tenderness; (+) bowel sounds; heme (–) stool

**Ext:** 1+ edema bilaterally

**Labs:** Sodium 136 mEq/L (136 mmol/L); potassium 5.7 mEq/L (5.7 mmol/L); chloride 99 mEq/L (99 mmol/L); carbon dioxide 17 mEq/L (17 mmol/L); BUN 36 mg/dL (12.9 mmol/L urea); SCr 3.0 mg/dL (265 μmol/L); glucose 113 mg/dL (6.3 mmol/L); calcium 8.4 mg/dL (2.10 mmol/L); phosphate 6.9 mg/dL (2.23 mmol/L); albumin 3.1 g/dL (31 g/L); intact parathyroid hormone (iPTH) 410 pg/mL (410 ng/L; 43.9 pmol/L); WBC $5.2 \times 10^3$ cells/mm³ ($5.2 \times 10^9$/L); RBC $4.2 \times 10^6$ cells/mm³ ($4.2 \times 10^{12}$/L); Hgb 9.4 g/dL (94 g/L; 5.83 mmol/L); Hct 28% (0.28); platelets $412 \times 10^3$ cells/mm³ ($412 \times 10^9$/L)

*What signs are consistent with CKD mineral and bone disorder (MBD)?*

*What treatment would you recommend for CKD-MBD?*

but impairs the ability of the kidneys to concentrate and dilute urine. Thus, urine becomes fixed at an osmolality close to that of the plasma, approximately 300 mOsm/kg (300 mmol/kg), and presents as nocturia. Sodium and fluid retention increases intravascular volume and raises systemic blood pressure, which can present as early as Stage 3 CKD.[38]

Potassium excretion occurs in both the distal tubules of the kidney and in the GI tract, which is mediated by aldosterone stimulation. Aldosterone increases in response to rising serum potassium, which then increases potassium excretion in both the functioning nephrons and GI tract. This maintains serum potassium concentrations within the normal range through GFR categories 1 to 4 CKD. Hyperkalemia begins to develop when GFR falls below 20% of normal, when the number of functioning nephrons and renal potassium secretion is so low that the capacity of the GI tract to excrete potassium has been exceeded.[39]

Medications can increase the risk of hyperkalemia in patients with CKD, including ACE-I and ARBs, used for the treatment of proteinuria and hypertension. Potassium-sparing diuretics, used for the treatment of edema and chronic heart failure, can also exacerbate the development of hyperkalemia, and they should be used with caution in patients with Stage 3 CKD (GFR category 3) or higher.

Hydrogen ions are excreted at the same rate of production by the kidney via buffers in the urine created by ammonia generation and phosphate excretion to maintain the pH of body fluids within a very narrow range. As kidney function declines, bicarbonate reabsorption is maintained, but hydrogen excretion is decreased because the ability of the kidney to generate ammonia is impaired. The positive hydrogen balance leads to metabolic acidosis, which is characterized by a serum bicarbonate level of 15 to 20 mEq/L (15–20 mmol/L), and an elevated anion gap greater than 17 mEq/L (17 mmol/L), resulting in a pH less than 7.35. Metabolic acidosis generally presents when the GFR declines below 25 mL/min/1.73 m² (0.24 mL/s/m²).[36]

Metabolic acidosis contributes to various complications associated with CKD. Metabolic acidosis can directly cause bone disease, particularly in children, and contribute significantly to the bone disease induced by secondary hyperparathyroidism, as discussed previously. Metabolic acidosis also decreases hepatic albumin synthesis, which contributes to hypoalbuminemia and muscle wasting. Furthermore, metabolic acidosis can accelerate progression of CKD by causing tubular injury. Reversal of metabolic acidosis has been demonstrated to decrease progression of CKD, improve bone disease, and increase serum albumin concentrations.[36]

▶ *Treatment*

**Nonpharmacologic treatment** The kidney is unable to adjust to abrupt changes in sodium and potassium intake in patients with severe CKD. Electrolyte disorders resulting from an acute increase in intake can be more severe and prolonged.

*Sodium and Water.* Patients should be advised to refrain from adding salt to their diet but should not restrict sodium intake. Changes in sodium intake should occur slowly over a period of several days to allow adequate time for the kidney to adjust urinary sodium content. Sodium restriction produces a negative sodium balance, which causes fluid excretion to restore sodium balance. The resulting volume contraction can decrease

---

**Clinical Presentation and Diagnosis of Electrolyte and Acid–Base Abnormalities**

**General**

Alterations in sodium and water balance in CKD manifests as increased edema.

Hyperkalemia is generally asymptomatic in patients with CKD until serum potassium levels are greater than 5.5 mEq/L (5.5 mmol/L), when cardiac abnormalities present.

Metabolic acidosis is generally asymptomatic in patients with CKD.

**Symptoms**

Nocturia can present in Stage 3 CKD.

Edema generally presents in Stage 4 CKD or later.

Mild hyperkalemia and metabolic acidosis are generally not associated with overt symptoms.

Symptoms of hyperkalemia generally appear when GFR falls below 20 ml/min/1.73m² (0.19 ml/s/m²), such as muscle weakness, fatigue, nausea, and paresthesias.

Symptoms of chronic metabolic acidosis present as bone abnormalities and growth retardation in children.

**Signs**

Cardiovascular:

Sodium: Worsening hypertension, edema.

Potassium: ECG changes (peaked T waves, widened QRS complex, loss of P wave).

Genitourinary: Sodium abnormalities result in change in urine volume and consistency.

**Laboratory Tests**

Sodium: Increased blood pressure; sodium levels remain within the normal range; urine osmolality is generally fixed at 300 mOsm/kg (300 mmol/kg).

Potassium: Increased serum potassium levels.

Metabolic acidosis: Decreased serum bicarbonate levels ($CO_2$); decreased pH.

---

perfusion of the kidney and hasten the decline in GFR. Saline-containing IV solutions should be used cautiously in patients with CKD because the salt load may precipitate volume overload.

Fluid restriction is generally unnecessary as long as sodium intake is controlled. The thirst mechanism remains intact in CKD to maintain total body water and plasma osmolality near normal levels. Fluid intake should be maintained at the rate of urine output to replace urine losses, usually fixed at approximately 2 L/day as urine concentrating ability is lost. Significant increases in free water intake orally or IV can precipitate volume overload and hyponatremia. Patients with Stage 5 CKD require RRT to maintain normal volume status. Fluid intake is often limited in patients receiving hemodialysis to prevent fluid overload between dialysis sessions.

Diuretic therapy is often necessary to prevent volume overload in patients with CKD in those who still produce urine. When GFR falls below 30 ml/min/1.73 m² (0.29 mL/s/m²),

thiazide diuretics alone may not be effective in reducing fluid retention.[17] Loop diuretics are most frequently used to increase sodium and water excretion. As CKD progresses, higher doses, as much as 80 to 1000 mg/day of furosemide, or continuous infusion of loop diuretics may be needed, or combination therapy with loop and thiazide diuretics to increase sodium and water excretion.[17]

*Potassium.* Patients who develop hyperkalemia should restrict dietary intake of potassium to 50 to 80 mEq (50–80 mmol) per day. Potassium concentrations can also be altered in the dialysate for patients receiving hemodialysis and peritoneal dialysis to manage hyperkalemia. Because GI excretion of potassium plays a large role in potassium homeostasis in patients with Stage 5 CKD, a good bowel regimen is essential to minimize constipation. Severe hyperkalemia is most effectively managed by hemodialysis.

Acute hyperkalemia can be managed medically until dialysis can be initiated. Diuretics, sodium polystyrene sulfonate, and fludrocortisone are useful in the management of hyperkalemia in patients with CKD. Acute hyperkalemia that results in cardiac abnormalities can be managed with calcium, insulin and dextrose. The management of hyperkalemia is discussed in more detail in Chapter 27.

*Metabolic Acidosis.* Pharmacologic therapy with sodium bicarbonate or citrate/citric acid preparations may be needed in patients with Stage 3 CKD (GFR category 3) or higher to replenish body stores of bicarbonate. Calcium carbonate and calcium acetate, used to bind phosphorus in sHPT, also aid in increasing serum bicarbonate levels, in conjunction with other agents.

Sodium bicarbonate tablets are administered in increments of 325- and 650-mg tablets. A 650-mg tablet of sodium bicarbonate contains 7.7 mEq (7.7 mmol) each of sodium and bicarbonate. Sodium retention associated with sodium bicarbonate can cause volume overload, which can exacerbate hypertension and chronic heart failure. Patient tolerability of sodium bicarbonate is low because of carbon dioxide production in the GI tract that occurs during dissolution.

Solutions that contain sodium citrate/citric acid (Shohl's solution and Bicitra) provide 1 mEq/L (1 mmol/L) each of sodium and bicarbonate. Polycitra is a sodium/potassium citrate solution that provides 2 mEq/L (2 mmol/L) of bicarbonate but contains 1 mEq/L (1 mmol/L) each of sodium and potassium, which can promote hyperkalemia in patients with severe CKD. The citrate portion of these preparations is metabolized in the liver to bicarbonate; the citric acid portion is metabolized to $CO_2$ and water, increasing tolerability compared with sodium bicarbonate. Sodium retention is also decreased with these preparations. However, these products are liquid preparations, which may not be palatable to some patients. Citrate can also promote aluminum intoxication by augmenting aluminum absorption in the GI tract.

When determining the dose of bicarbonate replacement, the goal for therapy is to achieve a normal serum bicarbonate level of 24 mEq/L (24 mmol/L). The dose is usually determined by calculating the base deficit: $(0.5 \text{ L/kg} \times [\text{body weight}]) \times ([\text{normal } CO_2] - [\text{measured } CO_2])$. Because of the risk of volume overload resulting from the sodium load administered with bicarbonate replacement, the total base deficit should be administered over several days. Once the goal serum bicarbonate level is attained, a maintenance dose of bicarbonate is necessary and should be titrated to maintain serum bicarbonate levels. Altering

bicarbonate levels in the dialysate fluid in patients receiving dialysis may assist with the treatment of metabolic acidosis, although pharmacologic therapy may still be required.

▶ *Outcome Evaluation*

Monitor serum electrolytes and arterial blood gases regularly. Monitor edema after initiation of diuretic therapy. Monitor fluid intake to ensure obligatory losses are being met and avoid dehydration. If adequate diuresis is not attained with a single agent, consider combination therapy with another diuretic. In patients with cardiac abnormalities due to elevated potassium levels, monitor ECG continuously until serum potassium levels drop below 5 mEq/L (5 mmol/L) or cardiac abnormalities resolve. Evaluate serum potassium and glucose levels within 1 hour in patients who receive insulin and dextrose therapy. Evaluate serum potassium levels within 2 to 4 hours after treatment with SPS or diuretics. Repeat doses of diuretics or SPS if necessary until serum potassium levels fall below 5 mEq/L (5 mmol/L). Monitor blood pressure and serum potassium levels in 1 week in patients who receive fludrocortisone. Correct metabolic acidosis slowly to prevent the development of metabolic alkalosis or other electrolyte abnormalities.

## RENAL REPLACEMENT THERAPY

Patients who progress to ESKD require RRT. The modalities that are used for RRT are dialysis, including hemodialysis (HD) and peritoneal dialysis (PD), and kidney transplantation. The United States Renal Data Service (USRDS) reported that the number of patients with ESKD was 636,905, with 114,813 new cases diagnosed in 201.[3] Kidney transplantation is the preferred method of RRT, owing to improved patient survival. The expected life expectancy of patients with ESKD is only 25% of the general population, while patients with a transplant have a life expectancy that approaches 75% to 80% of the general population.[3] However, organ availability limits the number of patients who can receive a kidney transplant. Only 2.5% of patients with newly diagnosed ESKD receive kidney transplants each year.[3] Therefore, the most common form of RRT is dialysis, accounting for 70% of all patients with ESKD.[3] The principles and complications associated with dialysis are discussed later. Chapter 55 discusses the principles of kidney transplantation.

### Indications for Dialysis

KEY CONCEPT *Planning for dialysis should begin when GFR falls less than 30 mL/min/1.73 m² (0.29 mL/s/m²) (Stage 4; GFR category 4),[1] when progression to ESKD is inevitable, to allow time to educate the patient and family on the treatment modalities and establish the appropriate access for the modality of choice.* Ideally, initiation of dialysis should be done at a point when the patient is ready to undergo treatment, rather than when the patient is in emergent need of dialysis.

Initiation of dialysis depends on the patient's clinical status and not based solely on laboratory values. Symptoms that may indicate the need for dialysis include persistent anorexia, nausea, vomiting, fatigue, and pruritus. Other criteria that indicate the need for dialysis include declining nutritional status, declining serum albumin levels, uncontrolled hypertension, and volume overload, which may manifest as chronic heart failure, and electrolyte abnormalities, particularly hyperkalemia. **Blood urea nitrogen** (BUN) and SCr levels may be used as a guide for the initiation of dialysis, but they should not be the absolute

| Table 26–9 |
| --- |
| **Advantages and Disadvantages of Hemodialysis** |

**Advantages**
1. Higher solute clearance allows intermittent treatment
2. Parameters of adequacy of dialysis are better defined and therefore underdialysis can be detected early
3. The technique's failure rate is low
4. Even though intermittent heparinization is required, hemostasis parameters are better corrected with hemodialysis than peritoneal dialysis
5. In-center hemodialysis enables closer monitoring of the patient

**Disadvantages**
1. Requires multiple visits each week to the hemodialysis center, which translates into loss of control by the patient
2. Dysequilibrium, dialysis, hypotension, and muscle cramps are common. May require months before patient adjusts to hemodialysis
3. Infections in hemodialysis patients may be related to the choice of membranes; the complement-activating membranes are more deleterious
4. Vascular access is frequently associated with infection and thrombosis
5. Decline of residual renal function is more rapid compared with peritoneal dialysis

From Sowinski KM, Churchwell MD, Decker BS. Hemodialysis and peritoneal dialysis. In: DiPiro JT, Talbert RL, Yee GC, et al., eds. Pharmacotherapy: A Pathophysiologic Approach, 9th ed. New York, NY: McGraw-Hill, 2014:666, with permission.

| Table 26–10 |
| --- |
| **Advantages and Disadvantages of Peritoneal Dialysis** |

**Advantages**
1. More hemodynamic stability (blood pressure) due to slow ultrafiltration rate
2. Increased clearance of larger solutes, which may explain good clinical status in spite of lower urea clearance
3. Better preservation of residual renal function
4. Convenient intraperitoneal route of administration of drugs such as antibiotics and insulin
5. Suitable for elderly and very young patients who may not tolerate hemodialysis well
6. Freedom from the "machine" gives the patient a sense of independence (for continuous ambulatory peritoneal dialysis)
7. Less blood loss and iron deficiency, resulting in easier management of anemia or reduced requirements for erythropoietin and parenteral iron
8. No systemic heparinization requirement
9. Subcutaneous versus IV erythropoietin or darbepoetin is usual, which may reduce overall doses and be more physiologic

**Disadvantages**
1. Protein and amino acid losses through the peritoneum and reduced appetite owing to continuous glucose load and sense of abdominal fullness predispose to malnutrition
2. Risk of peritonitis
3. Catheter malfunction, and exit site and tunnel infection
4. Inadequate ultrafiltration and solute dialysis in patients with a large body size, unless large volumes and frequent exchanges are employed
5. Patient burnout and high rate of technique failure
6. Risk of obesity with excessive glucose absorption
7. Mechanical problems such as hernias, dialysate leaks, hemorrhoids, or back pain may occur
8. Extensive abdominal surgery may preclude peritoneal dialysis
9. No convenient access for IV iron administration

From Sowinski KM, Churchwell MD, Decker BS. Hemodialysis and peritoneal dialysis. In: DiPiro JT, Talbert RL, Yee GC, et al., eds. Pharmacotherapy: A Pathophysiologic Approach, 9th ed. New York, NY: McGraw-Hill, 2014:667, with permission.

indicator. Dialysis is initiated in most patients after the GFR falls below 15 mL/min/1.73 m$^2$ (0.14 mL/s/m$^2$).[1] Patients should determine which modality of dialysis to use based on their own preferences. Advantages and disadvantages of hemodialysis and peritoneal dialysis are listed in **Tables 26–9** and **26–10**, respectively.

The goals of dialysis are to remove toxic metabolites to decrease uremic symptoms, correct electrolyte abnormalities, restore acid–base status, and maintain volume status to ultimately improve quality of life and decrease the morbidity and mortality associated with ESKD.

## Hemodialysis

Hemodialysis is the most common method of RRT, initiated in 91% of US patients with newly diagnosed ESKD each year, with a total of 408,711 patients receiving HD in 2012.[3] Home HD is becoming increasingly more popular, but most patients continue to receive HD from a dialysis center.

### ▶ *Principles of Hemodialysis*

KEY CONCEPT *Hemodialysis involves the exposure of blood to a semipermeable membrane (dialyzer) against which a physiologic solution (dialysate) is flowing (Figure 26–6).* The dialyzer is composed of thousands of capillary fibers made up of the semipermeable membrane, which are enclosed in the dialyzer, to increase the surface area of blood exposure to maximize the efficiency of removing substances. The dialysate is composed of purified water and electrolytes, and it is run through the dialyzer countercurrent to the blood on the other side of the semipermeable membrane. The process allows for the removal of several

substances from the bloodstream, including water, urea, creatinine, electrolytes, uremic toxins, and drugs. Sterilization is not required for dialysate because the membrane prevents bacteria from entering into the bloodstream. However, if the membrane ruptures during hemodialysis, infection becomes a major concern for the patient.

Three types of membranes used for dialysis are classified by the size of the pores and the ability to remove solutes from the bloodstream:

- Conventional (standard) membranes have small pores, which limit solute removal to relatively small molecules, such as creatinine and urea.
- High-efficiency membranes also have small pores but have a higher surface area that increases removal of small molecules, such as water, urea, and creatinine from the blood.
- High-flux membranes have larger pores that allow for the removal of substances with higher molecular-weight, including some drugs, such as vancomycin, than conventional membranes.

Three primary processes are utilized for the removal of substances from the blood:
**FIGURE 26–6.** In hemodialysis, the patient's blood is pumped to the dialyzer at a rate of 300 to 600 mL/min. An anticoagulant (usually heparin) is administered to prevent clotting in the dialyzer. The dialysate is pumped at the rate of 500 to 1000 mL/min through the dialyzer countercurrent to the flow of blood. The rate of fluid removal from the patient is controlled by adjusting the pressure in the dialysate compartment. (From Sowinski KM, Churchwell MD, Decker BS. Hemodialysis and peritoneal dialysis. In: DiPiro JT, Talbert RL, Yee GC, et al., eds. Pharmacotherapy: A Pathophysiologic Approach, 9th ed. New York, NY: McGraw-Hill, 2014:669, with permission.)

- **Diffusion** is the movement of a solute across the dialyzer membrane from an area of higher concentration (usually the blood) to a lower concentration (usually the dialysate). This process removes small molecules from the bloodstream, such as electrolytes. At times, solutes can be added to the dialysate that are diffused into the bloodstream. Changing the composition of the dialysate allows for control of the amount of electrolytes that are being removed.

- **Ultrafiltration** is the movement of solvent (plasma water) across the dialyzer membrane by applying hydrostatic or osmotic pressure, and it is the primary means for removing water from the bloodstream. Changing the hydrostatic

## Patient Encounter 4, Part 1

A 35-year-old Caucasian man with a history of IgA nephropathy presents to the clinic with complaints that he "feels awful." He hasn't felt like eating for several weeks and has lost 15 lb (6.8 kg) in the last 3 months.

**PMH:** IgA nephropathy; depression; hypertension; hyperlipidemia

**Current Meds:** Bupropion 150 mg orally daily; cinacalcet 30 mg orally daily; escitalopram 10 mg orally daily; hydralazine 50 mg orally three times daily; labetalol 200 mg orally twice daily; calcium acetate 1334 mg orally three times daily with meals; pravastatin 40 mg orally daily

**ROS:** Lethargic male in mild distress

**PE:**

**VS:** BP 178/108 mm Hg, P 86 beats/min, T 97.2°F (36.2°C), Ht 5'10" (178 cm), Wt 186 lb (84.4 kg)

**CV:** RRR, normal $S_1$, $S_2$, present

**Lungs:** Crackles at bases; mild inspiratory wheezes

**Ext:** 4+ bilateral lower extremity edema present to mid-thigh

**Labs:** Sodium 138 mEq/L (138 mmol/L); potassium 6.3 mEq/L (6.3 mmol/L); chloride 106 mEq/L (106 mmol/L); carbon dioxide 15 mEq/L (15 mmol/L); BUN 42 mg/dL (15.0 mmol/L); SCr 4.2 mg/dL (371 μmol/L); glucose 62 mg/dL (3.4 mmol/L); calcium 9.8 mg/dL (2.45 mmol/L); phosphate 5.6 mg/dL (1.81 mmol/L); iPTH 315 pg/mL (315 ng/L; 33.7 pmol/L); WBC $6.8 \times 10^3$ cells/mm³ ($6.8 \times 10^9$/L); RBC $4.0 \times 10^6$ cells/mm³ ($4.0 \times 10^{12}$/L); Hgb 10.4 g/dL (104 g/L; 6.46 mmol/L); Hct 30% (0.30); platelets $278 \times 10^3$ cells/mm³ ($278 \times 10^9$/L)

*What indications does the patient have for dialysis?*

*What alternatives for renal replacement therapy exist for the patient?*

*What are the advantages and disadvantages of each modality for renal replacement?*

pressure applied to the dialyzer or the osmotic concentration of the dialysate allows for control of the amount of water being removed.

- **Convection** is the movement of dissolved solutes across the dialyzer membrane by "dragging" the solutes along a pressure gradient with a fluid transport and is the primary means for larger molecules to be removed from the bloodstream, such as urea. Changing the pore size of the dialyzer membrane alters the efficiency of convection and allows for control of the amount of water removed in relation to the amount of solute being removed.

▶ *Vascular Access*

Long-term permanent access to the bloodstream is a key component of HD. There are three primary techniques used to obtain permanent vascular access in patients receiving HD: arteriovenous fistulas (AVFs), arteriovenous grafts (AVGs) and catheters. An AVF is the preferred access method because it has the longest survival rate and the fewest complications. An AVF is made by creating an anastomosis between an artery and a vein, usually in the forearm of the nondominant arm (**Figure 26–7**). An AVG results in a similar access site but uses a synthetic graft, usually made of polytetrafluoroethylene, to connect the artery and vein in the forearm (see Figure 26–7). The advantage of the AVG is that it is able to be used within 2 to 3 weeks, compared with 2 to 3 months for an AVF. However, AVGs are complicated by stenosis, thrombosis, and infections, which lead to a shorter survival time of the graft. Double-lumen venous catheters, placed in the femoral, subclavian, or jugular vein, are often used as temporary access while waiting for the AVF or AVG to mature. The catheters are tunneled beneath the skin to an exit site to reduce the risk of infection. Venous catheters can also be used as permanent access in patients in whom arteriovenous access cannot be established.

▶ *Complications of Hemodialysis*

Complications associated with HD include hypotension, muscle cramping, thrombosis, infection and vitamin depletion. The physiology of these complications is described below and the management is listed in **Table 26–11**.

**Hypotension**   Hypotension is the most common complication seen during hemodialysis. It has been reported to occur with approximately 10% to 30% of dialysis sessions but may be as frequent as 50% of sessions in some patients.[40]

*Pathophysiology.*   Hypotension associated with hemodialysis manifests as a symptomatic sudden drop of more than 30 mm Hg in mean arterial or systolic pressure or a systolic pressure drop to less than 90 mm Hg during the dialysis session. The primary cause is fluid removal from the bloodstream. Ultrafiltration removes fluid from the plasma, which promotes redistribution of fluids from extracellular spaces into the plasma. However, decreased serum albumin levels and removal of solutes from the bloodstream decrease the osmotic pressure of the plasma relative to the extracellular spaces, slowing redistribution during hemodialysis. The decreased plasma volume causes hypotension. Other factors that can contribute to hypotension include

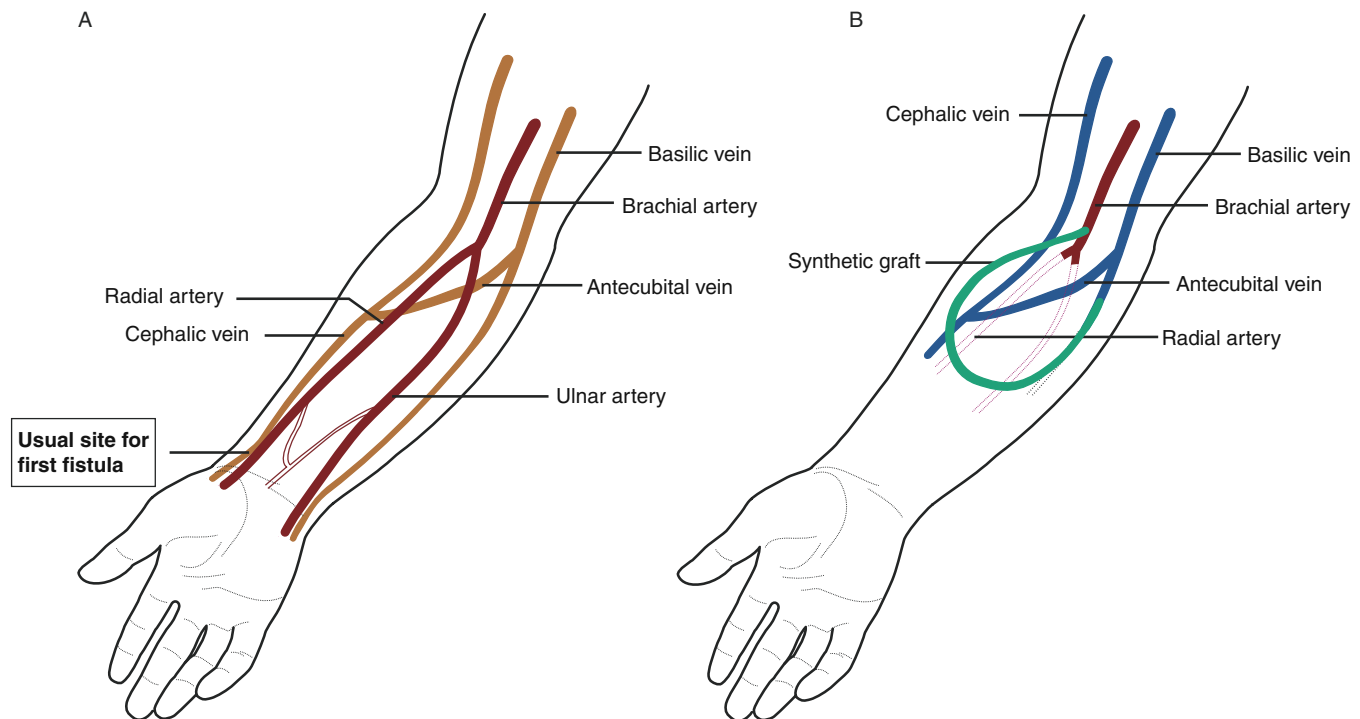

**FIGURE 26–7.**  The predominant types of vascular access for chronic dialysis patients are (A) the arteriovenous fistula and (B) the synthetic arteriovenous forearm graft. The first primary arteriovenous fistula is usually created by the surgical anastomosis of the cephalic vein with the radial artery. The flow of blood from the higher-pressure arterial system results in hypertrophy of the vein. The most common AV graft (depicted in green) is between the brachial artery and the basilic or cephalic vein. The flow of blood may be diminished in the radial and ulnar arteries because it preferentially flows into the low pressure graft. (From Sowinski KM, Churchwell MD, Decker BS. Hemodialysis and peritoneal dialysis. In: DiPiro JT, Talbert RL, Yee GC, et al., eds. Pharmacotherapy: A Pathophysiologic Approach, 9th ed. New York, NY: McGraw-Hill, 2014:668, with permission.)

| Table 26–11 | | |
|---|---|---|
| **Management of Complications Associated with Hemodialysis** | | |
| **Hypotension** | Acute treatment | Place in Trendelenburg position (head lower than feet) |
| | | Normal saline 100–200 mL |
| | | Hypertonic saline (23.4%) 10–20 mL |
| | | Mannitol 12.5 g |
| | Prevention | Accurate determination of "dry weight" |
| | | Midodrine 2.5–10 mg 30 minutes prior to HD |
| | | Other options with limited evidence: |
| | | Levocarnitine 20 mg/kg IV after HD |
| | | Sertraline 50–100 mg daily |
| | | Fludrocortisone 0.1 mg before HD |
| **Muscle Cramps** | Acute treatment | Normal saline 100–200 mL |
| | | Hypertonic saline (23.4%) 10–20 mL |
| | | Dextrose 50% 50 mL (for nondiabetic patients) |
| | Prevention | Decrease ultrafiltration rate |
| | | Accurate determination of "dry weight" |
| | | Stretching exercises, massage, flexing, compression devices |
| | | Vitamin E 400 IU daily |
| **Central Venous Catheter Thrombosis** | Acute treatment | Normal saline flush |
| | | Alteplase 2 mg/2 mL per catheter lumen port |
| | | Reteplase 0.4 units/0.4 mL per catheter lumen port |
| | Prevention | Heparin lock (1000–10,000 units/1 mL) |
| | | Sodium citrate 4% lock |
| **Vitamin Depletion** | Prevention | Multivitamin B complex with vitamin C supplement |

antihypertensive medications prior to HD, a target "dry weight" (the target weight after HD session is complete) that is too low, diastolic or autonomic dysfunction, low dialysate calcium or sodium, high dialysate temperature, or ingesting meals prior to or during HD.

Risk factors that may increase the potential for hypotension include elderly age, diabetes, autonomic neuropathy, uremia, and cardiac disease.[40] The symptoms associated with hypotension during dialysis include dizziness, nausea, vomiting, sweating, and chest pain.

**Muscle Cramps** Muscle cramps can occur with up to 20% of dialysis sessions.[40] The cause is often related to excessive ultrafiltration, which causes hypoperfusion of the muscles. Other contributing factors to the development of muscle cramps include hypotension and electrolyte and acid–base imbalances that occur during hemodialysis sessions.

**Thrombosis** Thrombosis associated with hemodialysis most commonly occurs in patients with venous catheter access for dialysis and is a common cause of catheter failure. However, thrombosis can occur in synthetic grafts and less frequently in AV fistulas.

**Infection** Infections are an important cause of morbidity and mortality in patients receiving hemodialysis. The cause of infection is usually related to organisms found on the skin, namely *Staphylococcus epidermidis* and *Staphylococcus aureus*. Methicillin-resistant *S. aureus* (MRSA) is a common cause of infections in patients receiving hemodialysis. Other organisms have also been found to cause access-related infections. The greatest risk to patients receiving hemodialysis is the development of bacteremia. As with thrombosis, venous catheters are most commonly infected, followed by synthetic AV grafts, and finally AV fistulas.

Blood cultures should be obtained for any patient receiving hemodialysis who develops a fever. Nonpharmacologic management of infections involves preventive measures with sterile technique, proper disinfection, and minimizing the use and duration of venous catheters for hemodialysis access.

Pharmacologic management of infections should cover the gram-positive organisms that most frequently cause access-related infections. Patients who have positive blood cultures should receive treatment tailored to the organism isolated. Preventive measures for access-related infections include mupirocin at the exit site and povidone-iodine ointment. The recommendations of the National Kidney Foundation (NKF) for treatment of infections associated with hemodialysis are listed in Table 26–12.

| Table 26–12 | |
|---|---|
| **Management of Hemodialysis Access Infections[41]** | |
| **AV Fistula** | Treat as subacute bacterial endocarditis for 6 weeks |
| | Initial antibiotic choice should always cover gram-positive organisms (eg, vancomycin 20 mg/kg IV with serum concentration monitoring or cefazolin 20 mg/kg IV three times per week) |
| | Gram-negative coverage is indicated for patients with diabetes, HIV infection, prosthetic valves, or those receiving immunosuppressive agents (gentamicin 2 mg/kg IV with serum concentration monitoring) |
| **Synthetic Grafts (AVG)** | |
| Local infection | Empiric antibiotic coverage for gram-positive, gram-negative, and *Enterococcus* (eg, gentamicin plus vancomycin, then individualize after culture results become available); continue for 2–4 weeks |
| Extensive infection | Antibiotics as above plus total resection |
| Access < 1 month old | Antibiotics as above plus removal of the graft |
| **Tunneled Cuffed Catheters (Internal Jugular, Subclavian)** | |
| Infection localized to catheter exit site | No drainage: topical antibiotics (eg, mupirocin ointment) |
| | Drainage present: Gram-positive coverage (eg, cefazolin 20 mg/kg IV three times a week) |
| Bacteremia with or without systemic signs or symptoms | Gram-positive coverage as above |
| | If stable and asymptomatic, change catheter and provide culture-specific antibiotic coverage for a minimum of 3 weeks |

AV, arteriovenous.

**Vitamin Depletion** Water-soluble vitamins removed by HD contribute to malnutrition and vitamin deficiency syndromes. Patients receiving HD often require replacement of water-soluble vitamins to prevent adverse effects. The vitamins that may require replacement are ascorbic acid, thiamine, biotin, folic acid, riboflavin, and pyridoxine. Patients receiving HD should receive a multivitamin B complex with vitamin C supplement, but they should not take supplements that include fat-soluble vitamins, such as vitamins A, E, or K, which can accumulate in patients with kidney failure.

## Peritoneal Dialysis

Peritoneal dialysis is initiated in 6% of patients with newly diagnosed ESKD each year. Currently, 40,631 patients were receiving PD dialysis in 2012.[3] Peritoneal dialysis is associated with improved survival compared with hemodialysis.[3] Peritoneal dialysis preserves residual renal function, which improves cardiovascular stability and may account for the improved survival. Thus PD may be the preferred method of dialysis in patients with residual renal function.

### ▶ Principles of Peritoneal Dialysis

PD utilizes similar principles as hemodialysis in that blood is exposed to a semipermeable membrane against which a physiologic solution is placed. In the case of PD, however, the semipermeable membrane is the peritoneal membrane, and a sterile dialysate is instilled into the peritoneal cavity. The peritoneal membrane is composed of a continuous single layer of mesothelial cells that covers the abdominal and pelvic walls on one side of the peritoneal cavity, and the visceral organs including the GI tract, liver, spleen, and diaphragm on the other side. The mesothelial cells are covered by microvilli that increase the surface area of the peritoneal membrane to approximate body surface area ($1–2$ m$^2$). Blood vessels that supply the abdominal organs, muscle, and mesentery serve as the blood component of the system.

The gaps between the mesothelial cells allow for large solutes to pass through into the bloodstream. Both the interstitium and endothelial cells of the blood vessels provide resistance to limit the solute size that is removed from the blood. Diffusion is the most important component of solute transport in PD, which is enhanced by the large surface area and volume of dialysate, as well as contact time with the peritoneal membrane. Ultrafiltration is achieved in PD by creating an osmotic pressure gradient between the dialysate and the blood. Traditionally, glucose has been used to create the osmotic gradient, but the solutions are not biocompatible with the peritoneal membrane, resulting in cytotoxicity of the cells. More recently, polymeric glucose derivatives such as icodextrin have been used to create a colloid-driven osmosis that results in ultrafiltration and convection of solute removal.

In PD, prewarmed dialysate is instilled into the peritoneal cavity where it "dwells" for a specified length of time (usually one to several hours, depending on the type of PD) to adequately clear metabolic waste products and excess fluids and electrolytes. At the end of the dwell time, the dialysate is drained and replaced with fresh dialysate. The continuous nature of PD provides for a more physiologic removal of waste products from the bloodstream, which mimics endogenous kidney function by decreasing the fluctuations seen in serum concentrations of the waste products. Similarly, water is removed at a more constant rate, lessening the fluctuations in intravascular fluid balance and providing for more hemodynamic stability.

**Patient Encounter 4, Part 2**

The patient returns to the dialysis clinic 6 months later for his follow-up after starting peritoneal dialysis. He states that his dialysate was cloudy yesterday evening.

**PE:**

**VS:** BP 145/88 mm Hg, P 78 beats/min, T 101.4 F (38.6° C), Wt 178 lb (80.7 kg)

**Abd:** Erythema and tenderness at the catheter site

*What organisms are most likely to cause his peritonitis?*

*What empiric antibiotic treatment is recommended?*

Several types of PD are used:

- Continuous ambulatory peritoneal dialysis (CAPD) is the most common. The patient exchanges 1 to 3 L of dialysate every 4 to 6 hours throughout the day with a longer dwell time overnight.
- Automated peritoneal dialysis (APD) procedures involve the use of a cycler machine that performs sequential exchanges overnight while the patient is sleeping.
- Continuous cycling PD (CCPD) performs three to five exchanges throughout the night. The final exchange remains in the peritoneal cavity to dwell for the duration of the day.
- Nightly intermittent PD (NIPD) performs six to eight exchanges throughout the night. The final exchange of dialysate is drained in the morning, and the peritoneal cavity remains empty throughout the day.
- Nocturnal tidal PD (NTPD) is similar to NIPD, with the exception that only a portion of the dialysate is exchanged throughout the night. The final exchange is drained in the morning, and the peritoneal cavity remains empty throughout the day.

### ▶ Peritoneal Access

Access to the peritoneal cavity requires placement of an indwelling catheter with the distal end of the catheter resting in the peritoneal cavity. The central portion of the catheter is generally tunneled under the abdominal wall and subcutaneous tissue where it is held in place by cuffs that provide stability and mechanical support to the catheter. The proximal portion of the catheter exits the abdomen near the umbilicus (Figure 26–8). Several types of indwelling catheters are available; the most common is the Tenckhoff catheter. Placement and handling of the catheter during PD exchanges requires a sterile environment to minimize the risk of infectious complications.

### ▶ Complications of Peritoneal Dialysis

Complications associated with PD include mechanical problems related to the PD catheter, metabolic problems associated with the components of the dialysate fluid, damage to the peritoneal membrane, and infections (Table 26–13). Strategies to manage infectious complications of PD are discussed below.

**Peritonitis** Peritonitis is a leading cause of morbidity in PD patients, which often leads to loss of the catheter and subsequent change to HD as the treatment modality. However, recent advances with connectors used during instillation and drainage
**FIGURE 26–8.** Diagram of the placement of a peritoneal dialysis catheter through the abdominal wall into the peritoneal cavity. (From Sowinski KM, Churchwell MD, Decker BS. Hemodialysis and peritoneal dialysis. In: DiPiro JT, Talbert RL, Yee GC, et al., eds. Pharmacotherapy: A Pathophysiologic Approach, 9th ed. New York, NY: McGraw-Hill, 2014:675, with permission.)

---

### Table 26–13

**Common Complications During Peritoneal Dialysis**

**Mechanical Complications**
Kinking in catheter
Catheter migration
Catheter adherence to peritoneal tissue
Excessive movement of catheter at exit site
**Peritoneal Damage**
Alterations in permeability of the peritoneal membrane
Sclerosis of the peritoneal membrane
**Pain**
Impingement of the catheter tip on visceral organs
Instillation pain
• Rapid inflow of dialysate
• Acidic pH of dialysate
• Chemical irritation from dialysate additives (eg, antibiotics)
• Low dialysate temperature
**Infections**
Peritonitis
Exit-site infections
Tunnel infections
**Metabolic Complications**
Exacerbation of diabetes mellitus from glucose load
Fluid overload
• Exacerbation of chronic heart failure
• Edema
• Pulmonary congestion
Electrolyte abnormalities
Malnutrition
• Albumin and amino acid loss
• Muscle wasting
• Increased adipose tissue
• Fibrin formation in dialysate
Weight gain

---

of dialysate and delivery systems have dramatically decreased the incidence of peritonitis. Peritonitis can be caused by chemical irritation or microorganisms.

*Pathophysiology.* Gram-positive organisms, namely *S. epidermidis*, are the most common cause of peritonitis. Other pathologic organisms include *S. aureus*, streptococcal species, enterococcus species, gram-negative organisms including *Escherichia coli* and *Pseudomonas* species, and fungal organisms. Peritonitis should be presumed if cloudy fluid is drained from the peritoneal cavity and the fluid should be evaluated by cultures. Antibiotic treatment should be initiated immediately, until cell counts and cultures prove otherwise.[42] Patients with peritonitis may also complain of abdominal pain, although pain may be absent in some cases.

*Treatment.* The International Society of Peritoneal Dialysis (ISPD) revised the recommendations for the treatment of PD-related infections in 2010.[42] Drug selection for empirical treatment of peritonitis should cover both gram-positive and gram-negative organisms specific to the dialysis center and be based on the protocols and sensitivity patterns of organisms known to cause peritonitis, as well as the history of infections in the patient. First-generation cephalosporins, such as cefazolin, or vancomycin are recommended for empirical coverage of gram-positive organisms. Appropriate coverage for gram-negative organisms includes third- or fourth-generation cephalosporins, such as ceftazidime or cefepime, or aminoglycosides. Alternatives for gram-negative coverage include oral fluoroquinolones. An example of an appropriate empiric treatment for peritonitis includes cefazolin in combination with ceftazidime, cefepime, or an aminoglycoside. If the patient has a cephalosporin allergy, vancomycin in combination with an aminoglycoside is an alternative empirical treatment.[42] It should be noted that aminoglycosides can decrease residual renal function in patients receiving peritoneal dialysis.

The preferred route of administration is intraperitoneal (IP) rather than IV to achieve maximum concentrations at the site of infection. Antibiotics can be administered IP intermittently as a single large dose in one exchange per day or continuously as multiple smaller doses with each exchange. Intermittent administration requires at least 6 hours of dwell time in the peritoneal cavity to allow for adequate systemic absorption and provides adequate levels to cover the 24-hour period. However, continuous administration is better suited for PD modalities that require more frequent exchanges (less than 6-hour dwell time). See the ISPD guidelines for dosing recommendations for IP antibiotics in CAPD and automated PD patients.[42] The dose of the antibiotics should be increased by 25% for patients with residual kidney function who are able to produce more than 100-mL urine output per day.

Once the organism has been identified and sensitivities are known, drug selection should be adjusted to reflect the susceptibilities of the organism. Streptococcal, staphylococcal, and enterococcal species sensitive to β-lactam antibiotics should be treated with continuous IP dosing to increase efficacy and minimize resistance.[42] Peritonitis caused by *S. aureus* or *P. aeruginosa* are often associated with catheter-related infections, which are difficult to treat and often require removal of the catheter. Rifampin 600 mg orally daily (in a single or divided dose) may be added to IP vancomycin for the treatment of methicillin-resistant *S. aureus* (MRSA) but should be limited to duration of 1 week to minimize the development of resistance. Two antibiotics are required for treatment of *P. aeruginosa* peritonitis.[42] If multiple organisms are cultured, treatment should cover all of the organisms, including anaerobic organisms, and the patient should be evaluated for other intra-abdominal pathologies.[42]

Peritonitis caused by fungal organisms is associated with mortality in 25% of patients,[42] which can be reduced by removing the catheter after fungal organisms are identified. Empirical treatment should include IP amphotericin B and flucytosine.[42] Although IP amphotericin administration is associated with chemical irritation and pain, penetration of amphotericin into the peritoneal cavity is poor with IV administration. Fluconazole, voriconazole, or caspofungin may be suitable alternatives, depending on culture results.

### Catheter-Related Infections
Catheter-related infections generally occur at the exit site or the portion of the catheter that is tunneled in the subcutaneous tissue. Previous infections increase the risk and incidence of catheter-related infections.

*Pathophysiology.* The major pathologic organisms responsible for causing catheter-related infections are *S. aureus* and *P. aeruginosa*. These organisms also cause the most serious catheter-related infections. *S. epidermidis* is found in less than 20% of catheter-related infections. Other organisms include diphtheroids, anaerobic bacteria, *Legionella*, and fungi.[42]

Exit-site infections present with purulent drainage at the site. Erythema may or may not be present with an exit-site infection. Tunnel infections are generally extensions of exit-site infections and rarely occur alone. Symptoms of a tunnel infection may include tenderness, edema, and erythema over the tunnel pathway but are often asymptomatic. Ultrasound can be used to detect tunnel infections in asymptomatic patients. Exit-site infections caused by *S. aureus* and *P. aeruginosa* often spread to tunnel infections and are the most common causes of catheter-infection–related peritonitis.

*Treatment.* Exit-site infections may be treated immediately with empiric coverage, or treatment may be delayed until cultures return. Empiric treatment of catheter-related infections should cover *S. aureus*. Coverage for *P. aeruginosa* should also be included if the patient has a history of infections with this organism.[42] Cultures and sensitivity testing are particularly important in tailoring antibiotic therapy for catheter-related infections to ensure eradication of the organism and prevent recurrence or related peritonitis.

Less severe infections may be treated with topical antibiotic cream, although this practice is controversial. Oral antibiotics are also effective for treatment of catheter-related infections. Empiric or routine use of vancomycin for gram-positive infections should be avoided unless the infection is caused by MRSA. Rifampin may be added to therapy for severe infections or slowly resolving *S. aureus* infections, but monotherapy is not recommended.[42] Oral fluoroquinolones are used as first-line agents to treat *P. aeruginosa*, which can be difficult to treat and require prolonged treatment. If the infection is slow to resolve or if it recurs, IP ceftazidime or a second agent should be added.[42] Treatment of catheter-related infections should be continued until the exit site appears normal with no erythema or drainage. Generally, at least 2 weeks of therapy or longer are required to ensure complete eradication of the organism and prevent future recurrence, which is common with *S. aureus* and *P. aeruginosa*. Infections that do not resolve may require replacement of the PD catheter. Catheter-related infections that present in conjunction with or progress to peritonitis with the same organism require removal of the PD catheter until the peritonitis is resolved.[42]

### Prophylaxis of Peritonitis and Catheter-Related Infections
Prevention of peritonitis and catheter-related infections starts when the catheter is placed. The exit site should be properly cared for until it is well healed before it can be used for PD. Patients should receive proper instructions for care of the catheter during this time period, which can last up to 2 weeks. Patients should also be instructed on the proper techniques to use for dialysate exchanges to minimize the risk of infections during exchanges, which is the most common cause of peritonitis.

Intranasal *S. aureus* increases the risk of *S. aureus* exit-site infections, tunnel infections, peritonitis, and subsequent catheter loss.[43] Several measures have been used to decrease the risk of peritonitis caused by *S. aureus*, including mupirocin cream or ointment applied daily around the exit site, intranasal mupirocin cream twice daily for 5 days each month, or rifampin 300 mg orally twice daily for 5 days, repeated every 3 months.[42,43] Mupirocin use is preferred over rifampin to prevent the development of resistance to rifampin, although mupirocin resistance has also been reported.[42] Other measures that have been used to decrease both *S. aureus* and *P. aeruginosa* infections include gentamicin cream applied twice daily and ciprofloxacin otic solution applied daily to the exit site.[42]

### Outcome Evaluation
Clinical improvement should be seen within 48 hours of initiating treatment for peritonitis or catheter-related infections. Perform daily inspections of peritoneal fluid or the exit site to determine clinical improvement. Peritoneal fluid should become clear with improvement of peritonitis and erythema, and discharge should remit with improvement of catheter-related infections. If no improvement is seen within 48 hours, obtain additional cultures and cell counts to determine the appropriate alterations in therapy.

## Patient Care Process: Chronic Kidney Disease

**Patient Assessment:**

- Determine if the patient should be evaluated for CKD. Does the patient have any risk factors for CKD? (see Table 26–3)

- Review medical and medication history. Does the patient have any concomitant diseases such as diabetes or hypertension that should be treated to prevent the progression of CKD? (see Table 26–3) Is the patient taking any medications that may contribute to kidney dysfunction?

- Review available laboratory tests to determine the staging of CKD (see Tables 26–1 and 26–2) and whether complications associated with CKD are present.

**Therapy Evaluation:**

- For DM, evaluate glucose and blood pressure control (see Figure 26–2).

- If proteinuria is present, determine if an ACE-I or ARB is appropriate for the patient. (see Figure 26–3).

- If anemia is present, determine other factors may be contributing to anemia of CKD (see Figure 26–4).

- If the patient has electrolyte or mineral imbalances, determine if medical therapy is necessary (see Figure 26–5).

- If the patient is already receiving pharmacotherapy, assess efficacy, safety, and patient adherence.

- For dialysis, determine if any dialysis complications are present (Tables 26–11, 26–12, and 26–13).

**Care Plan Development:**

- Select appropriate medical treatment to slow progression of CKD (see Figures 26–2 and 26–3).

- Select appropriate medical treatments to control complications of CKD, including anemia (see Figure 26–4, Tables 26–4 and 26–5); mineral and bone diseases (see Figure 26–5, Tables 26–7 and 26–8); and electrolyte imbalances.

- Ensure that all of the patient's medications are adjusted appropriately for his/her level of kidney function.

- Educate the patient on dietary and lifestyle changes to limit progression of CKD and manage electrolyte and mineral imbalances.

- Stress the importance of adherence with the treatments for CKD and associated complications, including lifestyle modifications and medications. Recommend a therapeutic regimen that is easy for the patient to accomplish.

**Follow-Up Evaluation:**

- Monitor serum creatinine and urine protein excretion at least annually in patients at risk for CKD.

- Monitor electrolyte and mineral levels and blood counts every 3 to 6 months or more frequently if patient requires treatment.

# Abbreviations Introduced in This Chapter

| | |
|---|---|
| 2,3-DPG | 2,3-Diphosphoglycerate |
| ACE-I | Angiotensin-converting enzyme inhibitor |
| AGE | Advanced glycation end-product |
| AKI | Acute kidney injury |
| APD | Automated peritoneal dialysis |
| ARB | Angiotensin receptor blocker |
| AVF | Arteriovenous fistula |
| AVG | Arteriovenous graft |
| BUN | Blood urea nitrogen |
| Ca–P | Calcium–phosphorus product |
| CAPD | Continuous ambulatory peritoneal dialysis |
| CCPD | Continuous cycling peritoneal dialysis |
| CHD | Coronary heart disease |
| CKD | Chronic kidney disease |
| CKD-MBD | Chronic kidney disease mineral and bone disease |
| CVD | Cardiovascular disease |
| DDAVP | Desmopressin |
| DKD | Diabetic kidney disease |
| DM | Diabetes mellitus |
| ECG | Electrocardiogram |
| EPO | Erythropoietin |
| ESA | Erythropoiesis-stimulating agent |
| $FE_K$ | Fractional excretion of potassium |
| $FE_{Na}$ | Fractional excretion of sodium |
| GFR | Glomerular filtration rate |
| GI | Gastrointestinal |
| $HbA_{1c}$ | Hemoglobin $A_{1c}$ |
| Hct | Hematocrit |
| HD | Hemodialysis |
| HDL-C | High-density lipoprotein cholesterol |
| Hgb | Hemoglobin |
| HMG-CoA | 3-Hydroxy-3-methylglutaryl coenzyme A |
| IP | Intraperitoneal |
| iPTH | Intact parathyroid hormone |

# 27 Fluids and Electrolytes

Mark A. Malesker and Lee E. Morrow

## LEARNING OBJECTIVES

**Upon completion of the chapter, the reader will be able to:**

1. Estimate the volumes of various body fluid compartments.
2. Calculate the daily maintenance fluid requirement for patients given their weight and gender.
3. Differentiate among currently available fluids for volume resuscitation.
4. Identify the electrolytes primarily found in the extracellular and intracellular fluid compartments.
5. Describe the unique relationship between serum sodium concentration and total body water (TBW).
6. Review the etiology, clinical presentation, and management for disorders of sodium, potassium, calcium, phosphorus, and magnesium.

## BODY FLUID COMPARTMENTS

A thorough understanding of the fundamentals of fluid and electrolyte homeostasis is essential given the frequency with which clinical disturbances are seen and the profound effects these disturbances can have on various aspects of patient care. However, the interplay of body fluids, serum electrolytes, and clinical monitoring is complex, and a thorough command of these issues is a challenging task even for advanced practitioners.[1] Practitioners must be familiar with the key concepts of body compartment volumes, calculation of daily fluid requirements, and the various types of fluid available for replacement. The management of disorders of sodium, potassium, calcium, phosphorus, and magnesium integrates these concepts with issues of dose recognition and patient safety.

The most fundamental concept to grasp is an assessment of total body water (TBW), which is directly related to body weight. **KEY CONCEPT** *TBW constitutes approximately 50% of lean body weight in healthy females and 60% of lean body weight in males. For clinical purposes, most clinicians generalize that total body water accounts for 60% of lean body weight in adults, regardless of gender.* The percentage of TBW decreases as body fat increases and/or with age (75%–85% of body weight is water for newborns). Unless the patient is obese (body weight greater than 120% of ideal body weight [IBW]), clinicians typically use a patient's actual body weight when calculating TBW.[2] In obese patients, it is customary to estimate TBW using lean body weight or IBW as calculated by the Devine–Devine method: males' lean body weight = 50 kg + (2.3 kg/in. × [height in inches – 60]) and females' lean body weight = 45.5 kg + (2.3 kg/in. × [height in inches – 60]).[3–5] Note that 1 kg is equivalent to 2.2 lb, 1 inch is equivalent to 2.54 cm, and 1 L of water weighs 1 kg (2.2 lb).

The intracellular fluid (ICF) represents the water contained within cells and is rich in electrolytes such as potassium, magnesium, phosphates, and proteins. **KEY CONCEPT** *The ICF is approximately two-thirds of TBW regardless of gender.* For a 70-kg person, this would mean that the TBW is 42 L and the ICF is approximately 28 L. Note that ICF represents approximately 40% of total body weight.

The extracellular fluid (ECF) is the fluid outside the cell and is rich in sodium, chloride, and bicarbonate. **KEY CONCEPT** *The ECF is approximately one-third of TBW (14 L in a 70-kg person) and is subdivided into two compartments: the interstitial fluid and the intravascular fluid.* The interstitial fluid represents the fluid occupying the spaces between cells and is about 25% of TBW (10.5 L in a 70-kg person). The intravascular fluid (also known as plasma) represents the fluid within the blood vessels and is about 8% of TBW (3.4 L in a 70-kg person). Because the exact percentages are cumbersome to recall, many clinicians accept that the ECF represents roughly 20% of body weight (regardless of gender) with 15% in the interstitial space and 5% in the intravascular space.[6] Note that serum electrolytes are routinely measured from the ECF.

The transcellular fluid includes the viscous components of the peritoneum, pleural space, and pericardium, as well as the cerebrospinal fluid, joint space fluid, and the GI digestive juices. Although the transcellular fluid normally accounts for about 1% of TBW, this amount can increase significantly during various illnesses favoring fluid collection in one of these spaces (eg, pleural effusions or ascites in the peritoneum). The accumulation of fluid in the transcellular space is often referred to as "third spacing." To review the calculations of the body fluid compartments in a representative patient, see Patient Encounter 1.

Fluid balance is assessed by several means each of which has its limitations. Blood pressure (BP) measurements estimate fluid status relative to the amount of blood volume pumped by the heart but are affected by cardiac function and vascular pliability. Patients with significant volume deficiency may appear hypotensive, but this is a late finding that may require greater than 20% of TBW to be lost. Patients with significant volume excess may appear edematous; however, third spacing may hide this finding

*Calculate the daily fluid requirement for an 80 kg adult man.*

until late in the course as well. The physical examination can indicate the presence of fluid deficits (dry mucous membranes) and fluid excess (peripheral edema, coarse breath sounds). More invasive assessments would include the use of an arterial catheter, a pulmonary artery catheter to measure left ventricular function and fluid status, and a central venous catheter that measures fluid status and right ventricular function. However, the correlation between these measured pressures and their associated volume is an area of debate.

To maintain fluid balance, the total amount of fluid gained throughout the day (input, or "ins") must equal the total amount of fluid lost (output, or "outs"). Although most forms of the body's input and output can be measured, several cannot. For a normal adult on an average diet, ingested fluids are easily measured and average 1400 mL/day. Other fluid inputs, such as those from ingested foods and the water by-product of oxidation, are not directly measurable. Fluid outputs such as urinary and stool losses are also easily measured and referred to as sensible losses. Other sources of fluid loss, such as evaporation of fluid through the skin and/or lungs, are not readily measured and are called insensible losses. Table 27–1 shows the estimated ins and outs (I&Os) for a healthy 68-kg (150-lb) man.[6] The measurable I&Os are routinely measured in hospitalized patients and are used to estimate total fluid balance for each 24-hour period. It is important to realize that in hospitalized patients, multiple other forms of fluid loss must be considered. These include losses from enteric suctioning (most commonly, nasogastric [NG] tubes), from surgical drains (eg, chest tubes, nephrostomy tubes, and pancreatic drains), via fistulous tracts, and enhanced evaporative losses (burns and fever).

TBW depletion (often referred to as "dehydration") is typically a gradual, chronic problem. Because TBW depletion represents a loss of hypotonic fluid (proportionally more water is lost than sodium) from all body compartments, a primary disturbance of osmolality is usually seen. The signs and symptoms of TBW depletion include CNS disturbances (mental status changes, seizures, and coma), excessive thirst, dry mucous membranes, decreased skin turgor, elevated serum sodium, increased plasma osmolality, concentrated urine, and acute weight loss. Common causes of TBW depletion include insufficient oral intake, excessive insensible losses, diabetes insipidus, excessive osmotic diuresis, and

impaired renal concentrating mechanisms. Elderly long-term care residents are frequently admitted to the acute care hospital with TBW depletion secondary to lack of adequate oral intake, often with concurrent excessive insensible losses.

The volume of fluid required to correct TBW depletion equals the basal fluid requirement plus ongoing exceptional losses plus the fluid deficit. Basal daily fluid requirements are calculated using the formulas in Table 27–2. For an adult, this represents 1500 mL/day for the first 20 kg of body weight plus 20 mL/day for each additional kilogram. The volume of replacement fluids required for a given patient (the fluid deficit) can be estimated by the acute weight change in the patient (1 kg = 1 L of fluid). Because the precise weight change is not typically known, it is often calculated as follows: fluid deficit = normal TBW – present TBW. Normal TBW is estimated based on the patient's weight using the formulas in Table 27–2, and the present TBW is estimated based on the patient's current body weight. The choice of fluids used for replacement is guided by the presence of concurrent electrolyte abnormalities. The adequacy of replacement is guided by each patient's objective response to fluid replacement (improved skin turgor, adequate urine output, normalization of heart rate, BP, etc).

Once TBW has been restored, the volume of "maintenance" fluid equals the basal fluid requirement plus ongoing exceptional losses. If the pathophysiologic process leading to TBW depletion has not been identified and corrected (or accounted for in the calculation of maintenance fluid requirements), TBW depletion will quickly recur. To review the concepts involved in the calculation of replacement fluids for a representative patient, see Patient Encounter 2.

Compared with TBW depletion, ECF depletion tends to occur acutely. In this setting, rapid and aggressive fluid replacement is required to maintain adequate organ perfusion. Because ECF depletion is generally due to the loss of isotonic fluid (proportional losses of sodium and water), major disturbances of plasma osmolality are not common. ECF depletion manifests clinically as signs and symptoms associated with decreased tissue perfusion: dizziness, orthostasis, tachycardia, decreased urine output, increased hematocrit, decreased central venous pressure, and/or hypovolemic shock. Common causes of ECF depletion include external fluid losses (burns, hemorrhage, diuresis, GI losses, and adrenal insufficiency) and third spacing of fluids (septic shock, anaphylactic shock, or abdominal ascites).

In clinical practice, the most commonly encountered problem is depletion of TBW and ECF. Accordingly, the fluid resuscitation strategy should address both of these compartments. As these

### Table 27–1

**Approximate I&Os for a Healthy 68-kg (150-lb) Man**

| Input | mL/day | Output | mL/day |
|---|---|---|---|
| Ingested fluid[a] | 1400 | Urine[a] | 1500 |
| Fluid in food | 850 | Skin losses | 500 |
| Water of oxidation | 350 | Respiratory tract losses | 400 |
| | | Stool | 200 |
| Total | 2600 | Total | 2600 |

[a]Readily quantifiable.

### Table 27–2

**Useful Calculations for the Estimation of Patient Maintenance Fluid Requirements**

Neonate (1–10 kg) = 100 mL/kg
Child (10–20 kg) = 1000 mL + 50 mL for each kilogram > 10
Adult (> 20 kg) = 1500 mL + 20 mL for each kilogram > 20

compartments are repleted, serum electrolytes must be monitored closely as discussed in subsequent sections of this chapter.

## THERAPEUTIC FLUIDS
### Crystalloids

KEY CONCEPT *Therapeutic IV fluids include crystalloid solutions and colloidal solutions.* Crystalloids are composed of water and electrolytes, all of which pass freely through semipermeable membranes and remain in the intravascular space for shorter periods of time. As such, these solutions are very useful for correcting electrolyte imbalances but result in smaller hemodynamic changes for a given unit of volume.

Crystalloids can be classified further according to their tonicity. Isotonic solutions (ie, normal saline or 0.9% sodium chloride [NaCl]) have a tonicity equal to that of the ICF (approximately 310 mEq/L or 310 mmol/L) and do not shift the distribution of water between the ECF and the ICF. Because hypertonic solutions (eg, hypertonic saline or 3% NaCl) have greater tonicity than the ICF (greater than 376 mEq/L or 376 mmol/L), they draw water from the ICF into the ECF. In contrast, hypotonic solutions (eg, 0.45% NaCl) have less tonicity than the ICF (less than 250 mEq/L or 250 mmol/L) leading to osmotic pressure gradient that favors shifts of water from the ECF into the ICF. The tonicity, electrolyte content, and glucose content of selected fluids are shown in Table 27–3.

The tonicity of crystalloid solutions is directly related to their sodium concentration. The most commonly used crystalloids include normal saline, dextrose/half-normal saline, hypertonic saline, and lactated Ringer's solution. Excessive administration of any fluid replacement therapy, regardless of tonicity, can lead to fluid overload, particularly in patients with cardiac or renal insufficiency. Glucose is often added to hypotonic crystalloids in amounts that result in isotonic fluids ($D_5$W, D5½NS, and D5¼NS). These solutions are often used as maintenance fluids to provide basal amounts of calories and water.

▶ *Normal Saline (0.9% NaCl or NS)*

Normal saline is an isotonic fluid composed of water, sodium, and chloride. It provides primarily ECF replacement and can be used for virtually any cause of TBW depletion. Common uses of normal saline include perioperative fluid administration; volume resuscitation of shock, sepsis, hemorrhage, or burn patients; fluid challenges in hypotensive or oliguric patients; and hyponatremia. Normal saline can also be used to treat metabolic alkalosis (also known as contraction alkalosis). Large volumes of normal saline can cause a hyperchloremic metabolic acidosis.

▶ *Half-Normal Saline (0.45% NaCl or ½ NS)*

Half-normal saline is a hypotonic fluid that provides free water in relative excess when compared with the sodium concentration. This crystalloid is typically used to treat patients who are hypertonic due to primary depletion of the ECF. Because half-normal saline is hypotonic, serum sodium must be closely monitored during administration.

▶ *5% Dextrose/Half-Normal Saline (D5 ½ NS)*

D5 ½ NS is a hypotonic fluid that is commonly used as a maintenance fluid. This crystalloid is typically used once fluids deficits have been corrected with normal saline or lactated Ringer's solution. Because half-normal saline is hypotonic, serum sodium must be closely monitored during administration.

## Table 27–3

**Electrolyte and Dextrose Content of Selected Crystalloid Fluids**

| IV Solution | Osmolarity (mOsm or mmol) | Dextrose (g/L) mmol/L | Sodium (mEq/L) mmol/L | Potassium (mEq/L) mmol/L | Calcium (mEq/L) mmol/L | Chloride (mEq/L) mmol/L | Lactate (mEq/L) mmol/L |
|---|---|---|---|---|---|---|---|
| D5% | 250 | 50 / 2.78 | | | | | |
| D10% | 505 | 100 / 5.55 | | | | | |
| 0.9% NaCl | 308 | | 154 | | | 154 | |
| 0.45% NaCl | 154 | | 77 | | | 77 | |
| 3% NaCl | 1025 | | 512 | | | 512 | |
| D5% and 0.45% NaCl | 405 | 50 / 2.78 | 77 | | | 77 | |
| D5% and 0.2% NaCl | 329 | 50 / 2.78 | 34 | | | 34 | |
| Ringer's injection | 310 | | 147 | 4 | 5 / 2.5 | 156 | |
| Lactated Ringer's solution | 274 | | 130 | 4 | 3 / 1.5 | 109 | 28 |
| Lactated Ringer's solution and D5% | 525 | 50 / 2.78 | 130 | 4 | 3 / 1.5 | 109 | 28 |

D, dextrose; NaCl, sodium chloride.

### ► *Hypertonic Saline (3% NaCl)*

Hypertonic saline is obviously hypertonic and provides a significant sodium load to the intravascular space. This solution is used very infrequently given the potential to cause significant shifts in the water balance between the ECF and the ICF. It is typically used to treat patients with severe hyponatremia who have symptoms attributable to low serum sodium. Hypertonic saline in concentrations of 7.5% to 23.4% has been used to acutely lower intracranial pressure in the setting of traumatic brain injury and stroke. The literature is inconsistent for the optimal hypertonic concentration, dosing, timing of replacement, and goals for use in this population. Serum sodium and neurologic status must be very closely monitored whenever given.

### ► *Ringer's Lactate*

This isotonic volume expander contains sodium, potassium, chloride, and lactate in concentrations that approximate the fluid and electrolyte composition of the blood. Ringer's lactate (also known as "Lactated Ringers," or LR) provides ECF replacement and is most often used in the perioperative setting and for patients with lower GI fluid losses, burns, or dehydration. The lactate component of LR works as a buffer to increase the pH. Accordingly, large volumes of LR may cause iatrogenic metabolic alkalosis. Because patients with significant liver disease are unable to metabolize lactate sufficiently, LR administration in this population may lead to accumulation of lactate with iatrogenic lactic acidosis.

### ► *5% Dextrose in Water ($D_5W$)*

$D_5W$ solution is a combination of free water and dextrose that provides a modest amount of calories but no electrolytes. Although it is technically isotonic, it acts as a hypotonic solution in the body. It is commonly used to treat severe hypernatremia. $D_5W$ is also used in small volumes (100 mL) to dilute many IV medications or at a low infusion rate (10–15 mL/hour) to "keep the vein open" (KVO) for IV medications.

## Colloids

In contrast to crystalloids, colloids do not dissolve into a true solution and therefore do not pass readily across semipermeable membranes. As such, colloids effectively remain in the intravascular space and increase the oncotic pressure of the plasma. This effectively shifts fluid from the interstitial compartment to the intravascular compartment. In clinical practice, these theoretical benefits are generally short lived (given metabolism of colloidal proteins/sugars), and for most patients there is little therapeutic advantage of colloids over crystalloids or vice versa. Examples of colloids include 5% albumin, 25% albumin, the dextrans, hetastarch, and fresh-frozen plasma (FFP). Because each of these agents contains a substance (proteins and complex sugars) that will ultimately be metabolized, the oncotic agent will be ultimately lost and only the remaining hypotonic fluid delivery agent will remain. As such, use of large volumes of colloidal agents is more likely to induce fluid overload compared with crystalloids. Although smaller volumes of colloids have equal efficacy as larger volumes of crystalloids, they generally must be infused more slowly. Often the net result is that the time to clinical benefit is the same regardless of which class of fluid is utilized. For example, 500 mL of normal saline is required to increase the systolic BP to the same degree as seen with approximately 250 mL of 5% albumin; however, the normal saline can be administered twice as fast.

### ► *Albumin*

Albumin is a protein derived from fractionating human plasma. Because albumin infusion is expensive and may be associated with adverse events, it should be used for acute volume expansion and *not* as a supplemental source of protein calories. Historically, albumin was used indiscriminately in the intensive care unit until anecdotal publications suggested that albumin may cause immunosuppression. However, the Saline Versus Albumin Fluid Evaluation (SAFE) trial randomized nearly 7000 hypovolemic patients to either albumin or normal saline therapy and found that the mortality for those who received albumin was the same as for those who received normal saline.[7] A subsequent post hoc analysis reported that patients with traumatic brain injury had higher mortality rates when given albumin for fluid resuscitation. These conflicting findings highlight the controversy and confusion surrounding the use of human albumin versus normal saline therapy for resuscitation of critically ill patients.[8–9] In 1818 patients with severe sepsis, albumin replacement with crystalloids as compared to crystalloids alone did not improve the rate of survival at 28 and 90 days.[10]

Based on limited availability, health systems and hospitals have had to define the appropriate albumin indications for their patients and ration albumin accordingly. Evidence-based indications for albumin include plasmapheresis/apheresis, large-volume paracentesis (greater than 4 L removed), hypotension in hemodialysis, and the need for aggressive diuresis in hypoalbuminemic hypotensive patients. Inappropriate uses of albumin include nutritional supplementation, impending hepatorenal syndrome, pancreatitis, alteration of drug pharmacokinetics, or acute normovolemic hemodilution in surgery. Practitioners can keep up with medication shortages by checking the American Society of Health-System Pharmacists (ASHP) Web site—www.ashp.org.

### ► *Hydroxyethyl Starch Solutions and Dextran*

While albumin is the most commonly used colloid, the other available products are not without their own risks and benefits. Hydroxyetyl starch solutions (HES) include Hetastarch (various manufacturers) and Voluven, Hospira, contain 6% starch and 0.9% NaCl. Hextend, Hospira, is a comparable plasma expander that contains 6% hetastarch in lactated electrolyte solution. HES products have no oxygen-carrying capacity and are administered intravenously as plasma expanders. Limitations of these products include acquisition cost, hypersensitivity reactions, and bleeding. Dosing should be reduced in the presence of renal dysfunction. Recent clinical data linking HES solutions with an increased risk of mortality and renal injury requiring renal replacement therapy in critically ill patients prompted the FDA to issue a MedWatch safety communication in November 2013. FDA concluded these solutions should not be used in critically ill patients, including sepsis and those admitted to the intensive care unit, and a boxed warning to highlight the risk of mortality and severe renal injury is warranted. A list of recommendations for patients and health care providers to consider before use of HES solutions can be found on the FDA website. (http://www.fda.gov/Safety/MedWatch/)

Low-molecular-weight dextran (various manufacturers) and high-molecular-weight dextran (various manufacturers) are polysaccharide plasma expanders. Anaphylactic reactions and prolonged bleeding times have limited the use of these products. Potential mechanisms of colloid solution-induced bleeding include platelet inhibition or possible dilution of clotting factors via infusion of a large-volume colloid solution.

A recent Cochrane review regarding the use of colloids versus crystalloids for fluid resuscitation in critically ill patients found no evidence from randomized clinical trials that resuscitation with colloids reduces the risk of death in patients with trauma, burns or following surgery. Additionally, the use of HES might be associated with mortality and given the lack of survival benefit and increased expense over crystalloids the continued of use of colloids is limited.[11]

## Fluid Management Strategies

Classic indications for IV fluid include maintenance of BP, restoring the ICF volume, replacing ongoing renal or insensible losses when oral intake is inadequate, and the need for glucose as a fuel for the brain.[12] Although large volumes of fluid are given during the resuscitation of most trauma patients, a recent analysis reported uncertainty about the use of early large-volume fluid replacement in patients with active bleeding, calling into question our understanding of the need for fluids in various patient populations.[13]

When determining the appropriate fluid to be utilized, it is important to first determine the type of fluid problem (TBW vs ECF depletion), and start therapy accordingly. For patients demonstrating signs of impaired tissue perfusion, the immediate therapeutic goal is to increase the intravascular volume and restore tissue perfusion. The standard therapy is normal saline given at 150 to 500 mL/hour (for adult patients) until perfusion is optimized. Although LR is a therapeutic alternative, lactic acidosis may arise with massive or prolonged infusions. LR has less chloride content versus normal saline (109 mEq/L [109 mmol/L] vs 154 mEq/L [154 mmol/L]) and has the advantage of use when large volumes of normal saline produce acidosis during fluid resuscitation. In severe cases, a colloid or blood transfusion may be indicated to increase oncotic pressure within the vascular space. Once euvolemia is achieved, patients may be switched to a more hypotonic maintenance solution (D5½ NS or 0.45% NaCl) at a rate that delivers estimated daily needs.

The clinical scenario and the severity of the volume abnormality dictate monitoring parameters during fluid replacement therapy. These may include the subjective sense of thirst, mental status, skin turgor, orthostatic vital signs, pulse rate, weight changes, blood chemistries, fluid input and output, central venous pressure, pulmonary capillary wedge pressure, and cardiac output. Fluid replacement requires particular caution in patient populations at risk of fluid overload, such as those with renal failure, cardiac failure, hepatic failure, or the elderly. Other complications of parenteral fluid therapy include IV site infiltration, infection, phlebitis, thrombophlebitis, and extravasation.

In summary, common settings for fluid resuscitation include hypovolemic patients (eg, sepsis or pneumonia), hypervolemic patients (eg, congestive heart failure [CHF], cirrhosis, or renal failure), euvolemic patients who are unable to take oral fluids in proportion to insensible losses (eg, the perioperative period), and patients with electrolyte abnormalities (see below).

## ELECTROLYTES

Normally, the number of anions (negatively charged ions) and cations (positively charged ions) in each fluid compartment are equal. Cell membranes play the critical role of maintaining distinct ICF and ECF spaces, which are biochemically distinct. Serum electrolyte measurements reflect the stores of ECF electrolytes rather than that of ICF electrolytes. Table 27–4 lists the chief cations and anions along with their normal concentrations

### Table 27–4

**Normal Cation and Anion Concentrations in the ECF and ICF**

| Ion Species | ECF | | ICF | |
| --- | --- | --- | --- | --- |
| | Plasma (mEq/L [mmol/L]) | Interstitial Fluid (mEq/L [mmol/L]) | Ion Species | mEq/L [mmol/L] |
| Cations | | | Cations | |
| $Na^+$ | 142 [142] | 144 [144] | $K^+$ | 135 [135] |
| $K^+$ | 4 [4] | 4 [4] | $Mg^{2+}$ | 43 [21.5] |
| $Ca^{2+}$ | 5 [2.5] | 2.5 [1.25] | | |
| $Mg^{2+}$ | 3 [1.5] | 1.5 [0.75] | | |
| Total | 154 [150] | 152 [150] | Total | 178 [156.5] |
| Anions | | | Anions | |
| $Cl^-$ | 103 [103] | 114 [114] | $PO_4^{2-}$ | 90 [45] |
| $HCO_3^-$ | 27 [27] | 30 [30] | Protein | 70 [70] |
| $PO_4^{2-}$ | 2 [1] | 2 [1] | $SO_4^{2-}$ | 18 [9] |
| $SO_4^{2-}$ | 1 [0.5] | 1 [0.5] | | |

| Protein | 16 [16] | 0 | | |
| Total | 154 [152.5] | 152 [150.5] | Total | 178 [124] |

ECF, extracellular fluid; ICF, intracellular fluid.

in the ECF and ICF. The principal cations are sodium, potassium, calcium, and magnesium; the key anions are chloride, bicarbonate, and phosphate. In the ECF, sodium is the most common cation and chloride is the most abundant anion; in the ICF, potassium is the primary cation and phosphate is the main anion. Normal serum electrolyte values are listed in Table 27–5.

*Osmolality* is a measure of the number of osmotically active particles per unit of solution, independent of the weight or nature of the particle. Equimolar concentrations of all substances in the undissociated state exert the same osmotic pressure. Although the normal serum osmolality is 280 to 300 mOsm/kg (280–300 mmol/kg), multiple scenarios exist where this value becomes markedly abnormal. **KEY CONCEPT** *The calculated serum osmolality helps determine deviations in TBW content.* As such, it is often useful to calculate the serum osmolality as follows:

Serum **osmolality** (mOsm/kg) =
    2 (Na mEq/L) + (glucose [mg/dL])/18 +
    (BUN [mg/dL])/2.8.

Serum osmolality using SI units (mmol/kg) =
    2 (Na mmol/L) + (glucose mmol/L) +
    (BUN mmol/L)/2.8.

### Table 27–5

**Normal Ranges for Serum Electrolyte Concentrations**

| | |
| --- | --- |
| Sodium | 135–145 mEq/L or 135–145 mmol/L |
| Potassium | 3.5–5.0 mEq/L or 3.5–5.0 mmol/L |
| Chloride | 98–106 mEq/L or 98–106 mmol/L |
| Bicarbonate | 21–30 mEq/L or 21–30 mmol/L |
| Magnesium | 1.4–2.2 mEq/L or 0.7–1.1 mmol/L |
| Calcium: | |
| Total | 4.4–5.2 mEq/L (9–10.5 mg/dL) or 2.2–2.6 mmol/L |
| Ionized | 2.2–2.8 mEq/L (4.5–5.6 mg/dL) or 1.1–1.4 mmol/L |
| Phosphorus | 3–4.5 mg/dL (1.0–1.5 mmol/L) |

## Patient Encounter 3: Calculate the Plasma Osmolality

A 50-year-old homeless man is brought to the emergency department staggering and smelling like beer. Rapid respiration, tachycardia, and a BP of 90/60 mm Hg were noted. The sodium is 140 mEq/L (140 mmol/L), potassium 3.6 mEq/L (3.6 mmol/L), chloride 100 mEq/L (100 mmol/L), bicarbonate 12 mEq/L (12 mmol/L), glucose 200 mg/dL ( 11.1 mmol/L), and BUN 28 mg/dL (10.0 mmol/L). The measured osmolarity is 360 mOsm/kg (360 mmol/kg).

*Calculate the osmolality.*

*Calculate the osmolar gap.*

*What is the likely cause of an increased gap in this patient?*

Because the body regulates water to maintain osmolality, deviations in serum osmolality are used to estimate TBW stores. Water moves freely across all cell membranes, making serum osmolality an accurate reflection of the osmolality within all body compartments. An increase in osmolality is equated with a loss of water greater than the loss of solute (TBW depletion). A decrease in serum osmolality is seen when water is retained in excess of solute (CHF or hepatic cirrhosis). The difference between the measured serum osmolality and the calculated serum osmolality, using the equation just stated, is referred to as the **osmolar gap**. Under normal circumstances the osmolar gap should be 10 mOsm/kg (10 mmol/kg) or less. An increased osmolar gap suggests the presence of a small osmotically active agent and is most commonly seen with the ingestion of alcohols (ethanol, methanol, ethylene glycol, or isopropyl alcohol) or medications such as mannitol or lorazepam. Patient Encounter 3 illustrates the utility of serum osmolality in a clinical setting.

Many of the electrolyte disturbances discussed in the remainder of this chapter represent medical emergencies that call for aggressive interventions including the use of concentrated electrolytes. It is very difficult to immediately reverse the effects of concentrated electrolytes when they are administered improperly, and these solutions are a frequent source of medical errors with significant potential for patient harm. **KEY CONCEPT** *As such, The Joint Commission recommends that concentrated electrolyte solutions (KCl, potassium phosphate, and NaCl greater than 0.9%) be removed from patient care areas*. Hospitals should keep concentrated electrolytes in patient care areas only when patient safety necessitates their immediate use and precautions are used to prevent inadvertent administration. Collaborative cooperation among pharmacists, nurses, and physicians is essential. In addition, The Joint Commission recommends standardizing and limiting the number of drug concentrations available in each institution and the use of ready-to-administer dosage forms so as to further reduce the risk of medication errors and improve outcomes.[14]

### Sodium

The body's normal daily sodium requirement is 1.0 to 1.5 mEq/kg (1.0–1.5 mmol/kg) (80–130 mEq [80–130 mmol]) to maintain a normal serum sodium concentration of 135 to 145 mEq/L (135–145 mmol/L). Sodium is the predominant cation of the ECF and largely determines ECF volume. Sodium is also the primary factor in establishing the osmotic pressure relationship between the ICF and ECF. All body fluids are in osmotic equilibrium, and changes in serum sodium concentration are associated with shifts of water into and out of body fluid compartments. When sodium is added to the intravascular fluid compartment, fluid is pulled intravascularly from the interstitial fluid and the ICF until osmotic balance is restored. As such, a patient's measured sodium concentration should *not* be viewed as an index of sodium need because this parameter reflects the balance between total body sodium content and TBW. Disturbances in the sodium concentration most often represent disturbances of TBW. Sodium imbalances cannot be properly assessed without first assessing body fluid status.

**KEY CONCEPT** *Hyponatremia is the most common electrolyte disorder in hospitalized patients and defined as a serum sodium concentration below 135 mEq/L (135 mmol/L).* Clinical signs and symptoms appear at concentrations below 120 mEq/L (120 mmol/L) and typically consist of irritability, mental slowing, unstable gait/falls fatigue, headache, and nausea. With profound hyponatremia (less than 110 mEq/L [110 mmol/L]), confusion, seizures, stupor/coma, and respiratory arrest may be seen. Clinical practice guidelines regarding the diagnosis and treatment of hyponatremia have recently been published. Hyponatremia can be classified based upon serum sodium concentration, rate of development, symptom severity, serum osmolality, and volume status.[15] Because therapy is also influenced by volume status, hyponatremia is further defined as (a) hypertonic hyponatremia, (b) hypotonic hyponatremia with an increased ECF volume, (c) hypotonic hyponatremia with a normal ECF volume, and (d) hypotonic hyponatremia with a decreased ECF volume.[16]

Hypertonic hyponatremia is usually associated with significant hyperglycemia. Glucose is an osmotically active agent that leads to an increase in TBW with little change in total body sodium. For every 60 mg/dL (3.3 mmol/L) increase in serum glucose above 200 mg/dL (11.1 mmol/L), the sodium concentration is expected to decrease by approximately 1 mEq/L (1 mmol/L). Appropriate treatment of the hyperglycemia will return the serum sodium concentration to normal.[15]

Hypotonic hyponatremia with an increase in ECF (hypervolemic hyponatremia) is also known as dilutional hyponatremia. In this scenario, patients have an excess of total body sodium and TBW; however, the excess in TBW is greater than the excess in total body sodium. Common causes include CHF, hepatic cirrhosis, and nephrotic syndrome. Treatment includes sodium and fluid restriction in conjunction with treatment of the underlying disorder, for example, salt and water restrictions are used in the setting of CHF along with loop diuretics, angiotensin-converting enzyme inhibitors, and spironolactone.

In hypotonic hyponatremia with a normal ECF volume (euvolemic hyponatremia), patients have an excess of TBW with relatively normal sodium content. In essence, there is a presence of excess free water. This is most frequently seen in patients with the syndrome of inappropriate antidiuretic hormone secretion (SIADH). Common causes of SIADH include carcinomas (eg, lung or pancreas), pulmonary disorders (eg, pneumonias or tuberculosis), CNS disorders (eg, meningitis, stroke, tumor, or trauma), and medications (eg, sulfonylureas, antineoplastic agents, barbiturates, morphine, antipsychotics, tricyclic antidepressants, nonsteroidal anti-inflammatory agents, selective serotonin reuptake inhibitors, dopamine agonists, and general anesthetics). These medications stimulate the release of antidiuretic hormone (ADH) from the pituitary gland resulting in water retention and dilution of the body's sodium stores.

Short-term treatment of euvolemic hyponatremia includes fluid restriction, isotonic normal saline, hypertonic saline, or conivaptan. Initial treatment generally consists of fluid

restriction alone. Hypertonic saline is used only when the sodium concentration is less than 110 mEq/L (110 mmol/L) and/or severe symptoms (eg, seizures) are present. Given the limitations associated with these treatment strategies (unpredictable therapeutic effects and side effects), the arginine vasopressin antagonist conivaptan (Vaprisol, Astellas Pharma) was developed for short-term treatment of euvolemic hyponatremia. While conivaptan can also be used to manage hypervolemic hyponatremia in hospitalized patients, it should not be used for hypovolemic hyponatremia. Conivaptan is dosed 20 mg IV over 30 minutes, followed by a 20-mg continuous infusion over 24 hours for up to 4 days.

Long-term treatment options for euvolemic hyponatremia include fluid restriction, demeclocycline, loop diuretics, saline, lithium, urea, and tolvaptan. Demeclocycline (available as generic) is dosed at 600 to 1200 mg/day, takes days before clinical effect is realized, and can cause nephrotoxicity. Lithium (various generics) also has a slow onset of action and is limited by CNS side effects, GI disturbances, and cardiotoxicity. Furosemide (various generics) or other loop diuretics allow relaxation of fluid restriction but can cause significant volume depletion and electrolyte disturbances, and it has the potential for ototoxicity. No specific USP formulation exists for urea and poor palatability, and side effects limits it use. Tolvaptan (Samsca, Otsuka) is an oral alternative to IV conivaptan. This product is indicated for treatment of clinically significant hypervolemic and euvolemic hyponatremia (sodium less than 125 mEq/L [125 mmol/L]) or less marked hyponatremia that is symptomatic and has resisted correction with fluid restriction. Patients with CHF, cirrhosis, and SIADH would be candidates for long-term use. Tolvaptan has a boxed warning for initiation of treatment in a hospital setting because of the need for close sodium monitoring. The initial dose is 15 mg orally daily and may be titrated up to a max of 60 mg. Concurrent use with potent CYP 3A4 inhibitors should be avoided: ketoconazole (available as generic), clarithromycin (available as generic), ritonavir (Norvir, Abbott), diltiazem (available as generic), verapamil (available as generic), fluconazole (available as generic), and grapefruit juice.

In hypotonic hyponatremia with a decreased ECF volume (hypovolemic hyponatremia), patients usually have a deficit of both total body sodium and TBW, but the sodium deficit exceeds the TBW deficit. Common causes include diuretic use, profuse sweating, wound drainage, burns, GI losses (vomiting or diarrhea), hypoadrenalism (low cortisol and low aldosterone), and renal tubular acidosis. Treatment includes the administration of sodium to correct the sodium deficit and water to correct the TBW deficit. The sodium deficit can be calculated with the following equation[2]:

Sodium deficit (mEq or mmol) =
(TBW [in liters]) (desired Na$^+$ concentration
[mEq/L or mmol/L] – current Na$^+$ concentration).

Although both water and sodium are required in this instance, sodium needs to be provided in excess of water to fully correct this abnormality. As such, hypertonic saline (3% NaCl) is often used. One can estimate the change in serum sodium concentration after 1 L of 3% NaCl infusion using the following equation[16]:

Change in serum Na$^+$ (mEq/L or mmol/L) =
(infusate Na$^+$ – serum Na$^+$)/(TBW + 1).

In this formula, TBW is increased by 1 to account for the addition of the liter of 3% NaCl. Patient Encounters 4 and 5 illustrate the concepts of calculating and correcting the sodium deficit.

**Patient Encounter 4: Calculation of Sodium Deficit**

*Calculate the sodium deficit for an 80 kg man with a serum sodium of 121 mEq/L (121 mmol/L).*

Depending on the severity of the hyponatremia and acuity of onset, 0.9%, 3%, or 5% NaCl can be utilized. Most patients can be adequately managed with normal saline rehydration, which is generally the safest agent. Hypertonic saline (3% or 5% NaCl) is generally reserved for patients with severe hyponatremia (less than 120 mEq/L [120 mmol/L]) accompanied by coma, seizures, or high urinary sodium losses. Roughly one-third of the sodium deficit can be replaced over the first 12 hours as long as the replacement rate is less than 0.5 mEq/hour (0.5 mmol/hour). The remaining two-thirds of the deficit can be administered over the ensuing days. Overly aggressive correction of symptomatic hyponatremia (greater than 12 mEq/L [12 mmol/L]) can result in central pontine myelinolysis.[17] Given the potential for irreversible neurologic damage if untreated or if improperly treated, acute hyponatremia is an urgent condition that should be promptly treated with careful attention to monitoring serial sodium values and adjusting therapeutic infusions accordingly.[18]

Hypernatremia is a serum sodium concentration greater than 145 mEq/L (145 mmol/L) and can occur in the absence of a sodium deficit (pure water loss) or in its presence (hypotonic fluid loss).[19] The signs and symptoms of hypernatremia manifest with a serum sodium concentration greater than 160 mEq/L (160 mmol/L) and are usually the same as those found in TBW depletion: thirst, mental slowing, and dry mucous membranes. Signs and symptoms become more profound as hypernatremia worsens, with the patient eventually demonstrating confusion, hallucinations, acute weight loss, decreased skin turgor, intracranial bleeding, and/or coma. Many coexisting disorders and medications may complicate the diagnosis.

The classic causes of hypernatremia are associated with TBW depletion. These include dehydration from loss of hypotonic fluid from the respiratory tract or skin, decreased water intake, osmotic diuresis (eg, mannitol, available as generic), and diabetes insipidus (eg, decreased ADH; phenytoin, available as generic; lithium, available as generic). Hypernatremia in hospitalized patients occurs secondary to inappropriate fluid management in patients at risk for increased free water losses and impaired thirst or restricted water intake.[20] Iatrogenic hypernatremia is occasionally caused by the administration of excessive hypertonic saline. Treatment of hypernatremia includes calculation of the TBW deficit followed by the administration of hypotonic fluids as previously described. The fluid volume should be replaced over 48 to 72 hours depending on the severity of symptoms and the degree of hypertonicity.[21] For asymptomatic patients, the rate of correction should not exceed 0.5 mEq/L/hour (0.5 mmol/L/hour).

**Patient Encounter 5: Estimate the Anticipated Change in Serum Sodium**

*Estimate the anticipated change in serum sodium concentration after the infusion of 1 L of 3% NaCl in an 80 kg man with a serum sodium of 121 mEq/L (121 mmol/L).*

## Patient Encounter 6: Calculate Water Deficit

*Calculate the water deficit in a 78 kg man with a serum sodium of 157 mEq/L (157 mmol/L).*

One rule of thumb is to replace half the calculated TBW deficit over 12 to 24 hours and the other half of the deficit over the next 24 to 48 hours.[2,19] Excessively rapid correction of hypernatremia may lead to cerebral edema and death. Patient Encounters 6 and 7 reinforce the concepts of calculating TBW deficit and expected changes in serum sodium concentration with therapy.

### Potassium

The body's normal daily potassium requirement is 0.5 to 1 mEq/kg (0.5–1 mmol/kg) or 40 to 80 mEq (40–80 mmol) to maintain a serum potassium concentration of 3.5 to 5 mEq/L (3.5–5 mmol/L). Potassium is the most abundant cation in the ICF, balancing the sodium contained in the ECF and maintaining electroneutrality of bodily fluids. Because the majority of potassium is intracellular, serum potassium concentration is not a good measure of total body potassium; however, clinical manifestations of potassium disorders correlate well with serum potassium. The acid–base balance of the body affects serum potassium concentrations: hyperkalemia is routinely seen in patients with decreased pH (acidosis). Potassium regulation is primarily under the control of the kidneys with excess dietary potassium being excreted in the urine. Although mild abnormalities of serum potassium are considered a nuisance, severe hyperkalemia or hypokalemia can be life threatening.[22–24]

Hypokalemia (serum potassium less than 3.5 mEq/L [3.5 mmol/L]) is a common clinical problem. While generally asymptomatic, signs and symptoms of hypokalemia include cramps, muscle weakness, polyuria, electrocardiogram (ECG) changes (flattened T waves and presence of U waves), and cardiac arrhythmias (bradycardia, heart block, atrial flutter, premature ventricular contractions, and ventricular fibrillation). Causes of hypokalemia include GI losses (vomiting, diarrhea, or NG tube suction), renal losses (high aldosterone and low magnesium), inadequate potassium intake (in IV fluids or oral), or alkalosis. Many medications can precipitate hypokalemia. $\beta_2$-agonists (eg, albuterol, available as generic) and insulin (multiple product formulations) lower potassium via cellular redistribution. The use of loop diuretics (furosemide, Lasix, also available as generic), thiazide diuretics (hydrochlorothiazide, available as generic), high-dose antibiotics (penicillin, available as generic), and corticosteroids (prednisone, available as generic) cause renal potassium wasting. In addition, amphotericin B (available as generic), cisplatin (available as generic), and foscarnet (available as generic) can also produce hypokalemia secondary to depletion of magnesium. Hypomagnesemia diminishes intracellular potassium concentration and produces potassium wasting. Given the potential for

## Patient Encounter 7: Calculate the Anticipated Change in Serum Sodium

*Calculate the anticipated change in serum sodium concentration after IV infusion of 1 L of 5% dextrose in a 78 kg man with a serum sodium of 157 mEq/L (157 mmol/L).*

### Table 27–6

**Potassium Content in Various Potassium Salt Preparations**

| Potassium Salt | mEq/g (mmol/g) |
|---|---|
| Potassium gluconate[a] | 4.3 |
| Potassium citrate[a] | 9.8 |
| Potassium bicarbonate[a] | 10.0 |
| Potassium acetate[a] | 10.2 |
| Potassium chloride[b] | 13.4 |

[a]Favored for hypokalemia and concurrent acidosis.
[b]Favored for hypokalemia and concurrent alkalosis.

significant morbidity and mortality, serum potassium concentrations should be monitored closely for patients with known (or suspected) hypokalemia.[2,24,25] Hypokalemia is a risk factor for digitalis toxicity.

Each 1 mEq/L (1 mmol/L) fall in serum potassium (ie, from 4 to 3 mEq/L [4 to 3 mmol/L]) represents a loss of approximately 200 mEq (200 mmol) of potassium in the adult. However, when the serum potassium is below 3 mEq/L (3 mmol/L), each 1 mEq/L (1 mmol/L) fall in serum potassium represents a 200 to 400 mEq (200–400 mmol) reduction in serum concentration in the adult patient. Potassium repletion should be guided by close monitoring of serial serum concentrations instead of using empirically chosen amounts. Of the five potassium salts available, potassium acetate (10.2 mEq/K$^+$/g or 10.2 mmol/K$^+$/g) and KCl (13.4 mEq/K$^+$/g or 13.4 mmol/K$^+$/g) are the most commonly used forms. When hypokalemia occurs in the setting of alkalosis, KCl is the preferred agent; in acidosis, potassium should be provided in the form of acetate, citrate, bicarbonate, or gluconate salt. Table 27–6 outlines the potassium content of each potassium salt preparation, and Table 27–7 lists each of the oral potassium replacement products. Potassium acetate and chloride are available for IV infusions as premixed solutions. The usual dose of these agents is 10 to 20 mEq (10–20 mmol) diluted in 100 mL of normal saline.[2,25,26]

Moderate hypokalemia is defined as a serum potassium of 2.5 to 3.5 mEq/L (2.5–3.5 mmol/L) without ECG changes. In

### Table 27–7

**Oral Potassium Replacement Products**

| Product | Salt | Strength[a] |
|---|---|---|
| Extended/controlled-release tablets | Chloride | 8 mEq (600 mg) |
| | | 10 mEq (750 mg) |
| | | 15 mEq (1125 mg) |
| | | 20 mEq (1500 mg) |
| Effervescent tablets | Chloride and bicarbonate | 10 mEq 20 mEq |
| | | 25 mEq |
| | | 50 mEq |
| Liquid | Chloride | 20 mEq/15 mL (10%) |
| | | 40 mEq/15 mL (20%) |
| Powder packets | Chloride | |
| | | 20 mEq |
| | | 25 mEq |

[a]For potassium, 1 mEq = 1 mmol.

this setting, potassium replacement can usually be given orally at a dose of 40 to 120 mEq/day (40–20 mmol/day). Anecdotally, oral potassium supplementation (see Table 27–7) is often more effective in repleting moderate hypokalemia. For patients with an ongoing source of potassium loss, chronic replacement therapy should be considered. The potassium deficit is a rough approximation of the amount of potassium needed to be replaced and can be estimated as follows:

Potassium deficit (mEq or mmol/L) =
    (4.0 – current serum potassium) × 100

Severe hypokalemia is defined as a serum potassium less than 2.5 mEq/L (2.5 mmol/L) or hypokalemia of any magnitude that is associated with ECG changes (eg, flattening of T wave or elevation of U wave) and cardiac arrhythmias. In these situations, IV replacement should be initiated urgently. **KEY CONCEPT** *Potassium infusion at rates exceeding 10 mEq/hour (10 mmol/hour) requires cardiac monitoring given the potential for cardiac arrhythmias.* Although the maximally concentrated solution for potassium replacement is 80 mEq/L (80 mmol/L), the maximum infusion rate is 40 mEq/hour (40 mmol/hour) and must be administered via a central line. Table 27–8 outlines current IV potassium replacement guidelines.

Caution must be exercised when repleting potassium with IV agents given possible vein irritation and/or thrombophlebitis. The risk of these complications is minimized by using less concentrated solutions and by giving infusions via central access if possible. Administration of potassium in vehicles containing glucose is discouraged because glucose facilitates the intracellular movement of potassium. Posttherapy improvements in serum potassium may be transient, and continuous monitoring is required. Patients with low serum magnesium will have exaggerated potassium losses from the kidneys and GI tract leading to refractory hypokalemia. In this situation, the magnesium deficit must be corrected in order to successfully treat the concurrent potassium deficiency. In the hypokalemic patient with concurrent acidosis, potassium is often given as the acetate salt, given that acetate is metabolized to bicarbonate. In the patient with depleted phosphorus and potassium, therapy with potassium phosphate is the natural choice.[22,27,28]

Hyperkalemia is defined as a serum potassium concentration greater than 5 mEq/L (5 mmol/L). Manifestations of hyperkalemia include muscle weakness, paresthesias, hypotension, ECG changes (eg, peaked T waves, shortened QT intervals, and wide QRS complexes), cardiac arrhythmias, and a decreased pH. Causes of hyperkalemia fall into three broad categories: (a)

increased potassium intake, (b) decreased potassium excretion, and (c) potassium release from the intracellular space.

Increased potassium intake results from excessive dietary potassium (salt substitutes), excess potassium in IV fluids, and other select medications (potassium-sparing diuretics, cyclosporine [available as generic], angiotensin-converting enzyme inhibitors, nonsteroidal anti-inflammatory agents, pentamidine [available as generic], unfractionated heparin, and low-molecular-weight heparins). Decreased potassium excretion results from acute renal failure, chronic renal failure, or Addison disease. Excess potassium release from cells results from tissue breakdown (surgery, trauma, hemolysis, or rhabdomyolysis), blood transfusions, and metabolic acidosis.

In addition to discontinuing all potassium supplements, potassium-sparing medications, and potassium-rich salt substitutes, management of hyperkalemia addresses three concurrent strategies: (a) agents to antagonize the proarrhythmic effects of hyperkalemia, (b) agents to drive potassium into the intracellular space and acutely lower the serum potassium, and (c) agents that will definitively (but more gradually) lower the total body potassium content.[29] If the serum potassium concentration is greater than 7 mEq/L (7 mmol/L) and/or ECG changes are present, IV calcium is provided to stabilize the myocardium. Depending on the acuity of the situation, 1 g of calcium chloride (13.5 mEq or 6.75 mmol) is administered by direct injection or diluted in 50 mL of $D_5W$ and delivered IV over 15 minutes. Clinical effects are seen within 1 to 2 minutes of infusion and persist for 10 to 30 minutes. Repeat doses may be administered as necessary. Because most patients with clinically significant hyperkalemia receive multiple boluses of calcium directed by ECG findings, iatrogenic hypercalcemia is a potential complication of hyperkalemia treatment. As such, total calcium concentration is commonly checked with each potassium concentration measurement. Ionized calcium measurements should be obtained in patients who have comorbid conditions that would lead to inconsistency between total serum calcium and free calcium (abnormal albumin, protein, or immunoglobulin concentrations).

Dextrose and insulin (with or without sodium bicarbonate) are typically given at the time of calcium therapy in order to redistribute potassium into the intracellular space. Dextrose 50% (25 g in 50 mL) can be given by slow IV push over 5 minutes or dextrose 10% with 20 units of regular insulin can be given by continuous IV infusion over 1 to 2 hours. The onset of action for this combination is 30 minutes; the duration of clinical effects is 2 to 6 hours. High-dose inhaled $\beta_2$-agonists (eg, albuterol, available as generic) may also be used to acutely drive potassium into the intracellular space.

It is critically important to recognize that the treatments of hyperkalemia discussed thus far are transient, temporizing measures. They are intended to provide time to institute definitive therapy aimed at removing excess potassium from the body. Agents that increase potassium excretion from the body include sodium polystyrene sulfonate (Kayexalate, available as generic), loop diuretics, and hemodialysis or hemofiltration (used only in patients with renal failure). Sodium polystyrene sulfonate can be given orally, via NG tube, or as a rectal retention enema and is dosed at 15 to 60 g in four divided doses per day. In September 2009, MedWatch issued a safety alert that cases of colonic necrosis and other serious GI-adverse events (bleeding, ischemic colitis, perforation) had been reported in association with Kayexalate use. The majority of these cases reported the concurrent use of sorbitol. Concurrent administration of sorbitol is no longer recommended. Medication safety alerts are available at www.fda.gov/MedWatch.

### Table 27–8

**Recommended Potassium Dosage/Infusion Rate**

| Clinical Scenario | Maximum Infusion Rate[a] | Maximum Concentration[a] | Maximum 24-Hour Dose[a] |
|---|---|---|---|
| K⁺ > 2.5 mEq/L *and* No ECG changes of hypokalemia | 10 mEq/hour | 40 mEq/L | 200 mEq |
| K⁺ < 2.5 mEq/L *or* ECG changes of hypokalemia | 40 mEq/hour | 80 mEq/L | 400 mEq |

[a]For potassium, 1 mEq = 1 mmol.

## Calcium

More than 99% of total body calcium is found in bone; the remaining less than 1% is in the ECF and ICF. Calcium plays a critical role in the transmission of nerve impulses, skeletal muscle contraction, myocardial contractions, maintenance of normal cellular permeability, and the formation of bones and teeth. There is a reciprocal relationship between the serum calcium concentration (normally 8.6–10.2 mg/dL [2.15–2.55 mmol/L]) and the serum phosphate concentration that is regulated by a complex interaction between parathyroid hormone, vitamin D, and calcitonin. About one-half of the serum calcium is bound to plasma proteins; the other half is free ionized calcium. Given that the serum calcium has significant protein binding, the serum calcium measurement must be corrected in patients who have low albumin concentrations (the major serum protein). The most commonly used formula adds 0.8 mg/dL (0.2 mmol/L) of calcium for each gram of albumin deficiency as follows:

Corrected [Ca mg/dL] =
    Measured [Ca mg/dL]
    + [0.8 × (4–measured albumin g/dL)][30–32]
Corrected [Ca mmol/L] =
    Measured [Ca mmol/L]
    + [0.02 × (40–measured albumin g/L)]

Hypocalcemia is caused by inadequate intake (vitamin deficiency, poor dietary calcium sources, alcoholism) or excessive losses (hypoparathyroidism, renal failure, alkalosis, pancreatitis). Clinical manifestations of hypocalcemia are seen with total serum concentrations less than 6.5 mg/dL (1.63 mmol/L) or an ionized calcium less than 1.12 mmol/L and include tetany, circumoral tingling, muscle spasms, hypoactive reflexes, anxiety, hallucinations, hypotension, myocardial infarction, seizures, lethargy, stupor, and **Trousseau's sign** or **Chvostek's sign**.[24,33] Trousseau's sign is elicited by inflating a BP cuff on the patient's upper arm, whereby hypocalcemic patients will experience tetany of the wrist and hand as evidenced by thumb adduction, wrist flexion, and metacarpophalangeal joint flexion. Chvostek sign is elicited by tapping on the proximal distribution of the facial nerve (adjacent to the ear). This will produce a brief spasm of the upper lip, eye, nose, or face in hypocalcemic patients. Ionized calcium concentrations are typically used to assess calcium status in the critically ill patient.

Causes of hypocalcemia include hypoparathyroidism, hypomagnesemia, alcoholism, hyperphosphatemia, blood product infusion (due to chelation by the citrate buffers), chronic renal failure, vitamin D deficiency, acute pancreatitis, alkalosis, and hypoalbuminemia. In the setting of hypocalcemia, magnesium concentration should be checked and corrected if low. Given that hypocalcemia may be caused by hypomagnesemia, clinicians should be aware that the serum calcium concentrations may not normalize until serum magnesium is replaced. Medications that cause hypocalcemia include phosphate replacement products, loop diuretics, phenytoin (Dilantin, available as generic), phenobarbital (available as generic), corticosteroids, aminoglycoside antibiotics, and acetazolamide (available as generic).[34–36]

Oral calcium replacement products include calcium carbonate (Os-Cal, GlaxoSmithKline and various generics; Tums, GlaxoSmithKline and various generics) and calcium citrate (Citracal, Mission Bayer and various generics). IV calcium replacement products include calcium gluconate and calcium chloride (both products available as generic). **KEY CONCEPT** *Calcium gluconate is preferred for peripheral use because it is less irritating to the veins; it may also be given intramuscularly.* Each 10 mL of a 10% calcium gluconate solution provides 90 mg (4.5 mEq or 2.25 mmol) of elemental calcium. **KEY CONCEPT** *Calcium chloride is associated with more venous irritation and extravasation and is generally reserved for administration via central line.* Each 10 mL of a 10% calcium chloride solution contains 270 mg (13.5 mEq or 6.75 mmol) of elemental calcium. IV calcium products are given as a slow push or added to 500 to 1000 mL of 0.9% normal saline for slow infusion.[33,36] In addition to hypocalcemia, IV calcium may also be used for massive blood transfusions, calcium channel blocker overdose, and emergent hyperkalemia and hypermagnesemia.

For acute symptomatic hypocalcemia, 200 to 300 mg of elemental calcium is administered IV and repeated until symptoms are fully controlled. This is achieved by infusing 1 g of calcium chloride or 2 to 3 g of calcium gluconate at a rate no faster than 30 to 60 mg of elemental calcium per minute. More rapid administration is associated with hypotension, bradycardia, or cardiac asystole. Total calcium concentration is commonly monitored in critically ill patients. Under normal circumstances, about half of calcium is loosely bound to serum proteins while the other half is free. Total calcium concentration measures bound and free calcium. Ionized calcium measures free calcium only. Under usual circumstances, a normal calcium concentration implies a normal free ionized calcium concentration. Ionized calcium should be obtained in patients with comorbid conditions that would lead to inconsistency between total calcium and free serum calcium (abnormal albumin, protein, or immunoglobulin concentrations). For chronic asymptomatic hypocalcemia, oral calcium supplements are given at doses of 2 to 4 g/day of elemental calcium. Many patients with calcium deficiency have concurrent vitamin D deficiency that must also be corrected in order to restore calcium homeostasis.[2,33,37]

Hypercalcemia is defined as a calcium concentration greater than 10.2 mg/dL (2.55 mmol/L). It may be categorized as mild if total serum calcium is 10.3 to 12 mg/dL (2.58–3.00 mmol/L), moderate if total serum calcium is 12.1 to 13 mg/dL (3.03–3.25 mmol/L), or severe when serum concentration is greater than 13 mg/dL (3.25 mmol/L). Causes of hypercalcemia include hyperparathyroidism, malignancy, Paget disease, Addison disease, granulomatous diseases (eg, tuberculosis, sarcoidosis, or histoplasmosis), hyperthyroidism, immobilization, multiple bony fractures, acidosis, and milk-alkali syndrome. Multiple medications cause hypercalcemia and include thiazide diuretics, estrogens, lithium (available as generic), tamoxifen (Nolvadex, available as generic), vitamin A, vitamin D, and calcium supplements.[2,33,36,37]

Because the severity of symptoms and the absolute serum concentration are poorly correlated in some patients, institution of therapy should be dictated by the clinical scenario. All patients with hypercalcemia should be treated with aggressive rehydration: normal saline at 200 to 300 mL/hour is a routine initial fluid prescription. For patients with mild hypercalcemia, hydration alone may provide adequate therapy. The moderate and severe forms of hypercalcemia are more likely to have significant manifestations and require prompt initiation of additional therapy. These patients may present with anorexia, confusion, and/or cardiac manifestations (bradycardia and arrhythmias with ECG changes). Total calcium concentrations greater than 13 mg/dL (3.25 mmol/L) are particularly worrisome because these concentrations can unexpectedly precipitate acute renal failure, ventricular arrhythmias, and sudden death.

**Table 27–9**

**Selected Treatment Options for the Management of Hypercalcemia**

| Therapy | Dose | Onset | Duration | Efficacy[a] |
|---|---|---|---|---|
| Normal saline | 3–6 L/day | Hours | Hours | 1–2 mg/dL (0.25–0.50 mmol/L) |
| Furosemide (Lasix, available as generic) | 80–160 mg/day | Hours | Hours | 1–2 mg/dL (0.25–0.50 mmol/L) |
| Hydrocortisone (available as generic) | 200 mg/day | Hours | Days | Mild/unpredictable |
| Calcitonin (Miacalcin, Novartis) | 4–8 units/kg | Hours | Hours | 1–2 mg/dL (0.25–0.50 mmol/L) |
| Pamidronate (Aredia, available as generic) | 30–90 mg/week | Days | 1–4 weeks | 1–5 mg/dL(0.25–1.25 mmol/L) |
| Zoledronic acid (Zometa, Novartis) | 4–8 mg | Days | Weeks | 1–5 mg/dL (0.25–1.25 mmol/L |
| Gallium (Ganite, Genta Inc.) | 200 mg/m² | Days | Days to weeks | 1–5 mg/dL (0.25–1.25 mmol/L) |

[a]Expected decrease in serum $Ca^{2+}$.

Once fluid administration has repleted the ECF, forced diuresis (with associated calcium loss) can be initiated with a loop diuretic. For this approach to be successful, normal kidney function is required. In renal failure patients, the alternative therapy is emergent hemodialysis. Other treatment options include bisphosphonates (zoledronic acid [Zometa, Novartis], pamidronate [Aredia, available as generic]), hydrocortisone (available as generic), calcitonin, and gallium. Given their efficacy and favorable side-effect profile, bisphosphonates are typically the agents of choice. Table 27–9 outlines the treatment options for hypercalcemia, including time to onset of effect, duration of effect, and efficacy.[2,33,34,37]

## Phosphorus

Phosphorus is primarily found in the bone (80%–85%) and ICF (15%–20%): the remaining less than 1% is found in the ECF. Note that phosphorus is the major anion within the cells. Given this distribution, serum phosphate concentration does not accurately reflect total body phosphorus stores. Phosphorus is expressed in milligrams (mg) or millimoles (mmol), not as milliequivalents (mEq). Because phosphorus is the source of phosphate for adenosine triphosphate (ATP) and phospholipid synthesis, manifestations of phosphorus imbalance are variable.

Dietary intake, parathyroid hormone levels, and renal function are the major determinants of the serum phosphorus concentration, which is normally 2.7 to 4.5 mg/dL (0.87–1.45 mmol/L).[2,33,39,40] Hypophosphatemia is defined by a serum phosphorus concentration less than 2.5 mg/dL (0.81 mmol/L); severe hypophosphatemia occurs when the phosphorus concentration is less than 1 mg/dL (0.32 mmol/L). Hypophosphatemia can be caused by increased distribution to the ICF (hyperglycemia, insulin therapy, or malnourishment), decreased absorption (starvation, excessive use of phosphorus-binding antacids, vitamin D deficiency, diarrhea, or laxative abuse) or increased renal loss (diuretic use, diabetic ketoacidosis, alcohol abuse, hyperparathyroidism, or burns).[35,37] **KEY CONCEPT** *Severe hypophosphatemia can result in impaired diaphragmatic contractility and acute respiratory failure.* Medications that cause hypophosphatemia include diuretics (acetazolamide [Diamox, available as generic], furosemide [Lasix, available as generic], hydrochlorothiazide [HydroDIURIL, available as generic]), sucralfate (Carafate, available as generic), corticosteroids, cisplatin (available as generic), antacids (aluminum carbonate, calcium carbonate, and magnesium oxide [antacids all available as generic]), foscarnet (available as generic), phenytoin (Dilantin, available as generic), phenobarbital (available as generic), and phosphate binders (sevelamer [Renvela, Genzyme Corp.], and calcium acetate [PhosLo, available as generic]).

Signs and symptoms of hypophosphatemia include paresthesias, muscle weakness, myalgias, bone pain, anorexia, nausea, vomiting, red blood cell breakdown (hemolysis), acute respiratory failure, seizures, and coma.[37,41] For mild hypophosphatemia, patients should be encouraged to eat a high-phosphorus diet, including eggs, nuts, whole grains, meat, fish, poultry, and milk products. For moderate hypophosphatemia (1–2.5 mg/dL, 0.32–0.81 mmol/L), oral supplementation of 1.5 to 2 g/day (30–60 mmol/day) is usually adequate. Diarrhea may be a dose-limiting side effect with oral phosphate replacement products.

Injectable phosphate products are reserved for patients with severe hypophosphatemia or those in the intensive care unit.[42] The available agents are provided as sodium or potassium salts; however, unless concurrent hypokalemia is present, sodium phosphate is usually used. Empirically, for a mild serum phosphorus deficiency (2.3–3.0 mg/dL, 0.74–0.97 mmol/L), the corresponding IV phosphorus dose is 0.32 mmol/kg; for a moderate deficiency of serum phosphorus 1.6 to 2.2 mg/dL (0.52–0.71 mmol/L), the replacement dose is 0.64 mmol/kg; and the dose is 1 mmol/kg when the serum phosphorus is less than 1.5 mg/dL (0.48 mmol/L).[36] IV phosphorus preparations are usually infused over 4 to 12 hours. Table 27–10 compares the available phosphate replacement products.

Hyperphosphatemia is defined by a serum phosphorus concentration greater than 4.5 mg/dL (1.45 mmol/L). The manifestations of hyperphosphatemia are similar to findings of hypocalcemia (see earlier), and include paresthesias, ECG changes (prolonged QT interval and prolonged ST segment), and metastatic calcifications. Causes of hyperphosphatemia include impaired phosphorus excretion (hypoparathyroidism or renal failure), redistribution of phosphorus to the ECF (acid–base imbalance, rhabdomyolysis, muscle necrosis, or tumor lysis during chemotherapy), and increased phosphorus intake (various medications).[37] Medications that can cause hyperphosphatemia include enemas containing phosphorus (eg, Fleet, Fleet), laxatives containing phosphate or phosphorus, parenteral or oral supplements (eg, K-Phos Neutral, Beach), vitamin D supplements, and the bisphosphonates (eg, pamidronate, various manufacturers).[43]

Hyperphosphatemia is generally benign and rarely needs aggressive therapy. Dietary restriction of phosphate and protein is effective for most minor elevations. Phosphate binders such as aluminum-based antacids, calcium carbonate, calcium acetate (PhosLo, available as generic), sevelamer hydrochloride (Renagel, Genzyme), sevelamer carbonate (Renvela, Genzyme, Global), and lanthanum carbonate (Fosrenol, Shire) may be necessary for some patients (typically those with chronic renal failure).[49] Sucroferric oxyhydroxide (Velphoro, Fresenius Medical Care)

| Table 27–10 |

and ferric citrate (Auryxia, Keryx Biopharmaceuticals) are iron-based phosphate binders. If patients exhibit findings of hypocalcemia (tetany), IV calcium should be administered empirically.

## Magnesium

The body's normal daily magnesium requirement is 300 to 350 mg/day to maintain a serum magnesium concentration of 1.5 to 2.4 mEq/L (0.75–1.20 mmol/L). Because magnesium is the second most abundant ICF cation, serum concentrations are a relatively poor measure of total body stores. Magnesium catalyzes and/or activates more than 300 enzymes, provides neuromuscular stability, and is involved in myocardial contraction. Magnesium is generally not part of standard chemistry panels and therefore must be ordered separately.[2,33,43-45]

Hypomagnesemia is defined as a serum magnesium less than 1.5 mEq/L (0.75 mmol/L) and is most frequently seen in the intensive care and postoperative settings. Hypomagnesemia results from inadequate intake (alcoholism, dietary restriction, or inadequate magnesium in total parenteral nutrition [TPN]), inadequate absorption (steatorrhea, cancer, malabsorption syndromes, or excess calcium or phosphorus in the GI tract), excessive GI loss of magnesium (diarrhea, laxative abuse, NG tube suctioning, or acute pancreatitis), or excessive urinary loss of magnesium (primary hyperaldosteronism, certain medications, diabetic ketoacidosis, and renal disorders). Hypomagnesemia often occurs in the setting of hypokalemia and hypocalcemia. Clinicians should evaluate the magnesium concentration in these patients and correct if low. In order for calcium and potassium concentrations to normalize, magnesium supplementation is often required. Medications that potentially can cause hypomagnesemia include aminoglycoside antibiotics, amphotericin B (available as generic), cisplatin (available as generic), insulin, cyclosporine (available as generic), loop diuretics, and thiazide diuretics. There is also a strong correlation between hypokalemia and hypomagnesemia.[37,38,43,46] Clinicians should be alerted that the long-term use of proton pump inhibitors may be associated with unexplained hypomagnesemia, with subsequent hypokalemia or hypocalcemia.

The findings of hypomagnesemia include muscle weakness, cramps, agitation, confusion, tremor, seizures, ECG changes (increased PR interval, prolonged QRS complex, and increased QT interval), findings of hypocalcemia (see earlier), refractory hypokalemia (see earlier), metabolic alkalosis, and digoxin toxicity.[43,47,48]

Asymptomatic mild magnesium deficiencies (1.0–1.5 mEq/L) (0.50–0.75 mmol/L) can be managed with increased oral intake of magnesium-containing foods or with oral supplementation.

Magnesium oxide (Mag-Ox, Blaine Pharmaceuticals and various manufacturers) 400-mg tablets contain 241 mg (20 mEq or 10 mmol) of magnesium, and magnesium chloride hexahydrate tablets (Slow-Mag, Purdue) contains 64 mg of elemental magnesium. Diarrhea is often a dose-limiting side effect of oral supplementation. Severely deficient patients (less than 1.0 mEq/L) (0.50 mmol/L) and all deficient critically ill patients should be managed with IV magnesium sulfate. Ten milliliters of a 10% magnesium sulfate solution contains 1 g of magnesium, which is equivalent to 98 mg (8.12 mEq or 4.06 mmol) of elemental magnesium. IV magnesium supplementation may also be used in the setting of status asthmaticus, premature labor, and torsade de pointes. In May 2013, the FDA released a drug safety communication recommending against the prolonged use of magnesium sulfate to stop preterm labor due to bone changes in exposed babies. Administration of magnesium sulfate injection to pregnant women longer than 5 to 7 days may lead to low calcium levels and bone fractures in the developing baby or fetus. (http://www.fda.gov/Safety/MedWatch/) Magnesium concentrations need to be monitored closely in these patients. **KEY CONCEPT** *Because magnesium concentration does not correlate well with total body magnesium stores, magnesium is often administered empirically to critically ill patients.*[2,33]

The most common causes of hypermagnesemia are renal failure, often in conjunction with magnesium-containing medications (cathartics, antacids, or magnesium supplements), and lithium therapy (available as generic). Hypermagnesemia is defined as a serum magnesium concentration greater than 2.4 mEq/L (1.20 mmol/L). Mild hypermagnesemia is present if the serum magnesium concentration is between 2.5 and 4 mEq/L (1.25–2.00 mmol/L) and manifests as nausea, vomiting, cutaneous vasodilation, and bradycardia. Moderate hypermagnesemia is present if the serum magnesium concentration is between 4 and 12 mEq/L (2–6 mmol/L) and may manifest with hyporeflexia, weakness, somnolence, hypotension, and ECG changes (increased QRS interval). Severe hypermagnesemia is present if the serum magnesium concentration is greater than 13 mEq/L (6.5 mmol/L) and can manifest as muscle paralysis, complete heart block, asystole, respiratory failure, refractory hypotension, and death.[2,50]

All patients with hypermagnesemia should have all magnesium supplements or magnesium-containing medications discontinued.[2,33] Iatrogenic hypermagnesemia has been observed after IV magnesium therapy for refractory asthma or preeclampsia. Mild hypermagnesemia and moderate hypermagnesemia without cardiac findings can be treated with normal saline infusion and furosemide therapy (assuming the patient has normal

## Patient Encounter 8: Putting It All Together

ND, a 77-year-old male nursing home resident, is admitted to the hospital with a 3-day history of altered mental status. The patient was unable to give a history or review of systems. On physical examination, the vital signs revealed a BP of 100/60 mm Hg, pulse 110 beats/min, respirations 14 breaths/min, and a temperature of 38.3°C (101°F). Rales and dullness to percussion were noted at the posterior right base. The cardiac examination was significant for tachycardia. No edema was present. Laboratory studies included sodium 160 mEq/L (160 mmol/L), potassium 4.6 mEq/L (4.6 mmol/L), chloride 120 mEq/L (120 mmol/L), bicarbonate 30 mEq/L (30 mmol/L), glucose 104 mg/dL (5.8 mmol/L), BUN 34 mg/dL (12.1 mmol/L), and creatinine 2.2 mg/dL (194 μmol/L). The CBC was within normal limits. Chest x-ray indicated a right lower lobe pneumonia. The patient is 5' 10" (178 cm) tall and currently weighs 72.7 kg (160 lb). His normal weight is 77.3 kg (170 lb).

*What are the likely causes for the increased sodium concentration in this patient?*

*Calculate the TBW, ICF, and ECF for this patient.*

*Calculate ND's fluid deficit if one is present.*

In the next 24 hours, the medical team wants to replace 50% of the fluid deficit plus an extra 240 mL to account for increased insensible losses in addition to the patient's maintenance needs. Using the equation (1500 mL + 20 mL for each kilogram greater than 20 kg), calculate the rate of fluid administration for the total fluids needed in this 24-hour period and over the next 48 hours.

*Calculate ND's daily maintenance fluids.*

*Calculate ND's fluid administration rate for the first 24 hours (hospital day 1).*

*Calculate ND's fluids for the subsequent 48 hours (hospital days 2 and 3) if the goal is to replete the remaining fluid deficit during that time.*

*What type of fluid should be used to treat ND's fluid disorder?*

## Abbreviations Introduced in This Chapter

| | |
|---|---|
| ADH | Antidiuretic hormone |
| ASHP | American Society of Health-System Pharmacists |
| ATP | Adenosine triphosphate |
| BP | Blood pressure |
| BUN | Blood urea nitrogen |
| $Ca^+$ | Calcium |
| CHF | Congestive heart failure |
| Cl | Chloride |
| $D_5W$ | Dextrose 5% water |
| ECF | Extracellular fluid |
| ECG | Electrocardiogram |
| FFP | Fresh-frozen plasma |
| IBW | Ideal body weight |
| ICF | Intracellular fluid |
| I&Os | Ins and outs |
| JCAHO | Joint Commission on Accreditation of Healthcare Organizations |
| $K^+$ | Potassium |
| $KPO^4$ | Potassium phosphate |
| KVO | Keep the vein open |
| LR | Lactated Ringer (solution) |
| $Mg^{++}$ | Magnesium |
| $Na^+$ | Sodium |
| NaCl | Sodium chloride |
| $NaPO_4$ | Sodium phosphate |
| NG | Nasogastric |
| NS | Normal saline |
| SI | Standardized international units |
| SIADH | Syndrome of inappropriate antidiuretic hormone secretion |
| TBW | Total body water |
| TPN | Total parenteral nutrition |

renal function). Moderate hypermagnesemia with cardiac irritability and severe hypermagnesemia require concurrent IV calcium gluconate to reverse the neuromuscular and cardiovascular effects. Calcium gluconate given at typical doses of 1 to 2 g IV will have transient effects and can be repeated as clinically indicated. Hemodialysis may be necessary for those with severely compromised renal function.

## CONCLUSION

Because disturbances in fluid balance are routinely encountered in clinical medicine, it is essential to have a thorough understanding of body fluid compartments and the therapeutic use of fluids. Similarly, disturbances in serum sodium, potassium, calcium, phosphorus, and magnesium are ubiquitous and must be mastered by all clinicians. Dysregulation of fluid and/or electrolyte status has serious implications regarding the concepts of drug absorption, volumes of distribution, and toxicity. Similarly, many medications can disrupt fluid and/or electrolyte balance as an unintended consequence.

# 28 Acid–Base Disturbances

Lee E. Morrow and Mark A. Malesker

## LEARNING OBJECTIVES

**Upon completion of the chapter, the reader will be able to:**

1. Compare and contrast the four primary acid–base disturbances within the human body.
2. Apply simple formulas in a systematic manner to determine the etiology of simple acid–base disturbances and the adequacy of compensation.
3. Integrate the supplemental concepts of the anion gap and the excess gap to further assess for complex acid–base disturbances.
4. Discuss the most common clinical causes for each primary acid–base abnormality.
5. Describe the potential clinical complications of altered acid–base homeostasis.
6. Propose an appropriate treatment plan for patients with deranged acid–base physiology.

Given its reputation for complexity and the need to memorize innumerable formulas, acid–base analysis intimidates many health care providers. In reality, acid–base disorders always obey well-defined biochemical and physiological principles. The pH determines a patient's acid–base status and an assessment of the bicarbonate ($HCO_3^-$) and arterial carbon dioxide ($Paco_2$) values identifies the underlying process. Rigorous use of a systematic approach to arterial blood gases increases the likelihood that derangements in acid–base physiology are recognized and correctly interpreted. This chapter outlines a clinically useful approach to acid–base abnormalities and then applies this approach in a series of increasingly complex clinical scenarios.

Disturbances of acid–base equilibrium occur in a wide variety of illnesses and are among the most frequently encountered disorders in critical care medicine. The importance of a thorough command of this content cannot be overstated given that acid–base disorders are remarkably common and may result in significant morbidity and mortality. Although severe derangements may affect virtually any organ system, the most serious clinical effects are cardiovascular (arrhythmias, impaired contractility), neurologic (coma, seizures), pulmonary (dyspnea, impaired oxygen delivery, respiratory fatigue, respiratory failure), and/or renal (hypokalemia). Changes in acid–base status also affect multiple aspects of pharmacokinetics (clearance, protein binding) and pharmacodynamics.

## ACID–BASE HOMEOSTASIS

Acid–base homeostasis is responsible for maintaining blood hydrogen ion concentration [$H^+$] near normal despite the daily acidic and/or alkaline loads derived from the intake and metabolism of foods. Acid–base status is traditionally represented in terms of pH, the negative logarithm of [$H^+$]. Because [$H^+$] is equal to 24 times the ratio of $Paco_2$ to $HCO_3^-$, the pH can be altered by a change in either the bicarbonate concentration or the dissolved carbon dioxide. A critically important concept is that [$H^+$] depends only on the *ratio* of $Paco_2$ to $HCO_3^-$ and not the absolute amount of either. As such, a normal $Paco_2$ or $HCO_3^-$ alone does not guarantee that the pH will be normal. Conversely, a normal pH does not imply that either the $Paco_2$ or $HCO_3^-$ will be normal.[1]

**KEY CONCEPT** *Acid–base homeostasis is tightly regulated by the complex, but predictable, interactions of the kidneys, the lungs, and various buffer systems. The kidneys control serum $HCO_3^-$ concentration through the excretion or reabsorption of filtered $HCO_3^-$, the excretion of metabolic acids, and synthesis of new $HCO_3^-$. The lungs control arterial carbon dioxide ($CO_2$) concentrations through changes in the depth and/or rate of respiration.* The net result is tight regulation of the blood pH by these three distinct mechanisms working in harmony: extracellular bicarbonate and intracellular protein buffering systems; pulmonary regulation of $Paco_2$, effectively allowing carbonic acid to be eliminated by the lungs as $CO_2$; and renal reclamation or excretion of $HCO_3^-$ and excretion of acids such as ammonium.

Because the kidneys excrete less than 1% of the estimated 13,000 mEq (13,000 mmol) of $H^+$ ions generated in an average day, renal failure can be present for prolonged periods before life-threatening imbalances occur. Conversely, cessation of breathing for minutes results in profound acid–base disturbances.[1]

The best way to assess a patient's acid–base status is to review the results of an arterial blood gas (ABG) specimen. Blood gas analyzers directly measure the pH and $Paco_2$, while the $HCO_3^-$ value is calculated using the Henderson–Hasselbalch equation. A more direct measure of serum $HCO_3^-$ is obtained by measuring the total venous carbon dioxide ($tCO_2$). Because dissolved carbon dioxide is almost exclusively in the form of $HCO_3^-$, $tCO_2$ is essentially equivalent to the measured serum $HCO_3^-$ concentration.

This value ($HCO_3^-$) is routinely reported on basic chemistry panels. In the remainder of this chapter, the pH and $Paco_2$ values should be assumed to come from an ABG while $HCO_3^-$ values should be considered to be measured serum concentrations.

## BASIC PATHOPHYSIOLOGY

Under normal circumstances, the arterial pH is tightly regulated between 7.35 and 7.45. **Acidemia** is an abnormally low arterial blood pH (less than 7.35) while **acidosis** is a pathologic process that acidifies body fluids. Similarly, **alkalemia** is an abnormally high arterial blood pH (greater than 7.45) while **alkalosis** is a pathologic process that alkalinizes body fluids. As such, although a patient can simultaneously have acidosis *and* alkalosis, the end result will be acidemia *or* alkalemia.

Changes in the arterial pH are driven by changes in the $Paco_2$ and/or the serum $HCO_3^-$. Carbon dioxide is a volatile acid regulated by the depth and rate of respiration. Because $CO_2$ can be either "blown off" or "retained" by the respiratory system, it is referred to as being under respiratory control. **KEY CONCEPT** *Respiratory acidosis and alkalosis result from primary disturbances in the arterial $CO_2$ concentration. Metabolic compensation of respiratory disturbances is a slow process, often requiring days for the serum $HCO_3^-$ to reach the steady state.* **KEY CONCEPT** *Respiratory acidosis is caused by respiratory insufficiency resulting in an increased arterial $CO_2$ concentration. The compensation for respiratory acidosis (if present for prolonged periods) is an increase in serum $HCO_3^-$.* **KEY CONCEPT** *Respiratory alkalosis is caused by hyperventilation resulting in a decreased arterial $CO_2$ concentration. The compensation for respiratory alkalosis (if present for prolonged periods) is a decrease in serum $HCO_3^-$.*

A respiratory acid–base disorder is a pH disturbance caused by pathologic alterations of the respiratory system or its CNS control. Such an alteration may result in the accumulation of $Paco_2$ beyond normal limits (more than 45 mm Hg or 6.0 kPa), a situation termed *respiratory acidosis*, or it may result in the loss of $Paco_2$ beyond normal limits (less than 35 mm Hg or 4.7 kPa), a condition termed *respiratory alkalosis*. Variations in respiratory rate and/or depth allow the lungs to achieve changes in the $Paco_2$ very quickly (within minutes).

Bicarbonate is a base regulated by renal metabolism via the enzyme carbonic anhydrase. As such, $HCO_3^-$ is often referred to as being under metabolic control. **KEY CONCEPT** *Metabolic acidosis and alkalosis result from primary disturbances in the serum $HCO_3^-$ concentration. Respiratory compensation of metabolic disturbances begins within minutes and is complete within 12 hours.* **KEY CONCEPT** *Metabolic acidosis is characterized by a decrease in serum $HCO_3^-$. The anion gap is used to narrow the differential diagnosis because metabolic acidosis may be caused by addition of acids (increased anion gap) or loss of $HCO_3^-$ (normal anion gap). The compensation for metabolic acidosis is an increase in ventilation with a decrease in arterial $CO_2$.* **KEY CONCEPT** *Metabolic alkalosis is characterized by an increase in serum $HCO_3^-$. This disorder requires loss of fluid that is low in $HCO_3^-$ from the body or addition of $HCO_3^-$ to the body. The compensation for metabolic alkalosis is a decrease in ventilation with an increase in arterial $CO_2$.*

A metabolic acid–base disorder is a pH disturbance caused by derangement of the pathways responsible for maintaining a normal $HCO_3^-$ concentration. This may result in a pathologic accumulation of $HCO_3^-$ (greater than 26 mEq/L [26 mmol/L]), a condition termed *metabolic alkalosis*, or it may result in the loss of $HCO_3^-$ beyond normal (less than 22 mEq/L [22 mmol/L]), a condition termed *metabolic acidosis*. In contrast to the lungs' rapid effects on $CO_2$, the kidneys change the $HCO_3^-$ very slowly (hours to days).

Respiratory and metabolic derangements can occur in isolation or in combination. If a patient has an isolated primary acid–base disorder that is not accompanied by another primary acid–base disorder, a **simple (uncomplicated) disorder** is present. The most common clinical disturbances are **simple acid–base disorders**. If two or three primary acid–base disorders are simultaneously present, the patient has a **mixed (complicated) disorder**. More complex clinical situations lead to mixed acid–base disturbances. Because $CO_2$ is a volatile acid, it can rapidly be changed by the respiratory system. If a respiratory acid–base disturbance is present for minutes to hours, it is considered an **acute disorder**, while if it is present for days or longer it is considered a **chronic disorder**. By definition, the metabolic machinery that regulates $HCO_3^-$ results in slow changes, and all metabolic disorders are chronic.

Changes that follow the primary disorder and attempt to restore the blood pH to normal are referred to as compensatory changes. It should be stressed that compensation never normalizes the pH. Because all metabolic acid–base disorders are chronic and the normal respiratory system can quickly alter the $Paco_2$, essentially all metabolic disorders are accompanied by some degree of respiratory compensation.[2,3] Similarly, chronic respiratory acid–base disorders are typically accompanied by attempts at metabolic compensation.[4,5] However, with acute respiratory acid–base disorders there is insufficient time for the metabolic pathways to compensate significantly.[6] As such, acute respiratory derangements are essentially uncompensated.

The amount of compensation (metabolic or respiratory) can be reliably predicted based on the degree of derangement in the primary disorder. Table 28–1 outlines the simple acid–base disorders and provides formulas for calculating the expected compensatory responses.[7] Although it is not mandatory to memorize these

---

| Table 28–1 |
| --- |

**The Six Simple Acid–Base Disorders**

| Type of Disorder | pH | $Paco_2$[a] | $HCO_3^-$ |
| --- | --- | --- | --- |
| 1. Metabolic acidosis | ↓ | Decreased[b] $Paco_2 = (1.5 \times HCO_3^-) + 8$ | Decreased[c] |
| 2. Metabolic alkalosis | ↑ | Increased[b] $Paco_2 = (0.9 \times HCO_3^-) + 15$ | Increased[c] |
| 3. Acute respiratory acidosis | ↓ | Increased[c] | Approximately normal $\Delta HCO_3^- = 0.1 \times \Delta Paco_2$[a] |
| 4. Chronic respiratory acidosis | ↓ | Increased[c] | Increased[d] $\Delta HCO_3^- = 0.35 \times \Delta Paco_2$[a] |
| 5. Acute respiratory alkalosis | ↑ | Decreased[c] | Approximately normal $\Delta HCO_3^- = 0.2 \times \Delta Paco_2$[a] |
| 6. Chronic respiratory alkalosis | ↑ | Decreased[c] | Decreased[d] $\Delta HCO_3^- = 0.4 \times \Delta Paco_2$[a] |

[a]$Paco_2$ in mm Hg. Multiply $Paco_2$ in mm Hg by 0.133 to convert to kPa.

[b]Respiratory compensation: If inappropriate, see Table 28–2.

[c]Primary disorder.

[d]Metabolic compensation: If inappropriate, see Table 28–2.

**Table 28–2**

**Diagnosis of Concurrent Acid–Base Disturbances When Compensation Is Inappropriate**

| Primary Acid–Base Disturbance | Assessment of Compensation | Concurrent Acid–Base Disturbance |
|---|---|---|
| Metabolic acidosis | $Pa_{CO_2}$ too low[a] | Respiratory alkalosis |
|  | $Pa_{CO_2}$ too high[a] | Respiratory acidosis |
| Metabolic alkalosis | $Pa_{CO_2}$ too low[a] | Respiratory alkalosis |
|  | $Pa_{CO_2}$ too high[a] | Respiratory acidosis |
| Respiratory acidosis | $HCO_3^-$ too low[b] | Metabolic acidosis |
|  | $HCO_3^-$ too high[b] | Metabolic alkalosis |
| Respiratory alkalosis | $HCO_3^-$ too low[b] | Metabolic acidosis |
|  | $HCO_3^-$ too high[b] | Metabolic alkalosis |

[a]Measured $Pa_{CO_2}$ more than 4 mm Hg (0.5 kPa) from the calculated value.

[b]Measured $HCO_3^-$ more than 2 mEq/L (2 mmol/L) from the calculated value.

formulas in order to interpret acid–base problems, they can be helpful tools. If the measured values differ markedly from the calculated values (the measured serum $HCO_3^-$ is greater than 2 mEq/L [2 mmol/L] from the calculated value or the measured $Pa_{CO_2}$ is greater than 4 mm Hg [0.5 kPa] from the calculated value), a second acid–base disorder is present as outlined in **Table 28–2**.

## APPLICATION OF BASIC PATHOPHYSIOLOGY

When given an ABG for interpretation, it is essential to use an approach that is focused yet comprehensive.[8] An algorithm illustrating this concept is shown in **Figure 28–1**. Using this algorithm, Step 1 is to identify all abnormalities in the pH, $Pa_{CO_2}$, and/or $HCO_3^-$ and then decide which abnormal values are primary and which are compensatory. This is best done by initially looking at the pH. Whichever side of 7.40 the pH is on, the process that caused it to shift to that side is the primary abnormality. If the arterial pH is lower than 7.40 (acidemia), an elevated $Pa_{CO_2}$ (greater than 45 mm Hg or 6.0 kPa, respiratory acidosis) or a lowered $HCO_3^-$ (less than 22 mEq/L [22 mmol/L], metabolic acidosis) would be the primary abnormality. If the arterial pH is higher than 7.40 (alkalemia), a decreased $Pa_{CO_2}$ (less than 35 mm Hg or 4.7 kPa, respiratory alkalosis) or an increased $HCO_3^-$ (greater than 26 mEq/L [26 mmol/L], metabolic alkalosis) would be the primary abnormality. Once the primary disorder is established, step 2 is to apply the formulas from Table 28–1 to assess whether compensation is appropriate and to look for concurrent processes.[7]

An alternative to a diagnostic algorithm is use of a graphic nomogram.[9] Nomograms are plots of the pH, $Pa_{CO_2}$, and $HCO_3^-$ that allow the user to rapidly determine whether arterial blood gas values are consistent with one of the six simple primary acid–base disturbances. Although nomograms are commonly used to identify acid–base disturbances in clinical practice, only individuals who fully comprehend the fundamental concepts of acid–base assessment should use these tools. Also, appreciate that nomograms have limited utility when dealing with complex acid–base derangements.

Acid–base disturbances are always manifestations of underlying clinical disorders. It is useful to specifically define the primary acid–base abnormality because each disorder is caused by a limited number of disease processes. Establishing the specific disease process responsible for the observed acid–base disorder is clinically important because treatment of a given disorder will only be accomplished by correcting the underlying disease process.

## ADVANCED PATHOPHYSIOLOGY

The concepts in this section are used to further expand on steps 3 and 4 of the diagnostic algorithm shown in Figure 28–1. Under normal circumstances the serum is in the isoelectric state. This means that the positively charged entities reported in a standard chemistry panel (cations: sodium and potassium) should be exactly balanced by the negatively charged entities (anions: chloride and bicarbonate). However, this relationship is consistently incorrect because the measured cations are higher than the measured anions by 10 to 12 mEq/L (10–12 mmol/L). This discrepancy results from the presence of unmeasured anions (eg, circulating proteins, phosphates, and sulfates). This apparent difference in charges, the serum anion gap, is calculated as follows:

$$Anion\ gap = Na^+ - (Cl^- + HCO_3^-)$$

Because the serum potassium content is relatively small and is very tightly regulated, it is generally omitted from the calculation.[10]

It is important to realize that the serum $HCO_3^-$ concentration may be affected by the presence of unmeasured endogenous acids (lactic acid or ketoacids). Bicarbonate will attempt to buffer these acids, resulting in a 1 mEq (1 mmol) loss of serum $HCO_3^-$ for each 1 mEq (1 mmol) of acid titrated. Because the cation side of the equation is not affected by this transaction, the loss of serum $HCO_3^-$ results in an increase in the calculated anion gap. Identification of an increased anion gap is very important because a limited number of clinical scenarios lead to this unique acid–base disorder. A mnemonic to recall the differential diagnosis for an anion gap acidosis is shown in **Table 28–3**. The concept of the increased anion gap is applied later in Patient Encounters 6 through 10.

Step 3 in Figure 28–1 suggests that any time an ABG is analyzed, it is wise to concurrently inspect the serum chemistry values and to calculate the anion gap. The body does not generate an anion gap to compensate for a primary disorder. As such, if the calculated anion gap exceeds 12 mEq/L (12 mmol/L), there is a primary metabolic acidosis regardless of the pH or the serum $HCO_3^-$ concentration. The anion gap may be artificially lowered by decreased serum albumin, multiple myeloma, lithium intoxication, or a profound increase in the serum potassium, calcium, or magnesium.[11]

Step 4 in Figure 28–1 shows how calculation of the anion gap also facilitates determination of the **excess gap** or the degree to which the calculated anion gap exceeds the normal anion gap. The excess gap is calculated as follows:

$$Excess\ gap = calculated\ anion\ gap - normal\ anion\ gap$$
$$= [Na^+ - (Cl^- + HCO_3^-)] - 12$$

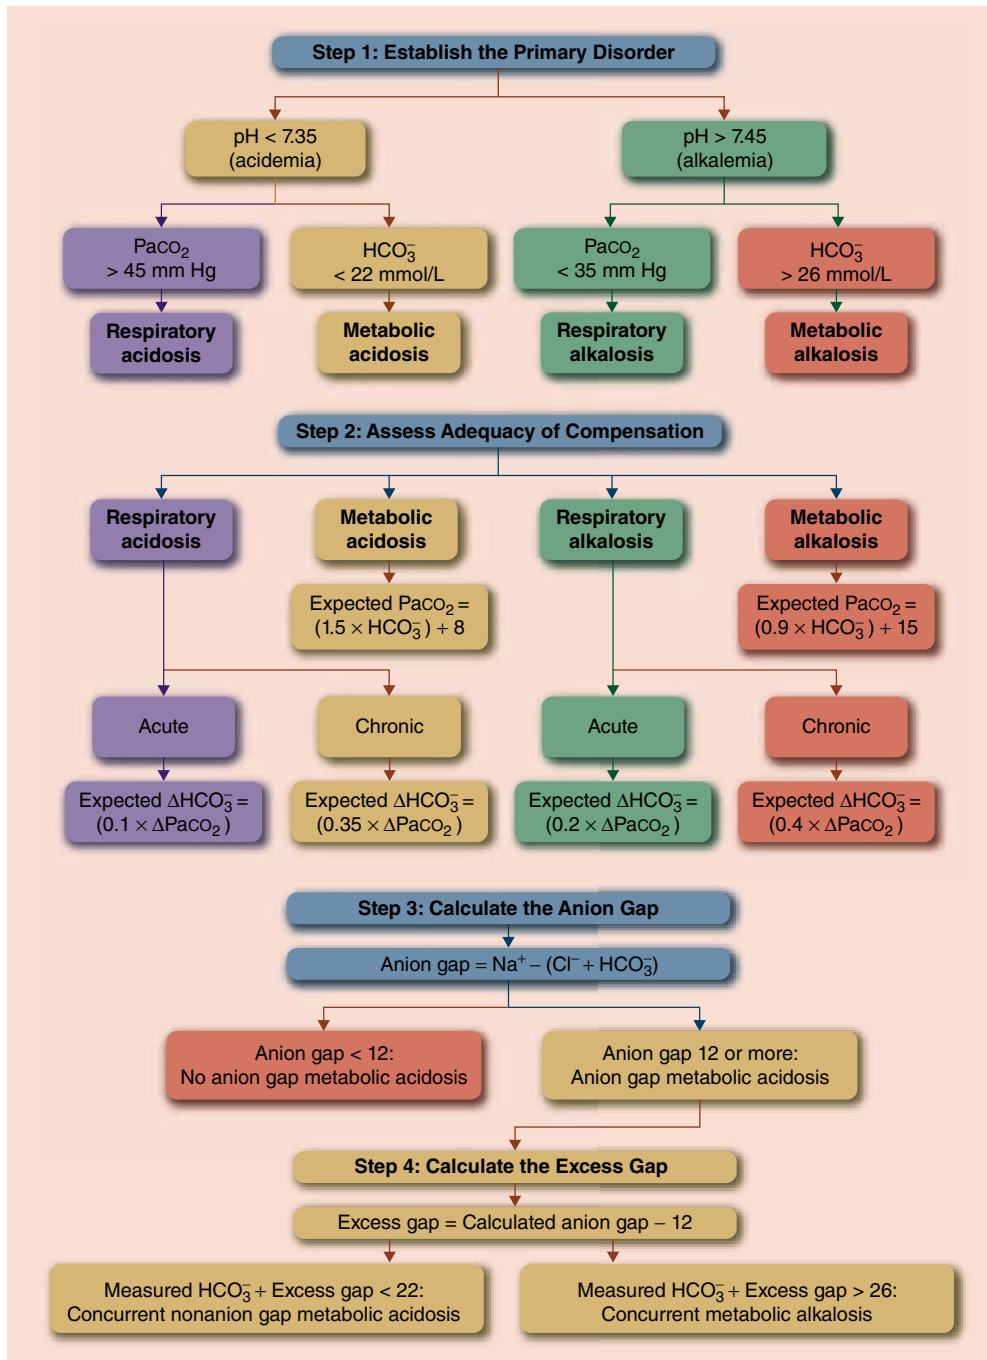
The excess gap represents the amount of $HCO_3^-$ that has been lost due to buffering unmeasured cations. The excess gap can be added back to the measured $HCO_3^-$ to determine what the patient's $HCO_3^-$ would be if these endogenous acids were not present. This is a very valuable tool that can be used in narrowing the differential diagnosis of certain acid–base disorders as well as in uncovering occult or mixed acid–base disorders.


**FIGURE 28–1.** An algorithmic approach to acid–base disorders. Normal values: pH 7.35 to 7.45, $Paco_2$ 35 to 45 mm Hg (4.7–6.0 kPa), $HCO_3^-$ 22 to 26 mEq/L (26 mmol/L), anion gap less than 12 mEq/L (12 mmol/L). Note that $Paco_2$ should be in millimeters of mercury to use the equations in the figure. ($Cl^-$, chloride ion; $HCO_3^-$, bicarbonate; $Na^+$, sodium ion; $Paco_2$, partial pressure of arterial carbon dioxide.)

In summary, the approach to assessment of acid–base status involves four key steps as outlined in Figure 28–1: step 1 = initial inspection of the pH, $Paco_2$, and $HCO_3^-$; step 2 = assessment of the adequacy of compensation; step 3 = calculation of the anion gap; and step 4 = calculation of the excess gap.

## ETIOLOGY AND TREATMENT

**KEY CONCEPT** *Arterial blood gases, serum electrolytes, physical examination findings, the clinical history, and the patient's recent medications must be reviewed in order to establish the etiology of a given acid–base disturbance.* Tables 28–4 through 28–7 outline the most commonly encountered causes for each of the primary acid–base disorders. The therapeutic approach to each of these acid–base

derangements should emphasize a search for the cause, as opposed to immediate attempts to normalize the pH.

**KEY CONCEPT** *It is critical to treat the underlying causative process to effectively resolve most observed acid–base disorders. However, supportive treatment of the pH and electrolytes is often needed until the underlying disease state is improved.*[12,13]

All patients with significant disturbances in their acid–base status require continuous cardiovascular and hemodynamic monitoring. Because frequent assessment of the patient's response to treatment is critical, an arterial line is often placed to minimize patient discomfort with serial ABG collections. If the anion gap was initially abnormal, serial chemistries should be followed to ensure that the anion gap resolves with treatment. Specific treatment decisions depend on the underlying pathophysiologic state

## Patient Encounters 1 Through 5: Application of Basic Pathophysiology

### Case Study 1

An unconscious 19-year-old man is brought to the emergency department by friends who state that the patient took a handful of pain pills at a college dorm "pill party." The patient's ABG has a pH of 7.16, $Paco_2$ of 70 (9.3 kPa), and $HCO_3^-$ of 27 mEq/L (27 mmol/L).

*What is the primary acid–base disorder?*

*Has compensation occurred?*

*Given the clinical history, what is the most likely explanation for the ABG findings?*

### Case Study 2

The next patient is a 59-year-old man undergoing lung transplant evaluation for advanced emphysema. An ABG drawn during the transplant workup shows a pH of 7.34, a $Paco_2$ of 70 mm Hg (9.3 kPa), and an $HCO_3^-$ of 35 mEq/L (35 mmol/L).

*What is the primary acid–base disorder?*

*Has compensation occurred?*

*Given the clinical history, what is the most likely explanation for the ABG findings?*

### Case Study 3

A healthy 24-year-old pharmacy student is having an ABG drawn as part of her clinical pulmonary rotation. Her ABG shows a pH of 7.50, a $Paco_2$ of 29 mm Hg (3.9 kPa), and an $HCO_3^-$ of 22 mEq/L (22 mmol/L).

*What is the primary acid–base disorder?*

*Has compensation occurred?*

*Given the clinical history, what is the most likely explanation for the ABG findings?*

### Case Study 4

This 62-year-old woman with hyperlipidemia has experienced multiple myocardial infarctions resulting in ischemic cardiomyopathy and congestive heart failure. She requires daily furosemide (Lasix) therapy to remain euvolemic. An ABG was drawn for increasing dyspnea and shows the following: pH of 7.50, a $Paco_2$ of 47 mm Hg (6.3 kPa), and an $HCO_3^-$ of 36 mEq/L (36 mmol/L).

*What is the primary acid–base disorder?*

*Has compensation occurred?*

*Given the clinical history, what is the most likely explanation for the ABG findings?*

### Case Study 5

The final patient in this section is a 46-year-old woman with chronic renal insufficiency who is being hospitalized for *Clostridium difficile*-associated diarrhea. Her ABG shows a pH of 7.20, a $Paco_2$ of 20 mm Hg (2.7 kPa), and an $HCO_3^-$ of 8 mEq/L (8 mmol/L).

*What is the primary acid–base disorder?*

*Has compensation occurred?*

*Given the clinical history, what is the most likely explanation for the ABG findings?*

---

(eg, dialysis for renal failure, insulin for diabetic ketoacidosis, or improving tissue perfusion and oxygenation for lactic acidosis).

### Metabolic Acidosis

Metabolic acidosis is characterized by a reduced arterial pH, a primary decrease in the $HCO_3^-$ concentration, and a compensatory reduction in the $Paco_2$. The etiologies of metabolic acidosis

### Table 28–3

**Mnemonics for the Differential Diagnoses of Metabolic Acidosis**

| Elevated Anion Gap[a] | Normal Anion Gap[a] |
|---|---|
| M—Methanol, metformin | U—Ureteral diversion |
| U—Uremia | S—Saline infusion |
| D—Diabetic (or alcoholic) ketoacidosis | E—Exogenous acid |
| P—Paraldehyde, phenformin | D—Diarrhea |
| I—Isoniazid, iron | C—Carbonic anhydrase inhibitors |
| L—Lactic acidosis | A—Adrenal insufficiency |
| E—Ethylene glycol, ethanol | R—Renal tubular acidosis |
| S—Salicylates | |

[a]Anion gap = serum sodium concentration – (serum chloride concentration + serum bicarbonate concentration). Under normal circumstances, the anion gap should be 10 mEq/L (10 mmol/L) or less.

are divided into those that lead to an increase in the anion gap and those associated with a normal anion gap and are listed in Table 28–4. Although there are numerous mnemonics to recall the differential diagnosis of the metabolic acidosis, two simple ones are shown in Table 28–3. High anion gap metabolic acidosis is most frequently caused by lactic acidosis, ketoacidosis, and/or renal failure. Although there is considerable variation, the largest anion gaps are caused by ketoacidosis, lactic acidosis, and methanol or ethylene glycol ingestion.[14]

Symptoms of metabolic acidosis are attributable to changes in cardiovascular, musculoskeletal, neurologic, or pulmonary functioning. Respiratory compensation requires marked increases in minute ventilation and may lead to dyspnea, respiratory fatigue, and respiratory failure. Acidemia predisposes to ventricular arrhythmias and reduces cardiac contractility, each of which can result in pulmonary edema and/or systemic hypotension.[15] Neurologic symptoms range from lethargy to coma and are usually proportional to the severity of the pH derangement. Chronic metabolic acidosis leads to a variety of musculoskeletal problems, including impaired growth, rickets, osteomalacia, or osteopenia. These changes are believed to be caused by the release of calcium and phosphate during bone buffering of excess $H^+$ ions.

As previously discussed, in anion gap metabolic acidosis, the isoelectric state is maintained because unmeasured anions are present. With a *normal* anion gap metabolic acidosis, the isoelectric state is maintained by an increase in the measured chloride. Because of this, normal anion gap metabolic acidosis is often referred to as hyperchloremic acidosis.

| Table 28–4 |
| --- |

**Common Causes of Metabolic Acidosis**

| Elevated Anion Gap[a] | Normal Anion Gap[a] |
| --- | --- |
| Intoxications | Bowel fistula |
|   Methanol | Diarrhea |
|   Ethylene glycol | Dilutional acidosis |
|   Salicylates | Drugs |
|   Paraldehyde |   Acetazolamide[b] |
|   Isoniazid |   Ammonium chloride[b] |
| Ketoacidosis |   Amphotericin B[b] |
|   Diabetic |   Arginine |
|   Ethanol |     hydrochloride[c] |
|   Starvation |   Cholestyramine[b] |
| Lactic acidosis |   Hydrochloric acid[b] |
|   Carbon monoxide poisoning |   Lithium[b] |
|   Drugs |   Parenteral nutrition[b] |
|     IV lorazepam (due to |   Topiramate[b] |
|     vehicle)[c] |   Zonisamide[b] |
|     Metformin[b] | Lead poisoning |
|     Nitroprusside (due to | Renal tubular acidosis |
|     cyanide accumulation)[b] | Surgical drains |
|     Nucleoside reverse | Ureteral diversion |
|     transcriptase inhibitors[b] | Villous adenomas (some) |
|     Propofol[c] | |
|   Seizures | |
|   Severe hypoxemia | |
|   Shock | |
| Renal failure | |

[a]Anion gap = serum sodium concentration – (serum chloride concentration + serum bicarbonate concentration). Under normal circumstances, the anion gap should be 10 mEq/L (10 mmol/L) or less.

[b]May be observed with therapeutic doses or overdoses.

[c]Typically observed only with overdoses.

In patients with a normal anion gap metabolic acidosis, it is often helpful to calculate the urine anion gap (UAG).[16] The UAG is calculated as follows:

$$UAG = (Urine\ Na^+ + Urine\ K^+) - Urine\ Cl^-$$

The normal UAG ranges from 0 to 5 mEq/L (0–5 mmol/L) and represents the presence of unmeasured urinary anions. In metabolic acidosis, the excretion of $NH_4^+$ and concurrent $Cl^-$ should increase markedly if renal acidification capacity is intact. This results in UAG values from –20 to –50 mEq/L (–20 to –50 mmol/L). This occurs because the urinary $Cl^-$ concentration now markedly exceeds the urinary $Na^+$ and $K^+$ concentrations. Diagnoses consistent with an excessively negative UAG include proximal (type 2) renal tubular acidosis, diarrhea, or administration of acetazolamide or hydrochloric acid (HCl). Excessively positive values of the UAG suggest a distal (type 1) renal tubular acidosis.

In order to effectively treat metabolic acidosis, the *causative process* must be identified and treated.[17] The precise role of adjunctive therapy with sodium bicarbonate ($NaHCO_3$) is not universally agreed upon. However, most practitioners accept that $NaHCO_3$ is indicated when renal dysfunction precludes adequate regeneration of $HCO_3^-$ or when severe acidemia (pH less than 7.15) is present. The metabolic acidosis seen with lactic acidosis and ketoacidosis generally resolves with therapy targeted at the underlying cause, and $NaHCO_3$ may be unnecessary regardless of the pH. The metabolic acidosis of renal failure, renal tubular acidosis, or intoxication with ethylene glycol, methanol, or salicylates is much more likely to require $NaHCO_3$ therapy.

- If $NaHCO_3$ is used, the plasma $HCO_3^-$ should not be corrected entirely. Instead, aim at increasing $HCO_3^-$ above an absolute value of 10 mEq/L (10 mmol/L). The total $HCO_3^-$ deficit can be calculated from the current bicarbonate concentration ($HCO_{3\ curr}^-$), the desired bicarbonate concentration ($HCO_{3\ post}^-$), and the body weight (in kilograms) as follows:

$$HCO_3^-\ deficit = [(2.4/HCO_{3\ curr}^-) + 0.4] \times weight \\ \times (HCO_{3\ curr}^- - HCO_{3\ post}^-)$$

- No more than half of the calculated $HCO_3^-$ deficit should be given initially to avoid volume overload, hypernatremia, hyperosmolarity, overshoot alkalemia, hypocalcemia and/or hypokalemia. The calculated $HCO_3^-$ deficit reflects only the present situation and does not account for ongoing $H^+$ production and $HCO_3^-$ loss. When giving $HCO_3^-$ therapy, serial blood gases are needed to monitor therapy.

- Another option for patients with severe acidemia is tromethamine (THAM).[18] This inert amino alcohol buffers acids and $CO_2$ through its amine ($-NH_2$) moiety:

$$THAM - NH_2 + H^+ = THAM - NH_3^+$$

$$THAM - NH_2 + H_2O + CO_2 = THAM - NH_3^+ + HCO_3^-$$
Protonated THAM (with $Cl^-$ or $HCO_3^-$) is excreted in the urine at a rate that is slightly higher than creatinine clearance. As such, THAM augments the buffering capacity of the blood without generating excess $CO_2$. THAM is less effective in patients with renal failure, and toxicities may include hyperkalemia, hypoglycemia, and possible respiratory depression. THAM is particularly useful in patients with volume overload because it does not contain sodium.

- THAM is often administered as an empiric dose of 18 g (150 mEq [150 mmol]) in 500-mL water via slow IV infusion. Additional infusions are given as dictated by the severity and progression of acidosis.

Chronic metabolic acidosis can successfully be managed using potassium citrate/citric acid (Polycitra-K, Cytra-K) or sodium citrate/citric acid (Bicitra, Oracit).

### Metabolic Alkalosis

- Metabolic alkalosis is characterized by an increased arterial pH, a primary increase in the $HCO_3^-$ concentration, and a compensatory increase in the $Paco_2$. Patients will always hypoventilate to compensate for metabolic alkalosis—even if it results in profound hypoxemia. For a metabolic alkalosis to persist, there must concurrently be a process that elevates serum $HCO_3^-$ concentration (gastric or renal loss of acids) and another that impairs renal $HCO_3^-$ excretion (hypovolemia, hypokalemia, or mineralocorticoid excess). The etiologies of metabolic alkalosis are listed in Table 28–5.

Patients with metabolic alkalosis rarely have symptoms attributable to alkalemia. Rather, complaints are usually related to volume depletion (muscle cramps, positional dizziness, weakness) or to hypokalemia (muscle weakness, polyuria, polydipsia).

In order to effectively treat metabolic alkalosis, the *causative process* must be identified and treated. The major causes of metabolic alkalosis are often readily apparent after carefully reviewing the patient's history and medication list. In hospitalized patients, always look for administration of compounds such as citrate in blood products and acetate in parenteral nutrition that can raise the $HCO_3^-$ concentration. If the etiology of the metabolic

## Patient Encounters 6 through 10: Application of Advanced Pathophysiology

### Case Study 6

A 31-year-old man with severe cognitive impairment is admitted to the intensive care unit after ingesting an unknown quantity of aspirin tablets. His presenting laboratory test results show a pH of 7.50, a $Pa_{CO_2}$ of 20 mm Hg (2.7 kPa), an $HCO_3^-$ of 16 mEq/L (16 mmol/L), a sodium concentration of 140 mEq/L (140 mmol/L), and a chloride level of 103 mEq/L (103 mmol/L).

*What is the primary acid–base disorder?*

*Is there a **mixed disorder**?*

*Given the clinical history, what is the most likely explanation for the ABG findings?*

### Case Study 7

A 56-year-old man is brought to the emergency room by his family. He has not felt well for the past week and did not attend his regular hemodialysis sessions. He began vomiting 36 hours ago but refused medical evaluation. When family members found him unresponsive this morning, they sought medical attention. Laboratory analyses show: pH of 7.40, $Pa_{CO_2}$ of 40 mm Hg (5.3 kPa), $HCO_3^-$ of 24 mEq/L (24 mmol/L), sodium concentration of 145 mEq/L (145 mmol/L), and chloride level of 100 mEq/L (100 mmol/L).

*What is the primary acid–base disorder?*

*Is there a mixed disorder?*

*Given the clinical history, what is the most likely explanation for the ABG findings?*

### Case Study 8

A 56-year-old woman is brought to the emergency room by rescue squad after several complaints were called in to 911 for a "profoundly intoxicated" individual in a city park. Shortly after arrival in the emergency room she has several episodes of emesis with witnessed aspiration. She is transferred to the ICU where she develops progressive hypoxia during the ensuing hours. Following elective intubation her blood work shows a pH of 7.50, a $Pa_{CO_2}$ of 20 mm Hg (2.7 kPa), an $HCO_3^-$ of 15 mEq/L (15 mmol/L), a sodium concentration of 145 mEq/L (145 mmol/L), and a chloride level of 100 mEq/L (100 mmol/L).

*What is the primary acid–base disorder?*

*Is there a mixed disorder?*

*Given the clinical history, what is the most likely explanation for the ABG findings?*

### Case Study 9

A 69-year-old insulin-dependent diabetic man is being evaluated for unresponsiveness. His wife says he had "stomach flu" for several days with frequent bouts of emesis. She thinks he has stopped taking his insulin since he hasn't been eating. He became somnolent yesterday and she called an ambulance when she noticed his breathing was very slow and shallow. The blood work drawn prior to urgent intubation shows a pH of 7.10, a $Pa_{CO_2}$ of 50 mm Hg (6.7 kPa), an $HCO_3^-$ of 15 mEq/L (15 mmol/L), a sodium concentration of 145 mEq/L (145 mmol/L), and a chloride level of 100 mEq/L (100 mmol/L).

*What is the primary acid–base disorder?*

*Is there a mixed disorder?*

*Given the clinical history, what is the most likely explanation for the ABG findings?*

### Case Study 10

The final patient is a 23-year-old woman who was admitted 6 hours ago for diabetic ketoacidosis. With appropriate therapy, her hyperglycemia has improved and her serum ketones are clearing. Because she continues to feel poorly, repeat blood work is obtained. Studies show a pH of 7.15, a $Pa_{CO_2}$ of 15 mm Hg (2.0 kPa), an $HCO_3^-$ of 5 mEq/L (5 mmol/L), a sodium concentration of 140 mEq/L (140 mmol/L), and a chloride level of 110 mEq/L (110 mmol/L).

*What is the primary acid–base disorder?*

*Is there a mixed disorder?*

*Given the clinical history, what is the most likely explanation for the ABG findings?*

---

alkalosis is still unclear, measurement of the urinary chloride may be useful. Some processes leading to metabolic alkalosis (vomiting, nasogastric suction losses, factitious diarrhea) will have low urinary $Cl^-$ concentrations (less than 25 mEq/L [25 mmol/L]) and are likely to respond to administration of saline. Other causes (diuretics, hypokalemia, and mineralocorticoid excess) will have higher urinary $Cl^-$ concentrations (greater than 40 mEq/L [40 mmol/L]) and are less likely to correct with saline infusion.

In general, contributing factors such as diuretics, nasogastric suction, and corticosteroids should be discontinued if possible. Any fluid deficits should be treated with IV normal saline. Again, patients with metabolic alkalosis and high urine $Cl^-$ (while relatively uncommon) are generally resistant to saline loading. Potassium supplementation should always be given if it is also deficient.

In patients with mild or moderate alkalosis who require ongoing diuresis but have rising $HCO_3^-$ concentrations, the carbonic anhydrase inhibitor acetazolamide can be used to reduce the $HCO_3^-$ concentration. Acetazolamide is typically dosed at 250 mg every 6 to 12 hours as needed to maintain the pH in a

clinically acceptable range. This agent results in gradual changes in the serum $HCO_3^-$ and is not used to acutely correct a patient's acid–base status. If alkalosis is profound and potentially life threatening (due to seizures or ventricular tachyarrhythmias), hemodialysis or transient HCl infusion can be considered. The hydrogen ion deficit (in milliequivalents or millimoles) can be estimated from the current bicarbonate concentration ($HCO_{3\,curr}^-$), the desired bicarbonate concentration ($HCO_{3\,post}^-$), and the body weight (in kilograms) as follows:

$$H^+ \text{ deficit} = 0.4 \times \text{weight} \times (HCO_{3\,curr}^- - HCO_{3\,post}^-)$$

After estimating the $H^+$ deficit, 0.1 to 0.2 N hydrochloric acid (HCl) is infused at 20 to 50 mEq/hour (20–50 mmol/hour) into a central vein. Arterial pH must be monitored at least hourly and the infusion stopped as soon as clinically feasible. Ammonium chloride and arginine hydrochloride, agents that result in the formation of HCl, are not commonly prescribed because they may lead to significant toxicity. Ammonium chloride may cause accumulation of ammonia leading to encephalopathy while arginine

hydrochloride can induce life-threatening hyperkalemia through unclear mechanisms.

## Respiratory Acidosis

Respiratory acidosis is characterized by a reduced arterial pH, a primary increase in the arterial $Paco_2$ and, when present for sufficient time, a compensatory rise in the $HCO_3^-$ concentration. Because increased $CO_2$ is a potent respiratory stimulus, respiratory acidosis represents ventilatory failure or impaired central control of ventilation as opposed to an increase in $CO_2$ production. As such, most patients will have hypoxemia in addition to hypercapnia. The most common etiologies of respiratory acidosis are listed in Table 28–6.

Severe, acute respiratory acidosis produces a variety of neurologic abnormalities. Initially these include headache, blurred vision, restlessness, and anxiety. These may progress to tremors, asterixis, somnolence, and/or delirium. If untreated, terminal manifestations include peripheral vasodilation leading to hypotension and cardiac arrhythmias. Chronic respiratory acidosis is typically associated with cor pulmonale and peripheral edema.

In order to effectively treat respiratory acidosis, the *causative process* must be identified and treated. If a cause is identified, specific therapy should be started. This may include naloxone for opiate-induced hypoventilation or bronchodilator therapy for acute bronchospasm. Because respiratory acidosis represents ventilatory failure, an increase in alveolar ventilation is required. This can often be achieved by controlling the underlying disease (eg, bronchodilators and corticosteroids in asthma) and/or physically augmenting ventilation.

Although their precise role and mechanisms of action are unclear, agents such as medroxyprogesterone, theophylline, and doxapram stimulate respiration and have been used to treat mild to moderate respiratory acidosis. Moderate or severe respiratory acidosis requires assisted ventilation. This can be provided to spontaneously breathing patients via bilevel positive airway pressure (BiPAP) delivered via a tight-fitting mask or by intubation followed by mechanical ventilation. In mechanically ventilated patients, respiratory acidosis is treated by increasing the minute ventilation. This is achieved by increasing the respiratory rate and/or tidal volume.

As with the treatment of metabolic acidosis, the role of $NaHCO_3$ therapy is not well defined for respiratory acidosis.

| Table 28–6 | |
|---|---|
| **Common Causes of Respiratory Acidosis** | |
| CNS disease | Pneumonia |

|   Chronic obstructive |   Inadequate mechanical |
|   pulmonary disease |   ventilation |
|   Foreign body | |
|   Status asthmaticus | |

[a]May be observed with therapeutic doses or overdoses.

Realize that administration of $NaHCO_3$ can paradoxically result in increased $CO_2$ generation ($HCO_3^- + H^+ \rightarrow H_2CO_3 + CO_2$) and worsened acidemia. Careful monitoring of the pH is required if $NaHCO_3$ therapy is started for this indication. The use of tromethamine in respiratory acidosis (see Metabolic Acidosis section earlier) has unproven safety and benefit.

The goals of therapy in patients with chronic respiratory acidosis are to maintain oxygenation and to improve alveolar ventilation if possible. Because of the presence of metabolic compensation, it is usually not necessary to treat the pH, even in patients with severe hypercapnia. Although the specific treatment varies with the underlying disease, excessive oxygen and sedatives should be avoided because they can worsen $CO_2$ retention.

## Respiratory Alkalosis

Respiratory alkalosis is characterized by an increased arterial pH, a primary decrease in the arterial $Paco_2$ and, when present for sufficient time, a compensatory fall in the $HCO_3^-$ concentration. Respiratory alkalosis represents hyperventilation and is remarkably common. The most common etiologies of respiratory alkalosis are listed in Table 28–7 and range from benign (anxiety) to life threatening (pulmonary embolism). Some causes of hyperventilation and respiratory acidosis are remarkably common (hypoxemia or anemia).

The symptoms produced by respiratory alkalosis result from increased irritability of the central and peripheral nervous

[a]May be observed with therapeutic doses or overdoses.

systems. These include light-headedness, altered consciousness, distal extremity paresthesias, circumoral paresthesia, cramps, carpopedal spasms, and syncope. Various supraventricular and ventricular cardiac arrhythmias may occur in extreme cases, particularly in critically ill patients. An additional finding in many patients with severe respiratory alkalosis is hypophosphatemia, reflecting a shift of phosphate from the extracellular space into the cells. Chronic respiratory alkalosis is generally asymptomatic.

It is imperative to identify serious causes of respiratory alkalosis and institute effective treatment. In spontaneously breathing patients, respiratory alkalosis is typically only mild or moderate in severity and no specific therapy is indicated. Severe alkalosis generally represents respiratory alkalosis imposed on metabolic alkalosis and may improve with sedation or rebreathing maneuvers (rebreathing mask, paper bag). Patients receiving mechanical ventilation are treated with reduced minute ventilation achieved by decreasing the respiratory rate and/or tidal volume. If the alkalosis persists in the ventilated patient, high-level sedation or paralysis is effective.

## SUMMARY

Acid–base disturbances are common clinical problems that are not difficult to analyze if approached in a consistent manner. The pH, $Paco_2$, and $HCO_3^-$ should be inspected to identify all abnormal values. This should lead to an assessment of which deviations represent the primary abnormality and which represent compensatory changes. The serum electrolytes should always be used to calculate the anion gap. In cases in which the anion gap is increased, the excess anion gap should be added back to the measured $HCO_3^-$. The anion gap and the excess gap are useful tools that can identify hidden disorders. This rigorous assessment of the patient's acid–base status, incorporated with the available clinical data, increases the likelihood that the clinician will successfully determine the cause of each identified disorder. Although supportive therapy is often required for profound acid–base disturbances, definitive therapy must target the underlying process that has led to the observed derangements.

## Patient Care Process

**Patient Assessment:**

- Based upon physical examination, review of systems, and laboratory data, determine whether the patient is experiencing manifestations of an acid-base disorder
- Determine whether pH is consistent with acidosis or alkalosis
- Check for laboratory validity (determine whether $CO_2$ and $HCO_3^-$ are consistent with the pH)
- Review the history to see if there are any clues to the cause of the disorder
- Determine whether the primary disorder is of respiratory or metabolic origin
  - Alkalemia
  - Respiratory alkalosis if $CO_2$ less than 40 mm Hg (5.3 kPa)
  - Metabolic alkalosis if $HCO_3$ greater than 26 mm Hg (3.3 kPa)
  - Acidemia
  - Respiratory acidosis if $CO_2$ greater than 40 mmHg (5.3 kPa)
  - Metabolic acidosis if $HCO_3$ less than 22 mmHg (3.3 kPa)
- Calculate compensatory response (determine whether mixed acid–base disorder)
- Calculate the anion gap
- Consider additional laboratory tests to further differentiate the cause of the disorder

**Therapy Evaluation:**

- If the patient demonstrates an acid–base disorder, determine whether pharmacotherapy is indicated
- If the patient has received pharmacotherapy to correct acid–base disorder, assess efficacy, safety, and patient response
- Determine if any medications on the patient profile are contributing to the existing acid–base disorder

**Care Plan Development:**

- Urgently correct any life-threatening acid–base disorder
- Assess the underlying etiology of the altered pH and intervene accordingly
- Ensure drug doses are optimal to correct the acid base disorder

**Follow-Up Evaluation:**

- Review medical history, physical examination findings, blood gas result, and laboratory tests

## Abbreviations Introduced In This Chapter

| | |
|---|---|
| ABG | Arterial blood gas |
| BiPAP | Bilevel positive airway pressure |
| Cl⁻ | Chloride ion |
| CO2 | Carbon dioxide |
| Δ(delta) | Change |
| H⁺ | Hydrogen ion |
| HCl | Hydrochloric acid |

| $HCO_3^-$ | Bicarbonate |
|---|---|
| $HCO_{3corr}^-$ | Current bicarbonate |
| $HCO_{3post}^-$ | Post-therapy bicarbonate |
| Hg | Mercury |
| $K^+$ | Potassium ion |
| $Na^+$ | Sodium ion |
| $NaHCO_3$ | Sodium bicarbonate |
| $NH_2$ | Terminal amine group |
| $NH_4^+$ | Ammonium |
| pH | Logarithm of the hydrogen ion concentration |
| $Paco_2$ | Partial pressure of arterial carbon dioxide |
| $tCO_2$ | Total venous carbon dioxide |
| THAM | Tromethamine |
| UAG | Urine anion gap |

# 29 Alzheimer Disease

Megan J. Ehret and Kevin W. Chamberlin

● **Upon completion of the chapter, the reader will be able to:**

1. Describe the epidemiology of Alzheimer disease (AD) and its effects on society.

2. Describe the pathophysiology, including genetic and environmental factors that may be associated with AD.

3. Detail the clinical presentation of the typical patient with AD.

4. Describe the clinical course of the disease and typical patient outcomes.

5. Explain how nonpharmacologic therapy is combined with pharmacologic therapy for patients with AD.

6. Recognize and recommend treatment options for disease-specific symptoms as well as behavioral/noncognitive symptoms associated with AD.

7. Educate patients and/or caregivers about the expected outcomes for patients with AD, and provide contact information for support/advocacy agencies.

## INTRODUCTION

**KEY CONCEPT** *A*lzheimer disease *(AD) is characterized by progressive cognitive decline including memory loss, disorientation, and impaired judgment and learning.* It is primarily diagnosed by exclusion of other potential causes for dementias. There is no single symptom unique to AD; therefore, diagnosis relies on a thorough patient history. The exact pathophysiologic mechanism underlying AD is not entirely known, although certain genetic and environmental factors may be associated with the disease. There is no cure for AD; however, drug treatment can slow symptom progression.

Family members of AD patients are profoundly affected by the increased dependence of their loved ones as the disease progresses. Referral to an advocacy organization, such as the Alzheimer Association, can provide early education and social support of both the patient and family. The Alzheimer Association has developed a list of common warning signs, which include memory loss, difficulty planning and doing usual tasks, disorientation, difficulty with visual images, problems with word finding, misplacing things, impaired judgment, social withdrawal, and changes in mood.[1]

## EPIDEMIOLOGY AND ETIOLOGY

● AD is the most common type of dementia, affecting an estimated 5.2 million Americans in 2014.[2] It is the sixth leading cause of death across all age groups in the United States and the fifth leading cause of death for individuals 65 years of age and older.[2] Various classifications of dementia include dementia of the Alzheimer type, vascular dementia, and dementia due to human immunodeficiency virus (HIV) disease, head trauma, Parkinson disease, Huntington disease, Pick disease, or Creutzfeldt-Jakob disease.[3] This chapter addresses only dementia of the Alzheimer type.

The prevalence of AD increases with age. Of those affected, one in nine are 65 years of age or older, and 1/3 are 85 years of age or older.[2] It is projected that by the year 2050, there will be a threefold increase in prevalence, yielding potentially 13.8 million AD patients due to a population increase in persons older than 65 years.[2] Additionally, total spending for AD is projected to increase from $214 billion in 2014 to over $1.2 trillion in 2050.[4] Furthermore, AD costs paid by Medicare and Medicaid in 2050 will have increased from 2010 by more than 600% and 400%, respectively.[4] The severity of AD also correlates with increasing age and is classified as mild, moderate, or severe. Other risk factors for AD include family history, female gender, and vascular risk factors such as diabetes, hypertension, heart disease, and current smoking.[5] It is unknown how other factors such as environment contribute and interact with the genetic predisposition for AD.

The mean survival time of persons with AD is reported to be approximately 6 years from the onset of symptoms. However, age at diagnosis, severity of AD, and other medical conditions affect survival time.[6] Although AD does not directly cause death, it is associated with an increase in various risk factors that often contribute to death, such as senility, sepsis, stroke, pneumonia, dehydration, and decubitus ulcers.

The etiology of AD is unknown; however, genetic factors may contribute to errors in protein synthesis resulting in the formation of abnormal proteins involved in pathogenesis.[7] Early onset, which is defined as AD prior to age 60, accounts for approximately 1% of all AD. This type is usually familial and follows an autosomal dominant pattern in approximately 50% of cases of early-onset AD. Mutations in three genes, presenilin 1 on

chromosome 14, amyloid precursor protein (APP) on chromosome 21, and presenilin 2 on chromosome 1, lead to an increase in the accumulation of amyloid beta (Aβ) in the brain, resulting in oxidative stress, neuronal destruction, and the clinical syndrome of AD.[8,9]

The genetic basis for the more common late-onset AD appears more complex. Genetic susceptibility is more sporadic, and it may be more dependent on environmental factors.[7] The apolipoprotein E (apo E) gene on chromosome 19 has been identified as a strong risk factor for late-onset AD. There are three variants of apo E; however, carriers of two or more of the apo E4 allele have an earlier onset of AD (~ 6 years earlier) compared with noncarriers.[7] Only 50% of AD patients have the apo E4 allele, thus indicating it is only a susceptibility marker.

## PATHOPHYSIOLOGY

KEY CONCEPT *Pathologic hallmarks of the disease in the brain include neurofibrillary tangles and neuritic plaques (senile plaques) made up of various proteins that result in a shortage of the neurotransmitter acetylcholine (Ach).* These are primarily located in brain regions involved in learning, memory, and emotional behaviors such as the cerebral cortex, hippocampus, basal forebrain, and amygdala.[10]

### Tangles

Neurofibrillary tangles (NFTs) are intracellular and consist of abnormally phosphorylated tau (τ) protein, which is involved in microtubule assembly. NFTs interfere with neuronal function, resulting in cell damage, and their presence has been correlated with the severity of dementia.[11] Unfortunately, NFTs are insoluble even after the cell dies, and they cannot be removed once established, thus prevention is key. The neurons that provide most of the cholinergic innervation to the cortex are most prominently affected.[12]

### Plaques

Neuritic or senile plaques are extracellular protein deposits of β-amyloid protein, which are central to the pathogenesis of AD.[10] The β-amyloid protein is present in a nontoxic, soluble form in human brains. In AD, conformational changes occur that render it insoluble and cause it to deposit into amorphous diffuse plaques associated with dystrophic neuritis.[13] Over time, these deposits become compacted into plaques, and the β-amyloid protein becomes fibrillar and neurotoxic. Inflammation occurs secondary to clusters of astrocytes and microglia surrounding these plaques.

### Acetylcholine

In AD, the plaques and tangles damage Ach pathways, leading to a shortage of Ach, resulting in learning and memory impairment.[14] The loss of Ach activity correlates with the severity of AD. The basis of pharmacologic treatment of AD has been to improve cholinergic neurotransmission in the brain. Blocking acetylcholinesterase, the enzyme that degrades Ach in the synaptic cleft, leads to an increased level of Ach with a goal of stabilizing neurotransmission.[14]

### Glutamate

Glutamate is the primary excitatory neurotransmitter in the central nervous system; it is involved in memory, learning, and neuronal plasticity. It affects cognition through facilitation of connections with cholinergic neurons in the cerebral cortex and basal forebrain.[15] In AD, one type of glutamate receptor,

*N*-methyl-D-aspartate (NMDA), is less prevalent than normal. There also appears to be overactivation of unregulated glutamate signaling. This results in a rise in calcium ions that induces secondary cascades, which lead to neuronal death and an increased production of APP.[14] The increased production of APP is associated with higher rates of plaque development and hyperphosphorylation of τ protein.[15]

### Cholesterol

Increased cholesterol concentrations have been associated with AD. The cholesterol increases β-amyloid protein synthesis, which can lead to plaque formation.[14] Also, the apo E4 allele is thought to be involved in cholesterol metabolism and is associated with higher cholesterol levels.[14]

### Estrogen

Estrogen appears to have properties that protect against memory loss associated with normal aging. Estrogen may block β-amyloid protein production and even trigger nerve growth in cholinergic nerve terminals.[16] Estrogen also helps prevent oxidative cell damage.[16] Despite this, the Women's Health Initiative Memory Study reported that hormone replacement therapy with either estrogen alone or estrogen plus medroxyprogesterone resulted in negative effects on memory.[17]

## CLINICAL PRESENTATION AND DIAGNOSIS

KEY CONCEPT *The diagnosis of AD is established following an extensive history and physical examination, and by ruling out other*

---

**Clinical Presentation and Diagnosis of Alzheimer Disease**

**General**

The diagnosis of AD, is primarily one of exclusion, but medical and psychiatric history, neurological examination, interview of caregivers and family members, and laboratory and imaging data also have a role.

**Signs and Symptoms**

- Cognitive: memory loss, problems with language, disorientation to time and place, poor or decreased judgment, problems with learning and abstract thinking, misplacing things
- Noncognitive: Changes in mood or behavior, changes in personality, or loss of initiative
- Functional: Difficulty performing familiar tasks

**Laboratory Tests**

- MRI or CT to measure changes in brain size and volume and rule out stroke, brain tumor, or cerebral edema.
- Tests to exclude possible causes of dementia: depression screen, vitamin $B_{12}$ levels, thyroid function tests (thyroid-stimulating hormone and free triiodothyronine and thyroxine), complete blood count, and chemistry panel.[18]
- Other diagnostic tests to consider for differential diagnosis: erythrocyte sedimentation rate, urinalysis, toxicology, chest x-ray, heavy metal screen, HIV testing, CSF examination, electroencephalography, and neuropsychological tests such as the Folstein Mini Mental State Examination.

## Table 29–1

### *DSM-5* Diagnostic Criteria for Major Neurocognitive Disorders

A. Evidence of significant cognitive decline from a previous level of performance in one or more cognitive domains (complex attention, executive function, learning and memory, language, perceptual-motor, or social cognition) based on:
1. Concern of the individual, a knowledgeable informant, or the clinician that there has been a significant decline in cognitive function and
2. A substantial impairment in cognitive performance, preferably documented by standardized neuropsychological testing or, in its absence, another quantified clinical assessment
B. Cognitive deficits interfere with independence in everyday activities
C. Cognitive deficits do not occur exclusively in the contest of delirium
D. Cognitive deficits are not better explained by another mental disorder

Data from American Psychiatric Association. Diagnostic and Statistical Manual of Mental Disorders, 5th ed, Washington, DC: American Psychiatric Association;2013:602–603, with permission.

*potential causes of dementia.* There are no biological markers other than those pathophysiological changes found at autopsy that can confirm AD, although the development of in vivo plaque detection methods may change this.

AD is a progressive disease that, over time, affects multiple areas of cognition. The American Psychiatric Association recently updated the criteria for AD in the *Diagnostic and Statistical Manual* (*DSM-5*). See **Tables 29–1**, **29–2**, and **29–3** for full criteria.[3]

## Table 29–2

### *DSM-5* Diagnostic Criteria for Mild Neurocognitive Disorder

A. Evidence of modest cognitive decline from a previous level of performance in one or more cognitive domains (complex attention, executive function, learning and memory, language, perceptual-motor, or social cognition) based on:

1. Concern of the individual, a knowledgeable informant, or the clinician that there has been a mild decline in cognitive function and

2. A modest impairment in cognitive performance, preferably documented by standardized neuropsychological testing, or in its absence, another quantified clinical assessment

B. Cognitive deficits do not interfere with capacity for independence in everyday activities

C. Cognitive deficits do not occur exclusively in the context of delirium

D. Cognitive deficits are not better explained by another mental disorder

Data from American Psychiatric Association. Diagnostic and Statistical Manual of Mental Disorders, 5th ed, Washington, DC: American Psychiatric Association;2013:605; with permission.

## Table 29–3

### *DSM-5* Diagnostic Criteria for Major or Mild Neurocognitive Disorder Due to Alzheimer Disease

A. Criteria are met for major or mild neurocognitive disorder
B. Insidious onset and gradual progression of impairment in one or more cognitive domains (for major neurocognitive disorder, at least two domains must be impaired)
C. Criteria are met for either probable or possible Alzheimer disease as follows:
   For Major Neurocognitive Disorder:
   Probable Alzheimer disease is diagnosed if either of the following is present; otherwise possible Alzheimer disease should be diagnosed.
1. Evidence of a causative Alzheimer disease genetic mutation from family history or genetic testing
2. All three of the following are present:
   a. Clear evidence of decline in memory and learning and at least one other cognitive domain
   b. Steadily progressive gradual decline in cognition, without extended plateaus
   c. No evidence of mixed etiology
   For Mild Neurocognitive Disorder:
   Probable Alzheimer disease: diagnosed if there is evidence of a causative Alzheimer disease genetic mutation from either genetic testing or family history
   Possible Alzheimer disease: diagnosed if there is no evidence of a causative Alzheimer disease genetic mutation from either genetic testing or family history, and all three of the following are present:
1. Clear evidence of decline in memory and learning
2. Steadily progressive, gradual decline in cognition, without extended plateaus
3. No evidence of mixed etiology
D. Disturbance is not better explained by cerebrovascular disease, another neurodegenerative disease, the effects of a substance, or another mental, neurological, or systematic disorder

Data from American Psychiatric Association. Diagnostic and Statistical Manual of Mental Disorders, 5th ed, Washington, DC: American Psychiatric Association;2013;611; with permission.

## TREATMENT

### Desired Outcomes

There are four agents approved for the treatment of AD, but none are curative or known to directly reverse the disease process.

**KEY CONCEPT** *Treatment is focused on delaying disease progression and preservation of functioning as long as possible.* Secondary goals include treating psychiatric and behavioral symptoms that may occur during the course of the disease.

### General Approach to Treatment

**KEY CONCEPT** *The current gold standard of treatment for cognitive symptoms includes pharmacologic management with a* **cholinesterase (ChE) inhibitor** *and/or an* **NMDA antagonist**. Donepezil, rivastigmine, and galantamine are three ChEs used for cognitive symptoms. The first ChE approved for AD was tacrine; however, it is no longer available in the United States. Its use was limited due to its propensity for hepatotoxicity, difficult titration schedule, four times daily dosing, poor bioavailability, and troublesome incidence of nausea, diarrhea, and urinary incontinence. The only NMDA antagonist is memantine. Psychiatric and behavioral

| Table 29–4 |
| --- |
| **Basic Principles in the Management of Patients with AD** |

- Using a gentle, calm approach to the patient
- Giving reassurance when needed
- Empathizing with the patient's concerns
- Using distraction and redirection
- Maintaining daily routines
- Providing a safe environment
- Providing daytime activities
- Avoiding overstimulation
- Using familiar decorative items in the living area
- Bringing abrupt declines in function and the appearance of new symptoms to professional attention

| Table 29–5 |
| --- |
| **Treatment Algorithm for Cognitive Symptoms of AD** |

1. Patient diagnosed with AD
2. Assess all comorbid medical disorders and drug therapies that may affect cognition
3. Rule out comorbid depression
4. Evaluate for pharmacotherapy based on illness stage
   a) Mild AD: **Cholinesterase inhibitor**
   b) Moderate to severe AD: Cholinesterase inhibitor, memantine, or combination cholinesterase inhibitor and memantine
3. Deteriorating Mini Mental State Exam (MMSE) score > 2–4 points after 1 year: Change to a different cholinesterase inhibitor
4. Stable MMSE: Continue regimen

symptoms that occur during the course of the disease should be treated as they occur.

Essential elements in the treatment of AD include education, communication, and planning with the patient's family/caregiver. Treatment options, legal and financial decisions, and course of the illness should be discussed with the patient and family members. In this regard, the clinician's emphasis should be on helping to maintain a therapeutic living environment while minimizing the burden of care resulting from the disease.

## Nonpharmacologic Therapy

The life of a patient with AD must become progressively more simple and structured as the disease progresses, and the caregiver must learn to keep requests and demands on the patient simple. Basic principles in the treatment of patients with AD are shown in Table 29–4.

## Pharmacologic Therapy

### ▶ *Conventional Pharmacologic Treatment for Cognitive Symptoms*

**ChE Inhibitors (Donepezil, Rivastigmine, and Galantamine)**
The ChE inhibitors are FDA approved for the treatment of AD. Guidelines recommend the use of ChE inhibitors as a valuable treatment for AD and the use of memantine for moderate to severe AD.[18] The few head-to-head studies comparing the ChE Inhibitors conclude there are no major differences in clinical outcomes, so the selection of one ChE over another should be based on differences in mechanisms of action, adverse reactions, and titration schedules.[19]

Treatment should begin as early as possible after diagnosis.[20] Table 29–5 provides a recommended treatment algorithm. Patients should be switched to another ChE inhibitor from their initial ChE inhibitor if they show an initial lack of efficacy, initially respond but then lose clinical benefit, or experience safety/tolerability issues. This switch should not be attempted until the patient has been on a maximally tolerated dose for 3 to 6 months. The switch should also be based on realistic expectations of the patient and/or caregiver.[21] ChE inhibitor therapy should be discontinued in patients who experience poor tolerance or adherence, who do not improve after 6 months at optimal dosing, who fail attempts at monotherapy with at least two agents or combination therapy, who continue to deteriorate at the pretreatment rate, who have dramatic clinical deterioration following initiation of treatment, or who deteriorate to the point where there is no significant effect on quality of life. Patients with a Mini Mental State Exam (MMSE) score less than 10 may also benefit

from discontinuation of medication; however, this has not been substantially proven in clinical studies.[22]

### Donepezil

Donepezil is a piperidine ChE inhibitor that reversibly and noncompetitively inhibits centrally active acetylcholinesterase.[23] A dose of 10 mg/day has demonstrated efficacy in patients with either mild to moderate or moderate to severe forms of AD. A 23-mg dose of donepezil is also approved for patients with moderate to severe disease. The 23-mg dose showed a small improvement in cognitive symptoms compared to the 10 mg/day dose; however, there was no improvement in overall functioning, and there was a higher incidence of adverse effects.[24] Table 29–6 describes dosing strategies for all of the approved agents for AD. The most frequent adverse effects are mild to moderate gastrointestinal symptoms. Others include headache, dizziness, syncope, bradycardia, and muscle weakness. Table 29–7 compares their major side effects.[23,25–28]

Only a small number of drug interactions have been reported with donepezil. In vitro studies show a low rate of binding of donepezil to cytochrome P450 (CYP)3A4 or 2D6. Whether donepezil has the potential for enzyme induction is unknown. Monitoring for increased peripheral side effects is advised when adding a CYP2D6 or 3A3/4 inhibitor to donepezil treatment. Also, inducers of CYP2D6 and 3A4 could increase the rate of elimination of donepezil.[23]

### Rivastigmine

Rivastigmine, approved for the treatment of mild to moderate AD, has central activity for both acetylcholinesterase and butyrylcholinesterase.[28] Acetylcholinesterase is found in two forms: globular 4 and globular 1. In postmortem studies, globular 4 is significantly depleted, whereas globular 1 is still abundant. Thus, blocking metabolism of globular 1 may lead to higher concentrations of Ach. Rivastigmine has higher activity at globular 1 than at globular 4. Theoretically, this may be advantageous because rivastigmine prevents the degradation of Ach via the acetylcholinesterase globular 1 pathways over the course of the disease, compared with the other ChE inhibitors.

The dual inhibition of acetylcholinesterase and butyrylcholinesterase may lead to broader efficacy. As acetylcholinesterase activity decreases with disease progression, the acetylcholinesterase-selective agents may lose their effect, whereas the dual inhibitors may still be effective due to the added inhibition of

**Table 29–6**

**Dosing Strategies for Cognitive Agents**

| | Donepezil (Aricept) | Rivastigmine (Exelon) | Galantamine (Razadyne) | Memantine (Namenda)[a] |
|---|---|---|---|---|
| Starting dose | 5 mg daily in the evening | 1.5 mg twice daily or 4.6 mg/24 hour applied daily (patch) | 4 mg twice daily or 8 mg daily in the morning | 5 mg daily or 7 mg daily (ER formulation) |
| Maintenance dose | 5–23 mg daily | 3–6 mg twice daily or 9.5 mg/24 hour applied daily (patch) | 8–12 mg twice daily or 16–24 mg daily | 10 mg twice daily or 28 mg daily (ER formulation) |
| Time between dose adjustments | 4–6 weeks between 5 and 10 mg increment; 3 months between 10 and 23 mg increment | 2 weeks for oral and 4 weeks for patch | 4 weeks | 1 week |
| Dosage adjustments for renal or hepatic impairment | None | Moderate to severe renal impairment, mild to moderate hepatic impairment, or low body weight (< 50 kg): consider maximum dose of 4.6 mg/24 hour | Do not exceed 16 mg for moderately impaired hepatic or renal function; do not administer in severe renal or hepatic impairment | Severe renal impairment: target maintenance dose of 5 mg twice daily or 14 mg daily |

[a]As of August 15, 2014, Forest Pharmaceuticals, Inc. plans to discontinue the sale of all configurations of Namenda. They will continue to sell oral solution of Namenda as well as once-daily Namenda XR. Namzaric, a fixed-dose combination of extended-release memantine and donepezil, (14/10 mg and 28/10 mg) was recently approved.

butyrylcholinesterase. However, this has not been demonstrated clinically.

Rivastigmine is available as an oral formulation and as a patch. When switching from the oral formulation to the patch, if the patient is taking less than 6 mg/day orally, the 4.6 mg/24 hour patch is recommended. If the patient is taking 6 to 12 mg/day orally, the 9.5 mg/24 hour patch is recommended. The first patch should be applied on the day following the last oral dose.[25]

Cholinergic side effects are common, but they are usually well tolerated if the recommended dosing schedule is followed. If side effects cause intolerance, several doses can be held, then dosing can be restarted at the same or next lower dose. Drugs that induce or inhibit CYP450 metabolism are not expected to alter rivastigmine metabolism.[25]

### Galantamine

Galantamine, approved for the treatment of mild to moderate AD, is a ChE inhibitor, which elevates Ach in the cerebral cortex.[26] It also modulates the nicotinic Ach receptors to increase Ach release from surviving presynaptic nerve terminals. It may also increase glutamate and serotonin levels, but whether this brings additional benefit is unknown.

CYP3A4 and 2D6 are the major metabolizing enzymes, and pharmacokinetic studies with inhibitors of these enzymes have shown increased galantamine concentrations or reductions in clearance. Similar to donepezil, if inhibitors are given concurrently with galantamine, monitoring for increased cholinergic side effects should be done.[26]

### NMDA Receptor Antagonist

Memantine is a noncompetitive antagonist of the NMDA type of glutamate receptors, which are located throughout the brain. It regulates activity throughout the brain by controlling the amount of calcium that enters the nerve cell, a process essential for establishing an environment required for information storage. Overstimulation of the NMDA receptor by excessive glutamate allows too much calcium into the cell, disrupting information processing. Blocking NMDA receptors with memantine may protect neurons from the effects of excessive glutamate without disrupting normal neurotransmission.[27,28]

Memantine is approved to treat moderate to severe AD. It can be given as monotherapy or in combination with ChE inhibitors. Memantine is not indicated for mild AD, and current evidence does not support its use in mild AD.[29] The 28-mg memantine extended release has not been compared with the immediate-release formulation; thus it is unknown if the 28 mg/day dose of memantine is more effective than the traditional 20 mg/day maximum. Adverse reactions associated with memantine include constipation, confusion, dizziness, headache, coughing, and hypertension. Closer monitoring should be done if memantine is given concurrently with a ChE inhibitor.

In vitro studies have shown that memantine produces minimal inhibition of CYP450 enzymes CYP1A2, 2A6, 2C9, 2D6, 2E1, and 3A4, and that no pharmacokinetic interactions with drugs metabolized by these enzymes should be expected.[27,28]

### Future Therapies

KEY CONCEPT *Future therapies for AD may include disease-modifying therapies.* Current investigations involving the amyloid hypothesis are evaluating various compounds in the secondary prevention of AD. Mechanisms by which these compounds are thought to work include[8]:

---

**Patient Encounter, Part 1**

A man presents at the clinic with his 73-year-old mother complaining that his mother's memory is worsening. He complains that his mother is continuing to forget things, including paying the bills and emptying the cat's litter box. Three months ago she was started on galantamine 8 mg daily, which was titrated to 16 mg daily. Her son organizes a weekly pillbox and helps administer the medications. The son asks if there is anything else his mother could take to help her memory.

*What education points about Alzheimer disease would you provide to the son?*

*Where would you recommend the son find more information about Alzheimer disease?*

*How would you address the son's question regarding the pharmacologic management of his mother's Alzheimer disease?*

---

- Reducing levels of brain Aβ or manipulating its configuration
- Targeting τ proteins
- Targeting inflammatory approaches
- Addressing insulin resistance in the brain

Recent studies of bapineuzumab and solanezumab, humanized monoclonal antibody targeting the Aβ, failed to demonstrate a significant change in the Alzheimer Disease Assessment Scale (ADAS-cog11) in phase 3 clinical trials.[30,31]

### Nonconventional Pharmacologic Treatment

Many other nonconventional treatments have historically been used as adjunctive treatments of AD. Vitamin E was previously recommended because of its antioxidant properties, but a meta-analysis suggested that greater than 400 IU/day should be avoided due to an increased all-cause mortality.[32] Currently, vitamin E is not recommended for the treatment of AD. Estrogen has been investigated for use in AD, but it was associated with an increased risk of dementia. For nonsteroidal anti-inflammatory drugs (NSAIDs) there is a lack of convincing data supporting efficacy, and gastritis, GI bleeds, and increased cardiovascular events are associated with their use. They are not recommended for treatment or prevention of AD at this time.[33] Statins (3-hydroxy-3-methylglutaryl-CoA reductase inhibitors) should be reserved for those who have other indications for their use.[34] Until Ginkgo biloba has a more standardized manufacturing process and its long-term safety and efficacy are established, it should be recommended with caution.[35] The medical food caprylidene (AC-1202, Axona) is a medium chain triglyceride approved for the dietary management of metabolic processes associated with mild to moderate AD.[36] Reduced neuronal metabolism of glucose has been associated with AD. Ketone bodies can potentially be used as an alternative energy source for AD patients.[36] Caprylidene is converted by the liver into the ketone body β-hydroxybutyrate (BHB). BHB crosses the blood–brain barrier and can be utilized by neurons as a potential energy source to generate ATP and increase pools of acetylcholine. Caprylidene requires a prescription and is supplied in 40-g powder packets. One packet can be mixed with 4 to 8 ounces of liquid (~120–240 mL) and dosed once daily after a meal. The most common side effects are mild

GI disturbances including nausea, diarrhea, flatulence, and dyspepsia.[37]

## Treatment of Behavioral Symptoms

**KEY CONCEPT** *Treatment of behavioral symptoms should begin with nonpharmacologic treatments but may also include antipsychotic agents and/or antidepressants.* Nonpharmacologic recommendations for treatment include[38]:

- Music
- Videotapes of family members
- Audiotapes of the voices of caregivers
- Walking and light exercise
- Sensory stimulation and relaxation

Antipsychotics are frequently used for neuropsychiatric symptoms associated with AD. A recent meta-analysis concluded that only 17% to 18% of dementia patients demonstrated treatment response to atypical antipsychotics.[39] A double-blind, placebo-controlled trial of olanzapine, quetiapine, or risperidone for the treatment of psychosis, aggression, or agitation in patients with AD showed that adverse effects offset the benefits in the efficacy of atypical antipsychotics.[40]

In April 2005, the FDA issued a statement requiring black-box warnings on all antipsychotics stating that elderly people with dementia-related psychosis treated with an antipsychotic are at an increased risk of death compared with those treated with placebo. Fifteen of 17 trials investigating olanzapine, aripiprazole, quetiapine, and risperidone in elderly demented patients with behavioral disorders showed an increase in mortality compared with the placebo-treated groups (1.6–1.7 times increased risk of death). Causes for these deaths were heart-related events (heart failure and sudden death) and infections (mostly pneumonia).

The antipsychotics are not approved for the treatment of elderly patients with dementia-related psychosis. Therefore, it is important to individually assess and balance the risk versus benefit of antipsychotic use in this population.

Depressive symptoms occur in as many as 50% of patients with AD and can be difficult to differentiate from symptoms of dementia, so symptoms of depression should be documented for several weeks prior to initiating therapy for depression with AD.[8] The selective serotonin reuptake inhibitors (SSRIs) are most commonly used based on their side-effect profile and evidence of efficacy.[8] Indications for the use of antidepressants include depression characterized by poor appetite, insomnia, hopelessness, anhedonia, withdrawal, suicidal thoughts, and agitation. A recent trial suggested a lack of benefit of sertraline and mirtazapine compared with placebo and an increased risk of adverse effects.[41]

Other miscellaneous therapies for AD include benzodiazepines for anxiety, agitation, and aggression. However, their routine use is not advised.[8] Additionally, benzodiazepines are associated with an increase in falls leading to the potential for hip fractures in the elderly.[42] Mood stabilizer anticonvulsants, carbamazepine, valproic acid, or gabapentin may be used as alternatives, but the current evidence is conflicting.[43] Buspirone has shown benefit in treating agitation and aggression in a limited number of patients with minimal adverse effects.[44,45] In open-label and controlled studies, selegiline decreased anxiety, depression, and agitation.[46,47] Finally, trazodone has been shown to decrease insomnia, agitation, and dysphoria, and it has been used to treat sundowning in AD patients. Table 29–8 provides dosing strategies for the noncognitive symptoms of AD.[48]

## Patient Encounter, Part 2

The patient returns to the clinic in 6 months. She has been receiving 24 mg/day of galantamine. Her memory symptoms have slowed in their decline, but recently she has been agitated at bedtime and talking to her deceased sister. The son is particularly concerned about the symptoms and wants to know what he could do to help. The patient's record is as follows:

**PMH:** Diabetes mellitus since age 51, it was well controlled until last year when she became confused about when to take her medication; hypertension treated for 23 years and well controlled; has been hypotensive on a few occasions recently during physicals; osteopenia, last bone mineral density test 12 months ago (T-score = – 1.2); on therapy; hypercholesterolemia, last cholesterol panel 12 months ago showed well-controlled levels in normal range; on therapy

**FH:** Father died of myocardial infarction at age 76; mother died of breast cancer at age 79

**SH:** Lives with wheelchair-bound husband; son lives across street and checks in daily; denies drinking alcohol or smoking

**Meds:** Metformin 1000 mg orally twice daily; insulin glargine 18 units subcutaneously at bedtime; hydrochlorothiazide 12.5 mg orally once daily in the morning; lisinopril 20 mg orally once daily in the morning; calcium carbonate and vitamin D 600 mg/200 international units orally twice daily with lunch and dinner; pravastatin 20 mg orally once daily with dinner; galantamine 24 mg daily in the morning

**ROS:** (+) Weight loss of 6.3 kg (14 lb) since last visit; (-) N/V/D, change in appetite, heartburn, chest pain, or shortness of breath

**PE:**

**VS:** BP 111/72 mm Hg supine, P 79 beats/min, RR 16 breaths/min, T 37°C (98.6°F)

**Gen:** Poorly groomed, thin woman looks stated age

**Neuro:** Folstein Mini-Mental State Exam score 18/30; disoriented to month, date, and day of week, clinic name and floor; poor registration with impaired attention and short-term memory; good language skills but problems with commands

**CT Scan:** Mild-to-moderate generalized cerebral atrophy

*What do you recommend with regard to her current galantamine treatment?*

*What nonpharmacologic and pharmacologic interventions could be recommended for the agitation and psychosis?*

## GENOMICS

**KEY CONCEPT** *Therapeutic response in AD is genotype specific, depending on the genes associated with pathogenesis and/or genes responsible for drug metabolism.* Apo E-4/4 carriers tend to show a faster disease progression and a poorer therapeutic response to all available treatments than any other polymorphic variants associated with AD. CYP450 enzyme extensive and intermediate metabolizers are the best responders to pharmacotherapy, while poor and ultrarapid metabolizers are the worst responders. The pharmacogenetic response in AD may depend on interaction of

| Table 29–8 |

**Medications Used for Noncognitive Symptoms of Dementia**

| Drugs | Starting Dose (mg) | Maintenance Dose in Dementia (mg/day) | Dosing Adjustment for Hepatic Impairment (mg) | Dosing Adjustment for Renal Impairment (mg) | Target Symptoms |
| :--- | :--- | :--- | :--- | :--- | :--- |
| **Antipsychotics** | | | | | |
| Aripiprazole | 10–15 | 30 (maximum) | None needed | None needed | Psychosis: hallucinations, delusions, suspiciousness |
| Olanzapine | 2.5 | 5–10 | None needed | None needed | |
| Quetiapine | 25 | 100–400 | Lower starting dose and longer titration schedule to effective dose based on response and tolerability | None needed | Disruptive behaviors: agitation, aggression |
| Risperidone | 0.25 | 0.5–2 | Lower starting dose and longer titration schedule to effective dose based on response and tolerability | Lower starting dose and longer titration schedule to effective dose based on response and tolerability | |
| **Antidepressants** | | | | | |
| Citalopram | 10 | 10–20 | 20 mg/day maximum; may increase only in nonresponsive patients | Mild to moderate impairment: none needed | Depression: poor appetite, insomnia, hopelessness, anhedonia, withdrawal, suicidal thoughts, agitation, anxiety |
| Escitalopram | 5 | 10 (maximum) | 10 mg/day maximum | Mild to moderate impairment: none needed | |
| Fluoxetine | 5 | 10–20 | A lower dose or less frequent schedule is recommended | None needed | |
| Paroxetine | 10 | 10–40 | 10 mg/day; may increase by 10 mg/day at intervals of at least 1 week | 10 mg/day; may increase by 10 mg/day at intervals of at least 1 week | |
| Sertraline | 12.5 | 150 (maximum) | Lower or less frequent doses should be used | None needed | |
| Mirtazapine | 15 | 15–50 | Caution should be used | Caution should be used | |
| Trazodone | 25 | 75–150 | None needed | None needed | |
| **Anticonvulsants** | | | | | |
| Carbamazepine | 100 | 300–600 | Should not be used in aggravated liver dysfunction or active liver disease | None needed | Agitation or aggression |
| Valproic acid | 125 | 500–1500 | Should not be administered | None needed | |

Adapted from Slattum PW, Peron EP, Massey-Hill A. Alzheimer's disease. In: Dipiro JT, Talbert RL, Yee GC, et al, eds. Pharmacotherapy: A Pathophysiologic Approach. 9th ed. New York, NY: McGraw-Hill;2014:828, with permission.

genes involved in drug metabolism and genes associated with AD pathogenesis.[49]

## OUTCOME EVALUATION

- The success of therapy is measured by the degree to which the care plan decreases the pretreatment rate of cognitive deterioration, preserves the patients' functioning, and treats psychiatric and behavioral symptoms. The primary outcome measure is thus subjective information from the patient and the caregiver, although the MMSE can be a helpful tool. There are no physical examination or laboratory parameters to evaluate the success of therapy.

**Patient Encounter, Part 3**

The patient returns to the clinic for follow-up 1 year later. Her son states her memory has continued getting worse. Her current MMSE is 16/30. The addition of olanzapine 2.5 mg at bedtime helped with her agitation. Her son would like to know if there are any other choices to help treat his mom.

*What changes to the patient's current medications would you recommend?*

## Patient Care Process

**Patient Assessment:**

- Assess the frequency and duration of cognitive and noncognitive symptoms. Could the patient be depressed?
- Review any available diagnostic data from the medical and psychiatric history including interviews from family, neuropsychologic testing, and other labs. (ie, MRI, CT, vitamin deficiencies, thyroid function tests, complete blood counts, and chemistry panel)
- Obtain a thorough history of prescription, nonprescription, and natural drug product use. Is the patient taking any medications that could contribute to cognitive changes in the elderly?

**Therapy Evaluation:**

- If needed, provide patients and caregivers information about lifestyle modification, and refer them to support when needed.
- Assess the current regimen for appropriateness, effectiveness, adverse effects, drug interactions, appropriate dosing, and medication adherence (see Table 29–7).

**Care Plan Development:**

- Be a resource and give continuous support to the patient and caregivers throughout the long course of the disease.
- Select an appropriate ChE inhibitor to avoid drug–drug interactions and adverse effects and in consideration of cost and patient preference (see Tables 29–6 and 29–8).

- Develop a plan to monitor cognitive response to treatment over time.
- Select appropriate medications for behavior symptoms if lifestyle modifications do not achieve goals (see Table 29–8).
- Educate patient and caregivers on what to expect from pharmacotherapy.

**Follow-Up Evaluation:**

- Follow up at needed intervals to assess effectiveness and safety of therapy. Review medical history and physical exam findings, lab tests, and results of other diagnostic tests.
- Monitor pharmacotherapy initiation (see Table 29–6), and regularly evaluate the patient for the presence of adverse drug reactions, drug allergies, drug–drug and drug–disease interactions, and adherence.
- If symptoms progress, consider stopping/switching the ChE inhibitor. Switch if there is initial lack of efficacy, loss of clinical benefit, or if poor tolerability develops. Discontinue if there is poor adherence, 6 months with no clinical improvement, or if there is continued deterioration at pretreatment rates.
- Continue to offer support to the patient and caregiver.

---

- Develop a plan to assess the effectiveness of the ChE inhibitor in slowing the deterioration of cognitive functioning after an appropriate interval (every 3–6 months).
- Assess improvement in quality-of-life measures such as ability to function independently and for slowing of memory deterioration (every 3–6 months).
- Evaluate the patient for the presence of adverse drug reactions, drug allergies, and drug interactions at appropriate intervals (soon after drug initiation or change and every 3–6 months).

## CONCLUSION

AD is a progressive deterioration of cognitive abilities usually with behavioral disturbances and personality changes in the later stages of the disease. In an effort to help prepare patients and their caregivers for the inevitable, the Alzheimer Association has developed ten quick tips on "Living with Alzheimer disease" and they can also provide many resources for patients and caregivers.[50] Access the association at:

## Abbreviations Introduced in This Chapter

| | |
|---|---|
| Ach | Acetylcholine |
| Aβ | Amyloid beta |
| AD | Alzheimer disease |
| apo E | Apolipoprotein E |
| APP | Amyloid precursor protein |
| BHB | β-Hydroxybutyrate |
| ChE | Cholinesterase |
| CYP | Cytochrome P450 |
| *DSM-5* | *Diagnostic and Statistical Manual of Mental Disorders*, 5th edition |
| MMSE | Mini Mental State Examination |
| NMDA | *N*-Methyl-D-aspartate |
| NFTs | Neurofibrillary Tangles |
| NSAID | Nonsteroidal anti-inflammatory drug |
| SSRI | Selective serotonin reuptake inhibitor |
| $\tau$ | Tau protein |

# Multiple Sclerosis

Melody Ryan

## LEARNING OBJECTIVES

● **Upon completion of the chapter, the reader will be able to:**

1. Identify risk factors for multiple sclerosis (MS).
2. Describe pathophysiologic findings of MS.
3. Distinguish between forms of MS based on patient presentation and disease course.
4. Compare and contrast MS disease-modifying treatment choices for a given patient.
5. Determine appropriate symptomatic treatment choices for a given patient.
6. Develop a monitoring plan for a patient placed on specific medications.

## INTRODUCTION

Multiple sclerosis (MS) is an inflammatory disease of the central nervous system (CNS), variable in symptoms and presentation. *Multiple* describes the number of CNS lesions, and *sclerosis* refers to the demyelinated lesions, today called plaques.

## EPIDEMIOLOGY AND ETIOLOGY

### Epidemiology

Approximately 2.3 million people worldwide have MS.[1] Diagnosis usually occurs between 20 and 50 years, affecting twice as many women as men.[1] Whites and people of northern European heritage are more likely to develop MS; prevalence decreases with decrease in latitude.[1,2] Risk factors include family history of MS, autoimmune diseases, or migraine; personal history of autoimmune diseases or migraine; and, in women, cigarette smoke exposure.

### Etiology

#### ▶ *Inheritance Theory*

Family members of MS patients have a 5% risk; monozygotic twins have a concordance rate of 25% to 30%.[2] Genetics cannot fully explain the etiology of MS because only a small proportion of patients report a family member with MS; however, genetic risks may explain up to 35% of cases.[3]

#### ▶ *Environment Theory*

Epstein-Barr virus is thought to be a possible infectious etiologic agent.[3] Infection cannot fully explain MS because there is a high rate of seropositivity in the population, but MS is much less common. Other environmental theories involve decreased patient or maternal vitamin D serum concentrations or high sodium consumption.[2,3]

## PATHOPHYSIOLOGY

While the causative agent of MS is unclear, the result is the development of an autoimmune disorder with areas of CNS inflammation and degeneration.

### Inflammation

An unknown antigen presented by the major histocompatibility complex (MHC) class II molecules causes T-cells to become autoreactive (**Figure 30–1**). Autoreactive T-cells enter lymphatic tissues to expand. Upon a signal involving sphingosine-1-phosphate, T-cells reenter the circulation.[4] Once activated, T-cells attach to upregulated adhesion molecules and produce matrix metalloproteinases (MMP) that cause blood–brain barrier breakdown. In the CNS, T-cells come into contact with antigen-presenting cells and proliferate. The T-helper cells differentiate into proinflammatory T-helper-1 cells (Th1 cells) and anti-inflammatory T-helper-2 cells (Th2 cells).[4] Th1 cells secrete cytokines that enhance macrophage and microglial cells that attack **myelin**.[4]

B-cells cross damaged sections of the blood–brain barrier where autoreactive T-cells trigger B-cells to form myelin autoantibodies. B-cell antibodies also initiate the complement cascade, causing myelin degradation.[4] These inflammatory processes probably cause relapses.[4] All current MS therapies are targeted toward preventing or slowing the inflammatory processes.

### Degeneration

Axonal injury and transection disrupts nerve signals. Growing evidence suggests cytotoxic T-cells cause axonal injury as early as 2 weeks after diagnosis and throughout the disease.[4] Axonal loss is likely responsible for MS progression.[4]

## CLINICAL PRESENTATION AND DIAGNOSIS

### Clinical Course

● **KEY CONCEPT** *MS is classified into relapsing and progressive disease* (**Figure 30–2**).[7] These categories are subclassifed according to disease activity and progression. Clinically isolated syndrome (CIS) is a first clinical presentation for which the criteria of dissemination in time has not been met to diagnose MS.[7]

Relapsing-remitting MS is the most common form (85%), developing into progressive form in 50% of patients within
**FIGURE 30–1.** Autoimmune theory of the pathogenesis of MS. In MS, the immunogenic cells tend to be more myelin-reactive, and these T-cells produce cytokines mimicking a Th1-mediated proinflammatory reaction. T-helper cells (CD4+) appear to be key initiators of myelin destruction in MS. These autoreactive CD4+ cells, especially of the Th1 subtype, are activated in the periphery, perhaps following a viral infection. The activation of T- and B-cells requires two signals. The first signal is the interaction between MHC and antigen presenting cell (APC) (macrophage, dendritic cell, B-cell). The second signal consists of the binding between B7 on the APC and CD28 on the T-cell for T-cell activation. Similarly, CD40 expressed on APCs and CD40L expressed on T-cells interaction to signal the proliferation of B-cells within the blood-brain barrier following the entry of T-cells. The T-cells in the periphery express adhesion molecules on their surfaces that allow them to attach and roll along the endothelial cells that constitute the blood-brain barrier. The activated T-cells also produce MMP that help to create openings in the blood–brain barrier, allowing entry of the activated T-cells past the blood–brain barrier and into the CNS. Once inside the CNS, the T cells produce proinflammatory cytokines, especially interleukins (ILs) 1, 2, 12, 17, and 23, tumor necrosis factor-α (TNF-α), and interferon-γ (INF-γ), which further create openings in the blood–brain barrier, allowing entry of B-cells, complement, macrophages, and antibodies. The T-cells also interact within the CNS with the resident microglia, astrocytes, and macrophages, further enhancing production of proinflammatory cytokines and other potential mediators of CNS damage, including reactive oxygen intermediates and nitric oxide. The role of modulating, or downregulating, cytokines such as IL-4, IL-5, IL-10, and transforming growth factor-β (TGF-β) also has been described. These cytokines are the products of CD4+, CD8+, and Th1-cells. New pathogenic mechanisms involve, but are not limited to, receptor-ligand–mediated T-cell entry via choroid plexus (CCR6-CCL20 axis), coupling of key receptor-ligands for inhibition of myelination/demyelination (LINGO-1/NOGO66/p75, or TROY complex, Jagged-Notch signaling). (AG, antigens; APC, antigen-presenting cell; DC, dendrite cell; IgG, immunoglobulin G; Mφ, macrophage; Na⁺, sodium ion; MMP, matrix metalloproteinases; MHC, major histocompatibility complex; OPC, oligodendrocyte precursor cell; VLA, very late antigen; VCAM, vascular cell adhesion molecule.) (From Bainbridge JL, Miravalle A, Corboy JR. Multiple sclerosis. In: DiPiro JT, Talbert RL, Yee GC, et al, eds. Pharmacotherapy: A Pathophysiologic Approach. 9th ed. New York, NY: McGraw-Hill; 2014:835–854, with permission.)

## Clinical Presentation of MS[5,6]

MS symptoms depend on the location of lesions within the CNS. Myelin increases the speed of nerve impulse transmission; demyelination slows the speed. No impulses can be transmitted if the axon is transected. The primary symptoms of MS are caused by this delay or cessation of impulses. Secondary symptoms of MS result from the primary symptoms.

| Primary Symptoms | Frequency of Occurrence (%) | Related Secondary Symptoms |
| --- | --- | --- |
| Urinary symptoms | 70 | |
|    Incontinence | | Decubitus ulcers |
|    Urinary retention | | Urinary tract infections |
| Spasticity | 70–80 | Falls, care difficulties, pain, gait problems |
| Visual symptoms | | |
|    Optic neuritis | 70 | Falls, care difficulties |
| Bowel symptoms | 39–73 | |
|    Incontinence | | Decubitus ulcers |
|    Constipation | | Pain |
| Depression | 50 | Suicide |
| Anxiety | 36 | |
| Cognitive deficits | 43–70 | Decline in work or social performance, care difficulties |
| Fatigue | 92 | Effects on employment and social roles |
| Uhthoff phenomenon | 80 | |
| Sexual dysfunction | | |
|    Erectile dysfunction | 50–90 | |
|    Female sexual dysfunction | 40–85 | |
| Tremor | 80 | Inability to perform activities of daily living |
| Pain | 86 | |
|    Trigeminal neuralgia | | |
|    Lhermitte sign | | |
| Dysesthetic pain | 14–29 | |
| Impaired gait | 64 | |

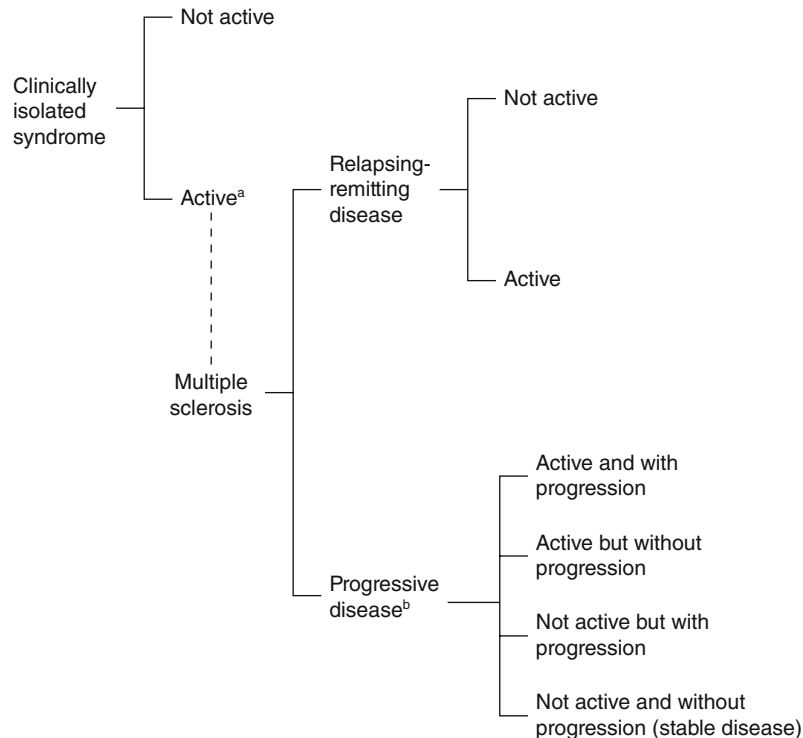

FIGURE 30–2. Clinical Patterns of Multiple Sclerosis.[7] [a]Clinically isolated syndrome, if active, may fulfill multiple sclerosis diagnostic criteria. [b]Progressive disease may be primary progressive with progressive accumulation of disability from onset or secondary progressive with progressive accumulation of disability after initial relapsing course.
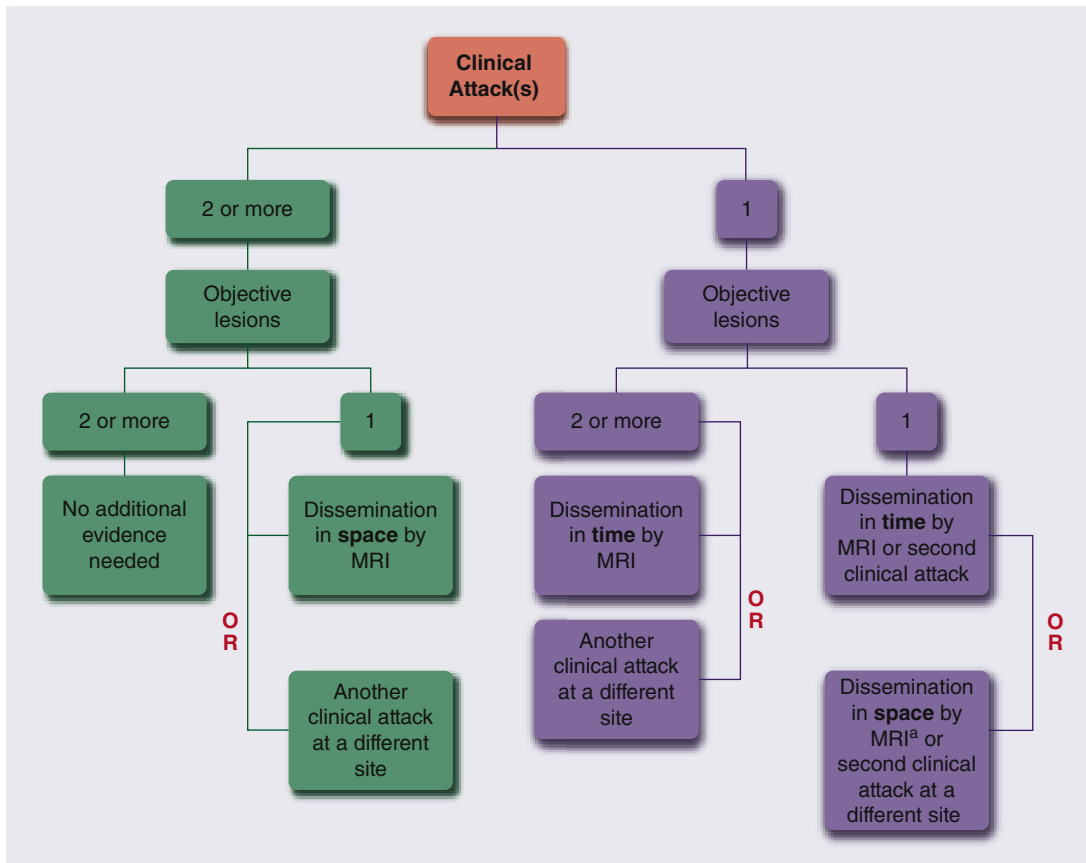

**FIGURE 30–3.** McDonald diagnostic criteria for MS.[9] An attack is defined as a patient-reported or objectively observed event typical of an acute inflammatory demyelinating event in the CNS with a duration of at least 24 hours in the absence of fever or infection. MRI evidence of dissemination over time is a new T2-weighted lesion after the initial clinical event or the simultaneous presence of asymptomatic gadolinium-enhancing and nonenhancing lesions at any time. [a]Dissemination in space by MRI evidence of one or more T2-weighted lesions in at least two of the following areas: periventricular, juxtacortical, infratentorial, spinal cord.

10 years.[1] MS reduces life expectancy by 10 to 12 years.[8] Suicide is high in MS patients, 7.5 times the rate of healthy controls.[8]

## Diagnosis

Relapsing MS diagnosis requires plaque dissemination in time and space. **KEY CONCEPT** *Using the clinical examination with magnetic resonance imaging (MRI) data facilitates earlier diagnosis and treatment* (Figure 30–3).[9] Progressive MS diagnosis requires 1 year of disease progression and two of the following: dissemination in space on MRI of the brain, dissemination in space on MRI in the spinal cord based on two or more T2-weighted lesions, and positive cerebrospinal fluid (CSF) (oligoclonal immunoglobulin G bands or elevated immunoglobulin G index).[9]

## TREATMENT

### Desired Outcomes and General Approach to Treatment

The goal of treatment is preventing permanent neurologic damage. There are three approaches to treatment. **KEY CONCEPT** *First, treat acute relapses with corticosteroids to speed recovery.* **KEY CONCEPT** *Second, disease-modifying therapies decrease the number of relapses, prevent permanent neurologic damage, and prevent disability.* **KEY CONCEPT** *Third, symptomatic treatments minimize quality of life impact of MS.*

## Pharmacologic Treatment

▶ *Treatment of Acute Relapses with Corticosteroids*

**Pharmacology and Mechanism of Action** The mechanism of action of corticosteroids may involve:

- Prevention of inflammatory cytokine activation
- Inhibition of T- and B-cell activation
- Prevention of immune cells from entering the CNS[10]

Corticosteroids hasten functional recovery.[10] Equal efficacy of equivalent doses of IV and oral dosage forms has been shown with oral dosing avoiding discomfort, inconvenience, and expense of IV therapy.[10]

**Adverse Effects** The most common adverse effects are gastrointestinal upset, insomnia, and mood disturbance.[10]

**Dosing and Administration** Methylprednisolone is given 500 to 1000 mg/day IV as one dose or in divided doses. Oral prednisone 1250 mg/day or oral methylprednisolone 1000 to 1250 mg/day provides an equivalent dose. These regimens are given for 3 to 7 days.[10] Clinical improvement usually begins during treatment. Recovery is equivalent with or without a subsequent oral corticosteroid taper.[11]

▶ *Outcome Evaluation*

- Monitor for symptom improvement
- Educate regarding adverse effects

## Disease-Modifying Therapies

Agents indicated for MS are shown in Table 30–1. These immunomodulators reduce annualized relapse rates 30% to 70%.[12–25] No agents are approved for primary progressive MS; however, the available disease-modifying therapies may be effective in patients with progressive disease who have relapses.

### ▶ β-Interferons

**Pharmacology and Mechanism of Action** The following mechanisms of action are thought to be important:

- Decrease in T-cell activation, decreasing cytokine secretion
- Prevention of upregulation of adhesion molecules on activated T-cells, limiting T-cells access to the CNS
- Suppression of MMPs, maintaining the integrity of the blood–brain barrier
- Decrease in microglial proliferation, preserving myelin
- Promotion of formation of Th2 cells rather than Th1 cells, decreasing inflammation
- Increase in neural growth factor production, assisting in repair of the CNS[12,26]

**Efficacy in Patients with Relapsing Remitting MS** β-Interferons reduce relapses by about one-third versus placebo.[12] CIS treatment resulted in fewer patients developing clinically definite MS compared with placebo.[12]

**Efficacy in Patients with Secondary Progressive MS Who Experience Relapses** β-Interferons reduce the risk of relapses, but do not slow progression.[13] Treatment is most effective if clinical relapses or MRI inflammatory activity is present.[13]

**Adverse Effects** Adverse effects are common with β-interferons (**Tables 30–1 and 30–2**). Flu-like symptoms (fever, fatigue, muscle aches, malaise, and chills) begin a few hours postinjection and dissipate within 8 to 24 hours.[14] Injection site reactions range from redness to necrosis. There are preventive and treatment measures for these reactions (Table 30–3). Because of conflicting data, it is difficult to determine if β-interferons cause depression.[15]

**Tests for Responsiveness** Some patients do not respond to β-interferons; it may be possible to identify nonresponders by determining the type I interferon signature. Patients who have increased expression of the type I interferon gene (interferon[high]) have more proinflammatory effects. Interferon[high] patients are less likely to respond to β-interferons than interferon[low] patients.[26] Antibodies to β-interferons can reduce effect.[12] Neutralizing antibodies develop 6 to 18 months after initiation. Neutralizing antibodies can form against any β-interferon and are cross-reactive.[12] Neutralizing antibodies may disappear even during continued treatment. There are no standardized recommendations for neutralizing antibody testing.[12]

### ▶ Glatiramer Acetate

**Pharmacology and Mechanism of Action** Glatiramer acetate's mechanism of action is unknown; the following properties are observed:

- Binds to MHC class II, blocking the activation of T-cells
- Activates Th2 cells, preventing inflammation
- Activated Th2 cells secrete brain-derived neurotrophic factor, which may be neuroprotective[17]

**Efficacy** Glatiramer acetate reduces relapses by 28% compared with placebo, but does not prevent sustained progression of MS.[18] It is used in CIS to prevent conversion to clinically definite MS.[17]

**Adverse Effects** Patients report injection site reactions (see Table 30–2). Icing the injection site preinjection and postinjection and/or topical anesthetics improve these reactions. If a systemic reaction (flushing, chest tightness, palpitations, anxiety, and shortness of breath) occurs, it is usually within 30 minutes of the injection; recurrence is infrequent. Doses may be reduced by 75% for the week following the reaction, then increased by 25% per week to the full dose.[14]

### ▶ Issues with Self-Injected Disease-Modifying Therapies

**Adherence** KEY CONCEPT *Adherence to injectable medications is a significant problem*, with 22% to 59% discontinuation. Realistic therapy expectations, higher educational levels, and higher self-efficacy improve adherence; depression and cognitive problems lower adherence.[19]

**Patient Education** Refer to Table 30–4 for patient self-injection education.

### ▶ Teriflunomide

**Pharmacology and Mechanism of Action** Teriflunomide's mechanism of action may include:

- Cytostatic effect on rapidly dividing B- and T-cells by inhibiting dihydro-orotate dehydrogenase
- Inhibiting T-cell activation, entry to the CNS, and secretion of proinflammatory cytokines[20]

**Pharmacokinetics** Half-life of teriflunomide is 2 weeks; taking 3 months to achieve steady-state concentrations. Metabolized by the liver, it is contraindicated in hepatic failure. Teriflunomide inhibits CYP2C8 and induces CYP1A2 and CYP2C9. It undergoes significant enterohepatic circulation; its half-life is substantially reduced by cholestyramine.

**Efficacy** Teriflunomide reduces relapse rate and progression of disease for relapsing forms of MS.[20] It also prevents CIS from converting to clinically definite MS.[21]

**Adverse Effects** Teriflunomide is generally well tolerated. If patients develop liver injury, teriflunomide must be stopped and accelerated elimination undertaken. Patients should be screened for tuberculosis prior to initiating therapy.[20]

---

**Patient Encounter, Part 1**

A 23-year-old white woman visits the emergency department today with complaints of loss of visual acuity in her left eye with some eye pain that developed over several hours. She has never experienced symptoms like this previously. She has been generally healthy and is up to date on her vaccinations. She has moved to your area to attend university. Before that, she lived in Maine her entire life.

*What information is suggestive of multiple sclerosis (MS)?*

*What risk factors does she have for MS?*

*What additional information or testing would assist in making the diagnosis of MS?*

*What treatment could be provided to the patient for the current acute event?*

| Table 30–1 | | | | |
|---|---|---|---|---|
| **Comparison of Disease-Modifying Therapies** | | | | |
| **Drug** | **Dose** | **Route** | **Frequency** | **Selected Adverse Effects** |
| Dimethyl fumarate (Tecfidera) | 240 mg | By mouth | Twice daily | Flushing 30% <br> Gastrointestinal effects 25% <br> Leucopenia/lymphopenia 4%–10% |
| Fingolimod (Gilenya) | 0.5 mg | By mouth | Daily | Headache 25% <br> Increased aspartate aminotransferase/alanine aminotransferase 14% <br> Influenza viral infections 13% <br> Diarrhea 12% <br> Cough 10% <br> Bradycardia 4% <br> Lymphopenia 4% |

### Table 30–2

**Monitoring Disease-Modifying Therapies**

| Therapy | Tests | Frequency |
| --- | --- | --- |
| β-Interferons | CBC, bilirubin, electrolytes, AST, ALT, γ-glutamyl transferase, alkaline phosphatase | Baseline, 1, 3, and 6 months; then every 3 months |
| | Thyroid function tests | Baseline and every 6 months in patients with a history of thyroid dysfunction |
| | EDSS, MSFC, neurologic history and examination | Every 3 months during the first year of therapy; then every 6 months |
| Dimethyl fumarate | CBC | Baseline |
| | EDSS, MSFC, neurologic history and examination | Every 3 months during the first year of therapy; then every 6 months |
| Glatiramer acetate (Copaxone) | EDSS, MSFC, neurologic history and examination | Every 3 months during the first year of therapy; then every 6 months |
| Mitoxantrone (Novantrone) | CBC, bilirubin, AST, ALT, alkaline phosphatase, pregnancy test | Before each infusion |
| | Electrocardiogram | Baseline and prior to each infusion |
| | Echocardiogram or MUGA scan | Baseline; prior to each infusion, and yearly after stopping mitoxantrone |
| | EDSS, MSFC, neurologic history and examination | Every 3 months during the first year of therapy; then every 6 months |
| Natalizumab | EDSS, MSFC, neurologic history and examination | Baseline; every 3 months during the first year of therapy; then every 6 months |
| | HIV, CBC, AST, ALT, MRI | Baseline; repeat MRI at 6 months; then yearly |
| | MRI, CSF examination for JC virus | Periodically and at onset of new neurologic symptoms not suggestive of MS |
| | Preinfusion patient checklist | Prior to every infusion |
| | Status report and reauthorization questionnaire | Every 6 months |
| Fingolimod | Varicella zoster immunity evaluation and/or vaccination and FEV$_1$ (full pulmonary function testing if patient has history of asthma or COPD), pregnancy test | Baseline |
| | CBC, ALT, AST, bilirubin | Baseline and every 6 months |
| | Pulse and blood pressure | Baseline; observe in clinical area for 6 hours after initial dose with hourly monitoring |
| | Ophthalmology evaluation | Baseline; 3–4 months; then as needed |
| | Dermatologic evaluation | Baseline; then as needed |
| | Electrocardiogram | Baseline and 6 hours after initial dose |
| | EDSS, MSFC, neurologic history and examination | Every 3 months during the first year of therapy; then every 6 months |
| Teriflunomide | CBC, screen for tuberculosis, pregnancy testing | Baseline |
| | ALT, AST, bilirubin | Baseline and monthly for first 6 months |
| | Blood pressure | Baseline; then periodically |
| | EDSS, MSFC, neurologic history and examination | Every 3 months during the first year of therapy; then every 6 months |

| Table 30–3 | | |
|---|---|---|
| **Prevention or Treatment Strategies for β- Interferon Adverse Effects** | | |
| **Flu-Like Symptoms** | **Injection Site Reaction** | **Laboratory Abnormalities[a]** |
| Inject dose in the evening | Bring medication to room temperature | Hemoglobin < 9.4 g/dL (94 g/L or 5.8 mmol/L) |
| Begin at ¼–½ dose for 2 weeks of treatment; then increase to a full dose | Ice injection site before and after injection Rotate injection sites | White blood cells < $3 \times 10^3$/mm³ ($3 \times 10^9$/L) Absolute neutrophil count < $1.5 \times 10^3$/mm³ ($1.5 \times 10^9$/L) |
| Use ibuprofen 200 mg before and 6 and 12 hours after injection | Inject in areas with more subcutaneous fat (buttocks or abdomen) | Platelets < $75 \times 10^3$/mm³ ($75 \times 10^9$/L) |
| Alternatives to ibuprofen include acetaminophen, prednisone taper, and pentoxifylline | Use an autoinjection device If severe, use hydrocortisone 1% cream on the site If necrotic: temporarily discontinue; consult dermatologist; do not use topical corticosteroids | Bilirubin > 2.5 × baseline AST/ALT > 5 × baseline Alkaline phosphatase > 5 × baseline |

ALT, alanine aminotransferase; AST, aspartate aminotransferase.

[a]At these threshold values, β-interferon should be temporarily discontinued and laboratory values monitored.

## ▶ Dimethyl Fumarate

**Pharmacology and Mechanism of Action**  Dimethyl fumarate is thought to treat MS in the following ways:

- Shift cytokine production from a proinflammatory state to an anti-inflammatory state
- Prevent macrophage entry into the CNS by an unknown mechanism
- Stabilization of transcription factor nuclear (erythroid-derived 2) related factor which may reduce oxidative stress[22]

**Efficacy**  Dimethyl fumarate reduced relapses approximately 50%. It slowed MS progression in some studies.[22]

**Adverse Effects**  Dimethyl fumarate causes a transient, dose-dependent flushing sometimes with itching. Likely due to histamine release, incidence decreases after the first month and may be improved by slower dose titration, administration with food, and/or H2-blocking antihistamines.[22] Gastrointestinal adverse effects may be lessened with a slow dose increase and administration with food.[22]

## ▶ Fingolimod

**Pharmacology and Mechanism of Action**  Fingolimod is a sphingosine 1-phosphate receptor modulator. It retains T-cells in

| Table 30–4 | 
|---|
| **Patient Education for Self-Injection** |
| Keep all nonrefrigerated supplies together and out of the reach of children and pets If refrigerated, allow medication to warm to room temperature Wash hands thoroughly Choose injection site, rotating among sites Ice area to be injected for no more than 15 minutes, if desired Clean injection site thoroughly with alcohol or soap and water Administer injection Ice injection site for no more than 15 minutes after injection, if desired |

lymphoid tissues, depleting peripheral blood and CNS lymphocytes. Fingolimod also binds to sphingosine 1-phospate receptors in the brain where may reduce inflammatory cytokines.[23]

**Pharmacokinetics**  Fingolimod is highly protein bound with a long half-life of 8 to 9 days (steady-state concentrations achieved in 1-2 months).[23]

**Efficacy**  Treatment reduced the annualized relapse rate to 0.18 compared with 0.40 for placebo. It also slowed MS progression.[23]

**Adverse Effects**  Fingolimod reduces circulating lymphocytes by about 75%; infections and malignancies are concerns.[23] Sphingosine 1-phosphate receptors elsewhere in the body are associated with first-dose bradycardia, macular edema, and reduced forced vital capacity.[23] Fingolimod is contraindicated in patients with myocardial infarctions, unstable angina, stroke, transient ischemic attacks, or some types of congestive heart failure within the past 6 months or in patients with many types of atrioventricular block, prolonged QT interval, or who are taking class Ia or III antiarrhythmic medicines.[23] Extensive monitoring is required at baseline and for the first dose; monitoring must be repeated if therapy is interrupted.[23]

## ▶ Natalizumab

**Pharmacology and Mechanism of Action**  Natalizumab is a $\alpha_4$-integrin antagonist; its postulated mechanism of action follows:

- Binds to $\alpha_4\beta_1$ and $\alpha_4\beta_7$ integrins, preventing lymphocyte migration into the CNS and inflammation
- Inhibits binding of $\alpha_4$-positive leukocytes to fibronectin and osteopontin, decreasing the activation of leukocytes already within the CNS[24]

**Efficacy**  Treatment with natalizumab reduced relapses by 68% at 1 year and disability by 42% at 2 years versus placebo.[24]

**Adverse Effects**  Hypersensitivity reactions (itching, dizziness, fever, rash, hypotension, dyspnea, chest pain, and anaphylaxis) have been observed, usually within 2 hours of administration. If hypersensitivity occurs, natalizumab is discontinued. A separate infusion reaction (headache, dizziness, fatigue, nausea, sweats, and rigors) may occur within 2 hours of dosing.[14] Histamine

1 and 2 receptor blockers can be used to prevent these symptoms, and discontinuation is not required. A serious, but rare, adverse effect is progressive multifocal leukoencephalopathy (PML). PML, caused by the JC polyomavirus virus, is rapidly progressive and often results in death or permanent disability. Though most associated with natalizumab, it has been reported in two patients treated with dimethyl fumarate.[14] Specific recommendations are to test for JC virus, avoid natalizumab in immunocompromised patients; carefully assess for immune compromise in patients previously treated with immunosuppression, radiation therapy, or chemotherapy; use only as monotherapy, and carefully monitor patients.[14] Risk of PML increases with increased infusions.[14] Vigilance is paramount because PML can mimic symptoms associated with MS.[24]

Due to this risk, natalizumab is distributed through a restricted program. KEY CONCEPT These concerns lead to the recommendation that *natalizumab be reserved for patients with rapidly advancing disease who have failed other therapies.*

Antinatalizumab antibodies develop in 9% to 12% of patients. If patients have antibodies 6 months after start of therapy, relapse rates and disability increase; antibody development is also associated with hypersensitivity reactions.[24]

### ▶ Mitoxantrone

**Pharmacology and Mechanism of Action** Mitoxantrone is an anthracenedione antineoplastic; the mechanisms of action important for MS include:

- Causes apoptosis in T-cells and APCs, preventing initial T-cell activation
- Inhibits DNA and RNA synthesis, decreasing proliferation of T cells, B cells, and macrophages
- Decreases cytokine release, preventing inflammation
- Inhibits macrophages, preventing myelin degradation[25]

**Efficacy** Mitoxantrone is indicated for secondary-progressive MS, progressive-relapsing MS, and for patients with worsening relapsing-remitting MS. It reduces the relapse rate and attack-related MRI outcome measures and MS progression.[25] KEY CONCEPT *Because of its potential for significant toxicities, mitoxantrone is reserved for patients with rapidly advancing disease who have failed other therapies.*

**Adverse Effects** Bluish discoloration of the sclera and urine lasts 24 hours or more postinfusion.[14] Transient leukopenia and neutropenia are common. Amenorrhea may be permanent.[25]

Cardiotoxicity is a serious adverse effect. Mitoxantrone should not be used in patients with baseline cardiomyopathy, even if asymptomatic. Cyclooxygenase-2 inhibitors potentially worsen cardiac toxicity and should be avoided.[25] Maximum lifetime dose of mitoxantrone is 140 mg/m$^2$.

Acute myelogenous leukemia occurred in 0.07% of mitoxantrone-treated patients, appearing within 2 to 4 years of initiating mitoxantrone and responsive to standard therapy.[25]

**Dosing and Administration** Mitoxantrone is infused intravenously over 30 minutes to reduce cardiotoxicity.[25] In standard dosing regimens, mitoxantrone is administered every 3 months. Some centers have used mitoxantrone as induction therapy in patients with very active MS. With this strategy, mitoxantrone either at usual or slightly higher dose is given for a short period of time. This treatment may be followed by β-interferon or glatiramer acetate. These regimens have been effective at reducing relapses and progression in small numbers of patients.[27]

### ▶ Other Therapy Considerations

**Pregnancy** Because MS affects many women of childbearing age, the teratogenic effects of medications is concerning. Women generally experience a decrease in relapses during the second and third trimesters of pregnancy with an increase in the first 3 months postpartum.[28] Although none of the disease modifying therapies is recommended for use during pregnancy, data from pregnancy registries demonstrate no adverse outcomes with interferon β, glatiramer acetate, and natalizumab.[28] Fetal risk is unknown for dimethyl fumarate. Sphingosine 1-phosphate receptors are important in fetal formation, thus fingolimod should be discontinued for at least 2 months before conception to allow for its elimination. Mitoxantrone and teriflunomide are contraindicated during pregnancy and teriflunomide is contraindicated for men who have sexual intercourse with women who may become pregnant.[28] Because of the long half-life of teriflunomide, accelerated elimination is recommended for women who wish to become pregnant.[28]

**Vaccinations** Patients taking teriflunomide, mitoxantrone, or fingolimod should not receive attenuated live virus vaccines.[20,24,29] Vaccines may be less effective while on fingolimod, and vaccines should be held for 4 to 6 weeks after a mitoxantrone dose.[20,24]

**Choosing Therapy** KEY CONCEPT *There is no consensus on the best medication for initial therapy.* Figure 30–4 suggests a treatment approach.

### ▶ Outcome Evaluation

- Assess symptom changes periodically.
- In β-interferon-treated patients with frequent relapses, test for neutralizing antibodies.
- Monitor medication-specific adverse effects (see Tables 30–1 and 30–3).
- Assess adherence.

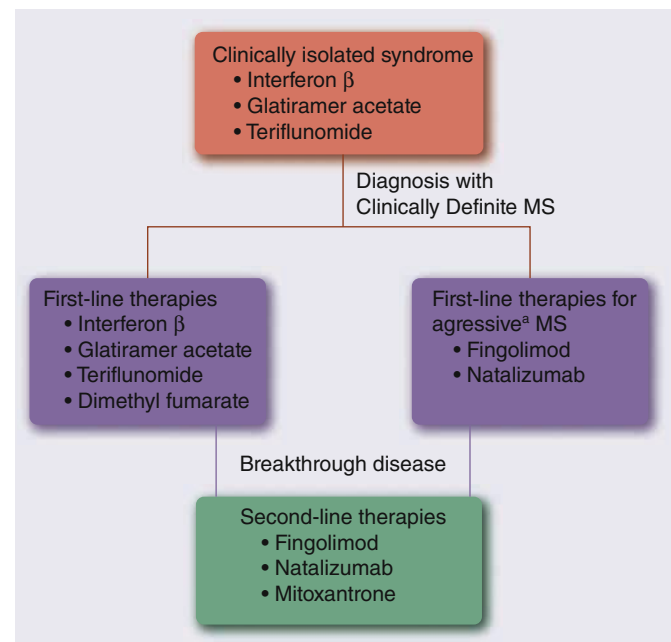

**FIGURE 30–4.** Treatment algorithm for CIS and relapsing-remitting MS.[30] [a]A definition of aggressive multiple sclerosis has been proposed as follows: two or more relapses in the preceding year and two or more gadolinium-enhancing lesions on brain MRI scans or a significant T2 lesion burden.[31]

## Patient Encounter, Part 2

**PMH:** None

**FH:** No family history of MS. Both parents alive and well. No siblings

**SH:** Graduate student in economics. Single. She does not smoke, drink alcohol, or use illicit drugs

**Allergies:** NKDA

**Meds:** None

**ROS:** (–) N/V/D, HA, SOB, chest pain, cough

**PE:**

**VS:** 126/74, P 70, RR 18, T 38°C (100.4°F)

**Skin:** Warm, dry

**HEENT:** Left pupillary response to light is sluggish, decreased visual acuity left eye

**CV:** RRR, normal S1 and S2, no m/r/g

**Chest:** CTA

**Abd:** Soft, NT/ND

**Neuro:** A & O × 3; CN II-XII intact, end point nystagmus on lateral gaze bilaterally

**Motor:** mild weakness in right arm, poor finger-to-nose left upper extremity

**Labs:** WNL

**Imaging: T2-weighted MRI** shows a gadolinium-enhancing T2-weighted lesion on the left optic nerve and two nonenhancing T2-weighted white matter lesions near the cortex (juxtacortical region)

*Given this additional information, what is your assessment of the patient's condition?*

*Identify your treatment goals for this patient.*

*What pharmacologic alternatives are available for her?*

*What counseling points will you give the patient for administration of the chosen therapy?*

▶ *Symptomatic Therapies*

Symptoms most unique to MS are fatigue, spasticity, impaired ambulation, and pseudobulbar affect. Treatment of other important symptoms such as urinary incontinence, pain, depression, cognitive impairment, and sexual dysfunction is addressed elsewhere in this text.

**Fatigue**    There are nonpharmacologic and pharmacologic strategies for coping with fatigue (Table 30–5). Medicines should be reviewed to identify possible contributors to fatigue. Pharmacologic management of fatigue includes amantadine or stimulants; however, efficacy evidence is limited.[32]

**Spasticity**    Spasticity treatment goals are patient specific. For ambulatory patients, reducing spasticity may improve mobility.

For bed-bound patients, treating spasticity may relieve pain and facilitate care. Physical therapy is a nonpharmacologic treatment for spasticity.[33]

**KEY CONCEPT** *MS patients must be treated with agents specific for upper motor neuron spasticity (Table 30–6).*[33] MS spasticity is classified as focal or generalized. If the spasticity involves only one muscle group, it is focal and may benefit from botulinum toxin administration.[33] Systemic medications are used for generalized spasticity. No conclusion can be reached regarding efficacy superiority of one agent.[33]

**Impaired Ambulation**    Nonpharmacological treatment includes assistive devices, physical therapy, and/or exercise. Extended-release dalfampridine is indicated for improvement in walking speed.

---

### Table 30–5

**Pharmacologic and Nonpharmacologic Treatments for Fatigue**

| Nonpharmacologic | Pharmacologic | Renal Dosing |
|---|---|---|
| Appropriate rest-to-activity ratio<br>Use of assistive devices to conserve energy<br><br>Environmental modifications to make activities more energy efficient | *First-line therapy:*<br>Amantadine 100 mg orally every morning and early afternoon | CrCl 30–50 mL/min (0.50–0.84 mL/s): 100 mg/day<br>CrCl 15–29 mL/min (0.25–0.49 mL/s): 100 mg every other day<br>CrCl < 15 mL/min (0.25 mL/s): 200 mg every 7 days |
| Cooling strategies to avoid fatigue caused by elevations in core body temperature due to heat, exercise-related exertion, and fever | *Second-line therapy:*<br>Methylphenidate 10–20 mg every morning and noon | |
| Regular aerobic exercise, geared to the person's ability, to promote cardiovascular health, strength, improved mood, and reduce fatigue<br>Progressive resistance training of lower limb muscles | | |
| Stress management techniques | | |

CrCl, creatinine clearance.

From Asano M, Finlayson ML. Meta-analysis of three different types of fatigue management interventions for people with multiple sclerosis: exercise, education, and medication. Mult Scler Int. 2014;2014:798285.

### Table 30–6

**Comparison of Antispasticity Agents**

| Place in Therapy | Medication | Mechanism of Action | Dose |
|---|---|---|---|
| First line | Baclofen | Presynaptic and postsynaptic γ-aminobutyric acid type B receptor agonist | 5 mg orally three times daily; increase by 5 mg/dose every 3 days to a maximum of 80 mg/day<br>*Renal dysfunction:* Dose reduction may be necessary |
| | Tizanidine | Centrally acting $α_2$-receptor agonist | 2 mg orally three times daily; increase gradually by 2 mg at each dose with 1–4 days between dose increases to a maximum of 36 mg/day<br>*Hepatic and renal dysfunction:* Dose reduction may be necessary |
| Second line | Dantrolene | Direct inhibitor of muscle contraction by decreasing the release of calcium from skeletal muscle sarcoplasmic reticulum | 25 mg orally daily; increase to 25 mg three to four times daily; then increase by 25 mg every 4–7 days to a maximum of 400 mg/day |
| | Diazepam | γ-aminobutyric acid agonist | 2–10 mg orally three to four times daily<br>*Cirrhosis:* Reduce dose by 50% |
| Third-line | Intrathecal baclofen | Presynaptic and postsynaptic γ-aminobutyric acid type B receptor agonist | Titrated individually; usual range: 62–749 mcg/day |
| Focal spasticity | Botulinum toxin | Prevents release of acetylcholine in the neuromuscular junction | Individualized |

Data from Gold R, Oreja-Guevera C. Advances in the management of multiple sclerosis spasticity: multiple sclerosis spasticity guidelines. Expert Rev Neurother. 2013;13(Suppl 12):55–59.

## Patient Encounter, Part 3

The patient begins therapy with teriflunomide 14 mg orally daily. She does very well with no relapses and minimal adverse effects for 2 years during which time she marries. At her next neurology appointment, she states that she would like to begin a family in the next 6 months. She also reports that she is having episodes of unexpected crying, but she does not endorse symptoms of depression. She is diagnosed with pseudobulbar affect.

*How will you respond to her interest in becoming pregnant?*

*What treatment will you recommend for her MS?*

*What treatment should you consider for pseudobulbar affect?*

## The Patient Care Process

**Patient Assessment:**

- Based on physical exam and review of systems, determine whether patient is experiencing a MS exacerbation currently. Determine presence of any symptoms such as urinary incontinence.
- Review the medical history and MRI findings. Does the patient have CIS? Does patient have aggressive MS (see Figure 30–4)? Is patient pregnant? Does patient want to become pregnant?
- Conduct a medication history (including prescription and nonprescription medications). Has patient been treated with any MS medications or immunosuppressants previously? Is patient experiencing adverse effects?
- Review available laboratory tests, especially leucocytes and liver function tests.

**Therapy Evaluation:**

- If patient is already receiving disease-modifying or symptomatic pharmacotherapy, assess efficacy, safety, and patient adherence. Are there any significant drug interactions?

- Determine if patient has prescription coverage or if recommended agents are included on patient's insurance formulary. If necessary, obtain prior authorizations.

**Care Plan Development:**

- Treat any relapses with IV or oral corticosteroids.
- Work with patient to select therapy, considering:
  - Route of administration
  - Frequency of administration
  - Adverse-effect profile and other concerns (eg, neutralizing antibodies)
  - Cost, including preauthorization needs for patient's insurance.
- Obtain required baseline laboratory studies (see Table 30–5).
- Educate patient regarding self-injection, if necessary (see Table 30–4), and adherence.
- Initiate needed symptomatic treatments.
- Address any concerns about MS and its management.

*(Continued)*

---

**The Patient Care Process (*Continued*)**

- Refer patient to the National MS Society for information, newsletters, and local support groups (www.nationalmssociety.org).
- Instruct patient to contact clinician for any sudden symptom changes suggestive of relapse.

**Follow-Up Evaluation:**

- Monitor patient for efficacy and adverse effects of disease-modifying and symptomatic therapies every 3 months for the first year and every 6 months thereafter and as required for therapy (see Tables 30–2 and 30–5).
- Obtain MRI annually or more frequently as dictated by symptoms and selected therapy.
- Assess adherence with medications at each visit.

---

This potassium channel blocker prolongs action potentials, improving conduction in demyelinated neurons.[34] Not all patients respond; response can be assessed at 2 months.[34] Urinary tract infections, insomnia, dizziness, headache, nausea, asthenia, back pain, and balance disorder all occur frequently with dalfampridine.[34] Seizures are an uncommon adverse effect; patients with seizure disorders should not receive dalfampridine.[34]

**Pseudobulbar Affect**  Ten percent of patients with MS develop pseudobulbar affect, characterized by inappropriate laughing or crying and causing social isolation.[35] Dextromethorphan prevents the release of excitatory neurotransmitters. Low-dose quinidine blocks first-pass metabolism of dextromethorphan and increases serum concentrations. A 49% decrease in episodes was seen with treatment.[35]

▶  *Outcome Evaluation*

- Assess improvement/recurrence of symptoms.
- Monitor adverse effects of medications.
- Monitor adherence.

## Abbreviations Introduced in This Chapter

| | |
|---|---|
| ALT | Alanine aminotransferase |
| APC | Antigen-presenting cell |
| AST | Aspartate aminotransferase |
| CBC | Complete blood count |
| CIS | Clinically isolated syndrome |
| CNS | Central nervous system |
| COPD | Chronic obstructive pulmonary disease |
| CrCl | Creatinine clearance |
| CSF | Cerebrospinal fluid |
| DC | Dendrite cell |
| ECG | Electrocardiogram |
| EDSS | Expanded Disability Status Scale |
| FEV$_1$ | Forced expiratory volume in 1 second |
| HIV | Human immunodeficiency virus |
| IgG | Immunoglobulin G |
| IL | Interleukin |
| INF | Interferon |
| MHC | Major histocompatibility complex |
| MMP | Matrix metalloproteinase |
| Mφ | Macrophage |
| MRI | Magnetic resonance imaging |

| | |
|---|---|
| MS | Multiple sclerosis |
| MSFC | Multiple Sclerosis Functional Composite |
| MUGA | Multiple-gated acquisition |
| OPC | Oligodendrocyte precursor cell |
| PML | Progressive multifocal leukoencephalopathy |
| TGF | Transforming growth factor |
| Th1 | T-helper-1 cells |
| Th2 | T-helper-2 cells |
| TNF | Tumor necrosis factor |
| VCAM | Vascular cell adhesion molecule |
| VLA | Very late antigen |

# 31 Epilepsy

Timothy E. Welty and Edward Faught

## LEARNING OBJECTIVES

● **Upon completion of the chapter, the reader will be able to:**

1. Describe the epidemiology and social impact of epilepsy.
2. Define terminology related to epilepsy, including seizure, convulsion, and epilepsy.
3. Describe the basic pathophysiology of seizures and epilepsy.
4. Differentiate and classify seizure types given a description of the clinical presentation of the seizure and electroencephalogram.
5. Identify key therapeutic decision points and therapeutic goals in the treatment of epilepsy.
6. Discuss nonpharmacologic treatments for epilepsy.
7. Recommend an appropriate pharmacotherapeutic regimen with monitoring parameters for the treatment of epilepsy.
8. Devise a plan for switching a patient from one antiepileptic regimen to a different regimen.
9. Manage potential drug interactions with antiepileptic drugs.
10. Determine when and how to discontinue antiepileptic drug therapy.
11. Educate a patient or caregiver on epilepsy and pharmacotherapy for this disorder.

## EPIDEMIOLOGY, SOCIAL IMPACT, AND ETIOLOGY

### Epidemiology

● Epilepsy is a disorder that afflicts approximately 2 million individuals in the United States, with an age-adjusted prevalence of approximately 4 to 7 cases per 1000 persons.[1] The incidence of epilepsy in the United States is estimated at 35 to 75 cases per 100,000 persons per year.[2,3] In developing countries, the incidence is higher at 100 to 190 cases per 100,000 persons per year. About 8% of the US population will experience a seizure during their lifetime. New-onset seizures occur most frequently in infants younger than 1 year of age and in adults after age 55.[4]

### Social Impact

● Epilepsy has a profound impact on a patient's life. Due to restrictions on driving in all states, individuals who have recently had a seizure face major impediments to engaging in simple activities[5] Fifty percent of patients with epilepsy report cognitive and learning difficulties.[6,7] Transportation and educational difficulties combine with persistent seizures to cause unemployment or underemployment, and as a result, problems with paying for health care. Additionally, the social stigma of embarrassment or injury due to seizures in public results in isolation of the patient.

Patients with epilepsy often depend on caregivers to assist with medications, transportation, and ensuring the patient's safety, so they should be informed about treatments and managing seizures.

### Etiology

In approximately 80% of patients with epilepsy, the underlying etiology is unknown.[8] The most common causes of epilepsy are head trauma and stroke. Developmental and identifiable genetic defects cause about 5% of cases. Genetic causes are presumed in up to 25% of patients, but are often unproven. Brain tumors, central nervous system (CNS) infections, and neurodegenerative diseases are other common causes. Human immunodeficiency virus infection and neurocysticercosis infection are also important causes.

Isolated seizures can be caused by stroke, CNS trauma, CNS infections, metabolic disturbances (eg, hyponatremia, hypoglycemia), and hypoxia. If these causes of seizures are not corrected, they may lead to the development of epilepsy. Drugs commonly associated with causing seizures are tramadol, bupropion, theophylline, some antidepressants, some antipsychotics, amphetamines, cocaine, imipenem, lithium, excessive doses of penicillins or cephalosporins, and sympathomimetics or stimulants.

## PATHOPHYSIOLOGY

### Seizures

● Regardless of the underlying etiology, all seizures involve a sudden electrical disturbance of the cerebral cortex. A population of neurons fires rapidly and repetitively for seconds to minutes. Cortical electrical discharges become excessively rapid, rhythmic, and synchronous. This phenomenon is presumably related

to an excess of excitatory neurotransmitter action, a failure of inhibitory neurotransmitter action, or a combination of the two. In individual patients, it is usually impossible to identify which neurochemical factors are responsible.

## Neurotransmitters

The major excitatory neurotransmitter is glutamate.[9] When glutamate is released from a presynaptic neuron, it attaches to receptors on the postsynaptic neuron. The result is opening of membrane channels to allow sodium or calcium to flow into the postsynaptic neuron, depolarizing it and transmitting the excitatory signal.[10] Many antiepileptic drugs (AED) (eg, phenytoin, carbamazepine, lamotrigine) work by interfering with this mechanism, blocking the release of glutamate or by blocking sodium or calcium channels.[11] At usual doses, these drugs typically do not block normal neuronal signaling, only the excessively rapid firing characteristic of seizures, usually not affecting normal brain function.

The major inhibitory neurotransmitter is *γ-aminobutyric acid (GABA)*. It attaches to neuronal membranes and opens chloride channels. When chloride flows into the neuron, it becomes hyperpolarized and less excitable. This mechanism is probably critical for suppressing seizure activity. Barbiturates and benzodiazepines primarily act to enhance the action of GABA.

Cortical function is modulated by many other neurotransmitters, but their role in the action of AEDs is poorly understood.

## Neuronal Mechanisms

Seizures originate in a group of neurons with abnormal electrical behavior, presumably due to an imbalance of neurotransmitter function.[12] In individual neurons, firing is excessively prolonged and repetitive. Instead of firing a single action potential, these neurons stay depolarized too long, firing many action potentials. This long, abnormal depolarization is called a *paroxysmal depolarizing shift (PDS)*.

Excessive electrical discharges can spread to adjacent neurons or distant ones connected by fiber tracts. The seizure spreads to other areas of the brain, by recruiting neurons into uncontrolled firing patterns. Recruited neurons may not be abnormal, but are diverted from their normal functioning to participate in the excessive discharges. The area of spread determines the clinical manifestations of the seizure.

Nearly all seizures stop spontaneously, because brain inhibitory mechanisms overcome the abnormal excitation.

## Epilepsy

Epilepsy is the tendency to have recurrent, unprovoked seizures. A recent statement by the International League Against Epilepsy (ILAE) recommends that this definition include persons with a single seizure, if they have at least a 70% chance of having another seizure. Practically, this defines two populations of patients who should be treated, and implies a permanent change in cortical function, rendering neurons more likely to participate in a seizure discharge. This process is called epileptogenesis, and the exact way in which it occurs is unknown. A process called kindling is considered similar to epileptogenesis in humans, and occurs in animals after prolonged, intermittent electrical brain stimulation.

Epilepsy may develop days, months, or years after a brain insult. It may be that a small group of abnormal neurons causes adjacent or connected normal neurons to gradually become abnormal. When a network of abnormal neurons becomes sufficiently large, it is capable of sustaining an excessive firing pattern for at least several seconds: a seizure. This hyperexcitable network of neurons is the seizure focus.

If the change in cortical electrical characteristics is permanent, why do seizures not occur all the time? This is probably because the occurrence of an individual seizure depends on an interplay of environmental and internal brain factors that intermittently result in loss of the normal mechanisms that control abnormal neuronal firing. Some causes of seizures are sleep loss and fatigue, but it is impossible to determine what triggers a specific seizure.

Epilepsy may remain stable, decrease in severity, or worsen over time. Repeated seizures may cause further damage to the cortex and loss of neurons, especially inhibitory neurons. Reorganization of connections between groups of neurons may strengthen excitatory connections and weaken inhibitory connections.

There are many reasons for controlling seizures completely. Epilepsy is associated with an increased mortality rate, from injuries with seizures or sudden death.[13] Early control of epileptic seizures may reduce the possibility of permanent changes in brain function, although this hypothesis is unproven.

## Genetic Factors

Patients with seizures may be concerned that their children or other family members will inherit epilepsy. Patients with acquired causes of seizures, such as head trauma or stroke, will not transmit epilepsy. Some patients may have inherited epilepsy. Most of these individuals have primary generalized epilepsy, and develop seizures during childhood.[14,15] However, the hereditary tendency is weak. Complex inheritance patterns are usually seen, indicating the likely involvement of several abnormal genes or other factors for seizures to occur in offspring. Most patients can be reassured that their children and siblings are unlikely to develop epilepsy.

## SEIZURE CLASSIFICATION AND PRESENTATION
### General Principles

Careful diagnosis and identification of seizure types is essential to proper treatment of epilepsy. Numerous schemes and descriptions of seizures exist, but the ILAE has established the currently accepted standard for classifying epileptic seizures (**Figure 31–1**) and epilepsies or epilepsy syndromes (**Table 31–1**).[16,17] Classification of epileptic seizures is based on **electroencephalographic** (EEG) findings combined with the clinical symptoms or semiology of the seizure events. Clinical presentation of seizures varies widely depending on the region and amount of brain involved in the seizure.

### Primary Generalized Seizures

If the entire cerebral cortex is involved in the seizure from the onset, the seizure is classified as primary generalized. This category is now referred to as "genetic generalized seizures," the apparent cause of most of these syndromes. Types of **primary generalized seizures** are: **Tonic-clonic, Absence, Myoclonic,** and **Atonic**.

### Partial Seizures

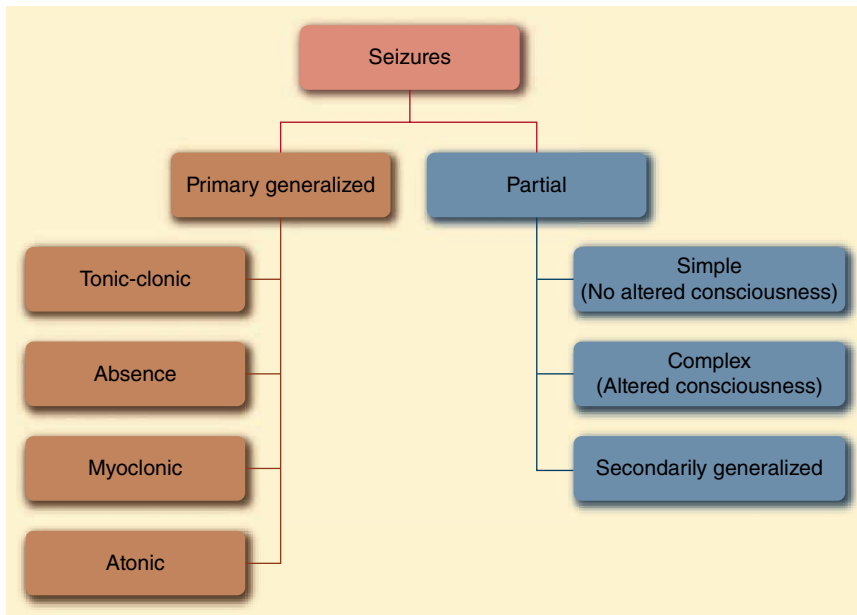
When the seizure begins in a localized area of the brain, it is defined as partial. There are three types of **partial seizures** in the current classification system (see Figure 31–1): **Simple, Complex,** and **Secondarily generalized**.


**FIGURE 31–1.** International League Against Epilepsy seizure classification.

## Epilepsy Syndromes

Classification of epilepsies and epilepsy syndromes is helpful in determining appropriate pharmacotherapy. This classification scheme is based on the type of seizures and the presumed cause: **Idiopathic (Genetic) epilepsies, Symptomatic epilepsies,** and **Cryptogenic (Cause Unknown) epilepsies**.

A complete description of a patient's epilepsy should include the seizure type with the epilepsy or syndrome type (eg, idiopathic, symptomatic, cryptogenic).

---

**Table 31–1**

**ILAE Classification Scheme for Epilepsies and Epilepsy Syndromes**

I. Localization-related (focal, local, partial) epilepsies and epileptic syndromes
  A. Idiopathic with age-related onset
    1. Benign childhood epilepsy with centrotemporal spikes
    2. Childhood epilepsy with occipital paroxysms
  B. Symptomatic

II. Generalized epilepsies and epileptic syndromes
  A. Idiopathic and age-related onset
    1. Benign neonatal epilepsy
    2. Childhood absence epilepsy (pyknolepsy)
    3. Juvenile myoclonic epilepsy (impulsive petit mal)
    4. Juvenile absence epilepsy with generalized tonic-clonic seizure on awakening
  B. Secondary (idiopathic or symptomatic)
    1. West syndrome (infantile spasms)
    2. Lennox-Gastaut syndrome
  C. Symptomatic
    1. Nonspecific etiology (early myoclonic encephalopathy)
    2. Specific syndromes (epileptic seizures that may complicate many diseases, eg, Ramsay-Hunt syndrome, Unverricht disease)

---

Data from Commission on Classification and Terminology of the International League Against Epilepsy. Proposal for revised classification of epilepsies and epileptic syndromes. Epilepsia. 1989;30:389–399.

Commonly encountered epilepsy syndromes are: **Juvenile myoclonic epilepsy (JME), Lennox-Gastaut syndrome (LGS), Mesial temporal lobe epilepsy (MTLE), and Infantile spasms (West's Syndrome)**.

## Other Classifications

A new ILAE classification system improves the description of the seizure type and epilepsy, and will be finalized soon.[18,19] The scheme involves five axes:

Axis 1: Description of the seizure event
Axis 2: Epileptic seizure type or types
Axis 3: Any syndrome type
Axis 4: Etiology when known
Axis 5: Degree of impairment by the epilepsy

The new system replaces "partial seizures" with "focal seizures", "idiopathic epilepsies" with "genetic epilepsies", and "cryptogenic epilepsies" with "epilepsies of unknown cause."

## DIAGNOSIS

A correct and accurate diagnosis is essential prior to starting pharmacotherapy. `KEY CONCEPT` *A distinction between a single seizure and epilepsy should be made, and other seizure-like disorders (eg, syncope, psychogenic, nonepileptic events, anxiety attacks, cardiac arrhythmias, hypoglycemia, transient ischemic attacks, tics, and complicated migraine headaches) should be ruled out.* Seizures are typically brief spells, lasting less than 5 minutes. However, prolonged seizures lasting greater than or equal to 5 minutes or occurring one after another without recovery in between are status epilepticus, which requires immediate medical attention (Chapter 32).

A proper diagnostic workup of a patient presenting with seizures includes the following elements:

- Complete neurologic examination
- EEG
- Laboratory tests (complete blood count [CBC], liver function tests [LFTs], serum chemistry)
- Neuroimaging (preferably **magnetic resonance imaging [MRI]**)

**Presentation**

- Episodes of sudden and brief loss of consciousness
- Episodes of uncontrolled jerking of groups of muscles
- Sudden unexplained falls
- Sudden and brief episodes of confusion

**Diagnosis**

- Thorough clinical history, including a complete description of the episodes
- Complete neurological physical examination
- Imaging of the brain: preferably a MRI, but a computerized tomogram (CT) of the brain may be used in absence of a MRI
- Laboratory tests: serum electrolytes, complete blood count, renal function, and liver function
- Electroencephalogram (EEG) recording: may be done with special techniques, including hyperventilation and photostimulation. Sleep deprivation may also be used
- Video-electroencephalogram (VEEG)

Many of the tests are done to rule out other causes of seizures (eg, infection, electrolyte imbalance), and in most patients will be normal. Often the EEG appears normal between seizures.[20] Sleep deprivation, photic stimulation, prolonged (greater than 20 minutes) EEG recording, and 24-hour EEG monitoring with video correlation can be done to capture seizure or seizure-like activity on the EEG.

## TREATMENT
### Desired Outcomes

The ultimate outcome goal for any patient with epilepsy is elimination of all seizures without adverse effects of the treatment. An effective treatment plan allows the patient to pursue a normal lifestyle with complete control of seizures. The treatment should enable the patient to drive, perform well in school, hold a reasonable job, and function effectively in the family and community. However, 30% to 50% of patients are not able to fully achieve these outcomes. In these cases, the goal of therapy is to provide a tolerable balance between reduced seizure severity and/or frequency and medication adverse effects, enabling the individual to have a lifestyle as nearly normal as possible.

### General Approach to Treatment

Once it is concluded that the patient has seizures, the type of seizure and epilepsy syndrome, if any, must be determined. **KEY CONCEPT** *Selection of appropriate pharmacotherapy depends on distinguishing, identifying, and understanding different seizure types.* Without an accurate classification of the seizure type, it is possible to select a medication that is ineffective or even harmful to the patient.

**KEY CONCEPT** *Prior to starting pharmacologic therapy, it is essential to determine the risk of having a subsequent seizure.* If there is an underlying treatable cause, such as hyponatremia or a CNS infection, the risks of another seizure and the development of

epilepsy are very small. In these cases, the only necessary pharmacotherapy is to correct the underlying problem and possibly use an AED short-term. Risk factors for repeated seizures in patients without an underlying disorder include:[21]

- Structural CNS lesion
- Abnormal EEG
- Partial seizure type
- Positive family history
- Postictal motor paralysis

If no risk factors are present, the risk of another seizure is 10% to 15%. However, if two or more risk factors are present, the risk of another seizure is 100%. If the estimated risk is over 70%, an epilepsy diagnosis is plausible. When sufficient evidence is available to determine the patient has seizures and is at risk for another seizure, pharmacotherapy is usually started (**Figure 31–2**). The patient should be in agreement with the plan, be willing to take the medication, and be able to monitor seizure frequency and adverse drug effects. **KEY CONCEPT** *Mechanisms of action, effectiveness for specific seizure types, common adverse effects, and potential drug interactions are key elements in selecting a medication.* Other patient factors such as gender, concomitant drugs, age, economic factors, and lifestyle also need to be considered.

### Nonpharmacologic Therapy

Nonpharmacologic treatments for epilepsy are available. For some patients, surgery is the treatment approach with the greatest probability of eliminating seizures.[22] The most common surgical approach for epilepsy is temporal lobectomy. When the seizure focus can be localized and it is in a region of the brain that is not too close to critical areas, such as those responsible for speech or muscle control, surgical removal of the focus can result in 80% to 90% of patients becoming seizure free. According to a National Institutes of Health Consensus Conference, three criteria should be met for patients to be candidates for surgery.[23] Other surgical procedures that are less likely to make a patient seizure free include corpus callosotomy and extratemporal lesion removal.

Vagal nerve stimulation is another nonpharmacologic approach to treating all types of seizures.[24] An unit that generates an intermittent electrical current is placed under the skin in the chest. A wire is tunneled under the skin to the left vagus nerve in the neck and delivers a small electrical stimulus to the vagus nerve. Additional stimulations can be initiated by swiping a magnet over the device located in the chest. This treatment is essentially equivalent to starting a new medication with regard to efficacy, with fewer than 10% of refractory patients becoming seizure free. Vagal nerve stimulation is usually reserved for patients who do not respond to several drugs and are not surgical candidates. Finally, a deep brain stimulation device has been approved for individuals with seizures refractory to other treatments. Some AED therapy is usually continued in patients with devices.

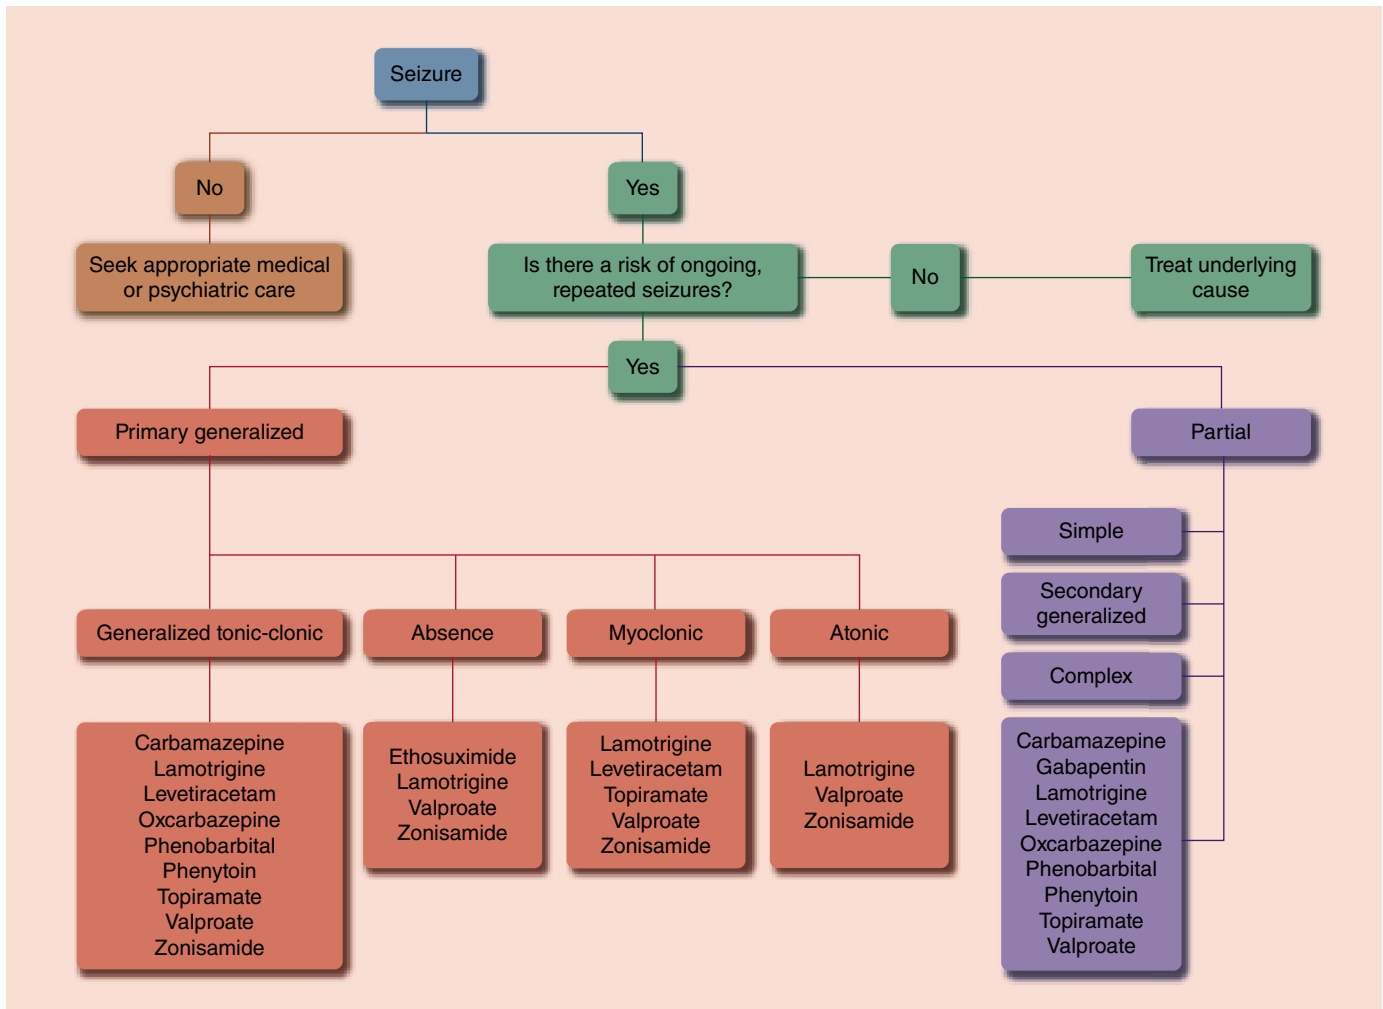
Another nonpharmacologic treatment is the ketogenic diet.[25] This diet produces a keto-acidotic state through the elimination of nearly all carbohydrates. The diet consists of dietary fats (eg, butter, heavy cream, fatty meats) and protein with no added sugar. Daily urinalysis for ketones is performed to ensure the patient remains in ketosis. Any inadvertent consumption of sugar results in the diet needing to be reinitiated. Pharmacists must be vigilant in maintaining the diet, by determining the sugar or carbohydrate content of medications the patient is taking.


**FIGURE 31–2.** Treatment algorithm for seizures.

This diet is typically used only in children with difficult-to-control seizures. In certain patients the diet can be extremely effective, resulting in complete seizure control and reduction of AEDs. However, it is difficult to maintain, and palatability of the diet, growth retardation, and hypercholesterolemia are concerns.

## Pharmacologic Therapy

### ▶ *Special Considerations*

Use of AEDs presents some unique challenges.[26]

**Michaelis-Menten Metabolism** Phenytoin metabolism is capacity limited. Michaelis-Menten pharmacokinetics occurs when the maximum capacity of hepatic enzymes to metabolize the drug is reached, and this may occur within the normal dose range. The clinical significance is that small changes in doses result in large changes in serum concentrations. Too large a dose change may result in concentration-related toxicity or break-through seizures. Individual differences in metabolism, result in a different relationship between dose and serum concentrations. These differences can be defined only by careful use of serum concentration and dosing data. There are numerous schemes for determining appropriate dosage adjustments of phenytoin, but for routine clinical practice, dosage adjustments for adults with

normal protein binding of phenytoin and a steady-state serum concentration can be made using the following plan:

- For serum concentrations less than 7 mcg/mL (mg/L; 28 μmol/L), the total daily dose is increased by 100 mg.
- For serum concentrations of 7 to 12 mcg/mL (mg/L; 28–48 μmol/L), the total daily dose is increased by 50 mg.
- For serum concentrations more than 12 mcg/mL (mg/L; 48 μmol/L), the total daily dose is increased by no more than 30 mg.[27]

**Protein Binding** Some AEDs, especially phenytoin and valproate, are highly bound to plasma proteins. When interpreting a reported concentration for these drugs, it is important to remember the value represents the total (ie, bound and unbound) concentration in the blood. Because of differences in the metabolism of these drugs, the clinical effects of altered protein binding are different.

Normally, 88% to 92% of phenytoin is bound to plasma protein, leaving 8% to 12% as unbound. The unbound component produces the clinical effect in the CNS, produces dose-related side effects in the CNS and at other sites, distributes to other peripheral sites, and gets metabolized. Certain patient

groups have decreased protein binding, resulting in an increased unbound percentage of drug. These patient groups include:

- Those with kidney failure
- Those with hypoalbuminemia
- Neonates
- Pregnant women
- Those taking multiple highly protein-bound drugs
- Patients in critical care

Due to the Michaelis-Menten metabolism of phenytoin, alterations in its protein binding result in increased concentration-related adverse effects. In patients with suspected changes in protein binding, it is useful to measure unbound phenytoin concentrations.

When valproate protein binding is altered, the risk for severe dose-related adverse effects is less compared with phenytoin. Michaelis-Menten metabolism is not a factor with valproate, so hepatic enzymes are able to efficiently metabolize the additional unbound portion.

**Autoinduction** Carbamazepine is a potent inducer of hepatic microsomal enzymes. It increases the rate of metabolism for many other drugs, and the rate of its own metabolism. Hepatic enzymes become maximally induced over several weeks, necessitating a small initial dose of carbamazepine that is increased over time to compensate for the enzyme induction (**Figure 31–3**). Most dosage regimens for carbamazepine call for a starting dose that is 25% to 30% of the typical maintenance dose of 15 mg/kg/day. The dosage is increased weekly until the target maintenance dose is achieved within 3 to 4 weeks. Titration of the carbamazepine dose lessens the risk for severe dose-related adverse effects.

▶ *Drug Selection and Seizure Type*

● The key to selecting effective pharmacotherapy is to base the decision on the seizure type. Several consensus treatment guidelines from the Scottish Intercollegiate Guidelines Network (SIGN), the National Institute for Clinical Excellence in the United Kingdom (NICE), the American Academy of Neurology (AAN), and ILAE all link seizure type to the selection of

**FIGURE 31–3.** Carbamazepine serum concentrations with a titration schedule compared to initiation with no titration. Concentrations are expressed in mcg/mL. Conversion of carbamazepine concentrations to μmol/L requires multiplying by 4.23.

## Patient Encounter 1: New-Onset Seizures

A 22-year-old man is seen by his physician 4 days after having a generalized tonic-clonic seizure in his college dorm room. The seizure lasted for 5 minutes, according to his roommate. He was confused for several minutes and went to sleep for a few hours after the seizure.

His physical examination is completely normal, and no focal neurologic deficits were observed. An MRI was ordered and reported as right mesial temporal sclerosis. An EEG shows right fronto-temporal sharp waves.

*What additional information is needed to make a decision about pharmacotherapy?*

*How should this information be used to make choices concerning AED therapy?*

During the visit, he mentions several previous brief episodes of loss of consciousness, and friends tell him his left hand fumbles with his shirt. These started a couple of years ago and now occur 2 to 3 days each week.

*Is pharmacotherapy indicated?*

*If it is indicated, what drug should be used, and how should it be started?*

*What adverse effects are important to monitor?*

Three months later he is doing well. He reports no generalized tonic-clonic seizures, and the brief spells are reduced to about 2 per month.

*What adjustments in pharmacotherapy should be made at this point?*

*Is it possible for him to discontinue AED therapy at some time in the future?*

pharmacotherapy (**Table 31–2**).[28–30] While the guidelines make recommendations for specific drugs to be used in certain seizure types, the consensus recommendations use only high-quality data available from the medical literature. In many cases, a recommendation is not made due to lack of sufficient data for an evidence-based decision. Therefore, a drug may not appear in a guideline because insufficient data was available at the time the guideline was developed. Absence of a recommendation does not mean the drug is ineffective for a specific seizure type. For example, according to the AAN Practice Parameter, topiramate is useful as monotherapy for primary generalized tonic-clonic seizures, but insufficient evidence was available at the time of guideline development to make any recommendation regarding gabapentin, lamotrigine, oxcarbazepine, tiagabine, levetiracetam, or zonisamide.[31]

● Outside of the evidence-based guidelines, other pharmacologic treatments are commonly used or avoided. For initial treatment of absence seizures, ethosuximide and valproate are used. In absence and myoclonic seizures, carbamazepine, oxcarbazepine, gabapentin, tiagabine, and pregabalin should be avoided due to association with worsening of these seizure types.

KEY CONCEPT *Antiepileptic drug therapy should usually be initiated carefully using a titration schedule to minimize adverse events.* Moderate target doses are chosen until the patient's response can be further evaluated in the clinic. If seizures continue, the dose is increased gradually until the patient becomes seizure free or

adverse effects appear. For some drugs like lamotrigine, specific titration guidelines are established by the manufacturer.

Treatment of refractory seizures (ie, unresponsive to at least two first-line AEDs) is somewhat different. Combinations of drugs may be useful in patients with difficult to control seizures. All AEDs, except ethosuximide, are effective in combination therapy for partial seizures.

▶ *Complications of Pharmacotherapy*

Adverse effects of AEDs are frequently dose limiting or cause a drug to be discontinued. Two types of adverse effects occur with AEDs: serum concentration-related and idiosyncratic (Table 31–3).

Concentration-related adverse effects happen with increasing frequency and severity as the dose or serum concentration of a drug is increased. Common concentration-related adverse effects include sedation, ataxia, and diplopia. Adverse effects are considered one of the AED selection criteria. For example, if a patient has a job that requires mental alertness, it is best to choose an AED that is less likely to cause sedation (eg, lamotrigine).

Idiosyncratic adverse effects are not dose or concentration related and almost always result in the AED being discontinued. Rash is the most common of these. Severe skin, hepatic, or hematological reactions occur rarely, but are potentially

life-threatening. The AED should be discontinued immediately when these reactions occur. Carbamazepine, phenytoin, phenobarbital, valproate, lamotrigine, oxcarbazepine, and felbamate are most likely to cause reactions. There is a possibility of cross-reactivity for these adverse effects, especially for carbamazepine, phenytoin, phenobarbital, and oxcarbazepine. It is estimated that 15% to 25% of patients who have an idiosyncratic reaction to one drug will have a similar reaction to the other drugs.

▶ *Chronic Adverse Effects*

Because AEDs are administered for long periods of time, adverse effects due to prolonged drug exposure are of concern. Some chronic adverse effects associated with AEDs include peripheral neuropathy and cerebellar atrophy. Other chronic adverse effects are extensions of acute adverse effects, for example, weight gain.

Osteoporosis is a major chronic adverse effect of several drugs.[32,33] Carbamazepine, phenytoin, phenobarbital, oxcarbazepine, and valproate decrease bone mineral density, after 6 months of treatment. The risk of osteoporosis due to chronic AED use is comparable to the risk with chronic use of glucocorticosteroids. Patients taking carbamazepine, oxcarbazepine, phenytoin, phenobarbital, or valproate more than 6 months should take supplemental calcium and vitamin D. Routine monitoring for osteoporosis should be performed every 2 years, and patients should be instructed on ways to protect themselves from fractures.

Table 31–3

**Characteristics of Common AEDs**

| Drug | Mechanism of Action | Dose | Pharmacokinetic Parameters | Usual Serum Concentration Range | Dose-Related Adverse Effects | Idiosyncratic Adverse Effects |
|------|---------------------|------|----------------------------|-------------------------------|------------------------------|-------------------------------|
| Carbamazepine (Tegretol, Tegretol XR, Carbatrol, generic) | Fast sodium channel inactivation | *Loading dose:* Not recommended due to excessive dose-related toxicity *Maintenance dose:* Titrate dosage to target over 3–4 weeks Adults: 10–20 mg/kg/day as a divided dose Children: 20–30 mg/kg/day as a divided dose | *Half-life:* 10–25 hours with chronic dosing *Apparent volume of distribution:* 0.8–1.9 L/kg *Protein binding:* 67%–81% *Primary elimination route:* Hepatic | 4–12 mcg/mL (mg/L; 17–51 µmol/L) | Diplopia, drowsiness, nausea, sedation | Aplastic anemia, hyponatremia, leucopenia, osteoporosis, rash |
| Clobazam (Onfi) | Enhance GABA | Weight < 30 kg, start 5 mg/day, titrate to 20 mg/day in two divided doses Weight > 30 kg start 10 mg/day, titrate to 40 mg/day in two divided doses | *Half-life:* 10–50 hours *Apparent volume of distribution:* ~0.9 L/kg *Protein binding:* ~90% *Primary elimination route:* Hepatic; metabolized to active metabolite that is further metabolized by CYP 2C19 | Not established | Sedation somnolence lethargy pyrexia irritability drooling aggression | |
| Clonazepam (Klonopin, generic) | Enhance GABA activity | *Loading dose:* Not recommended due to increased adverse effects *Maintenance dose:* Initiate at 0.5 mg one to three times daily, titrate dose to effectiveness, usually 3–5 mg daily in two or three divided doses | *Half-life:* 30–40 hours *Apparent volume of distribution:* 3.2 L/kg *Protein binding:* 47%–80% *Primary elimination route:* Hepatic | Not established | Ataxia, memory impairment, sedation, slowed thinking | |
| Ethosuximide (Zarontin, generic) | Modulate calcium channels | *Loading dose:* Not recommended due to increased adverse effects *Maintenance dose:* Initiate at 250 mg twice daily and titrate to 500–1000 mg twice daily | *Half-life:* 60 hours *Apparent volume of distribution:* 0.6–0.7 L/kg *Protein binding:* None *Primary elimination route:* Hepatic | 40–100 mcg/mL (mg/L; 283–708 µmol/L) | Ataxia, sedation | Hepatotoxicity, neutropenia, rash |

*(Continued)*

**Table 31–3**

**Characteristics of Common AEDs (*Continued*)**

| Drug | Mechanism of Action | Dose | Pharmacokinetic Parameters | Usual Serum Concentration Range | Dose-Related Adverse Effects | Idiosyncratic Adverse Effects |
|---|---|---|---|---|---|---|
| Felbamate (Felbatol) | Inhibit glutamate activity | *Loading dose:* Not recommended due to increased adverse effects *Maintenance dose:* 1200–3600 mg/day in three or four divided doses | *Half-life:* Monotherapy: 20 hours Concurrent enzyme inducers: 11–16 hours *Apparent volume of distribution:* 0.7–0.8 L/kg *Protein binding:* 25%–35% *Primary elimination route:* Hepatic | Not established | Anxiety, insomnia, nausea | Anorexia, aplastic anemia, headache, hepatotoxicity, weight loss |
| Gabapentin (Neurontin, generic) | Modulate calcium channels and enhance GABA activity | *Loading dose:* Not recommended due to short half-life *Maintenance dose:* 900–3600 mg/day in three or four divided doses (doses up to 10,000 mg/day have been tolerated) | *Half-life:* 5–7 hours (proportional to creatinine clearance) *Apparent volume of distribution:* 0.6–0.8 L/kg *Protein binding:* < 10% *Primary elimination route:* Renal | Not established | Drowsiness, sedation | Peripheral edema, weight gain |
| Lacosamide (Vimpat) | Slow sodium channel inactivation; modulate collapsin response; mediator protein-2 | *Loading dose:* Data unavailable *Maintenance dose:* 200–400 mg/day; Start at 100 mg/day in two divided doses and titrate upward according to response | *Half-life:* Approximately 13 hours *Volume of distribution:* 0.6 L/kg *Protein binding:* < 15% *Primary elimination route:* 40% renal 60% hepatic | Not established | Ataxia, dizziness, diplopia, headache, nausea, vomiting | PR interval prolongation |
| Lamotrigine (Lamictal, Lamictal XR, generic) | Fast sodium channel inactivation | *Loading dose:* Not recommended due to increased risk of rash *Maintenance dose:* 150–800 mg/day in 2 or 3 divided doses. Doses should be initiated and titrated according to the manufacturer's recommendations to reduce the risk of rash | *Half-life:* Monotherapy: 24 hours Concurrent enzyme inducers: 12–15 hours Concurrent enzyme inhibitors: 55–60 hours *Apparent volume of distribution:* 1.1 L/kg *Protein binding:* 55% *Primary elimination route:* Hepatic | Not established | Ataxia, drowsiness, headache, insomnia, sedation | Rash |

| Levetiracetam (Keppra, Keppra XR, generic) | Modulate synaptic vesicle protein | *Loading dose:* Not recommended due to excessive adverse effects *Maintenance dose:* 1000–3000 mg/day. Start at 1000 mg/day and titrated upward as indicated by response | *Half-life:* 6–8 hours *Apparent volume of distribution:* 0.5–0.7 L/kg *Protein binding:* < 10% *Primary elimination route:* 70% renal 30% hepatic | Not established | Somnolence, dizziness | Depression |
|---|---|---|---|---|---|---|
| Oxcarbazepine (Trileptal, generic) | Fast sodium channel inactivation | *Loading dose:* Not recommended due to excessive adverse effects *Maintenance dose:* 600–1200 mg/day. Start at 300 mg twice daily and titrated upward as indicated by response | *Half-life:* Parent drug Approximately 2 hours; 10-monohydroxy *Metabolite* Approximately 9 hours *Apparent volume of distribution:* 0.5–0.7 L/kg *Protein binding:* 40% *Primary elimination route:* Hepatic | Not established | Diplopia, dizziness, somnolence | Hyponatremia, 25–30% cross-sensitivity in patients with hypersensitivity to carbamazepine |
| Phenobarbital (Luminal, generic) | Fast sodium channel inactivation | *Loading dose:* 10–20 mg/kg as single or divided IV infusion or orally in divided doses over 24–48 hours *Maintenance dose:* Adults: 1–4 mg/kg/day as a single or divided dose Children: 3–6 mg/kg/day as divided dose Neonates: 1–3 mg/kg/day as divided dose | *Half-life:* Adults: 49–120 hours Children: 37–73 hours Neonates: approximately 115 hours *Volume of distribution:* 0.7–1 L/kg *Protein binding:* Approximately 50% *Primary elimination route:* Hepatic | 15–40 mcg/mL (mg/L; 65–172 μmol/L) | Ataxia, drowsiness, sedation | Attention deficit, cognitive impairment, hyperactivity, osteoporosis, passive-aggressive behavior |

## Patient Encounter 2: Managing Chronic Adverse Reactions

A 41-year-old woman with complex partial seizures has been treated with phenytoin 400 mg/day for 20 years. Her seizures are well controlled on this regimen, and she works as a pharmaceutical sales representative. She expresses concern about taking the phenytoin for so long.

*What chronic adverse effects are important to monitor in this patient?*

*How should monitoring for these adverse effects be done?*

*What measures can be taken to prevent these adverse effects?*

### ▶ Practical Issues

● **Comorbid Disease States** Patients with epilepsy often have comorbid disease states. Care must be taken when treating comorbid conditions, as numerous drugs can interact with AED. These interactions necessitate close monitoring for changes in efficacy or increased toxicity, and dosage changes of other drugs may be necessary when an AED is added or removed. Patients with headaches need special attention in the selection of an AED. Agents known to prevent headache (eg, valproate and topiramate) may be preferred, and agents associated with increased headaches (eg, lamotrigine and felbamate) may be secondary or tertiary alternatives.

Depression is common in patients with epilepsy. Approximately 30% have symptoms of major depression at some point.[34] Patients with epilepsy should be routinely assessed for signs of depression, and treatment initiated if necessary. Most AEDs can exacerbate depression, and patients should be warned to watch for mood changes. Some AEDs (eg, lamotrigine, carbamazepine, oxcarbazepine) may be useful in treating depression. If treatment for depression is necessary, an agent that is unlikely to increase seizures and does not interact with AEDs should be chosen. However, treatment with an appropriate antidepressant should not be withheld because of a small risk of increasing seizure frequency.

● **Switching Drugs** Changing from one AED to another can be a complex process. If the first drug is stopped too abruptly, breakthrough seizures may occur. KEY CONCEPT *Changes in AED regimens should be done in a stepwise fashion, keeping in mind drug interactions that may be present and may necessitate dosage changes in concomitant drugs.* Typically the new drug is started at a low initial dose and gradually increased over several weeks. Once the new drug is at a minimally effective dose, the drug to be discontinued is gradually tapered while the dose of the new drug continues to be increased to the target dose. During a transition between drugs, patients should be cautioned about the possibility of increased seizures or adverse reactions.

**Stopping Therapy** Epilepsy is generally considered to be a lifelong disorder requiring ongoing treatment. However, some patients who are seizure free may desire to discontinue their medications.[35] Patients who become seizure free following surgery for epilepsy may have medications slowly tapered starting 2 years after surgery. Many patients will choose to stay on at least one medication, following successful surgery, to ensure they
● remain seizure free. KEY CONCEPT *Discontinuation of AEDs should*

*be done gradually, only after the patient has been seizure free for 2 to 5 years and with careful consideration of factors predictive of seizure recurrence.*[36] They are:

- No seizures for 2 to 5 years
- Normal neurologic examination
- Normal intelligence quotient
- Single type of partial or generalized seizure
- Normal EEG with treatment

Individuals who fulfill all of these criteria have a 61% chance of remaining seizure free after AEDs are discontinued. Additionally, there is a direct relationship between the duration of seizure freedom with medications and the chance of remaining seizure free after medications are withdrawn. Withdrawal of AEDs is done slowly, usually with a tapering dose over at least 1 to 3 months.

### ▶ Dosing

● Dosing of AEDs is determined by general guidelines and response of the patient. Serum concentrations may be helpful in benchmarking a specific response. Therapeutic ranges that are often quoted are broad guidelines for dosing, but should never replace careful evaluation of the patient's response.

### ▶ Drug Interactions

● AEDs are associated with many different drug interactions.[37–39] Most interactions occur due to alterations in absorption, metabolism, and protein binding. Tube feedings and antacids are known to reduce the absorption of phenytoin and carbamazepine. Phenytoin, carbamazepine, and phenobarbital are potent inducers of various CYP450 isoenzymes, increasing the clearance of other drugs metabolized through these pathways (Table 31–4). In contrast, valproate is a CYP450 and UDP-glucuronosyltransferase (UGT) isoenzyme inhibitor and reduces the clearance of some drugs. Phenytoin and valproate are highly protein bound and can be displaced when taken together or with other highly protein-bound drugs. For example, when phenytoin and valproate are taken together, there may be increased dose-related adverse effects within several hours of dosing. This can be avoided by staggering doses or giving smaller doses more frequently during the day. Whenever a change in a medication regimen occurs, drug interactions should be considered and appropriate adjustments in dose of AEDs made.

### ▶ Special Populations

● KEY CONCEPT *Children and women with epilepsy have unique problems related to the use of AEDs.* In children, developmental changes occur rapidly, and metabolic rates are greater than those seen in adults. When treating a child, it is imperative to control seizures as quickly as possible to avoid interference with development of the brain and cognition. AED doses are increased rapidly, and frequent changes in the regimen are made to maximize seizure control. Due to rapid metabolic rates seen in children, doses of AEDs are typically higher on a milligram per kilogram basis compared with adults, and serum concentrations are used more extensively to help ensure an adequate trial of a drug has been given.

For women, the treatment of epilepsy poses challenges, including teratogenicity, breastfeeding, interactions between AEDs and hormonal contraceptives, and reduced fertility.[40,41] Recommendations are developed for managing women of childbearing potential and who are pregnant (Table 31–5). Several AEDs

are implicated in causing birth defects.[42] Neural tube defects (eg, spina bifida, microcephaly, anencephaly) are associated most commonly with valproate and possibly carbamazepine. Additionally, valproate is associated with impaired cognitive development in children born to women taking valproate during pregnancy. It is best to avoid the use of valproate, if possible, in women of childbearing potential. All women of childbearing potential who take AEDs should take 1 to 4 mg daily of supplemental folic acid to reduce the risk of birth defects. Many AEDs are excreted in breast milk. However, infants were exposed to higher concentrations of AED in utero, so it is unclear if drugs in breast milk are harmful to the child. Decisions about breastfeeding are made on an individual basis.

- Many AEDs induce hepatic microsomal enzyme systems and reduce the effectiveness of hormonal contraceptives. Women taking AEDs that may reduce the effectiveness of hormonal contraceptives should also use other forms of birth control. In contrast to these interactions, hormonal contraceptives induce glucuronidation of lamotrigine and valproate, and cause reductions in serum concentrations of these drugs during days of the cycle when hormones are taken; serum concentrations increase during days when hormones are not taken. Serum concentrations

---

**Patient Encounter 3: Birth Control**

A 21-year-old woman comes to clinic to discuss birth control. She is currently taking oxcarbazepine 1200 mg/day for complex partial seizures. Her seizures are well controlled, except for two seizures in the last year when she missed doses due to not getting refills on time. Otherwise she is in good health.

*What advice should be given regarding birth control?*

*What impact will oxcarbazepine have on hormonal contraceptives?*

*What AEDs should generally be avoided in women of childbearing potential?*

*What additional medications or supplements should be considered?*

---

**Table 31–5**

**Management of AEDs During Pregnancy**

Give supplemental folic acid 1–4 mg daily to all women of childbearing potential

Use monotherapy whenever possible

Use lowest doses that control seizures

Continue pharmacotherapy that best controls seizures prior to pregnancy

Monitor AED serum concentrations at start of pregnancy and monthly thereafter

Adjust AED doses to maintain baseline serum concentrations

Administer supplemental vitamin K during eighth month of pregnancy to women receiving enzyme-inducing AEDs

Monitor postpartum AED serum concentrations to guide adjustments of drug doses

## Patient Encounter 4: Seizures in Older Adults

An 80-year-old man has experienced spells where he is briefly unresponsive and has slight movements of his right hand. He has no recollection of these episodes. He has a history of atrial fibrillation and hypertension. His MRI and EEG are reported to be normal.

*Should pharmacotherapy be started in this patient?*

*If pharmacotherapy is started, what AED is preferable?*

*How should efficacy and toxicity be monitored in this patient?*

of many AEDs, drop during pregnancy, and dose increases based on frequent serum concentration monitoring is necessary. Due to induction or inhibition of sex hormone metabolism and changes in binding of hormones to sex hormone binding globulin, some AEDs reduce fertility. Valproate has been associated with a drug-induced polycystic ovarian syndrome. Women who experience difficulties with fertility should seek the advice of health care professionals with expertise in fertility.

**KEY CONCEPT** *Older adults have the highest incidence of newly diagnosed epilepsy and face unique challenges in treatment.* The highest incidence of seizures and epilepsy is in individuals older than 65 years. Cerebrovascular disease, tumors, trauma, and neurodegenerative diseases are the primary causes of epilepsy in this age group. Diagnosis of epilepsy in older adults is difficult. This is due to the subtle symptoms of seizures, often compromised memory in the elderly, and the fact that many elderly live alone. Carbamazepine, lamotrigine, and gabapentin have been studied in older adults, and all are effective in controlling seizures.[43–45] Fewer adverse events occur with lamotrigine and gabapentin. Elderly patients are more sensitive to adverse events, so smaller doses tend to be used in this age group.

## OUTCOME EVALUATION

**KEY CONCEPT** *Patients receiving AEDs for seizures should have regular monitoring for seizure frequency, seizure patterns, acute adverse effects, chronic adverse effects, comorbid conditions, and possible drug interactions.*

### Efficacy

- Seizure counts are the standard way to evaluate the efficacy of treatment.
- Encourage patients to keep a seizure calendar that notes the time and day a seizure occurs and the type of seizure. Compare seizure counts on a monthly basis to determine the level of seizure control.

### Toxicity

- Monitor acute toxicity of AEDs at every clinic visit.
- Question patients about common adverse effects of the AEDs they are receiving. Weigh the impact of acute adverse effects against the extent of seizure control. If it is determined, the adverse effects negatively impact the patient more than the extent of seizure control benefits the patient, adjust the therapeutic regimen. Continuously monitor chronic adverse effects of AEDs.

### Comorbid Conditions

Routinely evaluate patients for signs and symptoms of depression.

## Patient Care Process

**Patient Assessment:**

- Based on the description of a patient's spells, neurological examination, laboratory testing, EEG findings, and MRI, determine if the patient actually has seizures and is at risk for future seizures.
- Review the patient's medical history. For women, determine the potential for pregnancy.
- Take a medication history, including prescription medication, over-the-counter medication, and herbal supplement use.
- Identify allergies.
- Determine frequency of seizures.

**Therapy Evaluation:**

- Is the patient receiving medications that could cause seizures?
- Is the patient receiving treatment for seizures?
- Identify potential drug interactions between medications the patient may be currently taking and possible AEDs to be started.
- Identify lifestyle factors that will impact choice of AEDs.
- Determine insurance coverage for AEDs.

**Care Plan Development:**

- Determine the desired seizure outcomes for the patient.
- Select an AED taking into account seizure type, potential drug interactions, adverse effects of AEDs, and lifestyle factors.
- Design a dose titration plan that minimizes the risk for adverse effects.
- Educate the patient and caregivers on epilepsy, safety factors, including driving regulations, importance of adherence, dose titration schedule, and appropriate use of medications.
- For women of childbearing potential discuss interactions with hormonal contraception, risk of birth defects, and use of supplemental folic acid.
- Provide a seizure diary for recording the frequency and types of seizure events.

**Follow-Up Evaluation:**

- Schedule the patient to return to clinic every 2 to 4 months until stable, then schedule clinic visits every 6 to 12 months.
- Evaluate the seizure diary for changes in seizure frequency or types of seizure events.
- Identify idiosyncratic adverse effects in patients initiating a new AED.
- Identify dose-related adverse effects. Also identify psychological adverse effects, such as depression or anxiety.
- Monitor bone density at baseline and every 2 years for patients receiving phenobarbital, phenytoin, carbamazepine, oxcarbazepine, and valproate.
- Check AED serum concentrations, especially in children, pregnant women, and women immediately postpartum.
- Adjust medication doses for newly identified drug interactions.

# Status Epilepticus

Eljim P. Tesoro and Gretchen M. Brophy

## LEARNING OBJECTIVES

**Upon completion of the chapter, the reader will be able to:**

1. Describe the pathophysiology of status epilepticus.
2. Explain the urgency of diagnosis and treatment of status epilepticus.
3. Recognize the signs and symptoms of status epilepticus.
4. Identify the treatment goals for a patient in status epilepticus.
5. Formulate an initial treatment strategy for a patient in generalized convulsive status epilepticus.
6. Compare the pharmacotherapeutic options for refractory status epilepticus.
7. Describe adverse drug events associated with the pharmacotherapy of status epilepticus.
8. Recommend monitoring parameters for a patient in status epilepticus.

## INTRODUCTION

KEY CONCEPT **Status *epilepticus*** (SE) is a neurologic emergency that can lead to permanent brain damage or death. KEY CONCEPT *SE is defined as continuous seizure activity lasting more than 5 minutes or two or more seizures without complete recovery of consciousness.*[1] Refractory status epilepticus (RSE) is unresponsive to emergent (first-line) or urgent (second-line) therapy.

SE can present as nonconvulsive status epilepticus (NCSE) or generalized convulsive status epilepticus (GCSE). NCSE is characterized by persistent impaired consciousness without clinical seizure activity and is diagnosed with **electroencephalography** (EEG). GCSE is characterized by full-body motor seizures and involves the entire brain.

## EPIDEMIOLOGY AND ETIOLOGY

The incidence of SE in the United States is 12.5/100,000/year, with an in-hospital mortality rate of 9.2%,[2] and an estimated annual direct cost for inpatient admissions of $4 billion.[3] It occurs most frequently in males, African Americans, children, and the elderly.

KEY CONCEPT *It is important to evaluate etiologies of SE for timely and optimal seizure control.* Causes of SE include metabolic disturbances (eg, hyponatremia, hypernatremia, hyperkalemia, hypocalcemia, hypomagnesemia, hypoglycemia); central nervous system (CNS) disorders, infections, injuries; **hypoxia;** drug toxicity (eg, theophylline, isoniazid, cyclosporine, cocaine). Chronic causes of SE include preexisting **epilepsy,** chronic alcoholism (withdrawal seizures), CNS tumors, and strokes.[4] In epileptics, the common causes of SE are anticonvulsant withdrawal or subtherapeutic levels.

## PATHOPHYSIOLOGY

Status epilepticus occurs when the brain fails to stop isolated seizures, due to a mismatch of neurotransmitters. **Glutamate,** the primary excitatory neurotransmitter, stimulates postsynaptic *N*-methyl-D-aspartate (NMDA) receptors, causing neuronal depolarization. Sustained depolarization causes neuronal injury and death.[5] The primary inhibitory neurotransmitter, **γ-aminobutyric** acid (GABA), opposes excitation by stimulating $GABA_A$ receptors, producing hyperpolarization and inhibition of the postsynaptic cell membrane. GABA-mediated inhibition diminishes with continuous seizure activity, causing a decreased response to GABA-receptor agonists.[6] Seizures lasting more than 30 minutes cause significant injury and neuronal loss because of excessive electrical activity and cerebral metabolic demand.

Decreased $GABA_A$-receptor response and increasing neuronal injury with prolongation of seizure activity necessitates rapid control of SE.

Systemic changes appear in two phases during SE. Phase I occurs during the first 30 minutes, and phase II occurs after 30 to 60 minutes.[7]

### Phase I

During phase I, autonomic activity increases, resulting in hypertension, tachycardia, hyperglycemia, hyperthermia, sweating, and salivation. Cerebral blood flow increases to preserve oxygen supply to the brain. Increases in sympathetic and parasympathetic stimulation with muscle hypoxia can cause ventricular arrhythmias, severe acidosis, and rhabdomyolysis which can lead to hypotension, shock, hyperkalemia, and acute kidney injury.

## Patient Encounter 1, Part 1

A 79-year-old woman with a history of hypertension, diabetes, and arthritis was admitted with traumatic subdural hematoma after sustaining a fall down a flight of stairs in her home. She underwent surgery 2 days ago to evacuate the hematoma and is currently recovering in the ICU. She was started on fosphenytoin for seizure prophylaxis upon admission along with her home medications. She has only one peripheral IV line and has very poor vascular access. Her nurse reports that a few minutes ago she was alert and awake, but now she is unarousable and is having jerky, convulsive movements on both sides of her body. The doctor evaluates her and the jerky activity stops, but then starts again about 1 minute later. She never regained consciousness between these episodes. Her diagnosis is status epilepticus. Ht 165 cm (5′5″), Wt 133 kg (293 lbs).

*What initial assessments should be performed?*

*What are some possible etiologies for her seizure?*

*What nonpharmacologic interventions need to be performed at this time?*

### Phase II

After 30 to 60 minutes of continuous seizure activity, loss of cerebral autoregulation, decreased cerebral blood flow, increased intracranial pressure, and systemic hypotension occur. Cerebral metabolic demand remains high; however, the body is unable to compensate, resulting in hypoglycemia, hyperthermia, respiratory failure, hypoxia, respiratory and metabolic acidosis, hyperkalemia, hyponatremia, and uremia. Motor activity may not be clinically evident during prolonged seizures, but electrical activity may still exist (ie, NCSE) requiring prompt recognition and aggressive treatment.

## CLINICAL PRESENTATION AND DIAGNOSIS

### History

KEY CONCEPT *When a patient presents with seizures, a thorough history is needed to determine the type and duration of previous seizure activity. This will help guide therapy and clarify necessary laboratory and diagnostic tests.* A diagnosis of SE can be made when a patient with a history of repeated seizures and impaired consciousness has a seizure witnessed by a health care professional. However, emergent treatment should not be delayed if seizure activity is suspected based on reports from the patient's family or emergency response personnel.

### Physical Examination

Once seizures are controlled, a neurologic exam should evaluate the level of consciousness (coma, lethargy, or somnolence), motor function and reflexes (rhythmic contractions, rigidity, spasms, or posturing), and pupillary response. A physical exam can identify secondary injuries.

### Clinical Symptoms

Patients with SE usually present with generalized, convulsive, tonic-clonic seizures. They may also be hypertensive, tachycardic, febrile, and diaphoretic which resolve after seizure termination. A loss of bowel or bladder function, respiratory compromise, and **nystagmus** may also be observed. When seizure activity

## Clinical Presentation of Status Epilepticus

### General

The patient may present with or without clinically noticeable seizure activity.

### Symptoms

- Impaired consciousness ranging from lethargy to coma
- Disorientation after cessation of GCSE
- Pain from associated injuries (eg, tongue lacerations, dislocated shoulder, head trauma, facial trauma)

### Signs

| Phase I: | Phase II (greater than 30 minutes of SE): |
|---|---|
| Generalized convulsions | Respiratory failure with pulmonary edema |
| Hypertension, tachycardia | Cardiac failure (arrhythmias, shock) |
| Fever and sweating | Hypotension |
| Muscle contractions, spasms | Hyperthermia |
| Respiratory compromise | Rhabdomyolysis and multiorgan failure |
| Incontinence | |

### Laboratory Tests

- Hyperglycemia (phase I) and hypoglycemia (phase II) can occur
- Hyponatremia, hypernatremia, hyperkalemia, hypocalcemia, hypomagnesemia, and hypoglycemia can cause SE
- The white blood cell (WBC) count may slightly increase
- Abnormal arterial blood gases (ABGs) due to hypoxia and respiratory or metabolic acidosis
- Elevated serum creatinine will be present in renal failure patients
- Myoglobinuria can occur in patients with continuous seizures

### Diagnostic Tests

EEG to confirm seizure activity

CT or MRI may reveal mass lesions or hemorrhage

exceeds 30 to 60 minutes, muscle contractions may no longer be visible, necessitating an EEG to diagnosis SE. Twitching of the face, hands, or feet may be seen in these comatose patients with prolonged seizures.

### Laboratory Parameters

KEY CONCEPT *It is important to obtain a serum chemistry profile to help identify possible causes of SE, such as* hypoglycemia, hyponatremia or hypernatremia, hypomagnesemia, and hypocalcemia; patients with renal and liver failure are at high risk as well. In febrile patients with elevated white blood count (WBC) counts, active infections should be considered and treated appropriately. Cultures from the blood, cerebrospinal fluid (CSF), respiratory tract, and urine should be collected once seizures are controlled. Computed tomography (CT) or magnetic resonance imaging (MRI) can rule out CNS abscesses, bleeding, or tumors, all of which may be a source of seizures. Order a blood alcohol level

and urine toxicology screen to determine if SE is caused by alcohol withdrawal, illicit drug use, or a drug overdose. Serum drug levels should be obtained in an overdose situation to rule out toxicity. **KEY CONCEPT** *Knowing the cause of SE will guide initial antiepileptic therapy and increase the probability of seizure termination.*

In patients taking antiepileptic drugs (AEDs), a baseline serum concentration is useful to determine if the concentration is below the desired range and whether a loading dose (LD) is needed. Albumin levels, renal and liver function tests should also be utilized to assess therapy.

Hypoxia and respiratory or metabolic acidosis are common in patients with SE. Pulse oximetry and arterial blood gas (ABG) measurements are used to assess pulmonary status and determine if airway protection or supplemental oxygen is needed. Metabolic acidosis may resolve on its own without treatment after termination of clinical seizure activity.

### Diagnostic Tests

EEG is required to identify SE in a comatose patient. Continuous EEG monitoring should be used in patients who remain unconscious after initial antiepileptic treatment, those receiving long-acting paralytic agents, or those requiring prolonged RSE therapy. Treatment should not be delayed while awaiting EEG results. CT and MRI scans are useful to identify traumatic injury, mass lesions, or evidence of infection as the cause of SE.

## TREATMENT
### Desired Outcomes

**KEY CONCEPT** *The goal of therapy is to terminate physical and electroencephalographic evidence of seizures, prevent recurrence, and minimize adverse drug events.* Poor outcomes are associated with prolonged SE and refractory SE.[8] Complications of SE should also be treated.

### General Approach

The initial approach to SE involves removing the patient from harmful surroundings and ensuring maintenance of airway, breathing, and circulation. Benzodiazepines are the preferred initial drugs to stop acute seizure activity (emergent therapy), followed by an AED (urgent therapy) for suppression of seizures. Medications are given intravenously (IV) for immediate onset of action, but if IV access is not available, select medications may be given rectally, intramuscularly (IM), buccally, or nasally. After seizures stop, clinicians must identify and treat underlying causes of the seizures, such as toxins, hypoglycemia, or brain injury. Patients with known seizure disorders should be evaluated for abrupt cessation of their medications, noncompliance, or drug interactions. Recent guidelines provide treatment algorithms for SE.[1,9]

### Nonpharmacologic Treatment

Oxygen administration or intubation for mechanical ventilation should be performed in cases of hypoxia, and temperature management should be considered for febrile seizures. Specialists in neurology or epileptology should be consulted as appropriate. Admission to an intensive care unit (ICU) allows for aggressive treatment and monitoring.

### Pharmacologic Treatment
#### ▶ Initial Treatment

Hypoglycemia-induced SE is treated with IV dextrose. IV thiamine is given to alcoholics prior to administering any dextrose-containing solutions to prevent encephalopathy.

---

### Patient Encounter 1, Part 2

Physical examination and a review of her chart and recent laboratory studies reveal the following additional information about this patient:

**PE:**

**VS:** BP 178/92 mm Hg, pulse 109 beats/min, RR 26 breaths/min, T 39.0°C (102.2°F)

**CNS:** Unresponsive, unarousable

**CV:** Sinus tachycardia; normal S1, S2; no murmurs, rubs, gallops

**Pulm:** Tachypneic; oxygen saturation 88% (0.88) on room air; no rhonchi, wheezes, rales

**Abd:** Deferred

**Exts:** Rhythmic tonic-clonic movements of all extremities

**GU:** Incontinent of urine and stool

**HEENT:** Persistent upward gaze

**Current Meds:** Fosphenytoin 100 mg PE IV every 8 hours; famotidine 20 mg IV every 12 hours; metoprolol 50 mg by mouth every 12 hours; insulin glargine 25 units subcutaneous at bedtime; insulin aspart 5 units subcutaneous with meals; acetaminophen/hydrocodone 325 mg/5 mg tablet by mouth every 4 hours as needed for pain; morphine 2 mg IVP every 2 hours as needed for pain

**Labs:** Sodium 132 mEq/L (132 mmol/L); potassium 4.1 mEq/L (4.1 mmol/L); phenytoin 2.7 mcg/mL (11 μmol/L); albumin 3.5 g/dL (35 g/L); chloride 105 mEq/L (105 mmol/L); carbon dioxide 12 mEq/L (12 mmol/L); blood urea nitrogen 10 mg/dL (3.6 mmol/L); serum creatinine 0.9 mg/dL (80 μmol/L); glucose 54 mg/dL (3.0 mmol/L); WBC $15 \times 10^3$/mm³ ($15 \times 10^9$/L); hemoglobin 9.6 g/dL (96 g/L or 5.96 mmol/L); hematocrit 28% (0.28 volume fraction); platelets $235 \times 10^3$/mm³ ($235 \times 10^9$/L); prothrombin time 12 seconds; international normalized ratio 1.1; activated partial thromboplastin time 28 seconds

*What is your assessment of the cause of this patient's condition?*

*What pharmacologic interventions need to be performed at this time?*

*Identify your goals of therapy for this patient.*

*What therapies must be instituted next?*

---

#### ▶ Benzodiazepines

**KEY CONCEPT** *Initial or emergent drug therapy begins with IV administration of a benzodiazepine. This class of agents is highly effective in terminating seizures.*[10,11] *Intravenous bolus doses of diazepam, lorazepam, and midazolam have been used in SE because of their rapid effects on GABA receptors. Lorazepam is the preferred agent of most clinicians.* When treating patients on chronic benzodiazepine therapy, consider using higher doses to overcome tolerance. Diazepam and lorazepam should be diluted 1:1 with normal saline before parenteral administration via peripheral veins to avoid vascular irritation from the propylene glycol diluent.

**Diazepam** Being extremely **lipophilic,** diazepam penetrates the CNS quickly, but rapidly redistributes into body fat and muscle.

This results in a rapid decline in CNS levels and early recurrence of seizures. Doses can be given every 5 minutes until seizure activity stops or toxicities are seen (eg, respiratory depression). Diazepam can be administered as a rectal gel enabling non-medical personnel to provide timely therapy at home or in public areas.[12] IM administration of diazepam is not recommended because of erratic absorption.

**Lorazepam** Less lipophilic than diazepam, lorazepam has a longer redistribution half-life, resulting in longer duration of action and decreased need for repeated doses. Both lorazepam and diazepam are effective in stopping seizures,[13] but lorazepam is currently preferred due to a longer duration of action. It can be redosed every 5 to 10 minutes (up to a maximum cumulative dose of 8 mg) until seizure activity stops or side effects such as respiratory depression occur. IM administration is not preferred due to slow and unpredictable absorption.

**Midazolam** Midazolam is water-soluble and can be administered intramuscularly,[14] buccally,[15,16] and nasally.[17,18] Compared to diazepam and lorazepam, it has less respiratory and cardiovascular side effects. Its short half-life requires that it be redosed frequently or administered as a continuous IV infusion. Liquid or injectable formulations can be given buccally or intranasally (0.3 mg/kg) in pediatric patients. Rapid breathing and increased secretions can interfere with nasal administration. A recent study in adults and children showed that IM midazolam was as safe and effective as IV lorazepam for prehospital termination of seizures.[18]

▶ *Anticonvulsants*

**KEY CONCEPT** *After administering the first dose of benzodiazepine, an AED such as phenytoin, valproate sodium, or phenobarbital should be started to prevent further seizures (urgent therapy).* AEDs must not be given as first-line therapy since they are infused relatively slowly to avoid adverse effects, delaying their onset of action. If the underlying cause of the seizures has been corrected (eg,

hypoglycemia) and seizure activity has ceased, an AED may be unnecessary. This may be reasonable when patients become alert and oriented or if an EEG confirms absence of seizure activity.

After the AED LD is administered, maintenance doses should be initiated to ensure that therapeutic levels are sustained. Chronic and idiosyncratic side effects and potential drug interactions should be considered if the patient continues AED therapy. Drugs should be adjusted for any hepatic or renal dysfunction. Table 32–1 summarizes the doses used in SE, and Table 32–2 is an example algorithm for treatment of patients in SE.

**Phenytoin** The most widely used AED for urgent treatment of SE is phenytoin, which is available in its original form or as a prodrug, fosphenytoin. LDs must be modified in patients already taking phenytoin with subtherapeutic levels in order to avoid toxic serum concentrations. Doses are infused no faster than 50 mg/minute due to risks of hypotension or arrhythmias. Continuous monitoring of ECG and blood pressure is recommended. Maintenance doses can be started 12 hours after the LD. Phenytoin should not be infused with other medications because of stability concerns (it is soluble in propylene glycol and compatible only in 0.9% sodium chloride solutions). It should not be given IM due to its alkalinity. Extravasation of phenytoin can cause local tissue discoloration, edema, pain, and sometimes necrosis (purple glove syndrome). Oral loading is not recommended in SE due to the limitations of single dose absorption (ie, doses greater than 400 mg are not fully absorbed) and delayed peak concentrations when given orally. Obese patients require larger LDs due to a larger volume of distribution ($V_d$).[19] A dosing weight (DW) can be calculated using total body weight (TBW) and ideal body weight (IBW): DW = IBW + 1.33(TBW-IBW). $V_d$ can be calculated as follows: $V_d$ = 0.7 L/kg X DW (in kg). A LD can then be calculated using Vd and a target concentration: LD = $C_{target}$ X $V_d$.

**Fosphenytoin** Fosphenytoin is a water-soluble, phosphoester prodrug that is rapidly converted to phenytoin in the body. It is compatible with most IV solutions. It is dosed in phenytoin equivalents (PE), and it can be infused up to 150 mg PE/minute. Although it has fewer cardiovascular side effects than phenytoin, clinicians should continuously monitor blood pressure, ECG, and heart rate. Maintenance doses can be started 12 hours after the LD. Paresthesias, especially around the lips and groin are common, but typically resolve within a few minutes and should not necessitate stopping the infusion. If a postload serum level is desired, it should be obtained 2 hours after an IV load.

**Phenobarbital** If phenytoin or fosphenytoin fails to prevent seizure recurrence, phenobarbital can be considered. However, emerging evidence suggests that phenobarbital may not be effective if SE persists despite benzodiazepines and phenytoin. This may be due to progressive resistance of the $GABA_A$ receptor, where barbiturates also act.[20] Adverse reactions of phenobarbital include sedation, hypotension, and respiratory depression; therefore, patients receiving a rapid IV LD of phenobarbital should have hemodynamic monitoring and be mechanically ventilated if at high risk of respiratory compromise. Its long half-life makes it a popular agent for both acute treatment and chronic maintenance therapy or as adjunct therapy to prevent withdrawal seizures when weaning refractory SE patients off pentobarbital infusions.

**Valproate Sodium** Although valproate sodium is not Food and Drug Administration (FDA)-approved for SE, it has been used IV in various types of SE including generalized tonic-clonic, myoclonic, and NCSE.[21] It is particularly useful in patients with

---

### Patient Encounter 2, Part 1

A 19-year-old man admitted for two reported episodes of intermittent jerking in his left arm that were witnessed by his mother this morning. He is nonresponsive at the time of these episodes and does not remember anything during that period of time. He does not take any medications and has no allergies to medications. One week ago, he was seen in the emergency department as he was confused and having difficulties walking after being hit in the head with a soccer ball during a tournament. At that time, a CT scan of his head showed no hemorrhage, and he was diagnosed with having a mild traumatic brain injury. Today while the nurse is taking his vital signs, he becomes confused and then unarousable with jerky movements on the left side of his body. His diagnosis is status epilepticus after this seizure activity does not stop over the next 5 minutes.

**VS:** BP 111/75 mm Hg, HR 108 beats/min, RR 21 breaths/min, T 37.0°C (98.6°F), Wt 82 kg (180 lb), Ht 185 cm (6′1″)

*What is the most likely cause of this patient's SE?*

*What possible treatment options exist at this time?*

*How would you optimize this patient's outcome?*

**Table 32–1**

**Medications Used in Adult Status Epilepticus**

| Drug Name (Brand Name) | Loading Dose and RSE Maintenance Dose (If Applicable) | Administration Rate | Therapeutic Level | Side Effects | Comments |
|---|---|---|---|---|---|
| Diazepam (Valium) | 0.15 mg/kg (up to 10 mg per dose); may repeat in 5 minutes | 5 mg/min (IVP) | N/A | Hypotension, respiratory depression | Rapid redistribution rate; can be given rectally |
| Lorazepam (Ativan) | 0.1 mg/kg (up to 4 mg per dose); repeat in 5–10 minutes | 2 mg/min (IVP) | N/A | Hypotension, respiratory depression | May be longer acting than diazepam |
| Midazolam (Versed) | 0.2 mg/kg IM up to 10 mg per dose <br> RSE: 0.2 mg/kg (2 mg/min) IV then 0.05–2 mg/kg/hour | | N/A | Sedation, respiratory depression | Can also be given buccally, intranasally |
| Phenytoin (Dilantin) | 20 mg/kg | Up to 50 mg/min | Total phenytoin level: 10–20 mcg/mL (mg/L; 40–79 µmol/L) <br><br> Free phenytoin level: 1–2 mcg/mL (mg/L; 4–8 µmol/L) | Arrhythmias, hypotension, | Hypotension, especially in older adults |
| Fosphenytoin (Cerebyx) | 20 mg PE/kg | Up to 150 mg PE/min | Total phenytoin level: 10–20 mcg/mL (mg/L; 40–79 µmol/L) <br><br> Free phenytoin level: 1–2 mcg/mL (mg/L; 4–8 µmol/L) | Paresthesias, hypotension | Less CV side effects than phenytoin |
| Phenobarbital (Luminal) | 20 mg/kg | 50–100 mg/min | 15–40 mcg/mL (mg/L; 65–172 µmol/L) | Hypotension, sedation, respiratory depression | Long-acting |
| Valproate sodium (Depacon) | 20–40 mg/kg | 3–6 mg/kg/min | 50–150 mcg/mL (mg/L; 347–1040 µmol/L) | | Less CV side effects than phenytoin |
| Lacosamide (Vimpat) | 200–400 mg IV | Over 15 minutes | | PR prolongation, hypotension | |
| Topiramate (Topamax) | 200–400 mg NG/PO every 6 hours | | 2–20 mcg/mL (mg/L; 6–59 µmol/L) | Metabolic acidosis | |
| Propofol (Diprivan) | Bolus: 1–2 mg/kg <br> RSE: 30–250 mcg/kg/min | Approximately 40 mg every 10 seconds | N/A (typically titrated to EEG) | Hypotension, respiratory depression, PRIS | Requires mechanical intubation; high lipid load (increased calories); |
| Pentobarbital (Nembutal) | Bolus: 10–15 mg/kg <br> RSE: 0.5–4 mg/kg/hour | Up to 50 mg/min | 10–20 mcg/mL (mg/L; 44–89 µmol/L) (typically titrated to EEG) | Hypotension, respiratory depression, cardiac depression, infection, ileus | Requires mechanical intubation, vasopressors, hemodynamic monitoring |
| Ketamine | RSE: 0.5–4.5 mg/kg IV bolus, then infusion up to 5 mg/kg/hour | | N/A | Hypertension, arrhythmias | Has been associated with cerebral atrophy |

CV, cardiovascular; EEG, electroencephalogram; IM, intramuscular; IVP, intravenous push; N/A, not applicable; NG, nasogastric; PE, phenytoin equivalents; PO, by mouth; PRIS, propofol-related infusion syndrome

cardiorespiratory compromise and/or those allergic to phenytoin and phenobarbital.[22]

## Treatment of Refractory Status Epilepticus

**KEY CONCEPT** *Seizure activity unresponsive to emergent and urgent therapy is considered RSE.*[23] Refractory SE can occur in up to 30% of patients with SE and has a mortality rate approaching 50%. Patients in RSE are unlikely to regain independent function, even if seizures are controlled. Clinical signs may become subtle and an EEG may be required to detect ongoing seizure activity.

**KEY CONCEPT** *Even SE patients without clinical signs of seizing are at risk for brain damage or even death.*

Optimal therapy for RSE is undetermined.[24] Clinicians must aggressively investigate and treat possible causes including infection, tumors, drugs or toxins, metabolic disorders, liver failure, or fever. In general, patients with RSE are managed in an ICU where hemodynamic and respiratory support and frequent monitoring are available. Continuous EEG monitoring is essential and should not be delayed. Any AEDs initiated before treatment for RSE should be continued, and their serum levels optimized to

**Table 32–2**

**Algorithm for Treatment of Status Epilepticus in Adult**

| Time (minutes) | Assessment/Monitoring | Treatment |
|---|---|---|
| 0 | Vital signs (HR, RR, BP, T) Assess airway | Stabilize airway (intubate if necessary) |
| | Monitor cardiac function (ECG) | Administer oxygen |
| | Pulse oximeter | Secure IV access and start fluids |
| | Check blood glucose | Give IV thiamine (100 mg), then IV dextrose (50 mL of 50% solution) if hypoglycemic |
| | Check laboratory tests: complete blood count, serum chemistries, liver function tests, arterial blood gas, blood cultures, serum anticonvulsant levels, urine drug/alcohol screen | |
| 0–10 | Vital signs | Lorazepam 0.1 mg/kg (maximum 4 mg) IVP at 2 mg/min (may repeat in 5–10 minutes to maximum of 8 mg if no response) |
| | Physical exam | |
| | Patient history including medications (prescription, OTC, and herbals) | If no IV access, can give: diazepam 10 mg PR (may repeat in 10 minutes if no response); midazolam 0.2 mg/kg IM (maximum 10 mg; may repeat in 10 minutes if no response) |
| | | AED may not be necessary if underlying cause is corrected and seizures have ceased |
| 10–20 | Vital signs | Phenytoin 15–20 mg/kg IV at a maximum rate of 50 mg/min (or fosphenytoin 15–20 mg PE/kg IV at a maximum rate of 150 mg PE/min) |
| | Review laboratory results and correct any underlying abnormalities | |
| | CT scan (if seizures controlled) | In patients allergic to phenytoin, give valproate sodium 20 mg/kg IV at a maximum rate of 6 mg/kg/min |
| | | Treat for possible infection |
| 20–30 | Vital signs | If seizures continue: additional phenytoin bolus 5–10 mg/kg (or fosphenytoin 5–10 mg PE/kg) **OR** start phenobarbital at 20 mg/kg IV at a maximum rate of 100 mg/min **OR** start valproate sodium 20 mg/kg IV at a maximum rate of 6 mg/kg/min in patients who are not intubated |
| | Consult neurologist/epileptologist | |
| | Consider admission to ICU | |
| | Consider EEG | |
| > 30–60 *refractory status epilepticus* | Vital signs | Midazolam 0.2 mg/kg IV bolus followed by 0.05–2 mg/kg/hour CI **OR** propofol 1 mg/kg bolus followed by 30–250 mcg/kg/min CI **OR** pentobarbital 10–15 mg/kg bolus over 1–2 hours followed by 0.5–4 mg/kg/hour |
| | Transfer to ICU | |
| | Obtain EEG | |
| | Consider MRI when controlled | Consider intubation and/or vasopressor support if needed |
| | | Optimize AED levels: repeat boluses of phenobarbital 10 mg/kg **OR** valproate sodium 20 mg/kg at 6 mg/kg/min max |

BP, blood pressure; CI, continuous infusion; CT, computed tomography; ECG, electrocardiogram; EEG, electroencephalograph; HR, heart rate; ICU, intensive care unit; IV, intravenous; IVP, intravenous push; OTC, over the counter; MRI, magnetic resonance imaging; PE, phenytoin equivalents; PR, per rectum; RR, respiratory rate; T, temperature.

**Patient Encounter 2, Part 2**

Over the next hour, he is treated with your recommendations for emergent and urgent treatment of SE as above. His jerky movements have stopped, but he remains comatose.

**VS**: BP 110/72 mm Hg, HR 101 beats/min, RR 12 breaths/min, T 37.1°C (98.8°F)

A continuous EEG is started and reveals the patient is currently in SE

*What is your assessment of the patient's condition at this time?*

*What is your recommendation for further nonpharmacologic and pharmacologic therapy?*

*How would you optimize his outcome?*

prevent breakthrough or withdrawal seizures. **KEY CONCEPT** *Treatment of RSE consists of intensive monitoring, supportive care, and a continuous intravenous infusion of midazolam, propofol, or pentobarbital to suppress clinical and EEG evidence of seizures* (*Tables 32–1 and 32–3*).[25] These agents are typically titrated to achieve "burst suppression" on the EEG, although no strong evidence exists to support this practice. Patients should be intubated and mechanically ventilated before initiating treatment for RSE. Seizure control per EEG should be maintained for 24 to 48 hours before considering tapering therapy. Consultation with neurologists or epileptologists is highly recommended.

▶ *Midazolam*

Midazolam infusions must be adjusted, especially in patients with renal impairment, as the active metabolite can accumulate.[26] Breakthrough seizures are common with midazolam infusions and usually respond to boluses and a 20% increase in infusion

| Table 32–3 | | |
| --- | --- | --- |
| **Medications Used in Pediatric Status Epilepticus** | | |
| **Drug** | **Dose** | **Comments** |
| Diazepam (Valium injection, Diastat rectal gel) | IV: 0.2–0.3 mg/kg over 2–5 minutes | Maximum dose in children < 5 years: 5 mg |
| | | Maximum dose in children > 5 years: 15 mg |
| | PR: 2–5 years: 0.5 mg/kg | A second rectal dose can be given 4–12 hours after the first dose if necessary |
| | 6–11 years: 0.3 mg/kg | |
| | > 12 years: 0.2 mg/kg | |
| Lorazepam (Ativan) | 0.05–0.1 mg/kg IV over 2–4 minutes | May redose twice in 10–15 minutes if necessary |
| Midazolam (Versed) | 0.2 mg/kg IV bolus followed by 0.05–0.6 mg/kg/hour continuous infusion | Bolus dose may also be given intranasally, buccally, or intramuscularly |
| Phenytoin (Dilantin) | 15–20 mg/kg IV at 1–3 mg/kg/min *max* | |
| Fosphenytoin (Cerebyx) | 15–20 mg PE/kg IV at 3 mg PE/kg/min *max* | |
| Phenobarbital (Luminal) | 15–20 mg/kg IV at 100 mg/min *max* | |
| Valproate sodium (Depacon) | 15–20 mg/kg IV at 1.5–3 mg/kg/min | May have fewer cardiovascular side effects than other agents |
| Propofol (Diprivan) | | Not recommended due to adverse events (eg, propofol-related infusion syndrome) |
| Pentobarbital (Nembutal) | 10–15 mg/kg IV over 1–2 hours followed by continuous infusion at 1 mg/kg/hour | Titrated to EEG |

PR, per rectum; EEG, electroencephalograph; IV, intravenous; PE phenytoin equivalent.

rate. Despite this, tachyphylaxis can occur, and patients should be switched to another agent if seizures continue.

#### ▶ Propofol

LDs of the anesthetic propofol can be given every 3 to 5 minutes until clinical response, after which an infusion can be initiated. Propofol causes hypotension, especially with LDs; therefore, some clinicians avoid LDs and quickly titrate with a continuous infusion. Long-term, high-dose (greater than 80 mcg/kg/min) propofol infusions are associated with rhabdomyolysis, acidosis, and cardiac arrhythmias (propofol-related infusion syndrome), especially in children.[27] It has a very short serum half-life and should be tapered off slowly to avoid withdrawal seizures. Propofol infusions are a source of calories (1 kcal/mL [4.2 kJ/mL]), so nutrition requirements have to be adjusted accordingly.

#### ▶ Pentobarbital

Barbiturate infusions are reported to be highly effective in treating RSE,[28] but they cause significant hypotension, myocardial and respiratory depression, ileus, and infections. Therefore, patients require mechanical ventilation and invasive hemodynamic monitoring. Patients often require IV **vasopressor** therapy and total parenteral nutrition. Barbiturates are beneficial in decreasing elevated intracranial pressure (ICP).

A meta-analysis reported a lower incidence of treatment failure with pentobarbital (3%) compared to midazolam (21%) or propofol (20%), although the risk of hypotension requiring vasopressor therapy was higher with pentobarbital.[28] This relative efficacy for pentobarbital must be considered together with its complications when determining which agent to use. Patients who fail midazolam and/or propofol should be switched to pentobarbital.

#### ▶ Levetiracetam

Although not FDA-approved for SE, levetiracetam does not have the cardiopulmonary, hepatic, and sedative side effects seen with the other agents; nor does it have potentially harmful drug interactions. Both IV[29] and oral[30] formulations have been used in RSE patients as add-on therapy with some success, although it is unclear if levetiracetam would be effective as monotherapy.[31] LDs up to 2000 mg over 15 to 30 minutes in the critically ill have been given with very little toxicity.[32]

#### ▶ Other Agents

Ketamine,[33] topiramate, and inhaled anesthetics have also been used for RSE. Ketamine is an NMDA receptor antagonist that has been given orally[34] and intravenously[35] for RSE in children. Topiramate is an oral AED with multiple mechanisms of action in RSE. The oral dose in adults ranges from 300 to 1600 mg/day.[36] Children have also been administered topiramate at a starting dose of 2 to 3 mg/kg/day and titrated to a maintenance dose of 5 to 6 mg/kg/day.[16] Topiramate can induce metabolic acidosis, requiring careful monitoring. The inhaled anesthetics, desflurane and isoflurane,[37] require special equipment for administration in an ICU. Lacosamide, an enhancer of slow inhibition of sodium channels, has limited drug interactions.[38] It has been used orally[39] and intravenously[40] in the setting of refractory partial SE.

### Special Populations

Certain patients require special considerations due to their altered metabolism, unique volume of distribution, or increased risk for side effects.[41] Although many of these patients are excluded from clinical trials in SE, the standard algorithm for SE still applies in terms of immediate care, assessment, and drugs (see Table 32–2).

#### ▶ Pediatrics

The treatment approach for SE in children is similar to that in adults with a few exceptions (see Table 32–3). The doses are also weight-based but are typically higher than those used in adults due to faster hepatic clearance. Timely IV access in children may be difficult, so alternate routes of administration have been used,

including intranasal, buccal, rectal, and IM. Early administration of benzodiazepines and reduced time to hospital admission are important in decreasing prolonged seizures.[42]

▶ **Geriatrics**

Older adults are often vulnerable because of multiple disease states and polypharmacy. Seizures in older adults often arise from metabolic disorders, drug interactions, or incorrect dosing of medications in patients with impaired renal and hepatic function and decreased protein binding. Clinicians treating older adult patients with SE should investigate drug- and disease state–induced causes, since treating these etiologies alone may terminate seizures. Acute treatment with benzodiazepines and AEDs is no different in older adults, but they may experience more profound sedative and cardiorespiratory side effects. Phenytoin and fosphenytoin LDs should be carefully calculated in older adults whose weights may be overestimated, and who may not tolerate high doses. They should also be infused more slowly to minimize hypotension and arrhythmias. Phenobarbital may cause respiratory depression earlier in older adults, especially after benzodiazepines. Clinicians should consider using smaller doses and evaluate for renal and hepatic insufficiency if repeated doses are to be given.

▶ **Pregnancy**

The main concern in the treatment of pregnant females in SE is the safety of the fetus which is at risk of hypoxia during periods of prolonged seizures. Although many drugs used in SE are **teratogenic,** clinicians should still use them acutely to stop seizures, but consider alternative agents for maintenance therapy.[43] The volume of distribution and clearance of many drugs are increased during pregnancy, and this must be considered when calculating doses.

## OUTCOME EVALUATION

Start pharmacologic treatment as soon as possible.

- First-line (emergent) treatment for SE should halt seizure activity within minutes of administration.
- In patients who are unarousable following treatment, confirm termination of seizures with an EEG.
- Perform a physical exam and evaluation of the patient's laboratory results to help determine if the cause or complications of seizure activity are being appropriately treated.

Once seizure activity has ceased and the patient has stabilized, review the patient's therapeutic regimen.

- Evaluate and monitor serum trough concentrations of AEDs with defined target ranges to determine patient-specific therapeutic goals.
- In patients with RSE on multiple AEDs, slowly decrease the dose of one drug at a time while continuing to evaluate the patient for seizure activity.
- Continue to monitor AED serum trough concentrations approximately every 3 to 5 days until the AEDs have reached steady-state concentrations.
- Monitor for signs of drug toxicity and seizures until drug concentrations have stabilized.
- Closely evaluate medication profiles, and change drugs or doses to minimize any drug interactions, if possible.

---

### Patient Care Process

**Patient Assessment:**

- Based on physical exam and review of systems, determine whether the patient is in SE.
- Obtain a medical history to elucidate precipitating factors. Does the patient have epilepsy?
- Review laboratory data, including any recent anticonvulsant levels. Is there evidence of alcohol or illicit drug use?
- Review vital signs, oxygen saturation, and point of care glucose testing.

**Therapy Evaluation:**

- Correct reversible causes of status epilepticus. Is the patient hypoxic, hypoglycemic or hyponatremic? If the patient is taking anticonvulsants, are the patient's serum levels therapeutic? Is the patient taking illicit or toxic substances?
- Determine whether patient has cardiovascular or respiratory compromise.
- If the patient is taking anticonvulsants, assess efficacy, safety, and adherence.
- Identify and address drug interactions.
- If a patient has an anticonvulsant allergy or a genetic predisposition that increases adverse reactions, identify alternative agents.

**Care Plan Development:**

- Conduct a thorough medication history, including prescription, nonprescription, and alternative drugs as well as herbal/dietary supplement use. Does the patient take anticonvulsants? Is the patient adherent? Does the patient have any allergies?
- Provide therapeutic doses of emergent and urgent therapies within the appropriate time frame (see Tables 32–1 and 32–2). Is the patient a child or older adult? Is the patient obese or pregnant?
- Identify drug interactions with current drug therapy and adjust as needed.
- Obtain expertise of neurologist or epileptologist when appropriate.

**Follow-up Evaluation:**

- Determine if physical seizures have stopped and the patient regains consciousness. If not, consider continuous EEG monitoring for at least 24 to 48 hours to identify possible nonconvulsive SE.
- Obtain serum anticonvulsant levels at steady state; sooner if patient continues to have seizures. Obtain trough concentrations when possible.

## Abbreviations Introduced in This Chapter

| | |
|---|---|
| ABG | Arterial blood gas |
| AED | Antiepileptic drug |
| CNS | Central nervous system |
| CSF | Cerebrospinal fluid |
| CT | Computerized tomography |

ECG        Electrocardiogram
EEG        Electroencephalography
GABA       γ-aminobutyric acid
GCSE       Generalized convulsive status epilepticus
ICP        Intracranial pressure
ICU        Intensive care unit
IM         Intramuscular
IV         Intravenous
LD         Loading dose
MRI        Magnetic resonance imaging
NCSE       Nonconvulsive status epilepticus
NMDA       $N$-methyl-D-aspartate
PE         Phenytoin equivalent
RSE        Refractory status epilepticus
SE         Status epilepticus
WBC        White blood cell

# 33 Parkinson Disease

Thomas R. Smith and Mary L. Wagner

## LEARNING OBJECTIVES

- **Upon completion of the chapter, the reader will be able to:**

1. Describe the pathophysiology of Parkinson disease (PD) related to neurotransmitter involvement and targets for drug therapy in the brain.

2. Recognize the cardinal motor symptoms of PD and determine a patient's clinical status and disease progression based on the Movement Disorder Society Unified Parkinson Disease Rating Scale (MDS UPDRS).

3. For a patient initiating therapy for PD, recommend appropriate drug therapy and construct patient-specific treatment goals.

4. Recognize and recommend appropriate treatment for nonmotor symptoms.

5. Formulate a plan to minimize patient "off-time" and maximize "on-time" including timing, dosage, and frequency of medications.

6. Recognize and treat various motor complications that develop as PD progresses.

7. Construct appropriate patient counseling regarding medications and lifestyle modifications for a patient with PD.

8. Develop a monitoring plan to assess effectiveness and adverse effects of treatment.

## INTRODUCTION

**KEY CONCEPT** *P*arkinson disease (PD) is a slow, progressive neurodegenerative disease of the extrapyramidal motor system. Dopamine neurons in the sub-stantia nigra are primarily affected, and degeneration of these neurons causes a disruption in the ability to generate body movements. Cardinal features of PD include tremor at rest, rigidity, akinesia/bradykinesia, and postural instability. There is no cure, and treatment is aimed at controlling symptoms and slowing disease progression.

## EPIDEMIOLOGY AND ETIOLOGY

PD affects approximately 1 million Americans, and a lifetime risk of developing the disease is 1.5%. Median age of onset is 60 years, but about 10% of people with PD are younger than 45 years. The average duration of time from diagnosis to death is about 15 years. Approximately 15% of patients with PD have a first-degree relative with the disease.[1,2]

The etiology of neuron degeneration in PD remains unknown, but aging has been implicated as a primary risk factor. Other explanations for the cell death may include oxidative stress, mitochondrial dysfunction, increased concentrations of excito-toxic amino acids and inflammatory cytokines, immune system disorders, trophic factor deficiency, signal-mediated apoptosis, and environmental toxins. Conditions that may promote oxida-tive stress include increased monoamine oxidase-B (MAO-B) metabolism or decreased glutathione clearance of free radicals.[2–5]

Genetic mutations such as those in *LRRK2* have been linked to PD, and particular mutations may predict early versus late onset of the disease.[2,3] A combination of inducers of cell death and genetic mutations may be at play in the development of PD.[2] In PD pigmented cells in the substantia nigra that make and store dopamine are lost. When patients are diagnosed, they have lost 50% to 60% of their dopamine neurons located here, and the remaining neurons elsewhere in the central nervous system (CNS) may be dysfunctional. Neurons have lost about 80% of their activity in the striatum at the onset of PD. Cortical Lewy bodies along with Lewy neurites in various CNS locations as well as the GI system may explain some of the nonmotor symptoms of PD.[2,4,5]

## PATHOPHYSIOLOGY

The extrapyramidal motor system controls muscle movement through pathways and nerve tracts that connect the cerebral cortex, basal ganglia, thalamus, cerebellum, reticular formation, and spinal neurons. Patients with PD lose dopamine neurons in the substantia nigra, located in the midbrain within the brainstem. The substantia nigra sends nerve fibers to the corpus striatum, which is part of the basal ganglia in the cerebrum. The corpus striatum is made up of the caudate nucleus and the len-tiform nuclei that consist of the pallidum (globus pallidus) and putamen (Figure 33–1). As dopamine neurons die, dopamine-relayed messages cannot communicate to other motor centers of the brain, and patients develop motor symptoms. A variety
**FIGURE 33–1.** Anatomy of the extrapyramidal system. The extrapyramidal motor system controls muscle movement through a system of pathways and nerve tracts that connect the cerebral cortex, basal ganglia, thalamus, cerebellum, reticular formation, and spinal neurons. Patients with PD have a loss of dopamine neurons in the substantia nigra in the brainstem that leads to depletion of dopamine in the corpus striatum. The corpus striatum is made up of the caudate nucleus and the lentiform nuclei that are made up of the putamen and the globus pallidus.

of neurotransmitters are active in the basal ganglia, and their concentrations decrease with degeneration. These changes may explain some of the nonmotor symptoms seen in PD.[2,5,6] For example, loss of dopamine and norepinephrine neurons in the limbic system is associated with depression and anxiety, while loss of these neurotransmitters along with acetylcholine and serotonin in the limbic system and other regions is associated with cognitive impairment.[7]

## Clinical Presentation of PD

Patients with PD display both motor and nonmotor symptoms. The nonmotor symptoms may precede the motor symptoms.

**Motor Symptoms (Mnemonic TRAP)**

T = Tremor at rest ("pill rolling")

R = Rigidity (stiffness and cogwheel rigidity)

A = Akinesia or bradykinesia

P = Postural instability and gait abnormalities

**Nonmotor Symptoms (Mnemonic SOAP)**

S = Sleep disturbances (insomnia, REM sleep behavioral disorder, restless legs syndrome [RLS])

O = Other miscellaneous symptoms (problems with nausea, fatigue, speech, pain, dysesthesias, vision, seborrhea)

A = Autonomic symptoms (drooling, constipation, sexual dysfunction, urinary problems, sweating, orthostatic hypotension, dysphagia)

P = Psychological symptoms (anxiety, psychosis, cognitive impairment, depression)

**Response Fluctuations (Mnemonic MAD)**

M = Motor fluctuations (delayed peak, wearing off, random off, freezing)

A = Akathisia

D = Dyskinesias (eg, chorea, dystonia, diphasic dyskinesia)

## Patient Encounter, Part 1: Initial Visit—Medical History

A 68-year-old woman with a 5-year history of PD, comes in for an initial visit at the movement disorder clinic due to complaints of worsening symptoms. She was last seen 6 months ago by her family doctor where her UPDRS score was 40 (while on). The only change made to her medications at that time was the addition of prochlorperazine for nausea. Since her last visit, she has noticed a tremor in both hands instead of only her left hand as it was previously. During her off periods, she says her muscles are "stiff as a board," and she moves very slowly and has trouble maintaining balance occasionally. This affects her in the kitchen preparing food, and she is unable to walk her dog, an activity she enjoys that also provides her exercise. She reports a history of constipation that is somewhat improved from increased dietary fiber. Recently, she has had to use the restroom more often at night which disrupts her sleep.

*Identify this patient's motor and nonmotor symptoms of PD.*

*What additional information would you collect before creating this patient's treatment plan?*

The disease may begin in the autonomic system, olfactory system, or vagus nerve in the lower brainstem and then spread to the upper brainstem and cerebral hemisphere affecting dopamine pathways later in the course of disease progression.[2] It is essential to rule out drug-induced pseudoparkinsonism. Offending agents include drugs that deplete dopamine such as antipsychotics, metoclopramide, and certain antiemetics such as prochlorperazine. Removing the offending agent generally resolves symptoms.[1,8]

## CLINICAL PRESENTATION AND DIAGNOSIS

The diagnosis of PD is based substantially on signs and symptoms rather than diagnostic tests or imaging. A single-photon emission computed tomography scan in conjunction with DaTscan,

a radiopharmaceutical contrast agent, may help differentiate PD from other disorders such as essential tremor, but not from similar Parkinson-plus syndromes such as multiple system atrophy or progressive nuclear palsy.[9] Therefore, a thorough patient history and detailed description of symptom onset is essential in making an accurate diagnosis.

## Motor Symptoms

**KEY CONCEPT** *PD is a slow, progressive neurodegenerative disease of the extrapyramidal motor system with classic motor symptoms of tremor, rigidity, akinesia/bradykinesia, and postural/gait instability (TRAP).*

The onset of PD is gradual, and impairment of movement may go unnoticed initially. Tremor occurs during rest and disappears with purposeful movement. The hand tremor can appear as if the patient is rolling a pill between his or her fingers. Patients usually describe rigidity as stiffness, and muscles often display uniform resistance on examination. Cogwheel rigidity is found when the examiner extends or flexes the patient's extremities and feels rhythmical jerking as if hitting a series of teeth on the rim of a wheel. Bradykinesia is defined as hesitancy in movement initiation, slowness in movement performance, or rapid fatiguing during movement. Patients may have a decrease in automatic movements, such as eye blinking, hypomimia, or a decrease in arm swing while walking. Postural instability results from the loss of reflexes necessary to maintain balance when ambulating. Stooped posture resulting in unsteadiness is common. Gait abnormalities may include slow shuffling, leg dragging, festination, propulsion, retropulsion, or freezing. Rigidity and bradykinesia may make handwriting difficult as evidenced by micrographia.[2,10–14]

## Nonmotor Symptoms

Nonmotor symptoms associated with PD may precede the onset of motor symptoms by many years. These commonly include sleep disturbances, autonomic impairment, psychological disturbances, and others such as anosmia or sensory disturbances. Nonmotor symptoms may be a result of PD itself or medications.[2,6,10,15–21]

Speech problems may manifest as hypophonia, slurring, monotone speech, rapid speech, or stammering. Visual problems such as difficulty reading, double vision, decreased blinking, and burning or itchy eyes are the result of impairment of the ocular mucles.[2,6,10–14]

Because the autonomic nervous system is disturbed in PD, orthostatic hypotension, gastrointestinal (GI), urinary, sexual, and dermatologic symptoms are common. Orthostatic hypotension may cause dizziness, lightheadedness, fainting upon standing, or fall-related injuries. GI symptoms include constipation and dysphagia. Swallowing difficulties may lead to weight loss, sialorrhea, and aspiration.[15,17] Genitourinary symptoms include incontinence, urgency, and frequency. Symptoms may worsen at night, causing nocturia. Sexual dysfunction manifests as decreased libido or inability to achieve orgasm in both sexes and erectile or ejaculatory dysfunction in men. Dermatologic symptoms include sweating and intolerance to temperature changes.[2,6,10,15,17]

Psychological symptoms—psychosis, dementia, impaired cognitive function, depression, and anxiety—may occur during the natural course of PD, during symptom exacerbation, or as adverse effects from medications. Psychosis occurs in nearly 30% of PD patients and may include vivid dreams, hallucinations, paranoia, and delusions. Psychosis is rarely seen in untreated

patients. Dementia and depression occur frequently with the latter likely due to abnormalities in dopamine and serotonin activity. Some features of PD, such as decreased facial expression and bradykinesia, may make the diagnosis of depression more difficult. Often comorbid with depression, anxiety has been noted in up to 66% of patients with motor fluctuations.[2,7,15,18–20]

Sleep disorders occur commonly and may be due to loss of neuronal functioning or medication adverse effects. Excessive daytime sleepiness, insomnia, and abnormal sleep events, such as rapid eye movement (REM) sleep behavior disorder (RBD) may occur.[10,15,16]

## Motor Complications

Motor complications occur with disease progression as dopamine reserves are depleted and as a complication of treatment, particularly with levodopa. Motor complications include delayed peak response, early and unpredictable "wearing off," freezing, and dyskinesias. Dyskinesias include chorea and dystonia. Risk factors for developing motor complications include younger age at diagnosis, high dosage of levodopa, and longer duration and severity of disease. Wearing off can be conceptualized as the therapeutic window of levodopa narrowing over time. The therapeutic window is defined as the minimum effective concentration of levodopa required to control PD symptoms ("on" without dyskinesia) and the maximum concentration before experiencing side effects from too much levodopa ("on" with dyskinesia). Although the plasma half-life of levodopa is 1.5 to 2 hours, the therapeutic effect in early PD lasts about 5 hours, and the patient experiences no dyskinesias. This is due to supplemental dopamine production in the CNS. As PD progresses, this endogenous supply is decreased, the therapeutic window narrows, and each dose of levodopa acts unpredictably, with the therapeutic effect lasting only 2 to 3 hours. Dyskinesias become more likely to occur during the on state.[5,21,22]

**KEY CONCEPT** *The most useful diagnostic tool is the clinical history, including both presenting symptoms and associated risk factors. The Movement Disorder Society modified the previous Unified Parkinson Disease Rating Scale (MDS UPDRS), and it can be used to describe total symptom burden, track disease progression, and assess treatment efficacy.* This clinician and patient rated scale has four parts that can be used individually or in combination. It evaluates nonmotor symptoms associated with PD, activities of daily living (ADL), motor symptoms, and complications of therapy. Each symptom is given a numerical score from 0 to 4 (none to severe). It takes about 30 minutes to complete, so it may not be collected in its entirety at each visit.[23]

## TREATMENT
### Desired Outcomes

**KEY CONCEPT** *The goals of treatment include:*

- *maintaining patient independence, ADL, and quality of life (QOL)*
- *minimizing the development of response fluctuations*
- *limiting medication-related adverse effects*

### General Approach to Treatment

**KEY CONCEPT** *Treatment of PD is categorized into three types: (1) lifestyle changes, nutrition, and exercise; (2) pharmacologic intervention, primarily with drugs that enhance dopamine concentrations; and (3) surgical treatments for those who fail pharmacologic interventions.*

Initial treatment depends on the patient's age, risk of adverse effects, degree of physical impairment, and readiness to initiate therapy. Initiating therapy with levodopa may be more beneficial for mobility than starting with a MAO-B inhibitor or dopamine agonists.[24]

The 2002 American Academy of Neurology guidelines and 2006 European National Institute for Health and Clinical Excellence guidelines suggest that symptomatic treatment should be delayed until the patient experiences functional disability.[25,26] Some data, however, suggest that earlier treatment may delay the progression of disease. In support of this, some clinicians note that progression of symptoms occurs most rapidly around the time of diagnosis and in early PD, and slows later in the disease.[27,28] However, studies examining this have design flaws and inconsistent results.[12,14] Until current clinical practice guidelines are revised, one must weigh the pros and cons of delaying pharmacotherapy or starting medications early on an individual patient basis.[25]

## Nonpharmacologic Therapy

### ▶ Lifestyle Modifications

Nonpharmacologic therapy, including education and lifestyle modifications such as exercise, should be started early and continued throughout treatment for PD. These treatments may improve ADLs, gait, balance, and mental health. The most common interventions include maintaining good nutrition, physical condition, and social interactions.[1,10] Coordinated care with an optometrist/ophthalmologist, dentist, dietician, physical therapists, speech therapist, and social worker is needed to maximize patient outcomes. Each of these specialists plays a specific role in the treatment team (Table 33–1).[30]

## Surgery

As patients develop inadequate control of motor symptoms despite medical treatment, surgery with deep brain stimulation (DBS) may be considered. This procedure electrically stimulates the subthalamic nucleus or globus pallidus interna. DBS may significantly reduce motor symptoms and complications and improve QOL compared to medication management. Trials indicate that targeting the subthalamic nucleus is preferred when a decrease in PD medication use is desired while targeting the globus pallidus may be better suited when dyskinesias are present.[31,32] These surgeries are not without risk and are generally

### Patient Encounter, Part 2: Initial Visit— Physical Examination and Diagnostic Tests

**Chief Complaint:** Increased tremor, rigidity, and slowness, postural instability

**PMH:** Constipation for greater than 10 years

**SH:** Retired. Lives with husband and has two children. Denies alcohol use. Denies smoking

**Meds:** Carbidopa/levodopa 10 mg/100 mg orally—two tablets at 7 AM, one tablet at noon, and one tablet at 7 PM; prochlorperazine 10 mg orally three times a day

**ROS:** (–) Agitation, depression, or psychosis; reports nausea, denies vomiting, diarrhea, HA, dizziness, or pain

**PE:**

**Gen:** Flat affect, looks older than stated age, speaks softly and often difficult to hear, slow, shuffling gait

**VS:** BP: sitting 125/80 mm Hg, standing 105/70 mm Hg; P 65 beats/min, RR 18/min, Wt 59 kg (130 lb), Ht 165 cm (65 in)

**HEENT:** Decreased eye blinking and facial expression, CN II-XII intact, PERRLA, TMs intact

**CV:** RRR, normal S1, S2; no murmurs, rubs, gallop

**Abd:** Soft, nontender, nondistended; (+) bowel sounds, no hepatosplenomegaly

**Skin:** Normal

**Exts:** Mild tremor in both hands and feet. Cogwheel rigidity bilateral elbows, no edema

**Neuro:** Slow, shuffling gait, sensory function intact, normal muscle strength, normal reflexes, alert, mental status examination normal

**Rating Scales:** Mini Mental Status Exam (MMSE) = Normal 29/30; UPDRS = 50 while "on"

**Labs:** Normal metabolic profile and CBC

*Given this additional information, what is your assessment of the patient's condition?*

*Identify treatment goals for the patient.*

*Describe nonpharmacologic and pharmacologic treatments that are available for the patient.*

---

### Table 33–1

**Specialist Care for Patients with PD**

| Provider | Reason for Referral |
| --- | --- |
| Dentist | PD medications may decrease saliva flow and increase the risk of dental caries |
| Dietician | Recommend appropriate caloric intake, meal selection, and protein consumption which may: <br>• improve constipation and nausea <br>• decrease weight loss and aspiration <br>• minimize erratic drug absorption |
| Speech therapist | Improved swallowing, articulation, and force of speech |
| Physical therapy | Improve strength, activity, sleep quality and reduce fall risk <br>May provide neuroprotection |
| Occupational therapist | Educate on adaptive environment of home, specialized clothing, and personal training to evaluate and maximize: <br>• Independence <br>• Safety <br>• ADLs <br>• Handwriting <br>• Driving ability <br>• Use of communication software |
| Social worker | Arrange for community assistance programs <br>Increase engagement in family activities, and minimize conflict through family counseling |

utilized after complications with or poor response to medication management.

## Pharmacologic Therapy

KEY CONCEPT *Drug therapy is aimed at enhancing dopaminergic activity in the substantia nigra. The best time to initiate dopaminergic therapy is controversial and patient specific.* Medications help minimize motor symptoms, and improve QOL and ADLs, but they are not curative (Table 33–2).[1,2,33,34] PD patients with optimal treatment have greater mortality and morbidity than the general population.[1]

KEY CONCEPT *Choice of pharmacologic agent should be individualized based on patient-specific parameters, and dose frequency should be scheduled based on individual response to maximize "on time" and minimize "off time".*

Pharmacologic options for PD include anticholinergics (Ach), amantadine, MAO-B inhibitors, dopamine agonists, levodopa/carbidopa, and catechol-*O*-methyltransferase (COMT) inhibitors. Because most pharmacologic treatments in PD aim to avoid degeneration of the dopaminergic nigrostriatal pathway,

it is essential to understand how all drugs may affect dopamine concentrations (Figure 33–2). The American Academy of Neurology and the Movement Disorder Society determined that it is reasonable to start treatment with either levodopa or a dopamine agonist.[11–15]

Choice of agent varies based on clinical experience and patient preference. Starting with a dopamine agonist may help to delay the onset of dyskinesias and the on and off fluctuations seen with long-term levodopa use. However, this approach may result in less motor benefit and greater risk of hallucinations or somnolence. Levodopa results in greater motor improvement and should be used as initial therapy in the elderly (greater than 75 years) and in those with cognitive impairment.[28] Data are insufficient to recommend initiating treatment with combined levodopa and a dopamine agonist. Initiating treatment with anticholinergic medications, amantadine, or MAO-B inhibitors is recommended only for patients who have mild symptoms because they are not as effective as dopamine agonists or levodopa.[1,2,11–15,33,34]

Medications should be started at the lowest dose and increased gradually based on symptoms (see Table 33–2). Adjust dose timing, frequency, or both based on the patient's report of "on

### Table 33–2

**Dosing of Medications Used to Treat PD**

| Generic Name (Trade Name) | Initial Dose | Titration and Maintenance Dose | Available Formulations | Hepatic or Renal Adjustments |
|---|---|---|---|---|
| **Levodopa Formulations** | | | | |
| Levodopa with carbidopa (Sinemet) | Half tablet (100 mg LD, 25 mg CD) twice daily for 1 week, then half tablet three times daily | Increase by half tablet daily every week; usual MD is 300–2000 mg daily; because the duration of LD is 2–3 hours, patients may require doses every 2 hours. | Parcopa—orally disinteg rating LD Duodopa—Portable pump that continuously delivers LD and carbidopa via a duodenal tube—in phase III trials in the US Stalevo—CD/LD/Entacapone tablet | |
| Sinemet CR | One tablet (100 mg LD, 25 mg CD) two to three times daily | Increase to 200 mg LD tablet two to four times daily; usual MD is 200–2200 mg daily. | Sustained-release tablet | |
| Rytary (extended-release levodopa with carbidopa) | In levodopa naïve patients: 23.75 mg/95 mg taken orally three times a day for the first 3 days | On the fourth day of treatment, the dosage may be increased to 36.25 mg/145 mg taken three times a day. Individual doses may be increased and doses may be given up to five times a day based on individual response; patients previously on immediate release levodopa should follow recommended conversions. | Extended-release capsule | |
| **Dopamine Agonists** | | | | |
| Apomorphine (Apokyn) | Start an antiemetic for 3 days; then give apomorphine 2 mg SC injection (1 mg if outpatient) while monitoring blood pressure | Increase by 1–2 mg every ≥ 2 hours; usual MD is 2–6 mg three to five times daily for off periods. | Subcutaneous solution | Reduce initial dose to 1 mg in mild to moderate renal failure. |
| Bromocriptine (Parlodel) | 1.25 mg twice daily | Increase by 2.5 mg daily every 14 to 28 days. | Capsule, tablet | Dosing adjustments may be necessary with hepatic impairment. |

*(continued)*

| Table 33–2 | | | | |
|---|---|---|---|---|
| **Dosing of Medications Used to Treat PD (*Continued*)** | | | | |
| **Generic Name (Trade Name)** | **Initial Dose** | **Titration and Maintenance Dose** | **Available Formulations** | **Hepatic or Renal Adjustments** |
| Pramipexole (Mirapex) | 0.125 mg three times daily | Increase about weekly by 0.375–0.75 mg/day to a MD of 0.5–1.5 mg three times daily. | Tablet | Dosage reduction needed in creatinine clearance < 50 mL/min (0.83 mL/s). |
| Mirapex ER | 0.375 mg once daily | Increase up to 0.75 mg/day after a minimum of 5 days. Dose may then be increased in increments of 0.75 mg/day no more frequently than every 5–7 days. | Extended-release tablet | |
| Ropinirole (Requip) | 0.25 mg three times daily | Increase about weekly by 0.75–1.5 mg daily to a MD dose of 3–9 mg three times daily. Then may increase by 3 mg/day on a weekly basis to a maximum of 24 mg/day. | Tablet | |
| Requip XL | 2 mg once daily for 1–2 weeks | Increase by 2 mg/day in 1-week intervals; maximum dose is 24 mg/day. | Extended-release tablet | |
| Rotigotine (Neupro) | 2 mg patch once daily for early-stage PD; 4 mg patch for advanced-stage PD | Increase by 2 mg/24 hours on a weekly basis. | Patch | |
| **MAOIs** | | | | |
| Selegiline (Eldepryl) | 5 mg in the morning | If symptoms continue, add 5 mg at noon; 5 mg daily may be as clinically effective as 10 mg daily with fewer side effects. | Tablet, capsule | Use is not recommended for creatinine clearance < 30 mL/min (0.50 mL/s) or severe hepatic impairment. |
| Selegiline ODT (Zelapar) | 1.25 mg once daily | If symptoms continue after 6 weeks, increase dose to 2.5 mg every morning. Avoid food or liquid for 5 minutes before or after the dose. | Dispersable tablet | |
| Rasagiline (Azilect) | If used with levodopa, 0.5 mg daily | If symptoms continue, increase to 1 mg daily. | Tablet | Use 0.5 mg/day in mild hepatic impairment. Do not use in moderate to severe impairment. |
| **COMT Inhibitors** | | | | |
| Tolcapone (Tasmar) | 100 mg with first Sinemet dose once daily | If symptoms continue, increase to 2 and then 3 times daily, then to 200 mg each dose; usual MD is 100–200 mg three times daily. | Tablet | Do not use in patients with active liver disease or SGPT/ALT or SGOT/AST > the upper limit of normal. |
| Entacapone (Comtan) | 200 mg tab with each Sinemet dose | Usual MD is 200 mg three to four times daily (up to eight tablets per day). | Tablet | Decrease dose by 50% with hepatic impairment. |
| **Others** | | | | |
| Amantadine (Symmetrel) | 100 mg daily at breakfast | After 1 week, add 100 mg daily; usual MD is 200–300 mg daily with last dose in afternoons. | Capsule, tablet, oral syrup | Decrease dose for creatinine clearance < 80 mL/min (1.33 mL/s) |
| Benztropine (Cogentin) | 0.5 to 1 mg at bedtime | Assess if dose is adequate and titrate by 0.5 mg increments at 5- to 6-day intervals to a maximum of 6 mg if necessary. | Tablet, solution for injection | |

Ach, acetylcholine; CD, carbidopa; COMT, catechol-*O*-methyltransferase; DA, dopamine; LD, levodopa; MAO, monoamine oxidase; MD, maintenance dose; NMDA, *N*-methyl-D-aspartate.

Data from Refs. 1, 2, 33, 34, and 35.
**FIGURE 33–2.** Levodopa absorption and metabolism. Levodopa is absorbed in the small intestine and distributed into the plasma and brain compartments by an active transport mechanism. Levodopa is metabolized by dopa decarboxylase, monoamine oxidase, and catechol-*O*-methyltransferase. Carbidopa does not cross the blood–brain barrier. Large neutral amino acids in food compete with levodopa for intestinal absorption (transport across gut endothelium to plasma). They also compete for transport into the brain (plasma compartment to brain compartment). Food and Ach delay gastric emptying resulting in levodopa degradation in the stomach and a decreased amount of levodopa absorbed. If the interaction becomes a problem, administer levodopa 30 minutes before or 60 minutes after meals.

time" duration and wearing off symptoms. Dyskinesias related to dopamine concentrations can be managed by decreasing the dose, frequency, or use of medications that may enhance dopamine concentrations. If a dopaminergic medication is to be discontinued, it should be decreased gradually and the patient monitored for worsening of symptoms.

### ► *Anticholinergics*

Anticholinergics (Ach) block acetylcholine, decreasing the acetylcholine to dopamine concentration ratio. They minimize resting tremor and drooling, but are not as effective as other agents for rigidity, bradykinesia, and gait problems. Side effects include dry mouth, blurred vision, constipation, cognitive impairment, hallucinations, urinary retention, orthostatic hypotension, temperature sensitivity, and sedation. They are usually avoided or used with caution in patients older than 70 years because of an increased risk of cognitive impairment.[1,2,10,29,33] Ach should be discontinued gradually to avoid withdrawal effects or worsening of symptoms. Additionally, Achs may be associated with an increased incidence of amyloid plaques and neurofibrillary tangles in patients with PD. There is concern that this may translate to an increased risk of Alzheimer disease.[36] Ach decrease gastric motility, which may delay gastric emptying and lead to erratic and decreased levodopa absorption.[37]

### ► *Amantadine*

Amantadine is an *N*-methyl-D-aspartate (NMDA)-receptor antagonist that blocks glutamate transmission, promotes dopamine release, and blocks acetylcholine. It improves PD symptoms in mildly affected patients and may reduce dyskinesia severity and duration.[22,38,39] Patients who develop tolerance to amantadine's effects may benefit from a drug holiday through a gradual taper to discontinuation to minimize withdrawal effects. Side effects include nausea, dizziness, livedo reticularis, peripheral edema, orthostatic hypotension, hallucinations, restlessness, anticholinergic effects, and insomnia. It should be avoided in the elderly who cannot tolerate its anticholinergic effects.[29,33,39]

### ► *MAO-B Inhibitors*

Selegiline and rasagiline selectively and irreversibly block MAO-B metabolism of dopamine in the brain. They may provide a mild symptomatic benefit for patients who choose to delay dopaminergic medications, and they reduce off time when added to levodopa therapy.[10–13,39] Combining selegiline or rasagiline with levodopa in early treatment may delay motor complications.[22,27,40]

Both rasagiline and selegiline are thought to be neuroprotective, but there is no evidence to validate this.[41]

Selegiline is available in an orally disintegrating tablet designed to avoid first-pass metabolism. This improves bioavailability and

decreases serum concentrations of its amphetamine-like metabolite. This metabolite may improve fatigue but conversely may cause insomnia. Thus selegiline should not be dosed in the late afternoon or evening. Side effects of selegiline are minimal but include nausea, confusion, hallucinations, headache, jitteriness, and orthostatic hypotension. Daily doses are limited to 10 mg because MAO-B selectivity may be lost at higher doses increasing the risk of adverse effects and drug interactions.[27,28]

Rasagiline is less likely to cause insomnia because it is not metabolized to amphetamines. Side effects are primarily GI related. The labeling of rasagiline states that restriction of tyramine-containing foods is not ordinarily required at recommended dosages, but certain foods with extremely high levels of tyramine and exceeding recommend dosing of rasagiline may increase the risk of hypertensive crisis.[40]

Dyskinesias can be minimized by decreasing the levodopa dose when adding either of these agents. Because of risks of serotonin syndrome and hypertensive crisis, patients should avoid or use these medications cautiously with narcotic analgesics, antidepressants, and other serotonergic agents, or sympathomimetic amines (cold and weight loss products).[27,28]

### ▶ Dopamine Agonists

Dopamine agonists bind to postsynaptic dopamine receptors. They are useful as initial therapy, as suggested by the 2010 Scottish Intercollegiate Guidelines. Their advantages include delay of levodopa therapy and smaller risk of developing motor fluctuations during the first 4 to 5 years of treatment. Eventually, they inadequately control the patient's symptoms, and levodopa will need to be started. In advanced disease, they can be added to levodopa to minimize response fluctuations, decrease off time, improve wearing-off symptoms, allow a reduction in levodopa dose, and improve ADLs.[1,2,11,13,34,42]

Dopamine agonists include the ergot derivatives (bromocriptine) and the nonergot derivatives (rotigotine, pramipexole, ropinirole, and apomorphine). Generally, the nonergot agents are chosen first over bromocriptine due to a more favorable adverse effect profile and stronger evidence of efficacy.[43] If patients fail one dopamine agonist, another can be tried. Although not well established, it appears that bromocriptine 30 mg, ropinirole 15 mg, and pramipexole 4.5 mg are equivalent, and this relationship can be a guide when switching agents. Rotigotine is available as a once-daily skin patch which minimizes pulsatile dopaminergic stimulation.[1,28,29,33,38]

Common side effects include nausea, vomiting, sedation (highest with apomorphine), pedal edema, orthostatic hypotension (highest with pramipexole) and psychiatric effects that are greater than with levodopa (nightmares, confusion, and hallucinations). Uncommon ergot side effects include painful reddish discoloration of the skin over the shins and pleuropulmonary, retroperitoneal, and cardiac fibrosis.[1,29,33,38] Patients' therapy may be complicated by the dopamine dysregulation syndrome (DDS). This includes an addictive pattern of dopamine agonist use, complex stereotyped behavior known as **punding**, and impulse control disorders (ICDs) such as gambling or compulsive shopping. Reducing or eliminating the agonist usually resolves these problems.[44]

Dopamine agonists may cause excessive daytime sleepiness in 50% of PD patients. Sudden sleep attacks may occur and are potentially dangerous if occurring during certain activities such as driving. Modafinil and other agents to promote wakefulness may be used for daytime sleepiness, but use for sleep attacks remains controversial.[32,45]

All dopamine agonists are metabolized by the liver except pramipexole, which is eliminated unchanged in the urine. Ropinirole is metabolized by cytochrome P450 and subject to drug–drug interactions with drugs that induce (eg, smoking) or inhibit (eg, ciprofloxacin, fluvoxamine, and mexiletine) CYP1A2.[29,33]

Apomorphine is used subcutaneously for acute off episodes in advanced PD when rapid rescue therapy is needed. It requires premedication with an antiemetic because it causes nausea and vomiting.[29,33,38]

### ▶ Levodopa/Carbidopa

Although levodopa, a dopamine precursor, is the most effective agent for PD, when to initiate therapy remains controversial. Patients experience a 40% to 50% improvement in motor function with levodopa versus 30% with dopamine agonists.[1,2,28] However, some argue for delaying treatment with levodopa because approximately 70% of patients experience motor complications within 6 years. Others advocate starting therapy sooner because, historically, patients from the pre-levodopa era who delayed starting levodopa until it became available developed dyskinesias earlier than modern era patients. Delaying levodopa therapy in early disease in favor of other agents may not offer short or long-term benefits.[1,21,24,28,29,33]

Levodopa is absorbed in the small intestine and peaks in the plasma in 30 to 120 minutes. Excess stomach acid, food, or anticholinergic medications delay gastric emptying and decrease the amount of levodopa absorbed. Antacids decrease stomach acidity and improve levodopa absorption, while iron products bind levodopa and may reduce its absorption. Levodopa absorption requires active transport by a large neutral amino acid transporter protein (see Figure 33–2). Amino acids in food compete for this transport mechanism. Thus, in advanced disease, avoidance of protein-rich meals in relationship to levodopa doses may be helpful.[1,28,29,33]

Controlled-release (CR) formulations act longer than immediate-release tablets but are absorbed slower. This results in a delayed onset (45–60 minutes) compared with the standard formulation (15–30 minutes); thus patients may require immediate-release tablets or even a liquid formulation when they want a quicker onset of effect, such as with the first morning dose. Because of reduced bioavailability, the total daily dose of CR preparations should be increased by 30%. In early 2015, an extended-release formulation of levodopa (Rytary) was approved. Doses are not directly interchangeable with other levodopa preparations. Its ideal place in therapy is yet to be determined.[1,28,29,33]

Converting patients from oral formulations to enteral or duodenal levodopa administration reduces motor fluctuations and improves UPDRS scores. The levodopa/carbidopa combination can be administered directly to the duodenum via a small tube. This formulation is marketed under the trade name Duodopa in Europe and Canada, but it is unavailable in the United States. It is reserved for advanced PD with severe motor fluctuations.[46]

Levodopa is usually administered as a combination product with carbidopa, a dopa-decarboxylase inhibitor, which decreases the peripheral conversion of levodopa to dopamine. This allows for lower levodopa doses and minimizes levodopa peripheral side effects, eg, nausea, vomiting, anorexia, and hypotension. Carbidopa does not cross the blood–brain barrier and does not interfere with levodopa conversion in the brain. Generally 75 to 100 mg daily of carbidopa is required to adequately block peripheral dopa-decarboxylase. Higher doses of carbidopa may reduce nausea when initiating levodopa.[1,28,28,33]

Initial levodopa side effects include orthostatic hypotension, dizziness, anorexia, nausea, vomiting, and discoloration of urine/sweat. Most of these effects can be minimized by taking levodopa with food and by slowly titrating the dose. Side effects that develop later in therapy include dyskinesias, sleep attacks, impulse control disorders, and psychiatric effects (confusion, hallucinations, nightmares, and altered behavior). Dyskinesias caused by adding other PD drugs to levodopa may be improved by decreasing the levodopa dose.[1,28,29,33]

Because Levodopa is short acting, it has a greater risk of causing end of dose wearing off periods that require medication adjustments. Patients with severe dyskinesias and off periods may achieve more constant blood concentrations (lower peak and higher trough concentrations) with a liquid formulation of levodopa with carbidopa compounded from tablets. This may allow for more precise dosing and improvements in motor symptoms and complications.[28,29,33,46]

### ▶ Catechol–O–Methyltransferase (COMT) Inhibitors

Inhibitors of COMT, an enzyme that catalyzes levodopa to 3–omethyldopa, are added to levodopa/carbidopa to increase levodopa concentrations, extend its half-life, and decrease wearing off time. Using the COMT inhibitors entacapone or tolcapone may allow for a decrease in daily levodopa dose while increasing on time by 1 to 2 hours. Side effects include diarrhea (worse with tolcapone), nausea, vomiting, anorexia, dyskinesias, urine discoloration, daytime sleepiness, sleep attacks, orthostatic hypotension, and hallucinations. Dyskinesias should improve with a decrease in the levodopa dose.[28,29,33]

Tolcapone should be used only in patients who do not tolerate or respond to entacapone due to its hepatic safety profile. Serum liver function tests should be monitored at baseline, every 2 to 4 weeks for 6 months, and then periodically for the remainder of therapy. Patients who fail to show symptomatic benefit after 3 weeks should discontinue tolcapone.[28,33,34]

### ▶ Herbs and Supplements

There is very little support for using creatine, gingko, ginseng, green tea, ginger, yohimbine, or St. John's wort in patients with PD.

Patients should eat a balanced diet and consider a multivitamin with minerals, but supplementation with specific vitamins is generally unceccesary.[9]

## TREATMENT OF NONMOTOR SYMPTOMS

**KEY CONCEPT** *Treatment of nonmotor symptoms should be based on whether they are exacerbated by an off state or might be related to other neurotransmitter dysfunction.*

The treatment of nonmotor symptoms, such as psychological conditions, sleep disorders, and autonomic dysfunction, should include both pharmacologic and nonpharmacologic approaches. Patients should be supported to maintain ADLs, a positive self-image, family communication, and a safe environment.

## Psychological Symptoms

Psychological symptoms and psychosis are potential problems in PD patients. When psychological changes are suspected, potential causes to rule out include infections, metabolic changes, electrolyte disturbances, or toxic exposures.

### ▶ Depression

Depression is extremely common in patients with PD, affecting 40% or more of patients, and it often precedes the disease. Brain catecholamine changes and serotonin dysregulation contribute to depression associated with PD. Although evidence supports efficacy of tricyclic antidepressants in this population, their adverse effect profile limits their use. Alternatively, selective serotonin reuptake inhibitors may be considered because of their increased tolerability. Pramipexole may also improve depression.[19] Antidepressants are also useful for the treatment of anxiety disorders. Because off periods can both precipitate anxiety and worsen depression, therapy should be adjusted to maximize on periods.[2,7,8,15,18]

### ▶ Dementia

Dementia occurs in approximately 80% of patients with PD 20 years after diagnosis, and decreased cholinergic neurotransmission is implicated. Cholinesterase inhibitors may be effective, but the efficacy of memantine is unclear.[2,15,18–20,38]

### ▶ Psychosis

First treat any underlying medical causes for psychosis (infections, electrolyte disturbances). Then gradually decrease and stop low-efficacy PD medications. Antipsychotics should be used cautiously in patients with PD because they may worsen motor symptoms and may increase the risk of death in patients with concurrent dementia. However, if reducing PD medication compromises motor control or does not improve psychosis, low-dose quetiapine (12.5–200 mg) at bedtime may improve psychosis and is preferred with close monitoring for long-term metabolic side effects. Clozapine is also recommended but requires stringent monitoring (see Chapter 37).[2,15,16–20]

## Sleep Problems

Sleep problems and fatigue are common in PD and may be due to medications, uncontrolled PD symptoms, or other causes such as nocturia, sleep attacks during the day, depression, RBD, or restless legs syndrome (RLS). Instruction on good sleep hygiene, improvement in nighttime PD symptoms, or cognitive behavioral therapy may help.[7,15,16]

The rotigotine patch may improve early morning motor function and overall quality of sleep.[47]

Amantadine and selegiline may worsen insomnia, selegiline and tricyclic antidepressants may worsen REM sleep, and some antidepressants and antipsychotics may worsen RLS. Melatonin may improve patient perception of sleep, but this has not been fully validated. Levodopa/carbidopa reduces nighttime periodic leg movements; while data regarding nonergot dopamine agonists are lacking in patients with PD. When iron is used for RLS, it may decrease the absorption of levodopa and increase constipation. A nighttime dose of a COMT inhibitor may improve RLS.[2,6,16]

## Autonomic and Other Problems

Drooling may be accompanied by speech problems and dysphagia. Ach, botulinum toxin injections, and sublingual atropine can decrease drooling. Nausea improves if PD medications are taken with meals and with antiemetic therapy (eg, domperidone or trimethobenzamide).

Sexual dysfunction or urinary problems may require further evaluation. Adjustment of PD therapy to increase on time, removal of drugs that decrease sexual response, and pharmacologic therapy (eg, sildenafil) may improve sexual dysfunction. Studies of sexual dysfunction in women with PD are lacking.

Patients with urinary frequency may find a bedside urinal and a decrease in evening fluid intake helpful. Improvement in PD

symptom control can decrease urinary frequency, but worsening symptoms may require catheterization or pharmacologic measures (eg, oxybutynin, tolterodine, propantheline, imipramine, hyoscyamine, or nocturnal intranasal desmopressin).

Anticholinergic drugs can cause urinary retention and constipation. Constipation can be improved by increased fluid intake, a fiber-rich diet, probiotics, and physical activity. Stool softeners, osmotic or bulk-forming laxatives, glycerin suppositories, or enemas may help, while cathartic laxatives should be avoided.

Dyskinesia-related sweating may respond to PD therapy adjustment or β-blockers.

Treating orthostasis includes the removal of offending drugs (eg, tricyclic antidepressants, PD medications, alcohol, and antihypertensives) increasing carbidopa doses, increased salt or fluids to the diet, compression stockings, fludrocortisone, indomethacin, or midodrine. Droxidopa, a norepinephrine synthetic precursor, was recently approved for treating orthostatic hypotension associated with PD.[38]

Seborrhea usually responds to over-the-counter dandruff shampoos or topical steroids.[2,6,10,17]

### Treatment of Response Fluctuations

`KEY CONCEPT` *As the disease progresses, most patients develop response fluctuations. Treatment is based on capitalizing on the pharmacokinetic and pharmacodynamic properties of PD medications.*

Treatment includes adjusting or adding medications to maximize the patient's on time, minimizing the time on with dyskinesia, and minimizing off time (Table 33–3). Use various dosage plans to minimize suboptimal or delayed peak levodopa

---

### Patient Encounter, Part 3: First Follow-up Visit 3 Months Later

The patient returns for a follow-up visit 3 months after adjustments were made to her therapy. At her last appointment, ropinirole was added and prochlorperazine was removed. Since then, she reports improvement in her ability to cook and can go for longer walks. She feels that she has less tremor and stiffness throughout the day with no off periods. However, about an hour after she takes her morning dose of carbidopa/levodopa with ropinirole, her husband describes movements consistent with chorea. Additionally, her husband reports that she sometimes sees faces in the shadows at night. She also reports feeling dizzy and lightheaded when standing quickly from sitting in a chair and has fallen. She is more physically active with improved PD symptoms. She is taking polyethylene glycol one time per week with five to seven bowel movements per week. Her nighttime urgency to urinate is decreased with a reduction in fluids and her nausea has improved with a change to carbidopa/levodopa 25 mg/100 mg tablets.

UPDRS 40 (on)

*Create a problem list and provide an assessment of each problem.*

*Considering the goals of therapy, treatment options, and your assessment of each of the problems, create a care plan for each problem.*

---

### Patient Encounter, Part 4: Second Follow-up Visit 3 Months Later

The patient comes in for a follow-up visit with no new complaints. At her last visit 3 months ago, ropinirole was removed, and her daily Sinemet dose was increased to cover the afternoon off period that had previously been treated with ropinirole. Since then she reports a similar level of functioning with minimal off time and no dyskinesias. She denies any auditory or visual hallucinations or vivid dreams. She denies feeling dizzy when standing and does not report any more falls. She has joined an exercise class at the senior center. She continues to have five to seven bowel movements per week.

UPDRS 40 (on)

**Meds:** Carbidopa/levodopa 25 mg/100 mg orally—two tablets at 7 AM, one tablet at 11:30 AM, one tablet at 4 PM, and one tablet at 9 PM; polyethylene glycol (MiraLAX) 17 g/scoop. One scoop in 4 to 8 oz (120–240 mL) of liquid, one to two times per week as needed for constipation

*If her psychosis had continued and was determined to be a nonmotor symptom of PD rather than an adverse effect of her dopaminergic therapy, what options might you consider?*

*If this patient's dyskinesias in the morning continued despite removal of the dopamine agonist, what options might you consider?*

*Were therapeutic goals achieved in this patient after discontinuation of her dopamine agonist and adjustment of her carbidopa/levodopa?*

*How would you counsel a patient who has been on PD medications and is initiating an atypical antipsychotic such as quetiapine?*

*If a patient was unable to speak due to disease progression, what would be the advantages and disadvantages of having a significant other communicate for the patient?*

---

concentrations by adding longer acting medications to minimize wearing-off periods, adding or adjusting medications to stop an unpredicted off period, and providing treatments that decrease freezing episodes. Treatment plans also involve adjusting or adding medications to decrease chorea, dystonia, diphasic dyskinesias, or akathisia. Patients should schedule activities when they are on. An extra dose of medication carried with them when they are away from home in case their medication wears off is also adviseable.[2,7,12,14,22]

### OUTCOME EVALUATION

`KEY CONCEPT` *Patient monitoring involves a regular systematic evaluation of efficacy and adverse events, referral to appropriate specialists, and patient education.* Evaluate the clinical outcomes of treatment over time by assessing the change in the UPDRS from baseline. Instruct patients to record daily the amount of on and off time to guide medication adjustment. Patients with PD have an increased risk for falls. Assess fall risk and implement appropriate safety measures to prevent falls. Scales assessing QOL, depression, anxiety, and sleep disorders are useful to track progression.

**Table 33–3**

## Management of Motor Complications in Advanced PD

**I. Motor Fluctuations**

**A. Suboptimal or delayed peak response**

| Nonpharmacologic Approaches | Drugs to Alter Formulation or Dose | Drugs to Add |
|---|---|---|
| Take Sinemet on an empty stomach<br>Decrease dietary protein and fat around the delayed dose<br>Minimize constipation<br>Asses for *Helicobacter pylori* infection | Use Parcopa, crush Sinemet, or make liquid Sinemet<br>Substitute standard Sinemet for some of the Sinemet CR<br>Withdraw drugs with anticholinergic properties | Intermittent subcutaneous apomorphine |

**B. Optimal peak but early wearing off**

| Nonpharmacologic Approaches | Drugs to Alter Formulation or Dose | Drugs to Add |
|---|---|---|
| | Decrease dose and increase frequency of standard Sinemet<br>Substitute Sinemet CR for some of the standard Sinemet | Dopamine agonist<br>MAO-B inhibitor<br>Amantadine<br>COMT inhibitor |

**C. Optimal peak but unpredictable offs**

| Nonpharmacologic Approaches | Drugs to Alter Formulation or Dose | Drugs to Add |
|---|---|---|
| Adjust time of medications with meals and avoid high-protein meals or redistribute the amount of protein in diet<br>Deep brain stimulation procedure | Substitute or add rapid-dissolving tablet or liquid Sinemet<br>Switch to a different dopamine agonist if already on one<br>Consider continuous infusion of levodopa or apomorphine | COMT inhibitor<br>Dopamine agonist if not using one |

**D. Freezing**

| Nonpharmacologic Approaches | Drugs to Alter Formulation or Dose | Drugs to Add |
|---|---|---|
| Gait modifications (use visual cues such as walkover lines, tapping, rhythmic commands, rocking; use rolling walker)<br>Physical therapy | Due to the difficulty in directly treating this complication, adjust current medications based on other PD symptoms. Guide changes based on the following:<br>• On freezing, reduce dopamine medications, inject botulinum toxin<br>• Off freezing, increase Sinemet dose or add dopamine agonists | If present, treat anxiety with pharmacologic agents |

**II. Dyskinesias**

| Nonpharmacologic Approaches | Drugs to Alter Formulation or Dose | Drugs to Add |
|---|---|---|
| *Chorea*<br>Deep-brain stimulation | *Chorea*<br>Decrease risk of occurrence by lowering Sinemet dose when adding other PD medications<br>Evaluate the value of adjunctive PD medications and discontinue if motor complications outweigh benefit<br>Adjust levodopa formulation, dose, or frequency | *Chorea*<br>Amantadine<br>Propranolol<br>Fluoxetine<br>Buspirone<br>Clozapine |
| *Off period dystonia in the early morning (eg, foot cramping)*<br>No recommendations | *Off period dystonia in the early morning (eg, foot cramping)*<br>Add or change short acting to long acting formulations (Sinemet CR, ropinirole XL, pramipexole ER, or rotigotine patch) at bedtime if having nighttime offs<br>Change morning Sinemet CR dose to immediate-release with or without CR | *Off period dystonia in the early morning (eg, foot cramping)*<br>Lithium<br>Baclofen<br>Selective denervation with botulinum toxin |
| *Diphasic dyskinesia*<br>Deep-brain stimulation | *Diphasic dyskinesia*<br>Change controlled-release preparations to immediate release; consider liquid Sinemet<br>Increase Sinemet dose and frequency | *Diphasic dyskinesia*<br>Dopamine agonist<br>Amantadine<br>COMT inhibitor |

**III. Akathisia**

| Nonpharmacologic Approaches | Drugs to Alter Formulation or Dose | Drugs to Add |
|---|---|---|
| No recommendations | Evaluate if due to antidepressant or antipsychotic and decrease dose or change drug | Benzodiazepine<br>Propranolol<br>Dopamine agonist<br>Gabapentin |

From Refs. 2, 12, 21, and 22.

## Patient Care Process

**Patient Assessment:**

- Based on reported symptoms and physical exam, document type of symptoms, frequency, and exacerbating factors (clinical presentation table).

- Review diagnostic data and determine if symptoms are adequately controlled or if PD treatment-related complications exist. How does the current UPDRS score compare to previous measurements? Is there evidence of motor fluctuations or dyskinesias?

- Obtain a medication history. What treatments have been helpful? Is the patient taking any medications that may worsen PD symptoms?

**Therapy Evaluation:**

- Determine if therapy for motor symptoms of PD are maximizing on time and should be maintained or require adjustment.

- Evaluate for polypharmacy. Is this necessary or can medications be removed?

- Review nonmotor symptoms and evaluate if they are adequately treated. Have QOL measures improved?

- Assess the complete PD pharmacologic profile for efficacy, drug or diet interactions, adverse drug reactions, and adherence.

**Care Plan Development:**

- Educate the patient about lifestyle modifications that will improve symptoms and sustain independence.

- Recommend a therapeutic regimen that is easy for the patient to follow.

- Provide instruction on how to use medications, and allow the patient to adjust medications for fluctuations in response.

- Refer the patient and family members to further information such as books and websites (eg, http://www.apdaparkinson.org; http://www.parkinson.org). Provide information concerning local PD support groups when available.

**Follow-Up Evaluation**

- Assess the patient's symptoms and disease progression through the UPDRS and QOL measures periodically. This interval will vary depending on symptom control, stage of illness, and changes to therapy.

- Follow up at least every 6 to 12 months (or earlier) and determine when symptoms are controlled, if the patient is experiencing any drug interactions or adverse reactions, and provide patient education on medications and nonpharmacologic options as appropriate.

# Abbreviations Introduced in This Chapter

| | |
|---|---|
| Ach | Anticholinergics |
| ADLs | Activities of daily living |
| COMT | Catechol-*O*-methyltransferase |
| CR | Controlled-release |
| DBS | Deep brain stimulation |
| DDS | Dopamine dysregulation syndrome |
| GI | Gastrointestinal |
| ICD | Impulse control disorder |
| MAO | Monoamine oxidase |
| NMDA | *N*-methyl-D-aspartate |
| PD | Parkinson disease |
| QOL | Quality of life |
| RBD | Rapid eye movement sleep behavior disorder |
| RLS | Restless legs syndrome |
| TRAP | Tremor, rigidity, akinesia/bradykinesia, postural/gait instability |
| UPDRS | Unified Parkinson Disease Rating Scale |

# 34 Pain Management

Christine Karabin O'Neil

Christine Karabin O'Neil

---

## LEARNING OBJECTIVES

● **Upon completion of the chapter, the reader will be able to:**

1. Identify characteristics of the types of pain: nociceptive, inflammatory, neuropathic, and functional.
2. Explain the mechanisms involved in pain transmission.
3. Select an appropriate method of pain assessment.
4. Recommend an appropriate choice of analgesic, dose, and monitoring plan for a patient based on type and severity of pain and other patient-specific parameters.
5. Perform calculations involving equianalgesic doses, conversion of one opioid to another, rescue doses, and conversion to a continuous infusion.
6. Educate patients and caregivers about effective pain management, dealing with chronic pain, and the use of nonpharmacologic measures.

---

## INTRODUCTION

Pain is defined by the International Association for the Study of Pain (IASP) as "an unpleasant sensory and emotional experience associated with actual or potential tissue damage, or described in terms of such damage."[1] **KEY CONCEPT** *Pain is an unpleasant subjective experience that is the net effect of a complex interaction of the ascending and descending neurons involving biochemical, physiologic, psychological, and neocortical processes.* Pain can affect all areas of a person's life including sleep, thought, emotion, and activities of daily living. Because there are no reliable objective markers for pain, the patient is the only person who can describe the intensity and quality of their pain.

Pain is the most common symptom prompting patients to seek medical attention and is reported by more than 80% of individuals who visit their primary care provider.[2] Despite the frequency of pain symptoms, individuals often do not obtain satisfactory relief of pain. This has led to initiatives in health care to make pain the fifth vital sign, thus making pain assessment equal in importance to obtaining a patient's temperature, pulse, blood pressure, and respiratory rate.

## EPIDEMIOLOGY AND ETIOLOGY
### Prevalence of Pain

Most people experience pain at some time in their lives, and pain is a symptom of a variety of diseases. Thus identifying the exact prevalence of pain is a difficult task. According to the American Pain Foundation, more than 76 million people in the United States suffer from chronic pain, and an additional 25 million experience acute pain from injury or surgery.[2]

Prevalence rates for a variety of different types of pain have been described. Approximately one-fourth of US adults reported having low back pain lasting at least 1 day in the past 3 months.[3] Migraine affects more than 28 million Americans, and 78% of Americans experience a tension headache during their lifetime.[4] Pain resulting from fibromyalgia affects 10 million Americans.[5] Pain ranges in prevalence from 14% to 100% among cancer patients.[6] The prevalence of neuropathic pain is unknown because of the lack of epidemiologic studies. Current estimates suggest that approximately 1.5% of the population in the United States might be affected by neuropathic pain.[7] Approximately 25% to 50% of all pain clinic visits are related to neuropathic pain.[8] Central neuropathic pain is estimated to occur in 2% to 8% of all stroke patients.[9]

The elderly, defined as people 65 years and older, bear a significant burden of pain, and pain continues to be underrecognized and undertreated in this population. The prevalence of pain in people older than 60 years is twice that in those younger than 60 years.[10] Studies suggest that 25% to 50% of community-dwelling elderly suffer pain. Pain is quite common among nursing home residents. It is estimated that pain in 45% to 80% of nursing home patients contributes to functional impairment and a decreased quality of life.[11]

The financial impact of pain is considered to be significant. The American Productivity Audit of the US workforce, conducted from 2001 to 2002, revealed that the cost of lost productivity due to arthritis, back pain, headache, and other musculoskeletal pain was approximately $61.2 billion per year.[12]

### Undertreatment of Pain

Despite the growing emphasis on pain management, pain often remains undertreated and continues to be a problem in hospitals, long-term care facilities, and the community. In one series of reports, 50% of seriously ill hospitalized patients reported pain; however, 15% were dissatisfied with pain control, and some remained in pain after hospitalization.[13,14]

Misconceptions about pain management, both from patients and health care providers, are among the most common causes of analgesic failure. Concerns about opiate misuse, abuse, and diversion also contribute to less than optimal pain management and cause providers to exercise caution when prescribing opiates for pain. Misunderstandings about the terms addiction, physical dependence, tolerance, and pseudoaddiction are additional obstacles to optimal pain management.

Patients might present barriers to pain management by not reporting pain symptoms because of fear of becoming addicted or because of cultural beliefs. Elderly patients might not report pain for a variety of reasons including belief that pain is something they must live with, fear of consequences (eg, hospitalization, loss of independence), or fear that the pain might be forecasting impending illness, inability to understand terminology used by health care providers, or a belief that showing pain is unacceptable behavior.

## PATHOPHYSIOLOGY

### Types of Pain

Several distinct types of pain have been described, for example, nociceptive, inflammatory, neuropathic, and functional.[15] Nociceptive pain is a transient pain in response to a noxious stimulus at nociceptors that are located in cutaneous tissue, bone, muscle, connective tissue, vessels, and viscera. Nociceptors are classified as thermal, chemical, or mechanical. The nociceptive system extends from the receptors in the periphery to the spinal cord, brainstem, to the cerebral cortex where pain sensation is perceived. This system is a key physiologic function that prevents further tissue damage due to the body's autonomic withdrawal reflex. When tissue damage occurs despite the nociceptive defense system, inflammatory pain ensues. The body now changes focus from protecting against painful stimuli to protecting the injured tissue. The inflammatory response contributes to pain hypersensitivity that serves to prevent contact or movement of the injured part until healing is complete, thus reducing further damage.

Neuropathic pain is defined as spontaneous pain and hypersensitivity to pain associated with damage to or pathologic changes in the peripheral nervous system as in painful diabetic peripheral neuropathy (DPN), adult immune deficiency syndrome (AIDS), polyneuropathy, postherpetic neuralgia (PHN), or in the central nervous system (CNS), which occurs with spinal cord injury, multiple sclerosis, and stroke. Functional pain, a relatively newer concept, is pain sensitivity due to an abnormal processing or functioning of the CNS in response to normal stimuli. Several conditions considered to have this abnormal sensitivity or hyperresponsiveness include fibromyalgia and irritable bowel syndrome.

### Mechanisms of Pain

#### ▶ Pain Transmission

The mechanisms of nociceptive pain are well defined and provide a foundation for the understanding of other types of pain.[16] Following nociceptor stimulation, tissue injury causes the release of substances (bradykinin, serotonin, potassium, histamine, prostaglandins, and substance P) that might further sensitize and/or activate nociceptors. Nociceptor activation produces action potentials (transduction) that are transmitted along myelinated Aδ-fibers and unmyelinated C-fibers to the spinal cord. The Aδ-fibers are responsible for first, fast, sharp pain and release excitatory amino acids that activate α-amino-3-hydroxy-5-methylisoxazole-4-propionic

acid (AMPA) receptors in the dorsal horn. The C-fibers produce second pain, which is described as dull, aching, burning, and diffuse. These nerve fibers synapse in the dorsal horn of the spinal cord, where several neurotransmitters are released including glutamate, substance P, and calcitonin gene-related peptide. Transmission of pain signals continues along the spinal cord to the thalamus, which serves as the pain relay center, and eventually to the cortical regions of the brain where pain is perceived.

#### ▶ Pain Modulation

Modulation of pain (inhibition of nociceptive impulses) can occur by a number of processes. Based on the gate-control theory, pain modulation might occur at the level of the dorsal horn.[17] Because the brain can process only a limited number of signals at one time, other sensory stimuli at nociceptors might alter pain perception. This theory supports the effectiveness of counterirritants and transcutaneous electrical nerve stimulation (TENS) in pain management. Pain modulation can occur through several other complex processes. The endogenous opiate system consists of endorphins (enkephalins, dynorphins, and β-endorphins) that interact with μ-, δ-, and κ-receptors throughout the CNS to inhibit pain impulses and alter perception. The CNS also includes inhibitory descending pathways from the brain that can attenuate pain transmission in the dorsal horn. Neurotransmitters involved in this descending system include endogenous opioids, serotonin, norepinephrine, γ-aminobutyric acid (GABA), and neurotensin. The perception of pain involves not only nociceptive stimulation but physiologic and emotional input that contributes to the perception of pain. Consequently, cognitive behavioral treatments such as distraction, relaxation, and guided imagery can reduce pain perception by altering pain processing in the cortex.

#### ▶ Peripheral Sensitization, Central Sensitization, and Windup

Under normal conditions, a balance generally exists between excitatory and inhibitory neurotransmission. Changes in this balance can occur both peripherally and centrally, resulting in exaggerated responses and sensitization, such as that observed in inflammatory, neuropathic, or functional chronic pain. Pain in these settings might occur spontaneously without any stimulus or might be evoked by a stimulus. Evoked pain might arise from a stimulus that normally does not cause pain (allodynia) such as a light touch in neuropathic pain. Hyperalgesia, an exaggerated and/or prolonged pain response to a stimulus that normally causes pain, can also occur as a result of increased sensitivity in the CNS.

During normal pain transmission, the AMPA receptors are activated, but the N-methyl-D-aspartate (NMDA) receptor is blocked by magnesium.[16] Repeated nerve depolarization causes release of the magnesium block, allowing the influx of calcium and sodium, and results in excessive excitability and amplification of signals. Continued input from C-fibers and subsequent increases in substance P and glutamate causes the activation of the NMDA receptor, a process referred to as windup. Windup increases the number and responsiveness of neurons in the dorsal horn irrespective of the input from the periphery. Recruitment of neurons not normally involved in pain transmission or spread occurs, leading to allodynia, hyperalgesia, and spread to uninjured tissues.[18] The windup phenomenon supports the observation that untreated acute pain can lead to chronic pain and the belief that pain processes are plastic and not static.

## CLINICAL PRESENTATION AND DIAGNOSIS
### Classification of Pain

Pain has always been described as a symptom. However, recent advances in the understanding of neural mechanisms have demonstrated that unrelieved pain might lead to changes in the nervous system known as neural plasticity. Because these changes reflect a process that influences a physiologic response, pain, particularly chronic pain, might be considered a disease unto itself.

Pain can be divided into two broad categories: acute and chronic pain. Acute pain is also referred to as adaptive pain because it serves to protect the individual from further injury or promote healing.[17] However, chronic pain has been called maladaptive, a pathologic function of the nervous system or pain as a disease.

#### ▶ Acute Pain

Acute pain is pain that occurs as a result of injury or surgery and is usually self-limited, subsiding when the injury heals. Untreated acute pain can produce physiologic symptoms including tachypnea, tachycardia, and increased sympathetic nervous system activity, such as pallor, diaphoresis, and pupil dilation. Furthermore, poorly treated pain can cause psychological stress and compromise the immune system due to the release of endogenous corticosteroids. Somatic acute pain arises from injury to skin, bone, joint, muscle, and connective tissue, and it is generally localized to the site of injury. Visceral pain involves injury to nerves on internal organs (eg, intestines, liver) and can present as diffuse, poorly differentiated, and often referred pain. Acute pain should be treated aggressively, even before the diagnosis is established, except in conditions of head or abdominal injury where pain might assist in the differential diagnosis.

#### ▶ Chronic Pain

Chronic pain persists beyond the expected normal time for healing and serves no useful physiologic purpose. Chronic pain might be nociceptive, inflammatory, neuropathic, or functional in origin; however, all forms share some common characteristics. Chronic pain can be intermittent or persistent, or both. Physiologic responses observed in acute pain are often absent in chronic pain; however, other symptoms might predominate. The four main effects of chronic pain include (a) effects on the physical function, (b) psychological changes, (c) social consequences, and (d) societal consequences. Effects of chronic pain on physical function include impaired activities of daily living and sleep disturbances. Psychological components of chronic pain might include depression, anxiety, anger, and loss of self-esteem. As a result of physical and psychological changes, social consequences might ensue, such as changes in relationships with friends and family, intimacy, and isolation. Management of chronic pain should be multimodal and might involve cognitive interventions, physical manipulations, pharmacologic agents, surgical intervention, and regional or spinal anesthesia.

**Chronic Malignant Pain** Chronic malignant pain is associated with a progressive disease that is usually life threatening such as cancer, AIDS, progressive neurologic diseases, end-stage organ failure, and dementia.[19] The goal is pain alleviation and prevention, often through a systematic and stepwise approach. Tolerance, dependence, and addiction are often not a concern due to the terminal nature of the illness.

**Chronic Nonmalignant Pain** Pain not associated with a life-threatening disease and lasting more than 6 months beyond

---

---

the healing period is referred to as chronic nonmalignant pain. Pain associated with low back pain, osteoarthritis, previous bone fractures, peripheral vascular disease, genitourinary infection, rheumatoid arthritis, and coronary heart disease is considered nonmalignant. The numerous causes of this type of chronic pain make treatment complex and involves a multidisciplinary approach. Treatment is initially conservative but might involve the use of more potent analgesics including opiates in psychologically healthy patients.[20]

**Neuropathic Pain** Neuropathic pain is considered to be a type of chronic nonmalignant pain involving disease of the central and peripheral nervous systems. Neuropathic pain might be broadly categorized as peripheral or central in nature. Examples of neuropathic pain include PHN, which is pain associated with acute herpetic neuralgia or an acute shingles outbreak. Peripheral or polyneuropathic pain is associated with the distal polyneuropathies of diabetes, human immunodeficiency virus (HIV), and chemotherapeutic agents. Types of central pain include central stroke pain, trigeminal neuralgia, and a complex of syndromes known as complex regional pain syndrome (CRPS). CRPS includes both reflex sympathetic dystrophy and causalgia, both of which are neuropathic pain associated with abnormal functioning of the autonomic nervous system.

The symptoms of neuropathic pain are characterized as tingling, burning, shooting, stabbing, electric shock–like quality, or radiating pain. The patient might describe either a constant dull throbbing or burning pain, or an intermittent pain that is stabbing or shooting. Damage to the peripheral nerves might frequently be referred to the body region innervated by those nerves.

### Pain Assessment

Effective pain management begins with a thorough and accurate assessment of the patient. Even though pain is a common presenting complaint, lack of regular assessment and reassessment of pain remains a problem and contributes to the undertreatment of pain.[21]

▶ *Pain Assessment Guidelines/Regulations for Specific Practice Settings*

Screening for pain should be a part of a routine assessment, which has led several organizations such as the Veterans Health Administration (VHA) and the American Pain Society (APS) to declare pain as the fifth vital sign. Many states have adopted a bill of rights for patients in pain. In 2001, the Joint Commission on Accreditation of Health Care Organizations (JCAHO) incorporated pain as the fifth vital sign in its accreditation standards.[22] According to the JCAHO, patients have a right to appropriate assessment and management of their pain and education regarding their pain. **KEY CONCEPT** *Following initial assessment of pain, reassessment should be done as needed based on medication choice and the clinical situation.*

▶ *Methods of Pain Assessment*

A patient-oriented approach to pain is essential, and methods do not differ greatly from those used in other medical conditions. A comprehensive history (medical, family, and psychological) and physical are necessary to evaluate underlying disease processes for the source of pain and other factors contributing to the pain.[18] A thorough assessment of the characteristics of the pain should be completed, including questions about the pain (onset, duration, location, quality, severity, and intensity), pain relief efforts, and efficacy and side effects of current and past treatments for pain. A common mnemonic for pain assessment is PQRST (Palliative/precipitating, Quality, Radiation, Severity, and Time).[23] Some clinicians have suggested the addition of U ("you") to this mnemonic.[24] During the pain interview, the impact of the pain on the patient's functional status, behavior, and psychological states should also be assessed. Evaluation of psychological status is especially important in patients with chronic pain because depression and other affective disorders might be common comorbid conditions. A history of drug and alcohol use should be elicited due to the potential for addiction in patients who take opiates or other pain medications with a potential for abuse. Other conditions, such as renal or hepatic dysfunction, diabetes, and conditions that affect bowel function, can influence therapy choices and goals. A discussion of the patient's expectations and goals with respect to pain management (level of pain relief, functional status, and quality of life) should also be part of any pain interview.

▶ *Pain Assessment Tools*

Pain, particularly acute pain, might be accompanied by physiologic signs and symptoms, but there are no reliable objective markers for pain. Many tools have been designed for assessing the severity of pain including rating scales and multidimensional pain assessment tools.

Rating scales provide a simple way to classify the intensity of pain, and they should be selected based on the patient's ability to communicate (**Figure 34–1**).[25] Numeric scales are widely used and ask patients to rate their pain on a scale of 0 to 10, with 0 indicating no pain and 10 being the worst pain possible. Using this type of scale, 1 to 3 is considered mild pain, 4 to 6 is moderate pain, and 7 to 10 is severe pain. The visual analog scale (VAS) is similar to the numerical scale in that it requires patients to place a mark on a 10-cm line where one end is no pain, and the worst possible pain is on the other end. For patients who have difficulty assigning a number to their pain, a categorical scale might be an option to communicate the intensity of the pain experience. Examples of this include a simple descriptive list of words and the Wong–Baker FACES of Pain Rating Scale.[26]

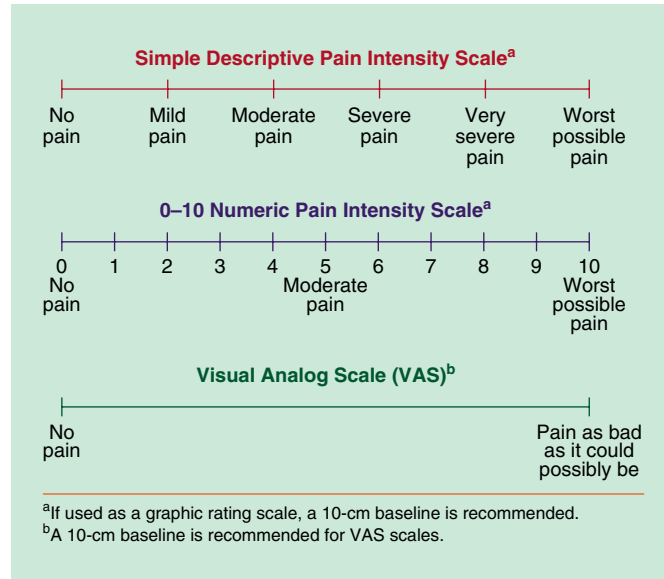

**FIGURE 34–1.** Pain rating scales. (From U.S. Department of Health and Human Services, Agency for Health Care Policy and Research. Clinical practice guideline, cancer pain management. Rockville, MD: AHCPR; 1994 [cited 2014 Nov 6]. http://www.ncbi.nlm.nih.gov/books/bookres.fcgi/hstat6/f37_capcf4.gif.)

Multidimensional assessment tools obtain information about the pain and impact on quality of life, but they are often more time consuming to complete. Examples of these types of tools include the Initial Pain Assessment Tool, Brief Pain Inventory, McGill Pain Questionnaire, the Neuropathic Pain Scale, and the Oswestry Disability Index.[27–31]

▶ *Pain Assessment in Challenging Populations*

**Children** Pain interviews can be conducted with children as young as 3 or 4 years of age; however, communication might be limited by vocabulary.[32] Terms familiar to children such as *hurt, owie,* or *boo boo* might be used to describe pain. The VAS is best used with children older than 7 years. Other scales based on numbers of objects (eg, pokers chips), increasing color intensity, or faces of pain might be helpful for children between 4 and 7 years of age. In children younger than 3 to 4 years, behavioral or physiologic measures, such as pulse or respiratory rate, might be more appropriate. Pain assessment in newborns and infants relies on behavioral observation for such clues as vocalizations (crying and fussing), facial expressions, body movements (flailing of limbs and pulling legs in), withdrawal, and change in eating and sleeping habits.[33] Preschool children experiencing pain might become clingy, lose motor and verbal skills, and start to deny pain because treatment might be linked to discomfort or punishment. School-age children might exhibit aggressiveness, nightmares, anxiety, and withdrawal when in pain; adolescents might respond to pain with oppositional behavior and depression.

**Elderly** Most of the previously discussed pain scales can be used in older persons who are cognitively intact or with mild dementia. The pain thermometer and FACES of pain have been studied in older persons. In persons with moderate to severe dementia or those who are nonverbal, observation of pain behaviors, such as guarding or grimacing, provides an alternative for pain assessment. The Pain Assessment in Advanced Dementia (PAINAD)

## Patient Encounter, Part 1

**HPI:** A 68-year-old woman who fell on a banana peel while vacationing at the lake sustained an ankle fracture. She is to undergo repair with pin placement

**PMH:** Hypertension for 18 years; diabetes type 2 for 13 years

**FH:** Mother had osteoporosis; father had diabetes

**SH:** Lives with husband; has two grown children

**Meds:** Lisinopril 20 mg daily, metformin 500 mg three times daily

**Pain Assessment:** Patient rates pain as 8 on a scale of 0 to 10

*Based on the type of injury, what type of pain is this patient likely to experience?*

*What type of pain management regimen would you recommend in the postoperative period? Explain your answer.*

tool might be used to quantify signs of pain and involves observing the older adult for 15 minutes for breathing, negative vocalizations, facial expression, body language, and consolability.[34] Regardless of which pain assessment tool is used, the practitioner should first determine if the patient understands the concept of the scale to ensure reliability of the instrument.

## TREATMENT
### Desired Outcomes

Prevention, reduction, and/or elimination of pain are important goals for the treatment of acute pain. With chronic pain, elimination of pain might not be possible, and goals might focus on improvement or maintenance of functional capacity and quality of life.

### General Approach to Treatment

**KEY CONCEPT** *Effective treatment involves an evaluation of the cause, duration, and intensity of the pain, and selection of an appropriate treatment modality for the pain situation.* Depending on the type of pain, treatment might involve pharmacologic and nonpharmacologic therapy or both. General principles for the pharmacologic management of pain are listed in the section "Patient Care Process." Two common approaches to the selection of treatment are based on severity of pain and the mechanism responsible for the pain (**Figure 34–2**). Clinical practice guidelines for pain management are available from the APS, the Agency for Healthcare Research and Quality (AHRQ), the American Geriatrics Society (AGS), and the American Society of Anesthesiologists (ASA).

▶ *Selection of Agent Based on Severity of Pain*

**KEY CONCEPT** *Whenever possible, the least potent oral analgesic should be selected.* Guidelines for the selection of therapeutic agents based on pain intensity are derived from the World Health Organization (WHO) analgesic ladder for the management of cancer pain (**Table 34–1**).[35] Mild to moderate pain is generally treated with nonopioid analgesics. Combinations of medium-potency opioids and acetaminophen (APAP) or nonsteroidal anti-inflammatory drugs (NSAIDs) are often used for moderate pain. Potent opioids are recommended for severe pain. Throughout this progression, adjuvant medications are added, as needed, to manage side effects and to augment analgesia. While these guidelines can be useful for initial therapy, the clinical situation (type of pain), cost, pharmacokinetic profile of available drugs, and patient-specific factors (age, concomitant illnesses,

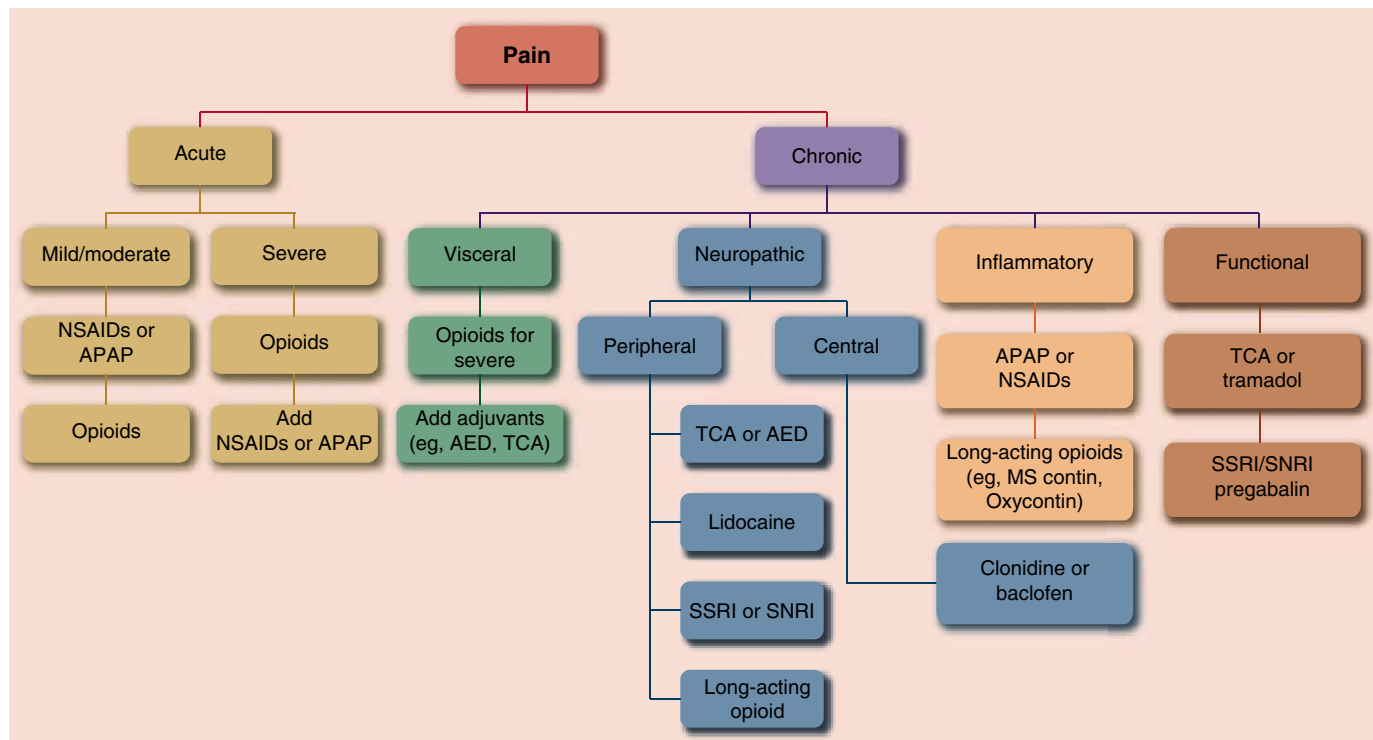

**FIGURE 34–2.** Pain algorithm. (AED, antiepileptic drugs; APAP, acetaminophen; MS, morphine sulfate; NSAIDs, nonsteroidal anti-inflammatory drugs; SNRI, serotonin norepinephrine reuptake inhibitors; SSRI, selective serotonin reuptake inhibitors; TCA, tricyclic antidepressants.)

| **Selection of Analgesics Based on Intensity of Pain** | | | | |
| **Pain Intensity** | **Corresponding Numerical Rating** | **WHO Therapeutic Recommendations** | **Examples of Initial Therapy** | **Comments** |
| Mild | 1–3/10 | Nonopioid analgesic; regular scheduled dosing | Acetaminophen 1000 mg every 6 hours; ibuprofen 600 mg every 6 hours | Consider adding an adjunct or using an alternate regimen if pain is not reduced in 1–2 days |
| Moderate | 4–6/10 | Add an opioid to the nonopioid for moderate pain; regular scheduled dosing | Acetaminophen 325 mg + codeine 60 mg every 4 hours; acetaminophen 325 mg + oxycodone 5 mg every 4 hours | Consider step-up therapy if pain is not relieved by two or more different drugs |
| Severe | 7–10/10 | Switch to a high-potency opioid; regular scheduled dosing | Morphine 10 mg every 4 hours; or hydromorphone 4 mg every 4 hours | |

Data from Refs. 35, 36, and 39.

previous response, and other medications) must also be considered. Pain medications might also be used in the absence of pain in anticipation of a painful event such as surgery to minimize peripheral and central sensitization.

### ▶ *Mechanistic Approach to Therapy*

Current analgesic therapy is aimed at controlling or blunting pain symptoms. However, diverse mechanisms contributing to the various types of pain continue to be further elucidated. An understanding of these new mechanisms of pain transmission might lead to improvement in pain management as pharmacologic management of pain becomes more mechanism specific. Use of NSAIDs for inflammatory types of pain is an example of a mechanistic approach. Because several mechanisms of pain often coexist, a polypharmacy approach seems rational to target each mechanism.

## Nonpharmacologic Therapy

Nonpharmacologic therapies (psychological interventions and physical therapy) might be used in both acute and chronic pain. Psychological interventions can reduce pain as well as the anxiety, depression, fear, and anger associated with pain. Psychological interventions helpful in management of acute pain are imagery (picturing oneself in a safe, peaceful place) and distraction (listening to music or focusing on breathing). Chronic pain patients might benefit from relaxation, biofeedback, cognitive behavioral therapy, psychotherapy, support groups, and spiritual counseling.

Physical therapy is an essential part of many types of pain situations. Treatment modalities include heat, cold, water, ultrasound therapy, TENS, massage, and therapeutic exercise. Heat and cold therapy are utilized in a variety of musculoskeletal conditions (muscle spasms, low back pain, fibromyalgia, sprains, and strains).

## Pharmacologic Therapy

### ▶ *Nonopioid Analgesics*

**Acetaminophen** APAP, an analgesic and antipyretic, is often selected as initial therapy for mild to moderate pain and is considered first line in several pain situations such as low back pain and osteoarthritis.[36] Mechanistically, APAP is believed to inhibit

prostaglandin synthesis in the CNS and block pain impulses in the periphery. APAP is well tolerated at usual doses and has few clinically significant drug interactions except causing increased hypoprothrombinemic response to warfarin in patients receiving APAP doses of more than 2000 mg/day. The maximum recommended dose for patients with normal renal and hepatic function is 4000 mg/day. Hepatotoxicity has been reported with excessive use and overdose, and the risk of this adverse effect increases in those with hepatitis or chronic alcohol use, as well as those who binge drink or are in a fasting state. Due to concerns of unintentional overuse and hepatoxicity, the FDA requires warning labels on OTC APAP products and limited the APAP component of narcotic analgesic combination to 325 mg per dosing unit. Regular chronic use of APAP has been associated with chronic renal failure, but reports are conflicting. For these reasons, the maximum dose should be reduced by 50% to 75% in patients with renal dysfunction or hepatic disease and in those who engage in excessive alcohol use.

**Aspirin and Other Salicylates** Aspirin, nonacetylated salicylates, and other NSAIDs have analgesic, antipyretic, and anti-inflammatory actions. These agents inhibit cyclooxygenase (COX-1 and COX-2) enzymes, thereby preventing prostaglandin synthesis, which results in reduced nociceptor sensitization and an increased pain threshold.

Aspirin is effective for mild to moderate pain; however, the risk of gastrointestinal (GI) irritation and bleeding limits frequent use of this drug for pain management. Direct effects of aspirin on the GI mucosa and irreversible platelet inhibition contribute to this risk, which can occur even at low doses. Hypersensitivity reactions are also possible and might occur in 25% of patients with coexisting asthma, nasal polyps, or chronic urticaria. Of additional concern is the potential for cross-sensitivity of other NSAIDs in this group of patients. Nonacetylated salicylates (choline magnesium salicylate and sodium salicylate) have a reduced risk of GI effects and platelet inhibition and might be used in aspirin-sensitive patients.

**Nonsteroidal Anti-inflammatory Drugs** NSAIDs are the preferred agents for mild to moderate pain in situations that are mediated by prostaglandins (rheumatoid arthritis, menstrual cramps, and postsurgical pain) and in the management of pain from bony metastasis, but they are of minimal use in neuropathic pain.

NSAIDs provide analgesia equal to or better than that of aspirin or APAP combined with codeine, and they are very effective for inflammatory pain and pain associated with bone metastasis.[16] These agents are classified by their chemical structures (fenamates, acetic acids, propionic acids, pyranocarboxylic acids, pyrrolizine carboxylic acids, and COX-2 inhibitors). Although only some members of this class have approval for treatment of pain, it is likely that all of them have similar analgesic effects. All members of this class appear to be equally effective, but there is great intrapatient variability in response. After an adequate trial of 2 to 3 weeks with a particular oral agent, it is reasonable to switch to another member of the class. Ketorolac and ibuprofen are available in parenteral and oral dosage forms; unlike other NSAIDs, ketorolac's duration of use is limited to 5 days. NSAIDs demonstrate a flat-dose response curve, with higher doses producing no greater efficacy than moderate doses but resulting in an increased incidence of adverse effects (GI irritation, hepatic dysfunction, renal insufficiency, platelet inhibition, sodium retention, and CNS dysfunction).

Patients at increased risk of NSAID-induced GI adverse effects (eg, dyspepsia, peptic ulcer formation, and bleeding) include the elderly, those with peptic ulcer disease, coagulopathy, and patients receiving high doses of concurrent corticosteroids. Nephrotoxicity is more common in the elderly, patients with creatinine clearance values less than 50 mL/min (0.84 mL/s), and those with volume depletion or on diuretic therapy. NSAIDs should be used with caution in patients with reduced cardiac output due to sodium retention and in patients receiving antihypertensives, warfarin, and lithium.

NSAIDs are classified as nonselective (they inhibit COX-1 and COX-2) or selective (inhibit only COX-2) based on degree of COX inhibition. COX-2 inhibition is responsible for anti-inflammatory effects, whereas COX-1 inhibition contributes to increased GI and renal toxicity associated with nonselective agents. Because the antiplatelet effect of nonselective NSAIDs is reversible, concurrent use might reduce the cardioprotective effect of aspirin due to competitive inhibition of COX-1. For this reason, administration of aspirin prior to the NSAID is recommended.[37] A boxed warning highlighting the potential for increased risk of cardiovascular events and GI bleeding is now required for all prescription nonselective NSAIDs and celecoxib. Stronger warnings about these adverse events are also required on nonprescription NSAIDs. When a NSAID is needed in a patient with cardiovascular risk, the benefits of therapy must outweigh the risks, and the lowest effective dose of the NSAID is recommended.[38]

### ▶ Opioid Analgesics

Opioids are considered the agents of choice for the treatment of severe acute pain and moderate to severe pain associated with cancer.[39] For chronic pain, use of long-term opioids has increased dramatically, however, evidence on the benefits, risk of abuse, and potential harm of long-term use of opioids in chronic pain is limited.[40] Opioids are classified by their activity at the receptor site, usual pain intensity treated, and duration of action (short acting versus long acting).

**Selection and Dosing** The opioids exert their analgesic efficacy by stimulating opioid receptors (μ, κ, and δ) in the CNS. There is a wide variety of potencies among the opioids, with some used for moderate pain (codeine, hydrocodone, tramadol, and partial agonists) and others reserved for severe pain (morphine and hydromorphone). Pure agonists (morphine) bind to μ-receptors to produce analgesia that increases with dose without a ceiling effect. Pure agonists are divided into three chemical classes: phenanthrenes or morphine-like, phenyl piperidine or meperidine-like, and diphenyl heptane or methadone-like. Partial agonists/antagonists (butorphanol, pentazocine, and nalbuphine) partially stimulate the μ-receptor and antagonize the κ-receptors. This activity results in reduced analgesic efficacy with a ceiling dose, reduced side effects at the μ-receptor, psychotomimetic side effects due to κ-receptor antagonism, and possible withdrawal symptoms in patients who are dependent on pure agonists.

Selection of the agent and route depend on individual patient-related factors including severity of pain, individual perceptions, weight, age, opioid tolerance, and concomitant disease (renal or hepatic dysfunction). Because pure agonists are pharmacologically similar, choice of agent might be also guided by pharmacokinetic parameters and other drug characteristics. Hepatic impairment can decrease the metabolism of most opioids, particularly methadone, meperidine, and pentazocine. Furthermore, the clearance of meperidine and morphine and their metabolites is reduced in renal dysfunction.

Table 34–2 provides a summary of opiate options, but several drugs warrant further discussion. Normeperidine, the active metabolite of meperidine, can produce tremors, myoclonus, delirium, and seizures. Due to the potential for accumulation of normeperidine, meperidine should not be used in the elderly, those with renal impairment, in patients using patient-controlled analgesia (PCA) devices, or for more than 1 to 2 days of intermittent dosing. Methadone is unique among the opiates because it has several mechanisms (μ-agonist, NMDA-receptor antagonist, and inhibition of reuptake of serotonin and norepinephrine). The long-half of methadone (30 hours) permits extended dosing

[a]Transdermal: 100 mcg/hour = 2–4 mg/hour of IV morphine.

[b]Dosage calculations when converting from morphine to methadone are not linear. The equianalgesic dose of methadone will decrease progressively as the morphine equivalents increase (Table 34–4).

Data from Refs. 24, 39, 42, and 43

intervals; however, the potential for accumulation with repeated dosing often results in challenging dose conversion and concerns for respiratory depression. Another safety concern with methadone involves risk of arrhythmia secondary to QT prolongation. Tramadol is a synthetic opioid with a dual mechanism of action (μ-agonist and inhibition of serotonin and norepinephrine reuptake) and efficacy and safety similar to that of equianalgesic doses of codeine plus APAP. Tramadol has been evaluated in several types of neuropathic pain and might have a role in the treatment of chronic pain. Tramadol is associated with an increased risk of seizures in patients with a seizure disorder, those at risk for seizures, and those taking medications that can lower the seizure threshold. Doses greater than 500 mg have also been associated with seizures. The use of tramadol with other serotonergic drugs (eg, selective serotonin reuptake inhibitors [SSRIs]) might precipitate serotonin syndrome. Although originally thought not to be habit forming, dependence can occur with tramadol.

About 70% of individuals will experience significant analgesia from 10 mg/70 kg of body weight of IV morphine or its equivalent.[16] For severe pain in opiate-naive patients, a usual starting dose is 5 to 10 mg of IV morphine every 4 hours. In the initial stages of severe pain, medication should be given around the clock. Rescue doses should be made available for breakthrough pain in doses equivalent to 10% to 20% of the total daily opioid requirement and administered every 2 to 6 hours if needed. Alternatively, one-sixth of the total daily dose or one-third of the 12-hourly dose might be used. Scheduled doses should be titrated based on the degree of pain. One method involves adjustment of the maintenance dose based on the total 24-hour rescue dose requirement. Alternatively, utilizing dose escalation, doses could be increased by 50% to 100% or 30% to 50% of the current dose, for those in severe and moderate pain, respectively. Once pain relief is achieved, and if treatment is necessary for more than a few days, conversion to a controlled-release or long-acting opioid should be made with an equal amount of agent. Several sustained-release products are available containing morphine, oxycodone, and fentanyl. Some clinicians will reduce the total daily dose of the long-acting dosage form by 25% when initiating a sustained-release product to reduce the likelihood of oversedation. The dose of a pure agonist is limited only by tolerability to side effects. Tolerance might develop to analgesic effects, necessitating increasing doses to achieve the same level of pain relief. Physical dependence will occur with the long-term use of opioids. However, addiction or psychological dependence is unlikely in legitimate pain patients unless there are predisposing risk factors. Pain patients who are undertreated might appear to be drug seeking (pseudoaddiction); however, effective pain management resolves the behaviors. When opioids are used for chronic pain, use of informed consent for chronic opioid therapy, medication management agreements, or pain contracts might be appropriate to monitor the use (prescribing and dispensing) of controlled substances.

Opioids are administered by a variety of routes, including oral (tablet and liquid), sublingual, rectal, transdermal, transmucosal, IV, subcutaneous, and intraspinal. Although the oral and transdermal routes are most common, the method of administration is based on patient needs (severity of pain) and characteristics (swallowing difficulty and preference). Oral opioids have an onset of effect of 45 minutes, so IV or subcutaneous administration might be preferred if more rapid relief is desired. Intramuscular (IM) injections are not recommended because of pain at the injection site and wide fluctuations in drug absorption and peak plasma concentrations achieved. More invasive routes of administration such as PCA and intraspinal (epidural and intrathecal) are primarily used postoperatively but might also be used in refractory chronic pain situations. PCA delivers a self-administered dose via an infusion pump with a preprogrammed dose, minimum dosing interval, and a maximum hourly dose. Morphine, fentanyl, and hydromorphone are commonly administered via PCA pumps by the IV route but less frequently by the subcutaneous or epidural route.

Epidural analgesia is frequently used for lower extremity procedures and pain (eg, knee surgery, labor pain, and some abdominal procedures). Intermittent bolus or continuous infusion of preservative-free opioids (morphine, hydromorphone, or fentanyl) and local anesthetics (bupivacaine) might be used for epidural analgesia. Opiates given by this route might cause pruritus that is relieved by naloxone. Adverse effects including respiratory depression, hypotension, and urinary retention might occur. When epidural routes are used in narcotic-dependent patients, systemic analgesics must also be used to prevent withdrawal because the opioid is not absorbed and remains in the epidural space. Doses of opioids used in epidural analgesia are 10 times less than IV doses, and intrathecal doses are 10 times less than epidural doses (ie, 10 mg of IV morphine is equivalent to 1 mg epidural morphine and 0.1 mg of intrathecally administered morphine).[38]

**Combination Analgesics** Combinations of opioids and nonopioids often result in enhanced analgesia and lower dose of each. Combination analgesics are frequently used in moderate pain. However, in severe pain, the nonopioid component reaches maximum dosage, and thus the usefulness of nonopioids in this situation is limited. Additionally, the combination products are short acting and often not suitable for chronic therapy. Single agents offer greater dosing flexibility than combination products.

**Opioid Allergy** True narcotic allergies are rare and should not be confused with pruritus associated with opiate use. Cross-sensitivity between morphine-like, meperidine-like, and methadone-like agents is unlikely. Therefore, when an individual is allergic to one drug in a chemical class of opioids, it is reasonable to select an agent in another chemical class. For the purpose of drug selection in patients with allergies, mixed agonists/antagonists should be treated as morphine-like agents.

**Tapering of Opioids** Tapering of opioids might be necessary once the painful situation has resolved in patients receiving doses greater than 160 mg/day of oral morphine (or the equivalent) or in those with prolonged opioid use. In these situations, the dose should be reduced by 15% to 20% each day to avoid withdrawal symptoms.

**Managing Opioid Side Effects and Drug Interactions** Side effects common to all opioids include sedation, hallucinations, constipation, nausea and vomiting, urinary retention, myoclonus, and respiratory depression. Table 34–3 shows management strategies for side effects. The most frequent side effects are sedation, nausea, and constipation. Sedation and nausea are common when initiating therapy and when increasing doses. Tolerance to respiratory depression develops rapidly with repeated doses, and respiratory depression is rarely a clinically significant problem in pain patients even those with respiratory impairment. Constipation is a significant adverse effect to which tolerance does develop, and prophylaxis with stimulant laxatives (eg, senna or bisacodyl) and stool softeners such as docusate is recommended.

## Table 34–3

**Managing Opioid Side Effects**

| Adverse Effects | Drug Treatment/Management |
|---|---|
| Excessive sedation | Reduce dose by 25% or increase dosing interval |
| Constipation | Casanthranol-docusate one capsule at bedtime or twice daily; senna one to two tablets at bedtime or twice daily; bisacodyl 5–10 mg daily plus docusate 100 mg twice daily; polyethylene glycol 3350 17 grams daily; methylnaltrexone 0.15 mg/kg SQ every other day; naloxegol 12.5–25 mg daily |
| Nausea and vomiting | Prevention: Hydroxyzine 25–100 mg (po/IM) every 4–6 hours as needed; diphenhydramine 25–50 mg (po/IM) every 6 hours as needed; ondansetron 4 mg IV or 16 mg po<br>Treatment: Prochlorperazine 5–10 mg (po/IM) every 3–4 hours as needed or 25 mg PR twice daily; ondansetron 4–8 mg IV every 8 hours as needed |
| Gastroparesis | Metoclopramide 10 mg (po/IV) every 6–8 hours |
| Vertigo | Meclizine 12.5–25 mg po every 6 hours as needed |
| Urticaria/itching | Hydroxyzine 25–100 mg (po/IM) every 4–6 hours as needed; diphenhydramine 25–50 mg (po/IM) every 6 hours as needed |
| Respiratory depression | Mild: Reduce dose by 25%<br>Moderate to severe: Naloxone 0.4–2 mg IV every 2–3 minutes (up to 10 mg) for complete reversal; 0.1–0.2 mg IV every 2–3 minutes until desired reversal for partial reversal; may need to repeat in 1–2 hours depending on narcotic half-life |
| CNS irritability | Discontinue opioid; treat with benzodiazepine |

IM, intramuscular; po, orally; PR, per rectum.

Data from Refs. 25, 39, and 42.

Codeine, hydrocodone, morphine, methadone, and oxycodone are substrates of the cytochrome P450 (CYP) enzyme: CYP2D6.[41] Inhibition of CYP2D6 results in decreased analgesia of codeine and hydrocodone due to decreased conversion to the active metabolites (eg, morphine and hydromorphone, respectively) and increased effects of morphine, methadone, and oxycodone. Methadone is also a substrate of CYP3A4, and its metabolism is increased by phenytoin and decreased by cimetidine. CNS depressants might potentiate the sedative effects of opiates.

**Opioid Rotation**  Opioid rotation is the switch from one opioid to another to achieve a better balance between analgesia and treatment-limiting adverse effects. This practice is often used when escalating doses (greater than 1 g morphine/day) become ineffective. In some settings, opioid rotation is used routinely to prevent the development of analgesic tolerance.[42]

**Equianalgesic Dosing of Opioid Analgesics**  Conversion from one dosage form to another or from one opioid to another might be necessary in situations such as ineffective pain control,

## Patient Encounter, Part 2

Following surgery she was placed on morphine patient-controlled analgesia (PCA). She has been using 55 mg of morphine/24 hours with adequate pain control; however, she has developed redness and itching on her neck that is believed to be due to the morphine.

**Current Meds:** Morphine PCA; lisinopril 20 mg daily; metformin 500 mg three times daily; lovenox 30 mg subcutaneously daily, until ambulating. She will be discharged to a skilled nursing facility for rehabilitation therapy.

The physician would like to convert her to a combination preparation of hydrocodone and APAP.

*What dosing regimen would you suggest?*

*Recommend a monitoring plan for this patient.*

*How would you assess pain response?*

*The patient is concerned about the redness and itching she developed while on morphine. What other interventions or education may be necessary at this time?*

emergence of side effects, change in patient status, and in formulary restrictions. **KEY CONCEPT** *Equianalgesic doses should be used when converting from one opioid to another.* Clinicians should be familiar with the equianalgesic dosing and conversion strategies to avoid analgesic failure. Opioid potency is compared using a reference standard of 10 mg parenteral morphine. Switching from one dosage form to another of the same opioid (ie, IV to oral) is relatively simple. The current total daily dose is calculated and the total of the new dosage form is determined using a ratio of the equianalgesic doses. This result is then adjusted based on the usual dosing frequency of the new form. When converting to a sustained-release form of the same opioid, the oral dosage may be reduced by 25% to avoid initial sedation; however, the specific product literature should also be consulted.

The first step in an opioid rotation is to calculate the patient's total daily dose of opioid based on the regularly scheduled dose and the total amount of rescue dose needed in 24 hours. This total is then converted to morphine-dosing equivalents using equianalgesic doses (see Table 34–2). The total daily morphine dose is then used to calculate the daily dose of the new opioid using dosing equivalents from an equianalgesic table. Because cross-tolerance may not be complete between opioids, some references suggest that the calculated equianalgesic dose be reduced by 25% to 50%.[39] If the opioid switch is due to uncontrolled pain, a dosage reduction may not be needed. The calculated equianalgesic dose may need to be reduced more in the medically frail and when converting to methadone.[43,44] Methadone appears to be much more potent than once believed, and morphine-to-methadone ratios vary according to the total dose of morphine taken at the time of making the conversion to methadone (Table 34–4).[45,46] Conversion to methadone is a complex process, and several different strategies have been proposed including a switch of the entire dose in 1 day or a gradual conversion over 3 days.

▶ *Adjuvant Agents for Chronic Pain*

The role of NSAIDs and opioids in chronic nonmalignant pain has been discussed; however, a review of adjuvant agents for

Data from Gazelle G, Fine PG. Fast fact and concepts #75. Methadone for the treatment of pain. End-of-life Physician Education Resource Center [Internet], [cited 2014 Aug 31]. http://www.eperc.mcw.edu/EPERC/FastFactsIndex/ff_075.htm, with permission.

chronic pain, particularly neuropathic pain, is warranted. Adjuvant analgesics are drugs that have indications other than pain but are useful as monotherapy or in combination with nonopioids and opioids. Common adjuvants include antiepileptic drugs (AEDs), antidepressants, antiarrhythmic drugs, local anesthetics, topical agents (eg, capsaicin), and a variety of other drugs (eg, NMDA antagonists, clonidine, and muscle relaxants).

There is little consensus on the optimal management of neuropathic pain because much of the evidence for treatment effectiveness consists of anecdotal reports or poorly designed trials. Published guidelines have been suggested for the general management of neuropathic pain.[47] Suggestions for first-line therapy include gabapentin or pregabalin, transdermal lidocaine, or tricyclic antidepressants (TCAs) (**Table 34–5**).[47–50] Newer antidepressants, such as the SSRIs, have fewer side effects but appear to be less effective than the TCAs for neuropathic pain. However, serotonin-norepinephrine reuptake inhibitors (SNRIs), (eg, duloxetine and venlafaxine) have been used successfully for painful DPN. A stepwise approach is suggested for managing the patient with neuropathic pain beginning with the least invasive, effective therapeutic choice and proceeding to the rational use of multiple drug regimens (see Figure 34–2). Choice of agent might also depend on dosing frequency and comorbidities. Data on combination therapy are lacking, and the use of combined treatment

**Patient Encounter, Part 3**

She was discharged to a skilled nursing facility and is receiving physical therapy and occupational therapy 6 days each week.

**Current Meds:** Lisinopril 20 mg daily; metformin 500 mg three times daily; lovenox 30 mg subcutaneously daily, until ambulating; hydrocodone/acetaminophen 5/325 mg every 6 hours as needed for pain

**Pain Assessment:** Patient reports pain of 7 out of 10; worse with movement

Physical therapy notes indicate patient is unable to complete therapy goals due to complaints of pain

Data from Refs. 47–50.

is empirical based on the additive therapeutic benefit. Scheduled medication regimens instead of "as-needed" dosing should be used when treating chronic pain, and the effectiveness of therapy should be reassessed regularly. If patients are managed on a multiple drug regimen and changes are indicated, changing only one drug at a time is suggested. Topical agents (eg, capsaicin) might be added to a regimen to reduce the oral medication load, particularly if adverse effects are a problem or if pain is not relieved.

▶ *Complementary and Alternative Medicine*

*Complementary and alternative medicine* (CAM) is a term used to encompass a variety of therapies (eg, acupuncture, chiropractic, botanical and nonbotanical dietary supplements, and homeopathy). Painful conditions are among the most common reasons

## Patient Encounter, Part 4

The patient has been at the skilled nursing facility for 3 weeks and is making progress toward rehabilitation goals. She is walking with a walker almost 200 ft (61 m); however, she complains that her feet feel "very heavy" and feel like pins and needles. As a result, she requests to rest several times during her therapy sessions. During unit rounds, her therapist inquires whether her previous pain medication should be reordered.

**Pain Assessment:** 0 out of 10

**Current Meds:** Lisinopril 20 mg daily; metformin 500 mg three times daily; lovenox 30 mg subcutaneously daily, until ambulating 200 ft

*What additional recommendations would you have at this time regarding pain management?*

*Are there any other therapeutic issues that should be addressed?*

individuals seek relief from CAM. A variety of dietary supplements have been suggested for painful conditions such as S-adenosylmethionine (SAM-e), ginger, fish oil, feverfew, γ-linoleic acid, glucosamine, and chondroitin. Of these, glucosamine and

chondroitin are the most popular and have the most evidence supporting their efficacy. Glucosamine in doses of 1500 mg/day has been shown to be effective in reducing the pain of osteoarthritis by fostering repair of cartilage, and it is recommended by the Osteoarthritis Research Society International (OARSI).[36]

## OUTCOME EVALUATION

Routine pain assessment is essential for evaluating outcomes of therapy. For example, pain goals for acute pain might include "pain scale less than 3." Functional goals such as "be able to play a game with grandchildren," or "be able to knit again" may be appropriate for chronic pain. Assess patients periodically, depending on the method of analgesia and pain condition, for achievement of pain goals. Evaluate the patient for the presence of adverse drug reactions, drug allergies, and drug interactions.

## Patient Care Process

**Patient Assessment:**

- Identify the source of pain.
- Assess the level of pain using a pain intensity scale.
- Review the medical and medication history.

**Therapy Evaluation:**

- If patient is already receiving drug therapy, assess efficacy, side effects, adherence, and drug interactions.
- Determine if patient has insurance coverage for prescription medications.

**Care Plan Development:**

- Base the initial choice of analgesic on the severity and type of pain, as well as on the patient's medical condition and concurrent medications.
- Select the least potent oral analgesic that provides adequate pain relief and causes the fewest side effects.
- Avoid excessive sedation.
- Adjust the route of administration if the patient is unable to take oral medications.
- Use equianalgesic doses as a guide when switching opioids.
- Use a dosing schedule versus as-needed dosing.

**Follow-up Evaluation:**

- Assess the patient for analgesic effectiveness and for side effects at each visit or more frequently, depending on the acuity of the patient's condition.
- Titrate the dose to one that achieves an adequate level of pain control.

# Headache

Joshua W. Fleming, Leigh Ann Ross, and
Brendan S. Ross

## LEARNING OBJECTIVES

● **Upon completion of the chapter, the reader will be able to:**

1. Differentiate types of headache syndromes based on clinical features.
2. Recommend nonpharmacologic measures for headache treatment and prevention.
3. Determine when the pharmacologic treatment of headache is indicated.
4. Construct individualized treatment regimens for the acute and chronic management of headache syndromes.
5. Monitor headache treatment to ensure its safety, tolerability, and efficacy.

## INTRODUCTION

Headache is a common medical complaint with approximately 47% of the adult population experiencing at least one headache per year.[1] KEY CONCEPT *Even when persistent or recurrent, headaches are usually a benign primary condition; secondary headaches are caused by an underlying medical disorder and may be medical emergencies.* Primary headache syndromes are the focus of this chapter. Patients may seek headache care from multiple providers. All clinicians should be familiar with the various types of headache, clinical indicators suggesting the need for urgent medical attention or specialist referral, and nonpharmacologic and pharmacologic options for treatment. KEY CONCEPT *The International Headache Society (IHS) classifies primary headaches as migraine, tension-type, or cluster and other trigeminal autonomic cephalalgias.*[2]

## EPIDEMIOLOGY OF HEADACHE DISORDERS

### Migraine Headache

Migraine is a primary headache disorder with an estimated 3-month prevalence rate in the United States of 16.6% to 22.7%, based on data from multiple general health surveillance studies.[3] Prevalence of migraine depends on age, gender, and income. In children and adolescents onset typically begins at age 7.9 years for males and 10.9 years for females.[4] In adults, prevalence is much higher in women (17.1%) than men (6.1%), and occur most often between 30 and 49 years of age.[5] The difference in gender distribution is thought to be due to hormonal differences. In households with an annual income greater than $90,000, migraine prevalence is much lower (13.6% women; 4.2% men) than in households with an annual income less than $22,500 (20.1% women; 8.8% men).[5]

### Tension-Type Headache

KEY CONCEPT *Tension-Type Headache (TTH) is the most common primary headache disorder and can be further divided into episodic or chronic.*[2] TTHs are underrepresented in clinical practice because most patients do not present for care.[6] The term *TTH* is used to describe all headache syndromes in which sensitization to pericranial nociception, noxious stimuli, is the most significant factor in the pathogenesis of pain.[7] Overall prevalence of TTH is approximately 86%, and incidence is more common in women than men. Episodic TTH is the most common type followed by frequent episodic TTH, and finally chronic TTH. Incidence of TTH increases until approximately age 40, then incidence begins to slowly decline.[6] Environmental factors, as opposed to genetic predisposition, play a central role in the development of TTH. The mean frequency of attacks is 3 days per month in episodic disorders; chronic TTH is defined as 15 or more attacks in a 1-month period.[2]

### Cluster Headache and Other Trigeminal Autonomic Cephalalgias

Cluster headache disorders are uncommon and severe primary headache syndromes.[2] In the most recent studies the lifetime prevalence is estimated to be 124 per 100,000.[8] Unlike migraine and TTH, cluster headaches are more frequently found in men. Onset most commonly occurs between 20 and 40 years.[2] A genetic predisposition is apparent, although affected individuals often provide the additional history of tobacco use, caffeine intake, and alcohol abuse.[8] Attacks consist of debilitating, unilateral head pains that occur in series lasting up to months at a time but may abate for extended periods, resulting in months or years between occurrences. In rare instances, cluster headache can be a chronic disorder without remission.[2]

## ETIOLOGY AND PATHOPHYSIOLOGY OF HEADACHE DISORDERS

### Migraine Headache

The exact mechanism by which migraines produce headache remains obscure, but the belief that only vascular changes are responsible for the pain is no longer accepted.[9] The vascular

hypothesis suggested that intracerebral vasoconstriction led to neural ischemia, which was followed by reflex extracranial vasodilation and pain. Negative neuroimaging evidence for such vascular changes and the effectiveness of medications with no vascular properties make this contention untenable.[7] A neuronal etiology has emerged as the leading mechanism for the development of migraine pain.[10] It is believed that depressed neuronal electrical activity spreads across the brain, producing transitory neural dysfunction.[11] Headache pain is likely due to compensatory overactivity in the trigeminovascular system of the brain. Activation of trigeminal sensory nerves leads to the release of vasoactive neuropeptides (eg, calcitonin gene-related peptide [CGRP], neurokinin A, substance P) that produce a sterile inflammatory response around vascular structures in the brain, provoking the sensation of pain.[10] Continued sensitization of CNS sensory neurons can potentiate and intensify headache pain as an attack progresses.[11] Bioamine pathways projecting from the brainstem regulate activity within the trigeminovascular system. The pathogenesis of migraine is most likely due to an imbalance in the modulation of nociception and blood vessel tone by serotonergic and noradrenergic neurons.[10]

### Tension-Type Headache

The pathophysiologic mechanisms producing TTHs are not clearly understood and are likely multifactorial. However, central sensitization to peripheral nociceptive input arising from the pericranial myofascia is the leading hypothesis. The belief that sustained muscle contraction is solely responsible for generating the pain cannot be supported. Muscle tenderness is prominent in this syndrome, but it only reflects a heightened sensitivity to pain. TTH pain is believed to arise by disturbances in the muscles and tissues of the head being misinterpreted due to disordered CNS pain processing.[12]

### Cluster Headache and Other Trigeminal Autonomic Cephalalgias

Cluster headache is one of a group of disorders referred to as trigeminal autonomic cephalalgias.[13] This autonomic nervous system dysfunction is characterized by sympathetic underactivity coupled with parasympathetic activation. Similar to migraine, the pain of a cluster headache is believed to be the result of vasoactive neuropeptide release and neurogenic inflammation. The exact cause of trigeminal activation in this intermittently manifest syndrome is unclear.[14] One hypothesis is that hypothalamic dysfunction, occasioned by diurnal or seasonal changes in neurohumoral balance, are responsible for headache periodicity.[7] Serotonin affects neuronal activity in the hypothalamus and trigeminal system and may play a role in the pathophysiology of cluster headache. The precipitation of cluster headache by high-altitude exposure also implicates hypoxemia in the pathogenesis of trigeminal autonomic cephalalgias.[15]

## CLINICAL PRESENTATION AND DIAGNOSIS OF HEADACHES

### Migraine Headache

Migraine presents as a recurrent headache that is severe enough to interfere with daily functioning. **KEY CONCEPT** *Migraine headaches are classified as migraine with aura and migraine without aura.*[2] Aura is defined as a transient focal neurologic symptom that can occur prior to or during an attack. These typically present as wavy lines or spots, but can also present as a scotoma.[2] The IHS outlines diagnostic criteria that differentiate migraine with and

---

### Clinical Presentation and Diagnosis of Migraine without Aura

Patients experiencing "migraine without aura" may display the following headache symptoms and characteristics:

Two or more of the following are present:

1. Pain interrupts or worsens with physical activity
2. Unilateral pain
3. Pulsating pain
4. Moderate to severe pain intensity

One or more of the following are present during headache:

1. Nausea/vomiting
2. Photophobia and phonophobia

Duration: 4 to 72 hours (treated or not treated)

Criteria for diagnosis: Five or more attacks fulfilling above criteria are necessary

Laboratory assessments that may be helpful in excluding medical comorbidities: Complete blood count (CBC), chemistry panel, thyroid function tests (TFTs), erythrocyte sedimentation rate (ESR)

---

without aura. Migraines can be triggered by changes in behavior, environment, diet, and hormone levels. Migraines can additionally be triggered by intake of tyramine, aspartame, monosodium glutamate, and nitrites.[16] Migraines occurring 15 or more days per month for a 3-month period or longer, without the overuse of analgesic medications, are classified as chronic migraines.[2] Severe and debilitating migraine pain lasting more than 72 hours is termed status migrainosus.[2]

---

### Clinical Presentation and Diagnosis of Migraine with Aura

Patients experiencing "migraine with aura" may display the following headache symptoms and characteristics:

One or more of the following present with no motor weakness:

1. Visual
2. Sensory
3. Speech and/or language
4. Motor
5. Brainstem
6. Retinal

Two or more of the following:

1. At least one aura symptom that spreads gradually over at least 5 minutes
2. Individual aura symptoms last 5 to 60 minutes
3. At least one aura symptom is unilateral
4. The aura is accompanied or followed by a headache within 60 minutes

Criteria for diagnosis: Two or more attacks fulfilling above criteria are necessary

## Clinical Presentation and Diagnosis of Tension-Type Headache

Patients experiencing TTH may display the following headache symptoms and characteristics:

Two or more of the following present and are not aggravated by routine physical activity:

1. Bilateral pain
2. Nonpulsating pain
3. Mild or moderate pain intensity

Both of the following:

1. No nausea or vomiting (anorexia possible)
2. Either photophobia or phonophobia (not both)

Duration: 30 minutes to 7 days

Criteria for diagnosis: 10 or more attacks fulfilling above criteria occurring on average less than 1 day per month are necessary

### Tension-Type Headache

TTH pain differs from migraine pain in that it is usually reported to be mild to moderate in severity, nonpulsating, and bilateral.[6] The pain is described by sufferers as a band-like tightness or pressure around the head. No transient neurologic deficits are noted, and systemic symptoms are rare. TTHs occurring more than 15 days per month for more than 3 months, without evidence medication overuse, would be classified as chronic TTH.[2]

### Cluster Headache

Pain associated with cluster headache differs from migraine and TTH in that it is severe, intermittent, and short in duration.[7] Headaches typically occur at night, but attacks may occur

## Clinical Presentation and Diagnosis of Cluster Headache

Patients experiencing "cluster headache" may display the following headache symptoms and characteristics:

At least one or more of the following symptoms:

1. Lacrimation
2. Nasal congestion and/or rhinorrhea
3. Eyelid edema
4. Forehead or facial sweating/flushing
5. Sensation of fullness in the ear
6. Miosis and/or ptosis

Or a sense of restlessness or agitation

Duration of pain: 15–180 minutes (untreated)

Frequency of attacks: One every other day and/or up to 8 per day for more than half the time the disorder is active (may have long periods when headaches are inactive)

Criteria for diagnosis: Five or more attacks fulfilling the above criteria

## Patient Encounter, Part 1

A 34-year-old woman complains of "almost monthly" headaches around the time of menstruation. She states that the pain is so severe that she has to stay home from work and lie down in a darkened room. She describes her pain as sharp, unilateral, and pulsating. She reports that she can tell when it is about to begin because she can see "floaters" then her peripheral vision begins to fade. She reports using OTC pain relievers to help ease the pain, but she has not had any success thus far.

*What type of headache is the patient most likely experiencing?*

*What characteristics of the headache support this diagnosis?*

*What are possible causes or triggers of headache in this patient?*

multiple times per day.[14] The pain is usually unilateral, but, unlike migraine, it is not described as pulsatile.[7] Aura is not a feature, and pain intensity peaks early after onset, although it may persist for hours.[7] The headache is described as explosive and excruciating. A constellation of features, ascribed to parasympathetic overactivity, can be seen, such as ipsilateral conjunctival injection and lacrimation, rhinorrhea, and sweating.[14] Cluster headache patients tend to become excited and restless during attacks, rather than seeking quiet and solitude as in migraine.[13]

## TREATMENT OF HEADACHE DISORDERS

### Desired Outcomes

The most important goal of acute headache management is pain relief. **KEY CONCEPT** *The short-term treatment goal of migraine is to achieve rapid pain relief to allow the patient to resume normal activities. The long-term goal of therapy is to prevent headache recurrences and to diminish headache severity.*[17] Similarly, the goal of TTH care is to lessen headache pain, whereas the long-term goal is to avoid analgesic overuse and dependence.[18] The short-term therapeutic goal in cluster headache is to achieve rapid pain relief. Prophylactic therapy may be necessary to obtain the intermediate-term outcome of reducing the frequency and severity of headaches within a periodic cluster series, as well as to achieve the long-term goal of delaying or eliminating recurrent periods.[19]

### General Approach to Treatment

First-line pharmacologic agents include nonsteroidal and opiate analgesics, and serotonin-receptor agonists (triptans).[17] **KEY CONCEPT** *Pharmacologic treatment of acute headache should be started early to abort the intensification of pain and to improve response to therapy.* The long-term management of headache syndromes focuses on lifestyle modification and other nonpharmacologic therapeutic options; if headaches are severe and frequent, then prophylactic pharmacologic therapy is needed.[17] **KEY CONCEPT** *Several clinical markers, so-called red flags, have been identified that warrant urgent physician referral and further diagnostic evaluation* (Table 35–1).[20]

### Nonpharmacologic Therapy

The successful management of headache disorders depends on comprehensive patient education. Recording headache frequency, duration, severity, possible triggers, and medication

---

**Table 35–1**

**Headache "Red Flags" Indicating Need for Urgent Medical Evaluation**

New-onset sudden and/or severe pain
Stereotyped pain pattern worsens
Systemic signs (eg, fever, weight loss, or accelerated hypertension)
Focal neurologic symptoms (ie, other than typical visual or sensory aura)
Papilledema
Cough-, exertion-, or Valsalva-triggered headache
Pregnancy or postpartum state
Patients with cancer, human immunodeficiency virus (HIV), and other infectious and immunodeficiency disorders
Seizures

response in a "headache diary" provides beneficial information for the patient regarding headache precipitants and useful insights for the clinician selecting appropriate management strategies.[21] To prevent future occurrences, exposure to headache triggers (**Table 35–2**) should be limited.[15] In the acute setting,

---

**Table 35–2**

**Migraine Triggers**

**Behavioral:**
Fatigue
Menstruation or menopause
Sleep excess or deficit
Stress
Vigorous physical activity

**Environmental:**
Flickering lights
High altitude
Loud noises
Strong smells
Tobacco smoke
Weather changes

**Food:**
Alcohol
Caffeine intake or withdrawal
Chocolate
Citrus fruits, bananas, figs, raisins
Dairy products
Fermented or pickled products

**Food Containing:**
Monosodium glutamate (MSG): Asian food, seasoned salt
Nitrites: processed meats
Saccharin/aspartame: diet soda or diet food
Sulfites: shrimp
Tyramine: cheese, wine, organ meats
Yeast: breads

**Medications:**
Cimetidine
Estrogen or oral contraceptives
Indomethacin
Nifedipine
Nitrates
Reserpine
Theophylline
Withdrawal due to overuse of analgesics, benzodiazepines, decongestants, or ergotamines

**Patient Encounter, Part 2: Medical History, Physical Examination, and Diagnostic Tests**

**PMH:** Hypertension (HTN)

**FH:** Father living, age 67 years: HTN, diabetes mellitus; mother living, age 62 years: migraine headaches; two sisters in good health

**SH:** Recently divorced; medical lab technician; former smoker; "social" alcohol intake (one to two mixed drinks on weekends), three to four cups of coffee per day

**Meds:** Hydrochlorothiazide/triamterene 50/25 mg orally per day; ibuprofen 200 mg, two tablets orally every 4 to 6 hours as needed for headache

**ROS:** Headache, moderate-severe intensity, sensitivity to light; no dizziness; no chest pain or palpitations; no shortness of breath with exertion; no weakness or joint discomfort

**PE:**

**VS:** BP 143/81, P 91, RR 18, T 37.0°C (98.6°F) oral

**HEENT:** No papilledema, neck tender without stiffness

**CV:** RRR, normal S1, S2, S4 gallop, no MR

**Chest:** CTA

**Abd:** Benign, bowel sounds positive

**Neuro:** Nonfocal

**Labs:** CBC and chemistry panel within normal limits

*What is your assessment of this patient's condition?*

environmental control can lessen the severity of an attack, so patients may benefit from resting in a dark, quiet area.[22] Behavioral interventions, such as biofeedback, relaxation therapy, and cognitive-behavioral training, are effective and can be recommended for headache prevention. Headache sufferers may also benefit from stress management training.[15] Acupuncture has yielded inconsistent benefits in clinical trials.[23] Although the response is variable, headache patients should be advised to moderate alcohol use and curtail tobacco abuse.[19] All such nonpharmacologic therapies may be useful in augmenting pharmacologic response.

## Pharmacologic Therapy

### ▶ *Migraine*

Analgesics, such as nonsteroidal anti-inflammatory drugs (NSAIDs) and acetaminophen, with or without an opioid, are the initial pharmacologic option for the acute management of migraine headache especially when severity is mild to moderate. If these analgesics prove to be ineffective, and when headaches

are severe, then migraine-specific medications, such as trip-tans, are administered.[17] Early abortive treatment should be the rule. If the orally administered route is selected for medication administration, then larger doses than otherwise required to produce pain relief may need to be provided, due to the enteric stasis and poor drug absorption accompanying migraine attacks. Intranasal, parenteral, and rectal administration can circumvent this complication.[17]

Clinical trial evidence supports many NSAID medications in the acute treatment of migraines with and without aura.[24] Acetaminophen alone or in proprietary combinations with aspirin, opioids, caffeine, or butalbital is also effective.[25]

The triptans are considered specific therapies in that they target the pathophysiology underlying migraine.[17] Triptans inhibit neurotransmission in the trigeminal complex and activate serotonin 1B/1D pathways in the brainstem, which modulate nociception. They also decrease the release of vasoactive neuropeptides leading to vascular reactivity and pain.[26] The triptans are available in intranasal, subcutaneous, and oral dosage forms. The available agents differ in their dosing and pharmacokinetic properties, but all are effective treatments to abort or diminish migraine headache (Table 35–3).[27] Patient responses can be variable; if a patient does not respond to one agent, then another is selected before a patient is prematurely labeled as triptan-unresponsive.[28] The initial severity of headache correlates with symptomatic response; thus administration should be prompt. Relief is usually experienced within 2 to 4 hours. Treatment delay may lead to decreased analgesia through the development of refractory central pain sensitization. Efficacy tends to be dose related, although adverse effects are less so.[29] These medications are well tolerated; the most common side effects are dizziness, a sensation of warmth, chest fullness, and nausea. Rarely, ischemic vascular events may be precipitated by the potential vasoconstrictive nature of these drugs.[30] An initial dose under direct practitioner supervision is indicated for patients at increased cardiovascular risk. Triptans are avoided in patients with migraine associated with neurologic focality, a history of previous stroke, poorly controlled hypertension, or unstable angina. Triptans are relatively contraindicated for routine use in pregnancy.[22] Triptans should not be used with concurrent ergotamine administration.[30]

Ergotamine derivatives produce salutary effects on serotonin receptors similar to triptans. They also impact adrenergic and dopaminergic receptors. Ergotamine tartrate and dihydroergotamine (DHE) are the most commonly used agents.[17] The latter is not available in an oral dosage form. Analgesic onset is within 4 hours, although additional dosing is required if an acceptable

## Table 35–3

**Comparison of Serotonin Receptor Agonists (Triptans)**

| Medication (Brand Name) | Dosage Forms | Strength (mg) | Usual Dosage (mg) | May Repeat (hours) | Hepatic and Renal Dosing Considerations (mg) | Potential Drug Interactions |
|---|---|---|---|---|---|---|
| Almotriptan (Axert) | Oral tablets | 6.25 12.5 | 6.25–12.5 | 2 | HI and Severe RI: 6.25 starting dose and ≤ 12.5 | Ergot derivatives Substrate: CYP 3A4, CYP 2D6 |
| Eletriptan (Relpax) | Oral tablets | 20 40 | 20–40 | 2 | Severe HI: Not recommended | Ergot derivatives Substrate: CYP 3A4, CYP 2D6 |

Mod-Severe HI: Not recommended | Ergot derivatives MAO-A inhibitors Substrate: CYP 1A2 |

CLcr, creatinine clearance; CYP, cytochrome P450 enzyme; HI, hepatic impairment; MAO-A, monoamine oxidase type A; RI, renal impairment.

Adapted from Refs. 15 and 31–38.

response is not achieved. When dosed parenterally, these drugs are usually provided with an antiemetic due to their potential to worsen the nausea associated with migraine. Metoclopramide and chlorpromazine are the drugs of choice in such instances. Intranasal DHE can be self-administered to abort an attack.[17] The outpatient use of subcutaneous ergotamines is limited by the lack of a prefilled syringe form. The same cautions associated with triptan use are also applicable to ergot use in patients at risk for vascular events.

The choice of initial therapy for acute migraine attacks is a subject of debate among specialists. Some believe that nonspecific analgesics should be used first line, whereas others believe migraine-specific drugs should be the choice for patients with severe pain or a history of significant disability.[39] A stepped-care approach within attacks from less to more specific drugs is usually recommended. Once a history of headache refractory to common analgesics is established, triptans should be used as initial therapy.[17] Selection of initial headache treatment is important in reducing the incidence of medication-overuse headache (MOH). This occurs when patients use ergotamines, triptans, opioids, or other combinations for more than 10 days per month. This can also be considered in patients who are using nonspecific analgesics for more than 15 days per month.[40] In patients who present to the hospital with intractable pain, IV metoclopramide supplemented with DHE may be needed. Oral medications in this setting are not used because nausea and vomiting limit their bioavailability.[17] Migraine patients with frequent and severe attacks are candidates for prophylactic treatment.[41]

#### ▶ Tension-Type Headache

Most individuals who experience episodic TTHs will not seek medical attention.[2] Instead, they will find relief with the use of widely available OTC analgesics. Acetaminophen products and NSAIDs are commonly utilized. An individual patient may benefit from topical analgesics (eg, ice packs) or physical manipulation (eg, massage) during an acute attack, but the evidence supporting nonpharmacologic therapies is inconsistent.[7] Relaxation techniques can often reduce headache frequency and severity. When pain is unrelieved, prescription-strength NSAID use is required, or the combination of acetaminophen with an opioid analgesic may be necessary. The frequent use of these more potent analgesics should be limited, so that the development of dependency is prevented. As described above, MOH can occur with frequent use of analgesics for TTH. For patients experiencing frequent TTH, prophylactic treatment should be considered.[40]

#### ▶ Cluster Headache

Cluster headache responds to many of the treatment modalities used in acute migraine; however, initial prophylactic therapy is required to limit the frequency of recurrent headaches within a periodic series. A therapy specific to cluster headaches is the administration of high-flow-rate oxygen: 100% at 5 to 10 L/min by nonrebreather face mask for approximately 15 minutes.[42] If the pain is not aborted, retreatment is indicated. No long-term side effects are seen with short-term oxygen use. If oxygen therapy is not wholly effective, then drugs are useful adjunctive therapy. Drug therapy is also used when supplemental oxygen is not readily available. The triptan class is safe and effective. Intranasal or subcutaneous sumatriptan as well as intranasal zolmitriptan has demonstrated efficacy in decreasing cluster headache pain.[43] Oral triptans are also effective, but their delayed onset

of action may limit their applicability in acute cluster headache treatment.[26] Cluster headache is rapid in onset and achieves peak intensity quickly, but it can be of short duration. Oral agents may have utility in limiting the recurrence of cluster attacks. Intranasal, intramuscular, or IV ergotamine agents are an alternative to triptan use.[7] Repeated dosing may break a cluster series. For those patients in whom triptans and ergotamine derivatives are contraindicated due to ischemic vascular disease, octreotide may be helpful to relieve pain.[43] Octreotide is a somatostatin analogue that has a short half-life and may be administered subcutaneously. Unlike the other abortive agents, it has no vasoconstrictive effects; the most prominent treatment emergent adverse effect is gastrointestinal (GI) upset. Glucocorticoids, provided IV and later tapered orally, are effective when cluster headache attacks are not satisfactorily controlled.[14]

### Pharmacologic Therapy for Headache Prophylaxis

**KEY CONCEPT** *Prophylaxis for headache disorders is indicated if headaches are frequent or severe, if significant disability occurs, if pain-relieving medications are used frequently, or if adverse events occur with acute therapies.*[17]

#### ▶ Migraine Prophylaxis

Migraine headaches that are severe, frequent, or lead to significant disability require long-term medication therapy. Prophylactic therapy is also recommended for migraines associated with neurologic focality because it may prevent permanent disability.[17] Although multiple medication classes have garnered Food and Drug Administration (FDA) labeling for migraine prevention, there is no consensus on the best initial therapy (**Table 35–4**).[41] **KEY CONCEPT** *The choice of pharmacologic agent is individually tailored to patient tolerability and medical comorbidities.*

#### Table 35–4

**Medications for Prophylaxis of Migraines**

| Medication (Brand Name) | Usual Dosage (mg/day) | Main Adverse Effects |
|---|---|---|
| **Antiepileptics:** | | |
| Topiramate (Topamax)[a] | 50–200 | Paresthesias, dizziness, fatigue, nausea |
| Valproic acid (Depakene)[a] | 500–1500 | |
| Divalproex sodium (Depakote)[a] | 500–1500 | |
| **β-Blockers:** | | |
| Atenolol (Tenormin)[b] | 50–200 | |
| Metoprolol (Lopressor)[a] | 50–200 | Fatigue, exercise intolerance |
| Nadolol (Corgard)[b] | 20–160 | |
| Propranolol (Inderal)[a] | 80–240 | |
| Timolol (Blocadren)[a] | 20–30 | |
| **Antidepressants:** | | |
| Amitriptyline (Elavil)[a] | 10–150 | Weight gain, dry mouth, sedation |
| Venlafaxine (Effexor)[a] | 37.5–150 | |

[a]Level A: Established efficacy.
[b]Level B: Probably effective.
Data from Refs. 17 and 39.

The β-blockers have long been a mainstay in migraine prevention, and many have been proven to be effective in improving patient symptoms. Cautious dosage titration is advised for those patients who do not have other indications for β-blocker use. Comorbid reactive airway disease is a relative contraindication to β-blocker prophylaxis, and patients with cardiac conduction disturbances should be closely monitored. Calcium channel antagonists are often used when patients cannot tolerate β-blockers. None of the calcium channel blockers carry an FDA indication, and their efficacy is considered to be variable. Angiotensin receptor blockers (ARBs) and angiotensin converting enzyme inhibitors (ACEIs) have been evaluated for migraine prevention, but only two, lisinopril and candesartan, have shown possible efficacy.[41]

Low-dose amitriptyline or other tricyclic antidepressants (TCAs) are of proven efficacy in migraine prevention.[41] Due to sedation, these medications are commonly administered at night. Later generation TCAs (eg, nortriptyline) or heterocyclic compounds (eg, trazodone) have fewer dose-limiting adverse effects than the TCAs, especially anticholinergic effects (eg, dry mouth, constipation, and urinary retention), but efficacy has been variable with these agents. Selective serotonin reuptake inhibitors (SSRIs) and serotonin norepinephrine reuptake inhibitors (SNRIs) have been evaluated for migraine prevention, but thus far, only venlafaxine has demonstrated probable efficacy. Caution is advised when using a serotenergic antidepressant and a triptan concurrently, as the combination may rarely precipitate serotonin syndrome, a serious and potentially life-threatening drug–drug interaction that presents clinically with confusion, GI upset, symptomatic blood pressure (BP) changes, and muscle rigidity.[17]

The antiepileptics valproic acid and topiramate are approved for migraine prophylaxis. In patients whose migraine headaches are believed to be related to trigeminal neuralgia, carbamazepine is used as prevention for both disorders.[41] The precise mechanism of action of these agents is unclear, but enhancement of γ-aminobutyric acid (GABA) neuroinhibition and modulation of the neuroexcitatory amino acid glutamate is likely.[44] Divalproex sodium doses are gradually titrated to 1000 mg/day; topiramate is titrated to a maximum of 100 mg twice per day. At these doses, serum drug level monitoring is infrequently needed. These medications are as effective as propranolol at reducing the frequency and severity of migraines and are preferred for prevention in patients intolerant to β-blockers.[45] Topiramate is especially useful in patients who have metabolic syndrome, diabetes, and dyslipidemia because it is unlikely to cause weight gain often seen with valproic acid. Patients prescribed topiramate should be advised to stay well hydrated to prevent dysgeusia, disordered taste, and more seriously, hyperthermia.[46]

Methysergide is an ergotamine derivative that impacts central serotonin balance. Inflammatory fibrosis is a rare but serious, adverse reaction associated with the prolonged use of methysergide. Retroperitoneal fibrosis, pulmonary fibrosis, or fibrosis in cardiac tissue can occur. These conditions may resolve upon drug withdrawal, but cardiac valvular damage can be irreversible. Some experts believe it is the best choice for refractory migraine with frequent attacks, but due to its significant adverse effect profile, it is not marketed in the United States.[47]

Given that migraines can be triggered by changes in hormonal balance, it is not surprising that some women have migraines around the time of menstruation. Often, these migraines can be prevented by starting NSAIDs prior to the beginning of menstruation. Triptans can be tried in patients unresponsive to NSAIDs.

Three triptans have been shown to be effective in preventing menstrual migraines. Frovatriptan, naratriptan, and zolmitriptan can be considered, and should be started 2 to 3 days prior to the beginning of menstruation.[41]

OnabotulinumtoxinA has received FDA approval for the treatment of chronic migraine, but the evidence supporting its use is conflicting. In 2008, the American Academy of Neurology conducted an evidence review, and concluded that OnabotulinumtoxinA was probably ineffective for the prevention of migraines.[48] In the PREEMPT 1 and PREEMPT 2 trials, there was a statistically significant reduction in the number of headache days per month when compared to placebo, but the absolute difference between the two groups was only 1.8 days.[49,50]

While evidence is limited, some complementary alternative therapies can be considered for migraine prophylaxis. Petasites (butterbur) has been associated with a potential 60% reduction in number of headaches experienced over a 1-month period when compared to placebo. Studies for riboflavin have been mixed, with some older studies supporting its use for migraine prevention, but some newer studies have failed to show efficacy. Finally, MIG-99 (feverfew) has also shown possible efficacy with very limited trial evidence.[24]

▶ *Tension-Type Headache Prophylaxis*

The prevention of chronic TTHs uses the same pharmacologic strategies as for migraine prophylaxis. TCAs are a mainstay of chronic therapy. The efficacy of serotonergic agonists remains in question. Although there is little need for muscle relaxants (eg, methocarbamol) in the treatment of acute TTH, they are often provided as a preventive intervention.[7] Combination prophylactic therapies may be needed to wean patients from daily analgesic abuse. Stress reduction techniques may be particularly effective in this setting.

▶ *Cluster Headache Prophylaxis*

The calcium channel blocker verapamil is the mainstay of cluster attack prevention and chronic prophylaxis.[7] Within an attack period, it is dosed at 240 to 360 mg/day. Higher doses may be necessary to stave off recurrent cluster periods. Beneficial effects may be appreciated after 1 week of treatment, but 4 to 6 weeks is usually needed. Adverse effects include smooth muscle relaxation with the subsequent exacerbation of gastroesophageal reflux and the development of constipation. Caution should be exercised in patients with myocardial disease because verapamil is an inotropic and chronotropic cardiac suppressant.[7] Pharmacokinetic drug–drug interactions must be considered, as verapamil is a potent inhibitor of oxidative metabolism through cytochrome P450 (CYP) enzyme 3A4. Eletriptan is a CYP 3A4 substrate and should not be administered concurrently with verapamil.[7,28] Lithium is another effective therapy to reduce headache frequency in a cluster series and to limit recurrences.[14] The dose administered should be individualized to achieve a low serum concentration (0.4–0.8 mEq/L [mmol/L]). Dose adjustments in the setting of renal disease or congestive heart failure are required.[7] Lithium is contraindicated in patients concurrently prescribed thiazide diuretics and ACEIs or ARBs. Patient persistence with long-term lithium therapy may be hindered by the emergence of tremor, GI distress, and lethargy. Verapamil and lithium doses can be lowered when used in combination with ergotamine. If possible, bedtime dosing is recommended, given the nocturnal predilection of cluster headache attacks.[13]

## Patient Encounter, Part 3: Creating a Care Plan

Based on the information presented, create a care plan for the acute and chronic management of this patient's headache. Your plan should include:

*A statement of the drug-related needs and/or problems.*

*The goals of therapy.*

*A detailed, patient-specific therapeutic plan.*

*A monitoring plan to determine whether the goals have been achieved and adverse effects avoided.*

## SPECIAL POPULATIONS

### Migraine Headache in Children and Adolescents

Migraine headaches are common in children, and their prevalence increases in the adolescent years.[51,52] The diagnosis and evaluation of headaches is especially difficult in children, given their decreased ability to articulate symptoms. Treatment presents another challenge because medications used for headache management in adults have not been fully evaluated for efficacy and safety in children. Consensus panel recommendations identify ibuprofen as effective and acetaminophen as probably effective in the acute treatment of headache in patients older than 6 years.[4] Aspirin use is avoided due to the risk of precipitating Reye syndrome. Antiemetic therapy can be used alone or in combination with analgesics; promethazine is usually prescribed, as it is less prone to cause extrapyramidal reactions than other antiemetics. For adolescents older than 12, triptans are effective and are beneficial for abortive migraine therapy.[4] Medication prophylaxis for migraines in children and adolescents is understudied. The data are conflicting, and no consensus recommendation for the use of preventive drug therapy exists.[4] Nonpharmacologic interventions and trigger identification and avoidance are advised.

### Pregnancy

Headaches are more common in women than in men. Fluctuations in estrogen levels are believed to account for this gender discrepancy. Headaches are common in pregnancy. TTHs predominate; migraine attacks may increase in frequency, but more usually frequency decreases during pregnancy.[53] Recommendations for headache care during pregnancy are based on limited evidence and are largely anecdotal. Because headaches are not associated with fetal harm, reflexive pharmacologic therapy should be avoided and drug treatment choices considered carefully. Standard nonpharmacologic therapies are often sufficient. Acetaminophen is safe for the pregnant woman and her fetus.[53] NSAIDs are avoided late in the third trimester to prevent detrimental prostaglandin alterations leading to premature ductus arteriosus closure. Opioids are second-line agents and should not to be used chronically because they can lead to dependence in the mother and to acute withdrawal in the infant after birth.[53] Centrally acting antiemetic agents are safe and may be useful as adjunctive agents. Corticosteroids may be needed for intractable headache relief. Prednisone and methylprednisone are preferred, as they are metabolized in the placenta and do not expose the fetus. In pregnant women with migraine, vasoconstrictive agents

## Patient Care Process

KEY CONCEPT *Individualized treatment regimens for headache disorders are based on: headache type, pattern of occurrence, response to therapy, medication tolerability, and comorbid medical conditions.*

**Patient Assessment:**

- Assess the patient complaint to yield a detailed description of the headache and to determine if immediate referral for emergency or specialist care is necessary.
- Obtain a complete medical and social history to identify any potential drug–disease interactions or social factors that may influence treatment choices.
- Obtain a family medical history, focusing on headache or mental health disorders in first-degree relatives.
- Complete a review of systems and physical examination to identify causes or complications of headache.
- Determine the type of headache disorder and rule out acute complications.

**Therapy Evaluation:**

- Identify medication allergies, and obtain a thorough history of nonprescription and prescription drug use to identify potential drug–drug interactions that may arise when selecting acute and prophylactic headache treatment.

- If patient is already receiving pharmacotherapy, assess for appropriateness and efficacy.

**Care Plan Development:**

- Recommend appropriate pharmacologic therapy to abort headache based on type, patient characteristics, current medication profile, and comorbid conditions.
- When selecting new agents for acute management or for prophylaxis, ensure that the medication is financially accessible.
- Educate the patient on the administration, maximum dosage, and anticipated adverse effects of the prescribed medication, and advise the patient when to seek emergency medical attention.
- Instruct the patient to keep a headache diary to assess therapeutic response.
- Educate on the potential for medication overuse headache.

**Follow-Up Evaluation:**

- Follow-up should be scheduled within 4 weeks of starting any new medications for headache to assess efficacy.
- As patient becomes more aware of headache symptoms and appropriate agents are on board for prevention and treatment of headache, follow-up can become less frequent (ie, 3–6 months).

such as triptans are relatively contraindicated, even though maternal registry data reveal little teratogenicity. If triptans are considered for acute migraine treatment, sumatriptan, naratriptan, and rizatriptan have the greatest evidence of safe use during pregnancy.[53] Ergot compounds are strictly avoided because they may precipitate uterine contractions and placental ischemia leading to hypoxemia in the fetus. Migraine prophylaxis is considered cautiously because β-blockers and calcium channel antagonists may lead to maternal hypotension and diminished placental blood flow or fetal bradycardia.[53] Antiepileptic drug use in this setting has not been sufficiently studied to allow definitive recommendations.

### Outcome Evaluation

Monitoring for therapeutic response is an important part of headache management. In acute management, monitor patients for the pain improvement within 2 to 4 hours and for normal functioning within 3 to 4 hours of treatment initiation. If pain control has not been achieved, additional therapy may be needed for a therapeutic effect. With chronic management for headache prevention, monitor overall headache status every several weeks to months for improvement. A slow decrease in headache frequency is anticipated over this time. Encourage patients to track progress in a headache diary to assist in monitoring improvements in frequency and severity of headaches and corresponding disability. Clinicians monitor attack frequency to determine therapeutic response, seeking a 50% or greater reduction over the course of treatment. Monitoring for adverse effects is central to successful treatment. For acute management, monitor for GI effects from analgesics such as NSAIDs or octreotide, vasoconstrictive symptoms from triptans, and nausea and vascular problems from ergotamine derivatives. Monitor those taking beta blockers for reactive airway disease and cardiac conduction disturbances. Monitor those taking TCAs for sedation and anticholinergic effects such as dry mouth, constipation, and urinary retention. Monitor those taking topiramate for dysguesia, disordered taste, or hyperthermia. Monitor patients taking calcium channel blockers for gastroesophageal reflux symptoms and constipation, and monitor those taking lithium for tremor, GI distress, and lethargy. To ensure optimal headache management, in acute treatment and prophylactic therapy, monitor regimens both for therapeutic outcomes and adverse events, which may impact quality of life and medication adherence.

## Abbreviations Introduced in This Chapter

ACEI    Angiotensin-converting enzyme inhibitor
ARB    Angiotensin receptor blocker
BP    Blood pressure
CGRP    Calcitonin gene-related peptide
CTA    Clear to auscultation
CYP    Cytochrome P450 isoenzyme system
DHE    Dihydroergotamine
FDA    Food and Drug Administration
GABA    γ-aminobutyric acid
HTN    Hypertension
IHS    International Headache Society
MAO-A    Monoamine oxidase type A
MOH    Medication overuse headache
MR    Murmur, rub
NSAID    Nonsteroidal anti-inflammatory drug
OTC    Over the counter
RR    Respiratory rate
SNRI    Serotonin-norepinephrine reuptake inhibitor
SSRI    Selective serotonin reuptake inhibitor
TCA    Tricyclic antidepressant
TTH    Tension-type headache

# Substance-Related Disorders

Christian J. Teter and Devon A. Sherwood

## LEARNING OBJECTIVES

● **Upon completion of the chapter, the reader will be able to:**

1. Identify the prevalence of use for commonly used substances (ie, alcohol, opioids, central nervous system [CNS] stimulants, cannabinoids, and nicotine) in the US population.

2. Explain the commonalities of action of abused substances on the reward system in the brain.

3. Identify the typical signs and symptoms of intoxication and withdrawal associated with the use of alcohol, opioids, CNS stimulants, cannabinoids, and nicotine.

4. Determine the appropriate treatment measures to produce a desired outcome after episodes of intoxication and withdrawal.

5. Determine when a patient meets criteria for substance use disorder.

6. Choose specific pharmacotherapeutic options based on patient-specific factors.

7. Recommend a comprehensive medication treatment and monitoring program to help maintain recovery and prevent relapse to substance use.

## INTRODUCTION

Substance use disorders are highly prevalent worldwide. In the United States (U.S.), historically, tolerance of substance use and abuse has been cyclical. For example, cocaine was first isolated from coca leaves in 1860. Its use was advocated by many in the medical establishment until around the mid-1890s when it became evident chronic use might be addictive in some individuals and could have deleterious physiologic effects. Its use decreased after restriction of prescribing and dispensing in the early 20th century. In the 1980s, a smokeable formulation of cocaine (ie, crack) became available, and cocaine use again became epidemic. This historically cyclic nature of substance abuse is common to many substances of abuse.

**KEY CONCEPT** *Pharmacotherapy has a role in treatment of some substance-related disorders, including intoxication, withdrawal, and/or long-term relapse prevention. These substances include alcohol, opioids, central nervous system (CNS) stimulants, cannabinoids (CB), and nicotine. This chapter focuses on pharmacotherapy for these common substance-related disorders.* Although other substances are misused (eg, prescription sedatives and tranquilizers), those are not the focus of this chapter.

## EPIDEMIOLOGY AND ETIOLOGY

The US federal government annually conducts the National Survey on Drug Use and Health (NSDUH) using a representative sample of persons aged 12 years or older to determine the prevalence of licit and illicit drug use.[1] In 2012, more than half (52.1%; 135.5 million) of Americans reported being a current (ie, past month) alcohol drinker. At least once in the 30 days prior to the survey, about one-quarter of Americans (23.0%; 59.7 million) reported binge drinking (ie, 5+ drinks), and 6.5% (17.0 million) reported heavy drinking (ie, binge drinking on 5+ occasions). Approximately one-quarter (26.7%; 69.5 million) were current users of tobacco products, with young adults aged 18 to 25 reporting the highest rates of current tobacco product use (38.1%). Regarding illicit drug use, 9.2% of the US population (23.9 million) reported current illicit drug use, with nonmedical psychotherapeutics being second only to marijuana (**Figure 36–1**). In 2012, there were 2.9 million illicit drug initiates, with marijuana being the first drug used in a majority of cases (65.6%). Notably, 1.4 million (roughly one-half of the entire drug initiate sample) first-time marijuana users were under the age of 18. Approximately one-quarter nonmedically used a psychotherapeutic as their first illicit drug (ie, 17.0% with pain relievers, 4.1% with tranquilizers, 3.6% with stimulants, and 1.3% with sedatives).[1] The NSDUH findings indicate that substance use is wide ranging; peaks at 18 to 25 years of age; and consists of a significant number of individuals using prescription medications nonmedically, which is a relatively new and growing public health concern.

### Reward Pathway

● **KEY CONCEPT** *Virtually all abused substances appear to activate the same brain reward pathway, which is highlighted by dopaminergic neurotransmission arising in the ventral tegmental area (VTA) and projecting to the nucleus accumbens (NA) and prefrontal cortex (PFC).*

● **Figure 36–2** depicts the mesocorticolimbic dopamine pathway. Key components are dopamine (DA) projections from the VTA to the NA and to the PFC.[2,3] Many studies support that this
**FIGURE 36–1.** Past-month illicit drug use among the US population in 2012. [a]Illicit drug use includes a wide variety of substances such as marijuana or hashish, cocaine (including crack), heroin, hallucinogens, inhalants, or prescription-type psychotherapeutics used nonmedically. (Data and figure in the public domain from Substance Abuse and Mental Health Services Administration, Results from the 2012 National Survey on Drug Use and Health: Summary of National Findings, NSDUH Series H-46, HHS Publication No. [SMA] 13-4795. Rockville, MD: Substance Abuse and Mental Health Services Administration, 2013.)

mesolimbic DA system is involved in natural rewards and drug reinforcement[4]; however, there is also evidence that dopamine-independent reinforcement exists.[5] In any case, abused drugs generally produce pleasant effects considered desirable by the user. The initial hedonic experiences secondary to use of drugs appear to be primarily attributable to activation of primary reward circuits in the brain. These same reward circuits operate under normal circumstances to reinforce activities that promote survival, such as consuming food and water, social affiliation, or sexual activity. However, these systems appear to be disrupted after drug use in susceptible individuals.

**FIGURE 36–2.** The mesocorticolimbic dopaminergic pathway (ie, the "reward pathway"). VTA, ventral tegmental area. (Data from The Neurobiology of Drug Addiction [Internet]. http://www.drugabuse.gov/publications/teaching-packets/neurobiology-drug-addiction/section-i-introduction-to-brain.)

Although most individuals experience pleasant effects, not everyone abuses these drugs or becomes dependent on them. Why some persons abuse drugs while most do not relates to complex genetic, environmental, and cultural factors.

## PATHOPHYSIOLOGY
### Neuronal Adaptation

KEY CONCEPT  *Although activation of reward pathways explains the pleasurable sensations associated with acute substance use, chronic use (which may result in substance-related disorders) may be related to neuroadaptive effects within the brain.*

A recent review by two preeminent researchers in the addiction sciences describes the addiction cycle moving past acute rewarding effects of substances of abuse and into other important processes.[5] They describe three phases of the addiction cycle: (a) binge/intoxication, (b) withdrawal/negative affect, and (c) preoccupation/anticipation. Binge/intoxication refers to the acute rewarding effects of drugs of abuse and the corresponding CNS circuitry. However, chronic use of substances leads to neuroadaptations in the brain and associated symptoms; more specifically, chronic drug abuse appears to cause a generalized decrease in DA neurotransmission. Additionally, with chronic drug use, release of corticotropin-releasing factor (CRF) is increased, indicating an activation of central stress pathways. In phase 3, other neurotransmitter systems (ie, beyond DA) are postulated to be involved. For example, elevated CRF, norepinephrine, and glutamate may exist in the "extended amygdala" during prolonged abstinence. Perhaps these changes lead to a long-term need to use substances to relieve unpleasant symptoms, such as stress.[5] Multiple factors are associated with an increased risk of relapse, including the availability of the abused drug, an increase in psychological stressors, and a triggering of cues such as seeing a white powder or going to a location where drugs were previously attained or used. These factors may trigger residual adaptive changes (eg, elevated glutamatergic activity) that occurred during the period of drug addiction.

### Patient Encounter 1

A 38-year-old man is being seen in the outpatient clinic for long-term substance use and a recent relapse to oxycodone. The patient has been treated with buprenorphine for close to one year with periods of stability. However, each time there is an attempt at tapering off buprenorphine, the patient experiences intense dysphoria causing him to relapse to oxycodone use. His buprenorphine treatment has been discontinued for approximately three weeks. Recently, he has come to realize that he is reluctant to return home because his girlfriend is still actively using opioids for recreational purposes. However, he states that he is committed to finally "shaking his habit and putting in the work to stay clean."

*What is the most immediate action to be taken regarding this man's treatment?*

*After acute detoxification, how can he be helped to maintain abstinence, and is there a medication that offers advantages over other first-line options?*

## CLINICAL PRESENTATION AND DIAGNOSIS

**KEY CONCEPT** *Individuals with a pattern of chronic use of commonly abused substances should be assessed to determine if they meet the Diagnostic and Statistical Manual of Mental Disorders, fifth edition (DSM-5) criteria for substance related disorders.*[6] Most notably, in cases of addiction, there is a loss of control over substance use or use has become compulsive. Criteria for substance use disorders from the *DSM-5* are listed in **Table 36–1**.[6] Consistent with the *DSM-5*, the remainder of this chapter is organized by pharmacologic class and discusses intoxication, withdrawal, and substance use disorders for each class (except tobacco use disorders, which do not have a *DSM-5* intoxication criteria set).

---

### Table 36–1

**DSM-5 Criteria for Diagnosis of Substance Use Disorders**

A problematic pattern of substance use leading to clinically significant impairment or distress; manifested by at least two of the following, occurring within a 12-month period:

1. Substance often taken in larger amounts or over longer period than intended.
2. Persistent desire or unsuccessful efforts to cut down or control substance use.
3. Great deal of time spent in activities necessary to obtain substance, use the substance, or recover from its effects.
4. Craving or a strong desire or urge to use the substance.
5. Recurrent substance use resulting in failure to fulfill major role obligations at work, school, or home.
6. Continued substance use despite having persistent or recurrent social or interpersonal problems caused or exacerbated by the effects of substance.
7. Important social, occupational, or recreational activities are given up or reduced because of substance use.
8. Recurrent substance use in situations in which it is physically hazardous.
9. Substance use is continued despite knowledge of having a persistent or recurrent physical or psychological problem likely to have been caused or exacerbated by the substance.
10. Tolerance, as defined by either of the following:
    a. Need for markedly increased amounts of substance to achieve intoxication or desired effect.
    b. Markedly diminished effect with continued use of same amount of substance.
11. Withdrawal, as manifested by either of the following:
    a. Characteristic withdrawal syndrome for the substance (refer to Criteria A and B of the *DSM-5* criteria set for substance withdrawal).
    b. Substance (or closely related substance) is taken to relieve or avoid withdrawal symptoms.

Specify[a] current severity:

Mild: Presence of two to three symptoms.

Moderate: Presence of four to five symptoms.

Severe: Presence of six or more symptoms.

Data from the American Psychiatric Association. Diagnostic and Statistical Manual of Mental Disorders. 5th ed. Arlington, VA: American Psychiatric Association, 2013; with permission.

[a]Additional specifiers (eg, early vs sustained remission) and substance-specific notes (eg, taking opioid under medical supervision) are included in the *DSM-5*.

---

A variety of standardized instruments are available to screen for and assess the various stages of substance use and its consequences, such as withdrawal symptoms and functional impairment (**Table 36–2**).[7–10] The Addiction Severity Index (ASI) is the gold-standard instrument that assesses seven problem areas associated with substance use, such as medical status and psychiatric status, in addition to measures of alcohol and drug use.

### Intoxication Signs and Symptoms

Intoxication caused by most substances is described in the *DSM-5* as clinically significant, problematic behavioral, or psychological changes to the user, which are caused by the physiological effects of the substance. These changes are seen during or shortly after use of the substance. Euphoria or experiencing a pleasurable sensation are effects of most drugs of abuse.[11] Other signs and symptoms are specific to the particular drug or drug class involved. **Table 36–3** lists the psychological/behavioral and physiologic effects of intoxication from selected substances.[6,12–15]

### Withdrawal Signs and Symptoms

Although most abused drugs can cause some degree of physiologic dependence, the severity of withdrawal varies considerably among these drugs. **Table 36–4** lists common withdrawal symptoms seen upon abstinence from drug use.[6,12–16] Typically, withdrawal symptoms are opposite of acute effects of the drug. For example, although alcohol is a CNS depressant, signs and symptoms of withdrawal signify a hyperalert physiologic response.

## TREATMENT OF SUBSTANCE USE DISORDER

### OVERALL THEORY OF USE OF PHARMACOLOGIC AGENTS TO TREAT SUBSTANCE-RELATED DISORDERS

Unlike some medical diseases, substance use disorders cannot be cured with medications alone. However, we can sometimes alleviate the effects of drug intoxication, attenuate adverse effects of withdrawal, or somewhat decrease craving and likelihood of relapse to substance abuse. For example, pleasurable and intoxicating effects of opioids appear to be caused by their action as

---

### Patient Encounter 2

A 43-year-old woman with a history of hypertension presents to your clinic for follow-up evaluation of her blood pressure. During the visit, you discover that she admits to drinking a bottle of wine each evening despite her uncontrolled hypertension. She states that her drinking has "crept up" on her over the years and that she finds a bottle of red wine helps to "take the edge off." The patient states that her strong urges to drink wine at times causes her concern. Notably, she reports experiencing headaches, which she attributes to the combination of red wine and her poor blood pressure management.

*What information would suggest this patient might have an alcohol use disorder?*

*Are there any standardized instruments that you can recommend to screen for an alcohol use disorder?*

| Table 36–2 | | |
|---|---|---|
| **Commonly Used Instruments for Assessing Patients with Substance Use Disorders** | | |
| **Instrument** | **Purpose** | **Values and Interpretation** |
| Addiction Severity Index (ASI)<br><br>Assessment tool (past 30 days or lifetime) for various substances | Semistructured interview that addresses seven problem areas: medical status, employment and support, alcohol use, drug use, legal status, family and social status, and psychiatric status<br>Questions include frequency, duration, and severity of problems | Patient and interviewer ratings included<br>Interviewer severity ratings of "need for additional treatment" + composite scores to measure severity<br>Scoring completed by a technician or computerized scoring and interpretation<br>Composite score normative data from nationally representative sample of treatment programs is available for those seeking to compare a patient's ASI data with national data (http://www.tresearch.org); otherwise, comparisons with previous (eg, baseline) composite scores are useful |
| Alcohol Use Disorders Identification Test (AUDIT) | Evaluates quantity and frequency of drinking; physiologic dependence on alcohol; harmful use | 10 items (scores 0–40)<br>Score of 8 or above identifies heavy drinkers and those with possible alcohol use disorders |
| Screening tool | Clinician administered | "Zones" of interventions based on scores |
| CAGE<br>C = Cut down<br>A = Angry/annoyed<br>G = Guilty<br>E = Eye opener<br>Screening tool | Used to identify the presence of problematic drinking<br>No training necessary; clinician or self-administered | Four items<br>Score of 2 or more is positive and suggests problem drinking<br>Positive screen prompts the need for further assessment |
| Clinical Institute for Withdrawal Assessment–Alcohol, Revised (CIWA-Ar) | Gold standard alcohol withdrawal assessment; used as part of symptom-triggered approach | 10 items; maximum score = 67<br>< 10: mild w/d<br>10–18: moderate w/d<br>Greater than 18: severe w/d |
| Assessment tool | Clinician administered | Monitor scores over time; 8 to 10 or greater (depending on institutional protocols or co-occurring conditions) indicate need for medication |
| Clinical Opiate Withdrawal Scale (COWS)<br>Assessment tool | Used to follow the course of withdrawal symptoms and effectiveness of medication regimens<br>Clinician administered | 11 items; scoring 0 (asymptomatic) to 4 or 5 (severely symptomatic) for each item based on intensity of signs and symptoms<br>Total score (sum of 11 items):<br>5–12: Mild<br>13–24: Moderate<br>25–36: Moderately severe<br>Greater than 36: Severe withdrawal<br>Monitor scores over time (lower score implies less opioid withdrawal severity); higher scores may indicate need for medication; no standard cut-off exists |
| Fagerström Test for Nicotine Dependence | Assesses extent of nicotine tolerance, dependence, and craving; contains six questions; higher scores may predict greater difficulty in quitting | Total scoring for dependence:<br>0–2: Very low<br>3–4: Low<br>5: Moderate<br>6–7: High<br>8–10: Very high |

w/d, withdrawal.

agonists on μ-receptors of the opioid neurotransmitter system. Competitive μ-opioid antagonists such as naloxone and naltrexone acutely reverse many opioid effects, including symptoms of intoxication. To date, we do not have specific antagonists for most other substances. Similarly, reversal of withdrawal syndromes caused by abused substances is not always possible. One pharmacologic solution for reversing withdrawal symptoms, most commonly used by substance dependent individuals, is to readminister the drug that caused the physiologic dependence. The more commonly used treatment method is to administer a medication that has some cross-dependence with the abused drug but has fewer reinforcing effects and a more predictable pharmacokinetic profile. For example, benzodiazepines are used for the withdrawal of ethanol. Although benzodiazepines can cause physiologic dependence, they are rated as less desirable than ethanol by substance abusers, cause fewer long-term adverse health effects than ethanol, and are easier to manage medically. Regarding longer term medication management, an example is maintaining an opioid-addicted individual on a regimen of medically managed, orally administered opioids (ie, substitution therapy) compared with more dangerous illicit opioid use. Regardless of the specific pharmacotherapy chosen,

**Table 36–3**

**Signs and Symptoms of Drug Intoxication for Select Substances**

| Drug | Behavioral Effects | Physiologic Effects |
|---|---|---|
| Ethanol | Changes in mood and behavior, inappropriate aggressive or sexual behavior, giddiness or verbally loud, impaired judgment; possibly progressing to somnolence and coma as the blood level increases | Blood levels 0.02%–0.1% (20–100 mg/dL or 4.3–21.7 mmol/L): Euphoria, feeling of well-being, disinhibition, slight impairment (eg, reaction time)<br>Blood levels 0.1%–0.2% (100–200 mg/dL or 21.7–43.4 mmol/L): Significant impairment (eg, balance, speech, vision and hearing, reaction times), dysphoria<br>Blood levels 0.2%–0.3% (200–300 mg/dL or 43.4–65.1 mmol/L): Marked ataxia, mental confusion, and nausea and vomiting<br>Blood levels 0.3%–0.4% (300–400 mg/dL or 65.1–86.8 mmol/L): Severe dysarthria, amnesia, hypothermia<br>Blood levels > 0.4% (400 mg/dL or 86.8 mmol/L): Alcoholic coma, decreased respiration or respiratory arrest; aspiration of gastric contents or airway obstruction caused by flaccid tongue, drop in blood pressure and body temperature |
| Opioids | Drowsiness, sedation, slurred speech, impaired memory and attention, psychomotor retardation | Nausea, vomiting, respiratory depression (dose-related), stupor, coma, constipation common in chronic users, itching, miosis, hypothermia, bradycardia |
| CNS stimulants | Elated mood, hypervigilance, anxiety or panic, impaired judgment, violence to others or self, paranoia or psychosis with delusions and hallucinations (generally tactile or auditory, rarely visual), increased motor activity, compulsive or stereotyped behavior (eg, skin picking) | Neurologic/Neuromuscular: mydriasis, headache, tremor, hyperreflexia, muscle twitching, flushing, hyperthermia or cold sweats, rhabdomyolysis (possibly resulting in renal failure), muscular weakness, dyskinesias, seizures, coma<br>Cardiovascular: increased pulse and blood pressure, peripheral vasoconstriction, arrhythmias, myocardial infarction, cerebral hemorrhage<br>GI: Nausea, vomiting, weight loss |
| Cannabinoids | Euphoria, impaired motor coordination, anxiety, impaired judgment, social withdrawal | Tachycardia (can exceed 20 beats/min increases), dry mouth, conjunctival injection, increased appetite |

CNS, central nervous system; GI, gastrointestinal.

Data from Refs. 6 and 12 to 15.

**Table 36–4**

**Signs and Symptoms of Drug Withdrawal for Select Substances**

| Drug | Timeline | Symptoms |
|---|---|---|
| Ethanol | As ethanol levels decrease:<br>Early symptoms<br><br>Peak (24 hours)<br><br>72–96 hours<br>Onset at any time | Tremor, nausea, vomiting, tachycardia (> 110 beats/min), hypertension (> 140/90 mm Hg), headache, vivid dreams, insomnia<br>Seizure-activity (usually one or two grand mal type but can be numerous and possibly fatal)<br>Delirium tremens<br>Hallucinations, usually visual |
| Opioids | For shorter acting opioids (eg, heroin, morphine, oxycodone) withdrawal may begin within 6–24 hours after last dose and last for about 1 week; with longer acting opioids (eg, methadone) it may take up to 2–4 days for withdrawal to emerge, and it will last longer | GI: Nausea, vomiting, diarrhea, dehydration<br>Neurologic or psychological: irritability, restlessness, yawning, tremulousness, twitching<br>Cardiovascular: Increased heart rate and blood pressure<br>Musculoskeletal: Chills, increased body temperature, piloerection, rhinorrhea<br>Ocular: Lacrimation, mydriasis |
| CNS stimulants | **Stage 1:** Immediately following binge<br>**Stage 2:** Within 1–4 hours<br>**Stage 3:** Days 3–4 | Stimulant craving, intense dysphoria, depression, anxiety, agitation<br>Desire for sleep, dysphoria continues<br>Hypersomnia, increased appetite, craving may dissipate but return later |
| Cannabinoids | Withdrawal symptoms onset typically within 24–72 hours; peak within 1 week | Severity reflects degree and duration of cannabinoid use; symptoms include irritability, nervousness, anxiety, sleep abnormalities, restlessness, depressed mood, headache, tremors, sweating, chills |
| Nicotine | Begins within 24 hours of cessation; may persist | Severity reflects degree and duration of nicotine use; symptoms include anxiety, irritability, frustration, anger, craving, difficulty concentrating, decreased heart rate, and increased appetite |

CNS, central nervous system; GI, gastrointestinal.

Data from Refs. 6 and 12 to 16.

medications should always be used as adjuncts to a comprehensive psychosocial approach.

## TREATMENT OF INTOXICATION SYNDROMES

**KEY CONCEPT** *The treatment goals for acute intoxication of ethanol, opioids, CNS stimulants, and cannabinoids include (a) management of psychological/psychiatric manifestations of intoxication, such as aggression, hostility, and psychosis and (b) management of medical manifestations of intoxication, such as respiratory depression, hyperthermia, hypertension, cardiac arrhythmias, and stroke.* In all cases of substance intoxication that requires medical intervention, referral to and participation in substance abuse treatment is desirable.

### Alcohol Intoxication

Desired outcomes are appropriate management of medical problems, prevention of harmful behaviors, and stabilization of mood. Most cases of mild to moderate intoxication with alcohol, including cases with blood alcohol concentrations (BACs) at lower limits of legal intoxication, do not require formal treatment. Providing a safe environment and reassurance until alcohol effects have worn off is sufficient in most cases. Initially, BACs may continue to rise if gastrointestinal (GI) absorption is still occurring. Otherwise, BACs generally decrease at a rate of 15 to 20 mg/dL (0.015%–0.02% or 3.3–4.3 mmol/L) per hour. See Table 36–3 for physiologic effects of alcohol, in nontolerant individuals, at various BACs. It is important to note that tolerant individuals may not show the same level of symptoms at a given BAC as nontolerant individuals.

At more severe levels of intoxication, confusion, stupor, coma, and death may occur. Clinicians must rule out other causes of these serious adverse events, because alcohol-intoxicated individuals commonly combine alcohol with other substances, sustain head or other injuries, and have vitamin deficiencies and electrolyte abnormalities. If consciousness is impaired, then thiamine should be given intravenously (IV) or intramuscularly (IM) at 100 mg/day for at least 3 days. If hypoglycemia is suspected, then thiamine administration should precede administration of glucose-containing fluids to prevent precipitation of acute Wernicke's syndrome (see Alcohol Withdrawal section). Patients may also develop adverse interactions between alcohol and prescribed medications including disulfiram. See Table 36–5 for drug–drug interactions associated with abused substances.[17,18]

Behaviorally, patients may insist on driving, become physically aggressive and agitated, or otherwise become a danger to themselves or others. Indeed, most suicidal behaviors among alcohol-dependent individuals occur while they are intoxicated. Antipsychotics may lower the seizure threshold and are best avoided. However, in some instances, agitation may require treatment with an antipsychotic (eg, haloperidol 5–10 mg by mouth every 2–4 hours or olanzapine 10 mg given IM with repeated doses at least 2 hours apart). Sedation with benzodiazepines has been used, but in the presence of alcohol, respiratory depression can be dangerous or even fatal.

There are no medications that can fully reverse the effects of alcohol intoxication. Caffeine and other stimulants are neither indicated nor considered a viable option to make driving safe.

### Opioid Intoxication

The word *opioid* refers to the class of medications and substances that exert their action through the opioid system. Opioids encompass a wide range of substances, including naturally occurring (eg, morphine) and synthetic (eg, oxycodone) substances.

Patients who are acutely intoxicated with an opioid usually present with miosis, euphoria, slow breathing, slow heart rate, low blood pressure, and constipation. Seizures may occur with certain agents, such as meperidine (Demerol). It is critically important to monitor patients carefully to avoid cardiac and respiratory depression and death from opioid overdose. One strategy is to reverse intoxication using naloxone (Narcan) 0.4 to 2 mg IV every 2 to 3 minutes up to 10 mg; the IM or subcutaneous (SC) route may be used if IV access is not available. Because naloxone is shorter acting than most abused opioids, it may need to be readministered at periodic intervals; otherwise, patients could lapse into cardiopulmonary arrest after a symptom-free interval of reversed intoxication. In addition, naloxone can induce withdrawal symptoms in opioid-dependent patients, so patients may awaken feeling distressed and agitated. It should be noted that buprenorphine intoxication may be more difficult to reverse.[19]

It is critically important to secure the airway and ensure breathing in cases of opioid overdose. In some cases, intubation and manual or mechanical ventilation might be required to avoid oxygen desaturation leading to brain hypoxia or anoxia and brain damage or death.

Recently, new opportunities for "take-home" naloxone have emerged in the United States. For example, naloxone hydrochloride injection (Evzio) was Food and Drug Administration (FDA)-approved for this purpose.[20] It is too early to determine the public health impact of this approach for treatment of opioid overdoses.

### Stimulant (Cocaine and Amphetamines) Intoxication

Desired outcomes of stimulant intoxication treatment are appropriate management of medical and psychiatric problems. Medical problems include hyperthermia, hypertension, cardiac arrhythmias, stroke, and seizures. Some medical problems are related to route of administration, such as nosebleeds with intranasal administration and infections with IV administration. Psychiatric effects include anxiety, irritability, aggression, and psychosis.

Notably, stimulant intoxication is the only stimulant use disorder for which specific pharmacotherapy has demonstrated effectiveness. Recommended medications in acute settings include benzodiazepines, aspirin, nitroglycerin, nitroprusside, and phentolamine.[21] The American Heart Association guidelines indicate that acute use of β-blockers is not recommended and may lead to worsening cocaine-related chest pain (caused by coronary vasoconstriction) and hypertension secondary to unopposed alpha activity.

Cocaine is short acting, and a single benzodiazepine sedative-hypnotic may be sufficient treatment for anxiety reactions. Depending on the half-life of the benzodiazepine, one or more sequential doses may be required for longer acting amphetamine intoxication. Antipsychotics are indicated when psychosis is present, and psychosis usually responds quite rapidly in the absence of other co-occurring psychiatric disorders.

### Cannabinoid (Marijuana, etc) Intoxication

There are no established treatment recommendations for CB intoxication. Symptomatic treatment (eg, tachycardia, anxiety, paranoia, and psychosis) is the commonly used approach. The exception is potent synthetic cannabinoids, which may require aggressive benzodiazepine treatment for intense symptoms of anxiety or psychosis. These intense psychiatric symptoms have been theorized to result either from the potent full-agonist cannabinoids that are used to prepare them, or possibly due to the

**Table 36–5**

**Clinically Relevant Drug Interactions with Substances or Medications Used to Treat Substance Use Disorders**

| Drug | Interacting Drug | Type of Interaction and Appropriate Action |
|---|---|---|
| Amphetamines (including dextro- and methamphetamine) | MAOIs (phenelzine, selegiline, tranylcypromine, possibly linezolid) | Pharmacodynamic interaction resulting in an increased blood pressure; possibly resulting in hypertensive emergency or stroke; **AVOID** this drug combination |
| | Sodium bicarbonate | Sodium bicarbonate increases renal tubular reabsorption of amphetamine, resulting in prolonged amphetamine elimination half-life; closely monitor this combination |
| Bupropion | MAOIs | Neurotoxicity; **AVOID** this drug combination |
| | Substances that lower seizure threshold | Alcohol (*withdrawal*); **AVOID** bupropion in patients at risk for experiencing alcohol withdrawal |
| Buprenorphine | Atazanavir | Combination of buprenorphine + atazanavir (without ritonavir) results in both lower atazanavir levels and greater buprenorphine exposure; **AVOID** this bidirectional-interacting drug combination |
| | Conivaptan | Conivaptan is a potent CYP3A4 inhibitor; manufacturer recommends its use be **avoided** with medications metabolized by CYP3A4 |
| | CYP3A4 inhibitors (in addition to specific medications listed) | May raise buprenorphine levels; monitor for greater than expected buprenorphine effects |
| Cannabinoids | Drugs that elevate heart rate: anticholinergics, caffeine, stimulants | Clinically significant elevations in heart rate may occur; AVOID combination |
| Cigarette smoking | Clozapine and olanzapine | Cigarette smoking induces CYP1A2, increasing metabolism of clozapine; may need to increase clozapine dose when patient begins to smoke or decrease clozapine dose if smoking is stopped |
| | Theophylline | Theophylline is CYP1A2 substrate; may need to increase theophylline dose when patient begins to smoke or decrease the theophylline dose if smoking is stopped |
| Disulfiram | Alcohol-containing solutions (variety of medications) | Disulfiram reaction; **AVOID** combination |
| | Metronidazole | Combination of disulfiram and metronidazole has lead to CNS effects (eg, psychosis); **AVOID** combination |
| | Benzodiazepines (including alprazolam, diazepam, flurazepam, triazolam) | Disulfiram (weakly) inhibits CYP enzymes 1A2, 2C9, and 3A4; many benzodiazepines are metabolized via these pathways; lorazepam, temazepam, and oxazepam are primarily conjugated to inactive products and are reasonable alternatives |
| | | Otherwise, if benzodiazepines are combined with disulfiram, the pharmacologic effect may be greater than expected, and the dose of benzodiazepine may need to be lowered |
| | Cocaine | Disulfiram decreases clearance of cocaine from the body; may see increased or prolonged cocaine effects with combination |
| | Phenytoin | Disulfiram decreases metabolism of phenytoin, resulting in higher phenytoin levels; phenytoin dose may need to be reduced; because phenytoin undergoes nonlinear metabolism, it is difficult to predict magnitude of increase in blood levels that could be seen; best to avoid this interaction if possible |
| Ethanol (alcohol) | Acetaminophen | Chronic ethanol use increases risk of hepatotoxicity when acetaminophen is used in high doses |
| | Bupropion | Abrupt *discontinuation* of alcohol with continued bupropion use may lower seizure threshold; combination should be **avoided** in those at risk for seizure activity (eg, alcoholics with cooccurring depressive symptoms) |
| | Cefamandole, cefoperazone, cefotetan, and moxalactam, metronidazole | Disulfiram-type reaction may occur when these anti-infectives are combined with alcohol; reaction includes flushing, diaphoresis, tachycardia, headache, and increases in blood pressure; **AVOID** alcohol if these drugs are used |
| | Cycloserine | Neurotoxicity (specifically seizure risk) may be enhanced with combination of alcohol and cycloserine; **AVOID** combination |
| | Didanosine | Risk for pancreatitis may be increased with combination of alcohol and didanosine; **AVOID** combination |
| | Methotrexate | Hepatotoxicity is a higher risk when methotrexate is given to those who chronically drink large amounts of alcohol; **AVOID** methotrexate in this group if possible; otherwise monitor LFTs |
| | MAOIs | Ethanol **DOES NOT** interact with MAOIs; however, tyramine may be a component of some aged alcoholic drinks, such as red wines or tap beers; if reaction occurs, hypertension and a pounding headache are most likely symptoms; usually white wine is tolerable (in moderation) and most widely available domestic canned beers do not contain significant amounts of tyramine |
| | Tapentadol | Combination of alcohol and *extended-release* tapentadol may result in increased maximum serum concentrations of tapentadol; **AVOID** this drug combination |

(*Continued*)

**Table 36–5**

**Clinically Relevant Drug Interactions with Substances or Medications Used to Treat Substance Use Disorders (*Continued*)**

| Drug | Interacting Drug | Type of Interaction and Appropriate Action |
|---|---|---|
| Methadone | Carbamazepine | Carbamazepine is potent inducer of CYP3A4 and methadone is primarily metabolized via CYP3A4; if carbamazepine is added to drug regimen containing methadone, the methadone dose will probably need to be adjusted upward to avoid withdrawal |
| | Conivaptan | Conivaptan is a potent inhibitor of CYP3A4; manufacturer recommends its use be **AVOIDED** in medications metabolized by CYP3A4 |
| | CYP3A4 inhibitors (in addition to specific medications listed) | Methadone serum concentrations may be increased when combined with potent CYP3A4 inhibitors; methadone dose adjustment should be based on clinical judgment, but a decrease of dose may be necessary |
| | Didanosine | Methadone decreases the amount of didanosine that is orally absorbed; therapeutic monitoring of didanosine effects are recommended, and doses may need to be increased |
| | Efavirenz | This HIV drug is a CYP3A4 inducer; efavirenz decreases methadone blood levels and has precipitated withdrawal in opioid-dependent individuals; may need to increase methadone dose |
| | MAOIs | Potential serotonin syndrome when MAOIs are combined with methadone; transdermal selegiline lists co-treatment with methadone as a **CONTRAINDICATION** |
| | Nevirapine | Nevirapine is an HIV drug that is a CYP3A4 inducer; in a small sample, nevirapine caused a 50% reduction in methadone blood levels, resulting in complaints of methadone withdrawal symptoms in patients receiving methadone maintenance; may need to increase methadone dose in patients who have nevirapine added to their drug regimen |
| | QTc-prolonging drugs or medications | Medications that prolong the QT interval (eg, ziprasidone) should be **AVOIDED** with methadone coadministration when possible because of potential additive QT-prolonging effects |
| | Stavudine | Methadone decreases the amount of stavudine (a reverse transcriptase inhibitor) by about 25%. Although this may not be clinically significant in some cases, the clinician should be aware of the possibility of this interaction |
| | St. John's wort | This herbal remedy may induce CYP3A4; the certainty of an interaction probably rests on the specific preparation being used, but caution dictates that this herbal product should be avoided in those receiving methadone treatment; withdrawal symptoms have been noted in patients taking methadone maintenance who have added St. John's wort to their drug regimen |
| | Tamoxifen | Methadone may inhibit the formation of important active tamoxifen metabolites (eg, endoxifen), and therapeutic monitoring is recommended |
| | Zidovudine | Methadone increases the blood level of this anti-HIV drug, probably via methadone inhibition of both metabolic and renal clearance of zidovudine; may need to decrease zidovudine dose to avoid toxicity |
| Naltrexone | Opioid-based pain medications | Blockade of pain relief; use nonopioid treatment approaches (eg, NSAIDs); refer to Special Dosing Considerations within Alcohol Use Disorder section |

CYP, cytochrome P450 isoenzyme; LFT, liver function test; MAOI, monoamine oxidase inhibitor.

Caution should always be exercised when combinations of medications with similar pharmacologic properties are used (eg, additive CNS depression associated with coingestion of alcohol and nonmedical use of prescription opioids).

Data from Refs. 17 and 18.

lack of cannabidiol in these synthetic products. Cannabidiol has been associated with antipsychotic effects.[22]

## TREATMENT OF WITHDRAWAL SYNDROMES

**KEY CONCEPT** *The treatment goals for withdrawal from ethanol, opioids, CNS stimulants, and cannabinoids include (a) a determination if pharmacologic treatment of withdrawal symptoms is necessary, (b) management of other medical manifestations, and (c) referral to the appropriate program for long-term substance abuse treatment.* The desired outcomes in the treatment of withdrawal syndromes are to ensure patient safety, comfort, and successful transition from treatment of withdrawal to longer-term maintenance. Referral to specialized treatment for substance use disorders is strongly

recommended after treatment of withdrawal syndromes. Achieving a drug-free state by detoxification and then rehabilitation with a focus on total abstinence is the ideal outcome.

### Alcohol Withdrawal

Alcohol withdrawal syndromes have two distinct presentations (ie, uncomplicated and complicated), which differ in terms of their pharmacologic treatment and need for hospitalization.

#### ▶ Uncomplicated Alcohol Withdrawal

This is the most commonly observed syndrome, and as the name denotes, is not complicated by seizures, **delirium tremens (DTs),** or hallucinosis. Symptoms are typically rated using a validated

scale such as the Clinical Institute Withdrawal Assessment–Alcohol, Revised (CIWA-Ar) (see Table 36–2). The recommended CIWA-Ar threshold score for treating uncomplicated alcohol withdrawal with medications on an outpatient basis is 8 to 10. For patients who score greater than or equal to 15, inpatient treatment should be considered. Patients who score 20 or higher on the CIWA-Ar should always be treated with medication. The risks of not treating high-scoring patients with medications are seizures and DTs, and those with a prior history of seizures or DTs have increased risk for subsequent episodes. There is some evidence for "kindling" during successive episodes of alcohol withdrawal, such that symptom severity and complications increase with additional withdrawal episodes. Therefore, with a history of seizures or DTs, the lower range of 8 to 10 is recommended, and hospitalization is safer than outpatient detoxification.

Benzodiazepines are the treatment of choice for uncomplicated alcohol withdrawal.[10,12] Anticonvulsants have been used to treat uncomplicated withdrawal (particularly carbamazepine and sodium valproate); however, they are not as well studied and are less commonly used. The most commonly used benzodiazepines are lorazepam, diazepam, and chlordiazepoxide. They differ in three major ways: (a) their pharmacokinetic properties, (b) the available routes for their administration, and (c) the rapidity of their onset of action due to the rate of GI absorption and rate of crossing the blood–brain barrier. Benzodiazepines are often given in one of two ways: (1) Symptom-triggered approach, or (2) loading dose strategy. Typically, adjunctive "as needed" medications are used as well.

Benzodiazepines can be administered using a symptom-triggered approach when withdrawal signs and symptoms are present.[23] Medication (eg, lorazepam) is administered every hour when the CIWA-Ar is greater than or equal to eight. For example, the shorter-acting agent lorazepam is given at the recommended 1 to 2 mg dose. The CIWA-Ar is repeated hourly after each administration during the first 24 hours until the patient is comfortably sedated. Due to a short half-life, dosing of lorazepam on subsequent days may be needed, and risk of seizures may possibly (although not definitively proven) be higher.

Longer-acting agents (eg, diazepam, chlordiazepoxide) are often used via the loading dose strategy in which larger doses are given initially followed by a taper over 3–5 days. The long half-lives of these drugs and their active metabolites usually provide a natural taper without further drug administration. This approach may be accompanied by as needed short-acting benzodiazepine doses for breakthrough alcohol withdrawal symptoms. The loading dose strategy is especially useful in the hospital, where patients can be medically monitored throughout the day. Diazepam may be "preferred" to chlordiazepoxide, given its less variable pharmacokinetic profile (eg, fewer active metabolites, narrower range for time to maximum concentration) and a faster onset of action (ie, quickly enters the CNS due to high lipophilicity).

**Special Dosing Considerations** In contrast to chlordiazepoxide and diazepam, lorazepam is not metabolized into active compounds in the liver. It is excreted by the kidneys after glucuronidation. This is important because many alcohol-dependent patients have compromised liver function. Therefore, when treatment is initiated before results of liver function tests (LFTs) are known, lorazepam may be preferred. Patients with liver disease may still be treated with diazepam or chlordiazepoxide at lower doses.

Diazepam is more lipophilic than lorazepam or chlordiazepoxide, resulting in quicker GI absorption and passage across the blood–brain barrier, making it valuable in an inpatient setting, especially to prevent seizures. However, a faster onset of action may be associated with feeling high (ie, "euphoria") and is a treatment disadvantage.

American Psychiatric Association (APA) Guidelines recommend thiamine be given routinely to patients being treated for moderate to severe alcohol use disorders to treat or prevent adverse neurologic symptoms.[12] However, according to a recent Cochrane Review, there are inadequate data from randomized, controlled trials regarding the most efficacious thiamine dose, frequency, and route of administration to prevent or treat Wernicke's syndrome associated with alcohol use disorders.[24] APA Guidelines recommend thiamine 50 to 100 mg per day given IV or IM, although some guidelines recommend higher doses (eg, thiamine 300 mg/day for low risk patients).[12,25] It is particularly important that administration of thiamine (essential for proper energy utilization by the CNS) precedes administration of glucose-containing IV fluids, which can help prevent an acute exacerbation of Wernicke's syndrome.

▶ *Complicated Alcohol Withdrawal*

**Alcohol Withdrawal Seizures** Alcohol withdrawal seizures, a medical emergency, should be treated in an inpatient setting. Withdrawal seizures are usually few in number and generalized. Although binge drinking and alcohol withdrawal can lead to status epilepticus, the occurrence of focal seizures or status epilepticus may also suggest another etiology. Management consists of keeping the airway open and preventing self-injury during convulsions. Benzodiazepines are the treatment of choice. IV diazepam 5 to 10 mg is preferred to terminate a seizure in progress if IV access is available. Dose may be repeated in 5 minutes if seizures persist. Alternatively, lorazepam 4 mg may be given IM followed by insertion of an IV line when convulsive movements have subsided. In the event of a recurrent seizure, lorazepam 2 mg IV may be administered if the patient received IM lorazepam. IM use of diazepam or chlordiazepoxide should be avoided because of erratic absorption that complicates the timing of subsequent doses and can result in delayed oversedation. IV benzodiazepines may depress respiration, so they should be administered only when and where advanced cardiopulmonary support is available. When the patient can take medication orally, then treatment may continue using the symptom-triggered or loading dose procedure. Electrolyte imbalances can contribute to seizures and should be corrected if they exist. For example, it may be advisable to administer magnesium in addition to benzodiazepine treatment. Phenytoin should be avoided for preventing or treating alcohol-related seizures as no data demonstrate efficacy.[26]

**Alcohol Withdrawal Delirium (Delirium Tremens)** Delirium tremens is a medical emergency necessitating hospitalization to prevent death. DTs are characterized by hallucinations, delirium, severe agitation, fever, elevation of blood pressure and heart rate, and possible cardiac arrhythmias. Parenterally administered benzodiazepines are the treatment of choice.[23] The antipsychotic haloperidol is given for severe agitation unresponsive to benzodiazepine therapy. Evidence does not support use of an antipsychotic as single agent.[27] Furthermore, newer generation antipsychotic agents have not been studied for treatment of DTs. Thiamine should be given according to the same guidelines described above.

## Opioid Withdrawal

It is rare to die from withdrawal from opioids alone; however, underlying medical complications (eg, hypertension) and recent

myocardial infarction increase risk of complications and death. Therefore, it is important to manage and stabilize any medical issues and then determine if hospitalization is appropriate. Patients with underlying medical problems should be evaluated for possible triage to an inpatient detoxification program to be followed up with either inpatient or outpatient substance abuse treatment. Rapid referral for substance abuse treatment can introduce patients to the concept of recovery while they still vividly remember negative consequences from using substances. Withdrawal from opioids is commonly described by patients as resembling "a bad case of the flu." Symptoms include nausea; vomiting; diarrhea; anxiety; headaches; mydriasis; rhinorrhea; lacrimation; muscle, bone, and joint pain; piloerection; yawning; fever; increased heart rate; and hypertension.

Use of clinical withdrawal scales (see Table 36–2), such as the Clinical Opiate Withdrawal Scale (COWS), provide high inter-rater reliability and clinical utility given objective measurement of withdrawal severity. The full items contained in the COWS instrument (*along with many other substance use disorder [SUD] instruments*) can be obtained free-of-charge from the Substance Abuse and Mental Health Services Administration (SAMHSA).[9] The baseline score assists in deciding whether to treat pharmacologically or to observe. As withdrawal scores become larger (eg, COWS scores five or greater), opioid substitution or a "symptoms-based approach" may be indicated. In severe withdrawal, either buprenorphine (ie, partial μ-opioid agonist) or methadone (ie, full μ-opioid agonist) are recommended for detoxification. Methadone is the gold-standard μ-opioid agonist for treating opioid use disorders, but under current US law, methadone detoxification requires referral to a federally approved methadone detoxification program. The two pharmacologic options for treatment of opioid withdrawal in regular clinical settings are opioid substitution with buprenorphine and symptomatic treatment (discussed in the following paragraphs).

▶ *Opioid Substitution*

Treatment with a μ-opioid agonist is accomplished with either buprenorphine or methadone. Methadone can be used for opioid detoxification and long-term relapse prevention, particularly among heavy opioid users. However, given extensive medical use restrictions (eg, used only in federally approved opioid treatment programs; OTP) and wide availability of methadone detoxification regimens, this chapter focuses on buprenorphine.

Buprenorphine is a partial agonist at μ-opioid receptors that is available in multiple formulations in the United States with varying pharmacokinetic profiles. For example, buprenorphine in combination with naloxone is available via sublingual tablet, sublingual film, and buccal film. Certain formulations (eg, sublingual film) may have greater buprenorphine bioavailability, and hence lower dosage requirements, compared to sublingual tablets. Buprenorphine plus naloxone is the recommended formulation (over buprenorphine alone) unless the patient is pregnant or hypersensitive to naloxone, in which case buprenorphine alone is appropriate. Opioid antagonists, such as naloxone, have been associated with severe negative outcomes among pregnant women (eg, spontaneous abortion) and should be avoided in this population. Naloxone was added to the Suboxone formulation to secure FDA approval in the United States. Naloxone is poorly absorbed via sublingual or buccal routes, but blocks opioid receptors if injected, thus minimizing diversion to the street for IV use.

To initiate buprenorphine induction, a patient has to be in moderate or severe withdrawal, and the last opioid use should be at least 12 to 24 hours earlier, depending on the half-life of the

---

| Table 36–6 |
| --- |

**Sample Regimen[a] for Buprenorphine Induction Treatment of Opioid Withdrawal and Long-Term Relapse Prevention**

| Day | Buprenorphine Sublingual/Buccal Dosage |
| --- | --- |
| 1 | 2 mg every 2 hours (maximum, 8 mg on first day) |
| 2 | Start with total day 1 dose; additional 2–4 mg every 2 hours (maximum, 16 mg) |
| 3+ | Start with total day 2 dose; additional 2–4 mg every 2 hours (maximum, 32 mg) |
| 4–5 | Maintain on dose required to alleviate withdrawal symptoms[b] |

[a]For withdrawal from any opioid.

[b]Patient will likely be transitioned to long-term maintenance dose indefinitely.

Data from Center for Substance Abuse Treatment. Clinical Guidelines for the Use of Buprenorphine in the Treatment of Opioid Addiction. Treatment Improvement Protocol (TIP) Series 40. DHHS Publication no. (SMA) 04–3939. Rockville, MD: Substance Abuse and Mental Health Services Administration; 2004.

opioid used (longer half-life, longer a clinician should wait before initiating buprenorphine induction). Otherwise, buprenorphine likely will induce withdrawal because it has high affinity for μ-receptors, and it will displace other full μ-opioid agonists. Buprenorphine can be initiated following a protocol such as the example in Table 36–6 to titrate the dosing.[9] When a final dose is established, there are generally two treatment approaches, depending on many factors such as patient preference. A maintenance dose can be prescribed or the dose can be tapered down gradually to zero within 1 to 2 weeks (a 25% reduction per day is a general rule of thumb).

▶ *Symptoms-Based Treatment*

Symptomatic treatment focuses on minimizing withdrawal symptoms to help patients be comfortable. Symptom-specific medications, as shown in Table 36–7, are often used as adjunct

---

| Table 36–7 |
| --- |

**A "Symptoms-Based" Treatment Approach for Opioid Withdrawal**

Following medications are used for symptoms that cause distress and includes use of any single or combination of two or more of the following agents, depending on symptoms reported:

1. Insomnia: Diphenhydramine 50–100 mg, trazodone 75–200 mg, or hydroxyzine 25–50 mg at bedtime

2. Headache, muscle aches, and pain: Acetaminophen 500 mg–1 g every 6 hours, ibuprofen 600 mg by mouth every 8 hours, or naproxen 600 mg by mouth every 12 hours

3. Noradrenergic hyperactivity: Clonidine (Catapres) 0.1–0.2 mg every 6–8 hours; maximum dosage not to exceed 1.2 mg in 24 hours

4. Abdominal cramps: Dicyclomine 10–20 mg every 6 hours

5. Constipation: Milk of magnesia at 30 mL daily

6. Diarrhea: Bismuth subcarbonate 30 mL can be given every 2 to 3 hours

Data from Refs. 9 and 12.

medication with opioid substitution.[9,12] Clonidine is one of the primary nonopioid medications used during withdrawal to decrease the excessive noradrenergic symptoms (eg, sweating) of opioid withdrawal. However, use of clonidine requires close monitoring of blood pressure; it should be held if systolic blood pressure is below 90 mm Hg or diastolic blood pressure is below 60 mm Hg. Compared with opioid substitution, clonidine does not help other withdrawal symptoms, such as craving.[12]

▶ *General Patient Guidelines for Outpatient Opioid Detoxification*

Patient safety is the highest priority. The first step is to educate patients about the course of withdrawal. Symptoms peak at around 5 to 7 days and may last up to 2 weeks, depending on half-life of the opioid being used before detoxification. Patients should be advised regarding the side effects of medications used to detoxify. There is an overdose potential if clonidine is mixed with opioids, other CNS sedatives, or antihypertensives. Risk of these adverse events needs to be balanced with potential benefits. Side effects of buprenorphine include constipation, sedation, and headaches. Potential for serious overdose exists when buprenorphine is mixed with benzodiazepines or other sedative–hypnotics.

Risk of developing physiologic tolerance to buprenorphine is high if used for prolonged periods. In this case, buprenorphine should be slowly tapered to discontinuation. Withdrawal from buprenorphine is generally easier and less severe than withdrawal from a pure agonist, such as methadone. However, there is concern regarding a subset of patients who have difficulty stopping buprenorphine treatment. This has prompted federal research into the issue (see www.clinicaltrials.gov regarding ongoing studies). The duration of buprenorphine treatment is specific to each individual's needs and resources, and difficulty in tapering the medication to discontinuation complicates this decision further.

Patients often think all they need is detoxification, but this is not accurate. Positive outcomes are tied to successful rehabilitation and acquiring recovery skills after detoxification. This goal can be accomplished by either achieving detoxification on-site during rehabilitation or by quick and seamless transition from detoxification to a rehabilitation program. The more time that elapses between the two modalities, the greater the likelihood of treatment failure and drug relapse.

## Stimulant (Cocaine, Amphetamines) Withdrawal

Cocaine and amphetamine withdrawal are grouped together because their symptom profiles as described in *DSM-5*[6] are similar, and the physiologic basis of their withdrawal syndromes involves the DA neurotransmitter system. Stimulants of this group also include methylphenidate, but not nicotine and caffeine, which have different neurophysiologic mechanisms of action. Major adverse complications of stimulant withdrawal are profound depression with suicidal thoughts, and the primary goal of treatment is to prevent suicide. Therefore, unless suicidality warrants hospitalization, stimulant withdrawal can be treated in outpatient settings with psychological support and reassurance with an emphasis on patient safety. A number of medications have been studied to alleviate symptoms of stimulant withdrawal and the intense craving that may accompany it, but inconsistent results preclude any recommendations for their routine use. Patients with stimulant use disorders should be referred for substance abuse treatment because of high risk for continued use either during or immediately following stimulant withdrawal.

## Cannabinoid (Marijuana, Hashish) Withdrawal

Symptoms of cannabinoid withdrawal are primarily behavioral. For example, significant anxiety may accompany cannabinoid withdrawal, which can lead many individuals to resume substance use. This is particularly problematic following heavy and prolonged cannabinoid use. Management of withdrawal focuses on these behavioral symptoms, as there are no FDA approved medications specifically targeted at cannabinoid withdrawal.

## GENERAL APPROACH TO THE TREATMENT OF SUBSTANCE USE DISORDERS

● **KEY CONCEPT** *A multimodal and comprehensive approach is preferred when treating individuals with substance use disorders given the heterogeneous nature of addiction. Pharmacologic treatment is always adjunctive to psychosocial therapy.* Steps to be taken in the management of addiction are similar for all substances, and are highlighted in the Patient Care Process.[12]

Comorbid psychiatric conditions such as anxiety, depression, insomnia, pain, and continued smoking should be addressed. All these conditions increase risk of relapse to drug use. Although complete abstinence may be desirable in many patients, decreasing substance use and negative consequences may be sufficient in certain cases (ie, "harm reduction" concept)."

## Nonpharmacologic Therapy

Although pharmacologic agents may help prevent relapse, psychotherapy should be the core therapeutic intervention. Psychotherapy typically addresses one or more of the following tasks:

- Motivation enhancement to stop or reduce drug use
- Coping skills education
- Providing alternative reinforcement
- Managing painful affect (eg, dysphoria)
- Enhancing social support and interpersonal functioning

A thorough review of these psychosocial approaches is beyond the scope of this chapter and are available elsewhere.[12] However, a few of the commonly used techniques are cognitive-behavioral therapy (CBT), motivational-enhancement therapy (MET), and other behavioral therapies (eg, community reinforcement).

## Pharmacologic Therapy

▶ *Maintenance Treatment*

● **KEY CONCEPT** *Certain pharmacologic agents have been shown to be helpful for long-term maintenance in patients with substance use disorders. Typically, these medications exert their effects by one of the following theorized mechanisms: (a) drug substitution therapy with an agonist, (b) blocking drug effects with an antagonist, and (c) miscellaneous relapse prevention medications with indirect mechanisms of action.* Medications from each of these categories are discussed in greater detail in the following paragraphs for alcohol, opioid, cannabinoid, stimulant, and tobacco use disorders.

▶ *Alcohol Use Disorder*

The three FDA-approved medications to treat alcohol use disorders are naltrexone (oral and depot), acamprosate, and disulfiram. Naltrexone and acamprosate are generally considered first-line agents as evidenced by their "grade A" efficacy rating in the seminal paper by Garbutt et al.[28] However, in motivated patients, disulfiram is another reasonable option.[29]

**Naltrexone** Naltrexone is a competitive opioid antagonist that decreases alcohol intake in both animals and humans. Evidence suggests that it both decreases craving for alcohol and alcohol-induced euphoria (ie, reduces positive reinforcement of drinking). Numerous controlled trials and meta-analyses have demonstrated that naltrexone is more efficacious than placebo for a variety of drinking measures.[12] One meta-analysis that included more than 20 controlled trials demonstrated naltrexone significantly decreased relapse risk compared with placebo.[30] Reported predictors of naltrexone efficacy include family history of alcoholism, genetic differences in opioid alleles, drinking problems at early age, and high levels of craving.[12,31] In a landmark study assessing efficacy of behavioral treatment, medication management, and their combinations for treatment of alcohol dependence, naltrexone was associated with a higher percent days abstinent.[32] An oversimplified interpretation of this complex study suggests that naltrexone was effective (eg, percent days abstinent), but that acamprosate was not associated with any treatment advantage.[32]

Naltrexone is available in both oral and sustained-release injections. Usual oral dose of naltrexone is 50 mg/day, with a range from 25 to 100 mg. The 25-mg dose is commonly given initially as a test dose and then increased to 50 mg/day as tolerated. Adherence to naltrexone strongly affects drinking outcomes; therefore, a sustained-release IM injection of naltrexone has been marketed. A 380-mg monthly injection of naltrexone (Vivitrol) resulted in significantly greater reductions in heavy drinking days compared with placebo injection.[33]

Most common naltrexone side effects are nausea, vomiting, headache, insomnia, and nervousness. Injectable naltrexone is associated with injection site pain or reactions. Because naltrexone can precipitate withdrawal in patients dependent on opioids, the first dose should be withheld 7 to 10 days after last opioid use and given only when urine drug screen for opioids is negative. Naltrexone can be hepatotoxic, albeit typically not at oral doses less than 250 mg/day or at recommended injectable dose of 380 mg/mo. Baseline and periodic LFTs are recommended.

**Drug Interactions** Naltrexone can block effects of opioid receptor agonists, rendering them therapeutically ineffective (see Table 36–5). Given that opioid agonists are a mainstay of pain management, alternative pain treatment (eg, conscious sedation) may be required in patients receiving naltrexone maintenance.

**Special Dosing Considerations** It is important for patients taking naltrexone to carry a pocket warning card or wear a warning bracelet because, in the event that emergency treatment is needed, they will be insensitive to opioid analgesia unless potentially toxic doses are administered. Patients need to be warned of the potential for opioid overdose under two conditions. First, dosing with opioids to reverse opioid insensitivity (ie, naltrexone's competitive blockade of opioid receptors) requires high doses of opioids that can cause respiratory depression and death. Second, chronic opioid antagonist therapy may cause patients to become hypersensitive to opioids after stopping naltrexone, thereby increasing risk of respiratory depression and death when opioids are used.

**Acamprosate** Acamprosate appears to be a glutamatergic antagonist and may have GABA-ergic effects.[3] Alcohol use acutely inhibits glutamatergic function. During acute and postacute alcohol withdrawal, increased activity of the glutamate system is caused by upregulation of receptors combined with absence of alcohol-related inhibition. Thus, acamprosate may correct glutamate/GABA imbalances that occur following chronic alcohol use (eg, reduce negative reinforcement associated with craving and withdrawal).

Generally, trials assessing efficacy of acamprosate have shown mixed results. This may be partly attributable to differences in research methodologies, such as varying levels of abstinence required in trials before acamprosate initiation.[12] Notably, in the landmark Combining Medications and Behavioral Interventions for Alcoholism (COMBINE) study mentioned earlier, acamprosate appeared to offer no treatment advantage,[32] but a meta-analysis of randomized control trials suggests it is more efficacious than placebo.[34] Another recent meta-analysis suggests that acamprosate may be more effective at maintaining abstinence, but naltrexone may more effectively prevent full relapse to heavy drinking in nonabstinent individuals.[35] Despite the variable methodologies and results, there appear to be sufficient evidence that acamprosate is more effective than placebo, although differences may be modest.

The dose of acamprosate is 666 mg orally three times daily. It is not metabolized by the liver and is excreted unchanged by the kidneys. Consequently, it is contraindicated in patients with severe renal impairment (creatinine clearance less than or equal to 30 mL/min [0.50 mL/s]), and dose reduction is necessary when creatinine clearance is between 30 and 50 mL/min (0.50 and 0.83 mL/s). Most common acamprosate side effects are GI, including nausea and diarrhea. CNS adverse effects include insomnia, anxiety, and depressive symptoms.

**Disulfiram** Disulfiram irreversibly blocks the enzyme aldehyde dehydrogenase (ALDH), a step in the metabolism of alcohol. This results in increased blood levels of the toxic metabolite acetaldehyde. As acetaldehyde levels increase, patients experience the disulfiram-ethanol reaction (decreased blood pressure, increased heart rate, chest pain, palpitations, dizziness, flushing, sweating, weakness, nausea and vomiting, headache, shortness of breath, blurred vision, and syncope). Symptom severity increases with amount of alcohol consumed, and emergency treatment may be warranted. Psychologically, disulfiram works through aversion, and drinking is avoided to prevent the aversive disulfiram–ethanol reaction. Efficacy of disulfiram is directly dependent on medication adherence,[36] and more recent reports advocate that disulfiram can be highly effective when procedures for enhancing adherence are used.[29]

The usual starting dose of disulfiram is 250 mg/day orally (can be started at 500 mg/day for first 1 to 2 weeks), and the range is 125 to 500 mg/day. Compared with 250 mg/day, the larger dose is recommended if a patient does not experience a disulfiram–ethanol reaction after alcohol consumption, and the smaller dose is given when intolerable side effects are experienced at higher doses. Dosing begins only after the BAC is zero (usually 12–24 hours after the last drink) and after the patient understands the consequences of the disulfiram–ethanol reaction.

Disulfiram is contraindicated in patients with cardiovascular or cerebrovascular disease or in combination with antihypertensive medications because the cardiovascular effects of the disulfiram–alcohol reaction could be fatal in such patients. Most common disulfiram side effects are rash, drowsiness, a metallic or garlic-like taste, and headache. If drowsiness occurs, dose may be lowered or given at night. Other less common, but concerning, adverse effects include neuropathies and hepatotoxicity. Given the serious nature of these adverse effects, baseline and periodic monitoring is recommended. If serum levels of alanine

aminotransferase (ALT) or aspartate aminotransferase (AST) are greater than three times the upper limit of normal values, then disulfiram should be withheld and testing repeated every 1 to 2 weeks until normal. When LFTs return to normal range, they may be repeated every 1 to 6 months. It is advisable to follow LFTs and clinical symptoms until resolution has been confirmed.[37] Although elevated LFTs may signal disulfiram-induced hepatotoxicity, it is also likely the patient was nonadherent to treatment and resumed drinking, ultimately leading to hepatotoxicity. Another uncommon side effect of disulfiram is psychosis, which has been reported in doses exceeding 500 mg/day, especially in predisposed patients. This may be related to disulfiram's ability to inhibit dopamine β-hydroxylase, resulting in increased dopamine activity. Nevertheless, alcohol-dependent patients with schizophrenia and other cooccurring mental disorders have received disulfiram at usual therapeutic doses without difficulties.[38]

**Drug Interactions** The disulfiram–ethanol interaction serves as disulfiram's mechanism of action. Depending on dose of disulfiram, sensitivity to disulfiram, amount of alcohol consumed, and metabolism, patients may be at risk for an adverse interaction with alcohol for 2 to 14 days after stopping disulfiram (5 days on average) and should be warned accordingly. See Table 36–5 for relevant interactions that occur with disulfiram (particularly with metronidazole).

**Medication Selection** See Table 36–8 for patient-specific factors that can guide medication selection for alcohol use disorders.[37] Universally accepted treatment algorithms for the treatment of alcohol use disorders are lacking.

---

**Patient Encounter 3**

A 19-year-old woman was transferred to the cardiology unit from the emergency department (ED) after she called 911 claiming that she had chest pain and that her heart was racing. This in turn caused her significant anxiety. Upon arrival in the ED, it was noted that her heart rate was 130 beats/min in a resting position. She was in otherwise good physical condition with no previous cardiac history, although her eyes appeared extremely red and hazy. After a comprehensive urine toxicology analysis was positive for cannabinoids, she admitted that she had used "K2" at a party. She said she almost never uses illegal drugs. However, she was told "K2" could "help her anxiety" (diagnosed with generalized anxiety disorder at age 15 years), which has worsened since starting college. The treatment plan is to address the patient's substance use and anxiety disorder after the acute cardiac issues are resolved.

*What physical signs and symptoms does she manifest that are consistent with cannabinoid intoxication?*

*What is the most appropriate pharmacotherapy for this patient's acute substance use condition?*

---

▶ **Opioid Use Disorders**

After conclusion of withdrawal, patients may not feel their usual selves for some time and could relapse to using opioids, just to "feel normal." Long-term use of opioids results in brain changes,

+ = particularly appropriate; A = appropriate to use; C = use with caution; X = contraindicated.

AUD, alcohol use disorder; IM, intramuscular.

Data from Center for Substance Abuse Treatment. Incorporating Alcohol Pharmacotherapies into Medical Practice. Treatment Improvement Protocol (TIP) Series 49. HHS Publication No. (SMA) 09-4380. Rockville, MD: Substance Abuse and Mental Health Services Administration; 2009.

and the brain might not readily return to its prior homeostasis. The goal of treatment is to encourage stability, both in the body and in the patient's life. If an individual is not successful in quitting opioids (eg, because of withdrawal symptoms or postacute craving), then maintenance treatment should be considered.

**Opioid Agonists** The time-honored opioid agonist treatment for opioid use disorders is methadone maintenance. However, methadone maintenance can be provided only in federally approved OTPs. The other first-line agent, which will be the focus of this chapter, is buprenorphine maintenance.

The more widely available office-based opioid treatment (OBOT) exclusively uses buprenorphine, a partial μ-agonist (typically in same medication formulation with naloxone).[9] Under provisions of the Drug Addiction Treatment Act of 2000, physicians may prescribe buprenorphine in their office if they meet predetermined requirements (eg, training) and become qualified providers. When these criteria are met, they obtain an "X" on their Drug Enforcement Administration (DEA) number.[9]

The effective maintenance dose of buprenorphine (with or without naloxone) is usually between 8 and 16 mg/day, with maximum reported efficacy at 64 mg/day. Patients receiving buprenorphine maintenance should sign a treatment contract requiring full adherence, financial responsibility for treatment, adherence to office policies, respectful behavior to staff, and agreement to provide random urine samples for drug screens. Patients should bring their prescribed medication for pill counts at every visit. In the event of OBOT failure, the alternative to buprenorphine maintenance is referral to an OTP for methadone administration.

In 2010, the injectable formulation of naltrexone was approved for prevention of opioid relapse following successful opioid detoxification. However, its place in the long-term treatment of opioid use disorders remains to be established. Please refer to alcohol use disorder section for additional naltrexone drug information. Chronic naltrexone use may complicate the risk of overdose with full opioid agonists as described above.

Although there are no treatment algorithms to guide medication selection, there are protocols for some medications that assist with dosing and titration. For example, the extensive buprenorphine treatment protocol available from SAMHSA provides guidelines on how to dose buprenorphine from induction to maintenance treatment.[9] Of note, findings from a recent Cochrane meta-analysis indicate that methadone may offer an advantage over buprenorphine for select treatment outcomes (eg, retention in treatment).[39] Therefore, there may be circumstances under which referral to methadone maintenance remains the best option.

#### ▶ Cannabinoid Use Disorders

There are no proven pharmacotherapies for treatment of cannabinoid use disorders. Pharmacotherapy trials have emerged in the literature[40–42], but it is too soon to evaluate the role of medications for the treatment of cannabinoid use disorders.

#### ▶ Stimulant Use Disorders

There are no proven pharmacotherapies for treatment of stimulant use disorders. However, the APA Practice Guidelines mention three medications as possible treatment options for CNS stimulant use disorders when combined with psychosocial approaches (ie, after psychosocial approaches alone have failed). These medications include topiramate, disulfiram, and modafinil. For example, disulfiram shows some promise in randomized, controlled trials possibly due to its inhibition of dopamine β-hydroxylase enzyme that converts DA to norepinephrine (NE) in the brain. The resulting increase in DA levels may counter DA deficiency states that are believed to underlie cocaine withdrawal and craving.[12]

#### ▶ Tobacco Cessation

**Nonpharmacologic** Behavioral treatment delivered by a variety of clinicians (eg, physician, psychologist, nurse, pharmacist, and dentist) increases abstinence rates. The five As should be applied by all clinicians.[16]

- Ask if they smoke.
- Advise to quit.
- Assess motivation for change.
- Assist if willing to change.
- Arrange for follow-up.

Smoking cessation counseling should be provided to all smokers, and those interested should be assisted to achieve cessation. It is now a standard of practice for clinicians to screen for smoking and provide all smokers with brief advice and assistance with appropriate medications to quit or provide referral to specialized services when needed.

**Pharmacologic** According to the seminal tobacco use clinical practice guideline,[16] there are seven first-line medications available to treat nicotine use disorders (Table 36–9).[43]

Symptomatic detoxification and maintenance for tobacco use disorders is achieved with any single or combination of the currently available nicotine replacement therapies (NRTs).[16] Similar to opioid agonists, these NRTs act as substitution therapy with a safer alternative. NRT is generally considered safe with one notable exception: Given the pregnancy category D assigned to NRT, the decision to use NRT for pregnant women must be made on a case-by-case basis. According to clinical practice guidelines, pregnant smokers should be encouraged to quit smoking without use of medication.[16] Given the various NRT products that are efficacious at treating tobacco use disorders, choice of specific NRT depends on other factors, such as patient preference.[12]

First-line non-nicotine medications proven beneficial for treating tobacco use disorders are bupropion and varenicline. The sustained-release form of the antidepressant bupropion (Zyban) was approved by the FDA for treatment of tobacco use disorders. Bupropion blocks reuptake of DA and NE, and it appears that one of its metabolites is a nicotinic antagonist.[3] These mechanisms may help explain how bupropion acts to reduce nicotine reinforcement, withdrawal, and craving.

Varenicline (Chantix) is a $\alpha_4\beta_2$ nicotinic acetylcholine (nACh) partial agonist.[3] Varenicline decreases withdrawal and craving and prevents reinforcing effects of nicotine if the patient relapses. It is at least as effective as bupropion in clinical trials. Both bupropion and varenicline have been associated with severe psychiatric disturbances when used for smoking cessation.[44,45]

As shown in Table 36–10, various NRTs, bupropion, and varenicline increase abstinence rates at 6 months compared to placebo.[16] Furthermore, combining the nicotine patch with ad libitum nicotine gum provides the highest likelihood of abstinence at 6 months. The single agent (ie, monotherapy) with the highest odds of maintaining abstinence is varenicline (2 mg/day dose).[16,43]

**Table 36–9**

**First-Line Medications for Treatment of Tobacco Use Disorders**

| Medication | Dosing and Administration | Adverse Effects |
|---|---|---|
| Nicotine patch (7, 14, and 21 mg) | One patch per day on a hairless area of body between the waist and neck; rotate patch site<br>≥ 10 cigarettes/day: 21 mg × 4 weeks, 14 mg × 2–4 weeks, 7 mg × 2–4 weeks<br>< 10 cigarettes/day: 14 mg × 4 weeks, 7 mg × 4 weeks<br>Duration: 8–12 weeks | Local skin reactions, insomnia, vivid dreams, headache<br>May apply hydrocortisone or triamcinolone to ameliorate skin reactions<br>Warnings and Precautions:<br>Pregnancy category D<br>CV risks: Recent (< 2 weeks) MI, arrhythmias, unstable angina |
| Nicotine gum (2 or 4 mg) | One piece every 1–2 hours (maximum, 24 pieces/day); chew and "park"<br>Use 2-mg dose if 25 cigarettes/day or less and the 4-mg dose if 25 cigarettes/day or more or chewing tobacco<br>Do not eat or drink (except water) 15 minutes before or during use<br>Duration: 12 weeks (or as needed) | Sore mouth, hiccups, stomachache, dyspepsia, insomnia<br>Avoid chewing (ie, should "park" the gum in cheek) and limit swallowing excess saliva to avoid GI problems<br>Warnings and Precautions:<br>Pregnancy category D<br>CV risks: Recent (< 2 weeks) MI, arrhythmias, unstable angina |
| Nicotine lozenge (2 or 4 mg) | Use 2-mg dose for first cigarette 30 minutes or more after waking or 4-mg dose for first cigarette < 30 minutes after waking<br>Weeks 1–6: 1 every 1–2 hours; weeks 7–9: 1 every 2–4 hours, weeks 10–12: 1 every 4–8 hours<br>Do not eat or drink 15 minutes before or during use<br>Maximum is 20 lozenges per day; use one lozenge at a time<br>Duration: 3 to 6 months | Hiccups, cough, heartburn, nausea, headache, insomnia<br>Avoid chewing (ie, should "park" the lozenge in cheek) and limit swallowing excess saliva to avoid GI problems<br>Warnings and Precautions:<br>Pregnancy category (not evaluated)<br>CV risks: Recent (< 2 weeks) MI, arrhythmias, unstable angina |
| Nicotine nasal spray (0.5 mg delivered to each nostril) | One "dose" = 1 squirt/nostril<br>One to two doses/hour (8–40 doses per day; maximum, five doses per hour)<br>Do not inhale<br>Duration: 3 to 6 months; taper (see dependence risk) | Nasal irritation, nasal congestion, changes in smell<br>Warnings and Precautions:<br>Pregnancy category D<br>CV risks: Recent (< 2 weeks) MI, arrhythmias, unstable angina<br>Avoid in persons with reactive airway disease<br>Dependence (risk is higher) |
| Nicotine inhaler (4 mg in each cartridge) | Use 6–16 cartridges per day<br>Inhale (ie, "puff") 80 times/cartridge<br>Do not eat or drink 15 minutes before or during use; puff lightly and do not inhale into lungs (avoid coughing); avoid cold temperatures<br>Duration: Up to 6 months; taper | Mouth and throat irritation (improves with use), cough, rhinitis, sneezing, headache<br>Warnings and Precautions:<br>Pregnancy category D<br>CV risks: Recent (< 2 weeks) MI, arrhythmias, unstable angina |
| Bupropion | Initial dosing: 150 mg once daily × 3 days<br>Maintenance dosing: 150 mg twice daily<br>Should initiate at least 1 week before target quit date; efficacy of maintenance at 300 mg/day has been shown up to 6 months | US Boxed Warning(s): Serious neuropsychiatric events (eg, mood disturbances) when used for smoking cessation |
| Varenicline | May be combined with NRT<br>Initial dosing:<br>Days 1–3: 0.5 mg once daily<br>Days 4–7: 0.5 mg twice daily<br>Maintenance dosing:<br>Day 8 and after: 1 mg twice daily<br>Renal dosing (CrCl < 30 mL/min [< 0.50 mL/s]): Requires lower doses; 0.5 mg once daily with a maximum of 0.5 mg twice daily<br>Initiate varenicline at least 1 week before target quit date or begin varenicline dosing and then quit smoking between days 8 and 35 | CNS: Insomnia, headache, abnormal dreams<br>GI: Dose-related nausea<br>US Boxed Warning: Serious neuropsychiatric events (depression, suicidal thoughts, and suicide) have been reported with varenicline use |

CNS, central nervous system; CrCl, creatinine clearance; CV, cardiovascular; GI, gastrointestinal; NRT, nicotine replacement therapy; MI, myocardial infarction.

**Table 36–10**

**Six-Month PostQuit Smoking Abstinence Rates and Associated Odds Ratios[a]**

| Medication | Abstinence Rate (%) | Odds Ratio (95% CI) |
|---|---|---|
| Placebo | 13.8 | 1.0 |
| NRTs | | |
| Nicotine gum (6–14 weeks) | 19.0 | 1.5 (1.2–1.7) |
| Nicotine patch (6–14 weeks) | 23.4 | 1.9 (1.7–2.2) |
| Nicotine gum (> 14 weeks) | 26.1 | 2.2 (1.5–3.2) |
| Nicotine patch (> 14 weeks) | 23.7 | 1.9 (1.7–2.3) |
| Non-NRTs | | |
| Bupropion SR | 24.2 | 2.0 (1.8–2.2) |
| Varenicline (1 mg/day) | 25.4 | 2.1 (1.5–3.0) |
| Varenicline (2 mg/day) | 33.2 | 3.1 (2.5–3.8) |
| Combination Strategies | | |
| Patch (>14 weeks) + ad lib gum or spray | 36.5 | 3.6 (2.5–5.2) |
| Patch + bupropion SR | 28.9 | 2.5 (1.9–3.4) |

[a]Meta-analysis; 83 studies included.

CI, confidence interval; NRT, nicotine replacement therapy; SR, sustained release.

Data from Refs. 16 and 43.

## OUTCOME EVALUATION

KEY CONCEPT *A major component of successful treatment of substance use disorders is to monitor use of medications and identify a mechanism for long-term support of sobriety that might be appropriate for a specific individual such as AA, or recovery programs for professionals such as doctors, nurses, and pharmacists.*

To determine immediate treatment outcomes for patients with intoxication and withdrawal syndromes, evaluate parameters such as blood pressure, heart rate, respirations, and body temperature, as well as mental state. Choose from a number of validated and standardized rating scales to monitor the responsiveness of withdrawal syndromes to medical treatment. To determine the overall effectiveness of your health system for the treatment of substance related disorders, monitor outcomes using sentinel events such as the rates of cardiopulmonary arrest, seizures, discharges against medical advice, patient violence, and use of physical restraints. The ultimate goal should be to enable the transition of patients to formal substance use treatment when indicated.

Important outcome indicators to evaluate postintoxication and/or postwithdrawal treatment can be divided into three major groups: decreased consumption of substances, decreased problems associated with substance use, and improved psychosocial functioning. When complete abstinence has not been achieved, quantify the consumption of substances using quantity–frequency measures, rates of abstinence, and time to first relapse as determined by interviews and self-report and by biological markers such as urine and blood tests. The Addiction Severity Index (see Table 36–2) can be used to assess alcohol and drug-related problems in various domains, and provides a more comprehensive picture of the substance user's life.

KEY CONCEPT *Clinicians must be familiar with "essential" resources, many of which are in the public domain.* Table 36–11 provides a list of these resources along with website addresses. These websites provide information useful for clinical management, research, teaching, and policy development purposes.

**Table 36–11**

**Essential Substance Use Disorder Treatment Resources[a]**

| Source | Website | Example Highlight |
|---|---|---|
| American Psychiatric Association (APA) | www.psych.org | Practice Guidelines (*evidence-based treatment recommendations*) |
| American Society of Addiction Medicine (ASAM) | www.asam.org | Principles of Addiction Medicine (*gold-standard addiction textbook*) |
| National Institute on Alcohol Abuse and Alcoholism (NIAAA) | www.niaaa.nih.gov | Alcohol Research & Health (*peer-reviewed journal*) |
| National Institute on Drug Abuse (NIDA) | www.drugabuse.gov | Education Resources (*downloadable teaching slides; see Figure 36–2 in this chapter, for example*) |
| Substance Abuse and Mental Health Services Administration (SAMHSA) | www.samhsa.gov | National Survey on Drug Use and Health (NSDUH) (*national, representative alcohol and drug use survey*) |
| | | Treatment Improvement Protocols (TIPs) (*evidence-based treatment recommendations*) |

[a]There is a great deal of information from these resources, some of which is available in the public domain and may be used without permission. For example, the Treatment Improvement Protocols are comprehensive documents that can be accessed (free of charge) via the internet.

## Patient Care Process

**Patient Assessment:**

- Evaluate patient's history and symptoms to determine if substance intoxication, withdrawal, or longer-term substance use disorder are likely (see Tables 36–1, 36–3, and 36–4).

- Conduct mental (eg, Mini-Mental Status Exam) and physical examination (eg, vital signs).

  - More detailed or substance-specific mental/physical examination may be required depending on presentation.

**Therapy Evaluation:**

- Assess medication adherence among patients receiving pharmacotherapy; substance use disorders are major risk factors for medication nonadherence.

- Assess all pharmacotherapy for effectiveness, safety, and drug interactions.

**Care Plan Development:**

- If substance *intoxication* is likely scenario:

  - Management of intoxication is typically supportive; most important goal is to maintain cardiopulmonary function. If consciousness is impaired, obtain blood chemistries to help identify causative substance and rule out other etiologies.

- Observe patient until intoxication has resolved for safety of patient and others.

- If substance *withdrawal* is the likely scenario:

  - Select appropriate withdrawal severity instrument to help guide medication use (see Table 36–2).

  - Severe symptoms (eg, alcohol withdrawal seizures) should be treated in the inpatient setting.

- Achieving long-term recovery: consider medication management as *adjunct* to psychosocial approaches.

**KEY CONCEPT** **Follow-Up Evaluation:**

- Regularly assess effectiveness and safety of therapy and emphasize importance of adherence to the treatment plan.

- Encourage patient to consider long-term treatment for substance use, especially after multiple episodes of intoxication or withdrawal.

  - Improved coping skills, functioning, and relapse prevention are key goals during long-term treatment.

## Abbreviations Introduced in This Chapter

| | |
|---|---|
| AA | Alcoholics Anonymous |
| ALDH | Aldehyde dehydrogenase |
| ALT | Alanine aminotransferase |
| APA | American Psychiatric Association |
| ASI | Addiction Severity Index |
| AST | Aspartate aminotransferase |
| AUDIT | Alcohol Use Disorders Identification Test |
| BAC | Blood alcohol concentration |
| CB | Cannabinoid |
| CBT | Cognitive-behavioral therapy |
| CIWA-Ar | Clinical Institute Withdrawal Assessment–Alcohol, Revised |
| CNS | Central nervous system |
| COWS | Clinical Opiate Withdrawal Scale |
| CRF | Corticotropin-releasing factor |
| DA | Dopamine |
| DEA | Drug Enforcement Administration |
| *DSM-5* | *Diagnostic and Statistical Manual of Mental Disorders,* 5th edition |
| DTs | Delirium tremens |
| ED | Emergency department |
| FDA | Food and Drug Administration |
| GABA | γ-aminobutyric acid |
| GI | Gastrointestinal |
| IM | Intramuscular |
| IV | Intravenous |
| LFT | Liver function test |
| MET | Motivational enhancement therapy |
| NA | Nucleus accumbens |
| nACh | Nicotinic acetylcholine |
| NE | Norepinephrine |
| NMDA | *N*-methyl-D-aspartate |
| NRT | Nicotine replacement therapy |
| NSDUH | National Survey on Drug Use and Health |
| OBOT | Office-based opioid treatment |
| OTP | Opioid Treatment Program |
| PFC | Prefrontal cortex |
| SAMHSA | Substance Abuse and Mental Health Services Administration |
| SC | Subcutaneous |
| SUD | Substance use disorder |
| VTA | Ventral tegmental area |

# 37 Schizophrenia

Deanna L. Kelly, Elaine Weiner, and
Heidi J. Wehring

## LEARNING OBJECTIVES

**Upon completion of the chapter, the reader will be able to:**

1. Recognize signs and symptoms of schizophrenia and be able to distinguish among positive, negative, and cognitive impairments associated with the illness.
2. Explain pathophysiologic mechanisms that are thought to underlie schizophrenia.
3. Identify treatment goals for a patient with schizophrenia.
4. Recommend appropriate antipsychotic medications based on patient-specific data.
5. Compare side-effect profiles of individual antipsychotics.
6. Educate patients and families about schizophrenia, treatments, and the importance of adherence to antipsychotic treatment.
7. Describe components of a monitoring plan to assess the effectiveness and safety of antipsychotic medications.

## INTRODUCTION

In most cases, schizophrenia is a devastating, chronically debilitating disorder. It may be thought of as a clinical syndrome, with many possible pathophysiological pathways that ultimately manifests with psychotic symptoms, including hallucinations, delusions, and disordered thinking. Commonly, these symptoms are accompanied by cognitive impairment (abnormalities in thinking, reasoning, attention, memory, and perception), impaired insight and judgment, and negative symptoms including loss of motivation (avolition), loss of emotional range (restricted affect), and a decrease in spontaneous speech (poverty of speech). Cognitive impairments and negative symptoms account for much of the poor social and functional outcomes. Schizophrenia is the fourth leading cause of disability among adults and is associated with substantially lower rates of employment, marriage, and independent living compared with population norms. However, earlier diagnosis, treatment, and advances in research and newer treatment developments have led to better outcomes.

## EPIDEMIOLOGY AND ETIOLOGY

Approximately 1% of the world population suffers from schizophrenia, with symptoms typically presenting in late adolescence or early adulthood.[1] Prevalence is equal in men and women, but symptoms appear earlier in men with first hospitalization typically occurring at 15 to 24 years compared to 25 to 34 years.

The etiology of schizophrenia remains unknown. A genetic basis is supported by the fact that first-degree relatives of patients with schizophrenia carry a 10% risk of developing the disorder, and when both parents have the diagnosis, the risk to their offspring is 40%. For monozygotic twins, the concordance rate is about 50%. Many genes have been weakly associated with the development of schizophrenia; however, there is probably no single "schizophrenia gene." Research continues to explore candidate genes, loci, and copy number variants, hoping to better understand the genetic contribution.[2] Possibly, when a genetic liability is present, environmental stimuli may trigger expression of the illness. Some data suggest intrauterine exposure to significant stress, viral or bacterial infections may be a risk factor; however, more research is needed.

## PATHOPHYSIOLOGY

The dopamine hypothesis, the oldest pathophysiologic theory, proposes that psychosis is caused by excessive dopamine in the brain. This hypothesis followed the discovery that chlorpromazine, the first antipsychotic medication, was a postsynaptic dopamine antagonist. Drugs that cause an increase in dopamine (eg, cocaine and amphetamines) worsen or cause psychotic symptoms, and drugs that decrease dopamine (eg, antipsychotics) improve psychotic symptoms. However, data reveal a more complicated picture with both hyperdopaminergic and hypodopaminergic brain regions in schizophrenia. Hypodopaminergic activity in the prefrontal lobe is thought to relate to the core negative symptoms. Thus, a more modern reworking of the dopamine hypothesis is the "dysregulation hypothesis," which takes these findings into account.[3] It is possible, however, that the hypothesized dopamine abnormalities may represent changes occurring secondary to other pathophysiologic abnormalities. Other implicated neurotransmitter systems include a combined dysfunction of the dopamine and glutamate neurotransmitter systems.[4] It is hypothesized that glutamate, possibly through malfunctioning $N$-methyl-D-aspartate (NMDA) receptors, impacts dopaminergic activity in

## Patient Encounter, Part 1

A 23-year-old single man presents to the clinic with his mother with an approximately 1-year history of being fearful in public and continuously hearing voices of "famous people" talking with him and giving him advice. He was psychiatrically hospitalized following an episode of hypothyroidism during his sophomore year in college. Following that, 1 year ago, he withdrew from college, as he was having difficulty concentrating, and he was struggling academically. He was employed briefly as a waiter, but he felt he was not able to concentrate there as well. He also felt that the stress of working with many people made his fears worse. He lives with his mother. His parents are divorced, and he does not see his father, as he feels fearful and harshly criticized by him. He has given consent for his mother to be involved in his treatment, and during her interview, she states that his father will be of "no use," as he is "from a culture that doesn't believe in mental illness." She worries that her son spends too much time in his room and that he no longer does the activities he used to enjoy, such as listening to music and going to movies. The patient states he "doesn't really miss" doing these things, and he doesn't want to be pressured to do them. His mother also worries that he has strange eating habits and that his sleep is "off"—up at night and sleeping too much during the day.

*What diagnoses are suggested by this presentation?*

*What additional information would help to clarify the diagnosis and why?*

*Should the patient's parents be involved in his care?*

the mesolimbic and **mesocortical** pathways. NMDA antagonists such as phencyclidine (PCP) and ketamine can elicit a state resembling schizophrenia, including positive and negative symptoms and cognitive impairments. There is speculation regarding a role for serotonin receptor antagonism in antipsychotic efficacy[5] because many second-generation antipsychotics (SGAs) are active at serotonin receptors. However, a compelling pathophysiologic theory relating to dopamine and serotonin receptor affinities does not yet exist. It is notable that to date, antipsychotics without any primary or secondary dopamine-modulating properties have been ineffective for the treatment of positive symptoms of schizophrenia.

## CLINICAL PRESENTATION AND DIAGNOSIS

In addition to the positive, negative, and cognitive symptoms of schizophrenia, people with schizophrenia may appear uncooperative, suspicious, hostile, anxious, or aggressive. Psychotic and depressive symptoms may lead to poor hygiene and impaired self-care. Sleep and appetite are often disturbed, and they often have difficulty living independently, forming close relationships with others, and initiating or maintaining employment. Comorbid medical disorders, such as type 2 diabetes and chronic obstructive pulmonary disease, are prevalent in people with schizophrenia because of sedentary lifestyles, poor dietary habits, obesity, or cigarette smoking. Approximately 60% of people with schizophrenia smoke, and approximately 50% use illicit drugs and alcohol.[6]

**KEY CONCEPT** *A diagnosis of schizophrenia is made clinically because there are no psychological assessments, brain imaging, or laboratory examinations that confirm the diagnosis.*

The diagnosis is made by ruling out other causes of psychosis and meeting specified diagnostic criteria. When present, a family history of mental illness supports the diagnosis. The commonly accepted diagnostic criteria for schizophrenia are from the *Diagnostic and Statistical Manual of Mental Disorders*, 5th edition (*DSM-5*)[7] (**Table 37–1**).

**KEY CONCEPT** *Patients presenting with odd behaviors, illogical thought processes, fixed false beliefs, and hallucinations should be comprehensively assessed to rule out other diagnoses or contributing factors.*[8,9]

At minimum, patients with psychosis should have a medical workup at the time of admission to rule out other diagnoses or contributing factors. Often, people with psychosis are poor historians and the gathering of collateral information is necessary. Comorbid substance abuse, medical illnesses, and psychosocial stressors, often confound the diagnosis.

## COURSE AND PROGNOSIS

Treatment of schizophrenia is often associated with poor long-term outcomes, however, some people can achieve remission. Typically there are intermittent acute psychotic episodes with a downward decline in psychosocial functioning. Though many of the more dramatic and acute symptoms may fade with time, severe residual symptoms may persist. Involvement with law enforcement is fairly common for vagrancy, loitering, and disturbing the peace. Life expectancy is shortened primarily because of suicide, cardiovascular disease, accidents, and compromised self-care. Lifetime risk of suicide for people with schizophrenia is 5% to 10%.[10] Persistent compliance with a tolerable drug regimen improves prognosis, while relapse without medication exceeds 50% in the year following noncompliance.

The onset of schizophrenia can be rapid with acute psychosis presenting as the first symptom, or onset can be insidious with negative symptoms and social impairments predating psychosis by many years. Whether insidious or acute, the period around the diagnosis is difficult for patients, families, and clinicians. Patients may hide symptoms from family and friends and isolate themselves from social support networks. Gradual development of psychosis and the misunderstanding of symptoms can delay diagnosis and treatment. Recent data suggest that people treated early in their illness may have a better prognosis. Therefore, the first challenge of optimal therapy is to initiate treatment closer to the onset of psychosis.

## TREATMENT
### Desired Outcomes

**KEY CONCEPT** *The goals of treatment are to reduce symptomatology and psychotic relapses and to improve functional and social outcomes.*[9] Patients should receive comprehensive treatment as early as possible. In the past, the primary treatment goal was to decrease positive symptoms and associated hostile and aggressive behaviors. Newer approaches also focus on functional and social outcomes. Though antipsychotic medications may improve combativeness, hostility, sleep, and appetite, other aspects of the illness are less responsive to treatment. Improvements in negative symptoms, cognitive functioning, social skills, and judgment generally require adjunctive treatments and a longer period to improve.

## Clinical Presentation of Schizophrenia

### General

Schizophrenia is a chronic disorder of thought and affect, causing significantly impaired vocational and interpersonal function. Onset is usually preceded by gradual social withdrawal, diminished interests, changes in appearance and hygiene, changes in cognition, and bizarre or odd behaviors. The clinical presentation of a person with schizophrenia is extremely varied.

### Symptoms

*Psychotic symptoms (positive symptoms):*

- Hallucinations (distortions or exaggeration of perception)
  - Most frequently auditory, can also be visual, olfactory, gustatory, and tactile.
  - Can be voices or thoughts that feel distinct from the person's mind.
  - Voices may be threatening or commanding (eg, commanding the person to perform a particular action).
- Delusions (fixed false beliefs)
  - Beliefs despite invalidating evidence
  - May be bizarre in nature
  - Often paranoid in nature which may cause suspiciousness
- Thought disorder (illogical thought and speech)
  - Loosening of associations
  - Tangentiality
  - Thought blocking
  - Concreteness
  - Circumstantiality
  - Perseveration
  - Thinking and speech may be incomprehensible and illogical

*Negative symptoms:*

- Impoverished speech and thinking
- Lack of social drive (avolition)
- Flatness of emotional expression
- Apathy
- May be primary or occur secondarily to medication side effects, mood disorder, environmental understimulation, or demoralization
- The best strategy for differentiating primary from secondary negative symptoms is to observe for their persistence over time despite efforts at resolving the other causes

*Cognitive impairments (diminished function in the following):*

- Attention
- Processing speed
- Verbal, visual memory, and working memory
- Problem solving
- There is a loss of, on average, one standard deviation of preillness IQ, with the average IQ between 80 and 84.

### Laboratory and Other Diagnostic Assessments

- An initial psychotic work up includes a thorough neurologic, medical and laboratory evaluation to rule out other causes
  - Electrolytes
  - Blood urea nitrogen
  - Serum creatinine
  - Urinalysis
  - Liver and thyroid function profile
  - Syphilis serology
  - Serum pregnancy test
  - Urine toxicology

## General Approach to Treatment

The concept of recovery has become an increasingly prominent treatment goal. Treatment planning increasingly includes providing recovery-oriented services to people with schizophrenia. A range of nonpharmacologic interventions are now part of the long-term strategy to improve functioning. Implementation of evidence-based practice and prescribing behaviors, has led to the use of interventions that promote a remission or recovery attitude.[11-13] Moreover, recent attempts to improve and measure patient satisfaction have fostered patient empowerment and hope. Despite these conceptual advances and treatment improvements, many patients still fail to receive comprehensive care, and long-term outcomes remain poor.

**KEY CONCEPT** *The cornerstone of treatment is antipsychotic medications, and most patients with schizophrenia relapse when not medicated.* Treatment with antipsychotic medications should begin as soon as psychotic symptoms are recognized. Most patients are on lifelong antipsychotic medication because nonadherence and discontinuation are associated with high relapse rates. Often, adjunctive medications may also be necessary for specific symptoms or comorbid diagnoses. If other symptoms are present, such as depression and anxiety, these symptoms should be aggressively treated. Psychosocial treatments are also often used concomitantly.

## Antipsychotic Treatment

Historically, only first-generation antipsychotics (FGAs; typical antipsychotics) were available, but since 1990, the SGAs (ie, atypical antipsychotics) have been marketed in the United States. These agents include risperidone, olanzapine, quetiapine, ziprasidone, aripiprazole, paliperidone, iloperidone, asenapine, lurasidone, and clozapine. Clozapine, the prototype SGA, is reserved as second-line therapy because of its unusual side-effect profile (see below).

**KEY CONCEPT** *Compared with the FGAs, the SGAs are associated with a lower risk of motor side effects (tremor, stiffness, restlessness, and dyskinesia).*

With the introduction of SGAs, the use of FGAs has progressively decreased, and FGAs have less than 10% market share of the antipsychotics used for schizophrenia. This decline occurred

## Table 37–1

### Diagnostic Criteria for Schizophrenia

A. Two (or more) of the following, each present for a significant portion of time during a 1-month period (or less if successfully treated). At least one of these must be 1, 2, or 3:

1. Delusions

2. Hallucinations

3. Disorganized speech (eg, frequent derailment or incoherence)

4. Grossly disorganized or catatonic behavior

5. Negative symptoms (ie, diminished emotional expression or avolition)

B. For a significant portion of the time since the onset of the disturbance, level of functioning in one or more major areas, such as work, interpersonal relations, or self-care, is markedly below the level achieved before onset (or when onset is in childhood or adolescence, there is a failure to achieve expected level of interpersonal, academic, or occupational functioning).

C. Continuous signs of the disturbance persist for at least 6 months. This 6-month period must include at least 1 month of symptoms (or less if successfully treated) that meets Criterion A (ie, active-phase symptoms) and may include periods of prodromal or residual symptoms. During these prodromal or residual periods, the signs of disturbance may be manifested by only negative symptoms or by two or more symptoms listed in Criterion A present in an attenuated form (eg, odd beliefs, unusual perceptual experiences).

D. Schizoaffective disorder and depressive or bipolar disorder with psychotic features have been ruled out because either (1) no major depressive or manic episodes have occurred concurrently with the active-phase symptoms or (2) if mood episodes have occurred during active-phase symptoms, they have been present for a minority of the total duration of the active and residual periods of the illness

E. The disturbance is not attributable to the physiological effects of a substance (eg, drug of abuse or medication) or another medical condition

F. If there is a history of autism spectrum disorder or communication disorder of childhood onset, the additional diagnosis of schizophrenia is made only if prominent delusions or hallucinations, in addition to the other required symptoms of schizophrenia, are also present for at least 1 month (or less if successfully treated)

Reproduced with permission from the American Psychiatric Association. Diagnostic and Statistical Manual of Mental Disorders. 5th ed. Washington, DC: American Psychiatric Association; 2013.

## Patient Encounter, Part 2

**PPH:** The patient was seen for his first ever mental health appointment by a psychologist in his late teens, when he had family therapy with his father to address relationship issues. He has started to see that psychologist again, following his first psychiatric hospitalization. His toxicology screens have been negative for alcohol and drugs of abuse.

**PMH:** He was first psychiatrically hospitalized following an episode of hypothyroidism during his sophomore year in college, but his symptoms continued even when his thyroid disease was stabilized. He has no other medical illness, history of head trauma, or seizure disorder.

**SH:** His parents divorced in a contentious custody battle, when he was in grade school. Prior to his sophomore year in college, he had no academic or social problems. He used alcohol periodically in college but denies using since leaving college. He denies ever using marijuana or other substances of abuse. He has held several part time jobs from the ages of 18 to 23 years, the last of which was as a waiter. He has no health insurance.

**FH:** His grandfather had an alcohol problem, and his great uncle has a history of psychiatric hospitalization, though the specific circumstances are unknown. His mother and aunt reportedly have depression.

### Mental Status Examination

*Appearance:* Appears somewhat disheveled, dressed in dirty clothes, and hair looks like it has not been washed or brushed for several days. No abnormal movements. Poor eye contact.

*Speech:* Quiet and somewhat monotonous

*Mood:* Nervous. He denies feeling depressed, down, or blue.

*Affect:* Guarded and mildly anxious with restricted range. He denies feeling sad, guilty, hopeless, or helpless.

*Thought content:* He is an adequate historian but has a tendency to leave out detail. He hears the voices of famous Hollywood movie stars and pop music artists. Intermittently, he hears his dad's voice saying critical things. Sometimes, he feels that others know his thoughts. He denies suicidal or homicidal thoughts.

*Thought processes:* Vague and sometimes illogical.

*Cognition:* Grossly intact.

*Insight and judgment:* Impaired at this time. He is not sure he has a mental illness, as he continues to think his problems are related to his thyroid illness.

*Given this additional information, how has your differential diagnosis changed?*

*What medications would you consider to be first-line options, and why?*

*What are the goals of initial treatment?*

because of the touted better side-effect profile and other possible benefits of SGAs in nonpyshcotic domains of the illness. However, a large landmark study (the Clinical Antipsychotics Trials of Intervention Effectiveness; CATIE trial; $n$ greater than 1400) examined the effectiveness of SGAs relative to a midpotency FGA, perphenazine. The study revealed that the FGA was equal to the SGAs for the primary endpoint of time to discontinuation of medication.[14] SGAs have historically been much more expensive than the FGAs; however risperidone, olanzapine, quetiapine, ziprasidone, aripiprazole, and clozapine are now available in generic formulations. In conclusion, when selecting an antipsychotic, the risk-to-benefit profile becomes fundamental and the varying side-effect profiles must be considered.

## Second-Generation (Atypical) Antipsychotics

FGAs exert most of their effects through dopamine-receptor blockade at the dopamine$_2$ ($D_2$) receptor. SGAs have greater affinity for serotonin receptors than for dopamine receptors. Despite heterogeneous receptor binding, the efficacy among the SGAs is similar.[14] Additionally, recent data for SGAs and FGAs (lower doses) document similar overall efficacy with an effect size for acute treatment of 0.30 to 0.60 for most antipsychotics.[15] These findings have led to a modest resurgence of FGA use. Only clozapine, however, has demonstrated superior efficacy and that is in treatment-resistant patients. An important distinction of the SGAs is their lower propensity to cause extrapyramidal symptoms (EPSs) and tardive dyskinesia (TD). TD risk with SGAs is 1.5% annually in adults (less than 54 years of age) compared to approximately a 5% annual risk with FGA treatment.[16]

**KEY CONCEPT** *The SGAs are heterogeneous with regard to side-effect profiles. Many SGAs carry an increased risk for weight gain and for the development of glucose and lipid abnormalities; therefore, careful monitoring is essential.* Dosing and comparative side effects of SGA are shown in Tables 37–2 and 37–3.

### ▶ Risperidone

Risperidone, a benzisoxazole derivative, was the initial first-line oral SGA to become available generically. It has high binding affinity to both serotonin 2$_A$ (5-HT$_{2A}$) and $D_2$ receptors and binds to $\alpha_1$ and $\alpha_2$ receptors, with very little blockade of cholinergic receptors.[17] Risperidone is also approved for relapse prevention and is associated with significantly lower relapse rates than long-term haloperidol treatment.[18] At doses less than or equal to 6 mg/day, EPSs are low, although higher doses are associated with a greater incidence of EPS. Risperidone use causes serum prolactin elevations similar to or greater than FGAs. Elevated prolactin levels can, but do not always, lead to amenorrhea, galactorrhea, gynecomastia, and sexual dysfunction. Mild to moderate weight gain and mild elevations in serum lipids and glucose may occur. However, patients chronically treated with other antipsychotics may experience a decline in cholesterol and triglyceride levels when changed to risperidone monotherapy.[14]

### ▶ Olanzapine

Olanzapine has greater affinity for 5-HT$_{2A}$ than for $D_2$ receptors. It also has affinity at the binding sites of $D_4$, $D_3$, 5-HT$_3$, 5-HT$_6$, $\alpha_1$-adrenergic, muscarinic$_{1-5}$ (M$_{1-5}$), and histamine$_1$ (H$_1$) receptors.[19] In the CATIE trial, olanzapine was associated with the longest time to treatment discontinuation,[14] suggesting it may differ from the other SGAs in effectiveness. Olanzapine has a low rate of EPS and causes slight, transient prolactin elevations. Olanzapine causes significant weight gain across the dosage

range, similar to that seen with clozapine and greater than that observed with the other SGAs. Olanzapine is also associated with hypertriglyceridemia, increased fasting glucose, and new-onset type 2 diabetes (ie, metabolic syndrome). Among the first-line SGAs, it is associated with the greatest elevations in these metabolic parameters.[14]

### ▶ Quetiapine

Quetiapine, structurally related to clozapine and olanzapine, has high affinity for 5-HT$_{2A}$ receptors and lower affinity for $D_2$ and $D_1$ receptors. It has some affinity for $\alpha_1$, $\alpha_2$, and H$_1$ receptors but very little for muscarinic receptors. Quetiapine may be beneficial for anxiety and depression. Motor side effects and prolactin elevations are uncommon. Orthostasis occurred in 4% of subjects in clinical trials. Sedation is generally transient. Mild weight gain and minor elevations in triglycerides can occur. Use of quetiapine with agents that can prolong the QTc interval or in patients with prolonged QTc should be avoided.

### ▶ Ziprasidone

Ziprasidone was developed to block $D_2$ receptors but also to bind with greater affinity to central 5-HT$_{2A}$ receptors. It has a binding affinity ratio of 11:1 for 5-HT$_{2A}$:$D_2$ receptors. It has a relatively high affinity for 5-HT$_{2C}$, 5-HT$_{1D}$, $\alpha_1$-adrenergic, and $D_1$ receptors.[20] It should be taken with food. Liability for EPS, weight gain, and lipid elevations is low but does occur. Ziprasidone causes some prolongation of the QTc interval in adults. However, overdose data and pharmacokinetic interaction data show little evidence that significant QTc prolongation occurs. Use of ziprasidone with agents that can prolong the QTc interval or in patients with existing diseases associated with prolonged QTc should be avoided.

### ▶ Aripiprazole

Aripiprazole is a dopamine modulator, with both antagonist and agonist activity at the $D_2$ receptor. It is the only $D_2$ partial agonist available for the treatment of schizophrenia. The goal was to have an agent that functions as an antagonist in hyperdopaminergic states and as an agonist in hypodopaminergic states. Aripiprazole is also a partial agonist at 5-HT$_{1A}$ receptors, an antagonist at 5-HT$_{2A}$ receptors, and has affinity for $D_3$ receptors. Additionally, it has moderate affinity for $\alpha_1$ and H$_1$ receptors with no appreciable affinity for the M$_1$ receptor.[21] In CYP2D6-poor metabolizers start dosing with one-half the usual dose with adjustment to clinical efficacy. Give one-quarter the usual dose if given concomitantly with a CYP3A4 inhibitor. Sedation, nausea, and vomiting are the most often seen side effects. Elevations in weight, lipids, and glucose are generally negligible, and it does not usually cause elevations in serum prolactin. In fact, patients switched to aripiprazole from other antipsychotic agents may experience decreases in prolactin.

### ▶ Paliperidone

Paliperidone is the 9-hydroxy (9-OH) metabolite of risperidone. The efficacy of risperidone and paliperidone are similar. Receptor binding affinity is also similar between the two agents, with paliperidone having a greater affinity at 5-HT$_{2A}$ compared with $D_2$ receptors. Unlike many other antipsychotic medications, paliperidone is mostly excreted unchanged, a potential advantage in patients with liver impairment. Patients should be told to expect to see the shell of the tablet in the stool because it may not dissolve in the digestive tract.[22] Side effects of paliperidone are expected to be similar to those of risperidone, including the potential for dose-related EPS and prolactin elevation.[22]

**Table 37–2**

**Second-Generation (Atypical) Antipsychotics**

| Second-Generation Antipsychotic | Usual Starting and Target Dose (mg/day) (Schizophrenia) | Maximum Dose Likely to Be Beneficial (mg/day) | Available Dosage Forms |
|---|---|---|---|
| Aripiprazole (Abilify) | Initial: 10–15<br>Target: 15–30 | 30 | • 2-, 5-, 10-, 15-, 20-, and 30-mg tablets<br>• 1-mg/mL oral solution<br>• 10- and 15-mg Abilify Discmelt orally disintegrating tablets<br>• IM 9.75 mg/1.3 mL<br>• Abilify Maintena extended-release 300- and 400-mg vial powder for suspension long acting injection |
| Asenapine (Saphris) | Initial: 5 twice daily<br>Target: 10–20 total daily dose | 10–20 | • 5- and 10-mg sublingual tablets |
| Clozapine (Clozaril, Fazaclo, Versacloz, also available generically) | Initial: 12.5–25/day<br>Target: 300–450 | 500–800 | • 25-, 50-, 100-, and 200-mg tablets<br>• FazaClo (orally disintegrating tablets) 12.5-, 25-, 100-, 150-, 200-mg<br>• Versacloz (oral suspension) 50 mg/mL |
| Iloperidone (Fanapt) | Initial: 1 twice daily<br>Target: 12–24 total daily dose | 24 | • 1-, 2-, 4-, 6-, 8-, 10-, 12-mg tablets |
| Lurasidone (Latuda) | Initial: 40<br>Target: 40–160 | 160 | • 20-, 40-, 60-, 80-, 120 mg tablets |
| Olanzapine (Zyprexa, also available generically) | Initial: 2.5-10<br>Target: up to –20 | 30–40[a] | • 2.5-, 5-, 7.5-, 10-, 15-, and 20-mg tablets<br>• Zyprexa Zydis (orally disintegrating tablets) 5, 10, 15, and 20 mg<br>• IM 10 mg vial (after reconstitution, ~5 mg/mL)<br>• Zyprexa Relprevv 210-, 300-, and 405-mg/vial powder for suspension long-acting injection |
| Paliperidone (Invega) | Initial: 6<br>Target: 6–12 | 6–12 | • 1.5-, 3-, 6-, and 9-mg tablets<br>• Invega Sustenna 39-, 78-, 117-, 156-, 234-mg prefilled syringes |
| Quetiapine (Seroquel, also available generically) | **Regular release**<br>Initial: 25 twice daily<br>Target: 300–750<br>**Extended release**<br>Initial: 300<br>Target 400–800 | 800 | • 25-, 50-, 100-, 200-, 300-, and 400-mg tablets<br>• Seroquel XR (extended-release tablets) 50-, 150-, 200-, 300-, and 400-mg tablets |
| Risperidone (Risperdal, also available generically) | Initial: 1–2<br>Target: 4–6 | 6–8 | • 0.25-, 0.5-, 1-, 2-, 3-, and 4-mg tablets<br>• 1 mg/mL (30 mL) solution<br>• Risperdal M-tab (orally disintegrating tablets) 0.5-, 1-, 2-, 3-, and 4-mg tablets<br>• Risperdal Consta long-acting injectable 12.5-, 25-, 37.5-, and 50-mg vial/kit |
| Ziprasidone (Geodon, also available generically) | Initial: 20 twice daily<br>Target: 120–160 total daily dose | 160–240[a] | • 20-, 40-, 60-, and 80-mg capsules<br>• IM 20 mg/mL |

Cloz, clozapine; Risp, risperidone; Olan, olanzapine; Quet, quetiapine; Zip, ziprasidone; Ari, aripiprazole; Ilo, iloperidone; Asen, asenapine; Lur, lurasidone; Hal, haloperidol.

[a]Side effects similar for paliperidone.

0, absent; ±, minimal; +, mild or low risk; ++, moderate; +++, severe; EPS, extrapyramidal side effects; SGA, second-generation antipsychotic.

#### ▶ Iloperidone

Iloperidone is indicated for acute treatment of adults with schizophrenia. It exhibits high affinity for $5HT_{2a}$, dopamine $D_2$, and $D_3$ receptors and acts as an antagonist at these, as well as at the $5HT_{1a}$ and norepinephrine $\alpha_1/\alpha_{2c}$ receptors. Doses must be titrated because of the risk of orthostatic hypotension, and dosing should be reduced by half in CYP2D6 poor metabolizers. Common adverse reactions include dizziness, dry mouth, fatigue, orthostatic hypotension, tachycardia, and weight gain. Dizziness, tachycardia, and weight gain were twice as common with higher dose (20–24 mg total daily dose) versus lower doses (10–16 mg total daily dose).[23] Use of iloperidone with agents that can prolong the QTc interval or in patients with diseases that are associated with prolonged QTc should be avoided.

#### ▶ Asenapine

Asenapine is approved for the acute treatment of schizophrenia in adults. Its mechanism of action is thought to be its antagonistic activity at $5HT_{2a}$ and $D_2$ receptors. It also exhibits a high affinity for other serotonergic and dopaminergic receptors, as well as $\alpha_1$- and $\alpha_2$-adrenergic receptors and $H_1$-receptors. Asenapine tablets must be placed under the tongue and allowed to dissolve completely; tablets should not be chewed or swallowed. Patients should not drink or eat for 10 minutes after administration. No added benefit was seen with doses above 10 mg twice daily, but adverse effects increase. Common adverse effects include somnolence, dizziness, and akathisia. It has shown little effect on metabolic parameters and weight change. Labeling for asenapine was modified to address rare occurrence of hypersensitivity reactions, including anaphylaxis and angioedema.[24]

#### ▶ Lurasidone

Lurasidone antagonizes $D_2$ and $5HT_{2A}$ receptors. It also has moderate affinity as an antagonist at $\alpha_{2C}$, is a partial agonist at $5HT_{1A}$, and is an antagonist at $\alpha_{2A}$-receptors. Lurasidone should be taken with food. Adverse reactions reported in at least 5% of patients (and at least twice the placebo rate) include somnolence, akathisia, nausea, parkinsonism, and agitation. Lurasidone has shown only a small effect on body weight and causes minimal changes in other metabolic parameters.[24]

### First-Generation (Typical) Antipsychotics

The FGAs are high-affinity $D_2$-receptor antagonists. During chronic treatment, they block 65% to 80% of $D_2$ receptors in the striatum and other dopamine tracts in the brain.[25] Clinical response is generally associated with 60% $D_2$-receptor blockade, while 70% and 80% are associated with hyperprolactinemia and EPS, respectively. During the 1990s, SGAs began to replace FGAs as first-line therapy.

### Patient Encounter, Part 3

The patient is taking risperidone, following an unsuccessful trial of aripiprazole titrated up to 20 mg. He has been titrated up to 6 mg/day of risperidone, and his sleep pattern has normalized. He is also less preoccupied by his auditory hallucinations and the feeling that he has a relationship with famous movie stars. He is pleased that he has been able to stay out of the hospital for the last month but is anxious that he will need to be hospitalized again. Sure enough, when he comes in for his next appointment, he is anxious, as his father's voice is saying critical things to him. He is vague regarding his medication compliance. He is upset that he has gained weight on the medication. His mother, who is with him at the appointment, cannot vouch for his taking his medications and does not want to begin monitoring them, as she is worried they will get into power struggles over it. The possibility of hospitalization is discussed, but neither want hospitalization, and because he is not assessed to be a danger to self or others, his care provider does not force the issue and suggests, instead, the use of a long-acting intramuscular form of antipsychotic medication. Using an IM, they can all be sure that he is getting his medication regularly.

*How would a clinician discuss the advantages of taking a long-acting intramuscular mediation?*

*What drug choices would the patient have for a long-acting antipsychotic, and how would you help him make the choice?*

**Table 37–4**

**First-Generation (Typical) Antipsychotics**[a]

| Class | Agent (Brand Name) | Dosage Range (mg/day) | Chlorpromazine Equivalents (mg) | Available Formulations |
|---|---|---|---|---|
| Butyrophenone | Haloperidol (Haldol) | 5–30 | 2 | T, LC, I |
| Dibenzoxazepine | Loxapine (Loxitane, Adasuve) | 25–100 | 10 | C, IP |
| Diphenylbutylpiperidine | Pimozide (Orap) | 1–10 | 1–2 | T |
| Phenothiazines | Chlorpromazine (Thorazine) | 300–800 | 100 | T, LC, I, R |
| | Fluphenazine (Prolixin) | 2–40 | 2 | T, L, I |
| | Perphenazine (Trilafon) | 8–64 | 10 | T, LC |
| | Thioridazine (Mellaril) | 300–800 | 100 | T, LC |
| | Trifluoperazine (Stelazine) | 15–30 | 5 | T |
| Thioxanthenes | Thiothixene (Navane) | 5–40 | 4 | C |

[a]Low-potency antipsychotics include thioridazine, mesoridazine, and chlorpromazine. High-potency antipsychotics include haloperidol, fluphenazine, thiothixene, and pimozide.

C, capsule; C-SR, controlled or sustained release; I, injection; L, liquid solution, elixir, or suspension; LC, liquid concentrate; R, rectal suppository; T, tablet; IP, inhalation powder.

Doses for FGAs are frequently given as **chlorpromazine equivalents,** which are defined as the FGA equipotent dose with 100 mg of chlorpromazine. The target dose recommendation for acute psychosis is 400 to 600 chlorpromazine equivalents unless the patient's history indicates that dose may not be tolerated. Generally, maintenance therapy is 300 to 600 chlorpromazine equivalents daily. Dosing and available dosage forms are shown in **Table 37–4**. All FGAs are equally efficacious when studied in equipotent doses in groups of patients. However, an individual patient may not respond equally to each antipsychotic. Selection of a particular antipsychotic is based on patient variables, such as the need to avoid certain side effects or drug–drug interactions or previous patient or family history of response.

▶ *Decanoates*

Long-acting, depot preparations are available for two FGAs (fluphenazine decanoate and haloperidol decanoate) in the United States. These compounds are esterified antipsychotics in sesame seed oil for deep intramuscular (IM) injection. Patients should be exposed to the oral form of the drug first to ensure tolerability. With initial dosing of haloperidol decanoate, concomitant oral supplementation may be temporarily necessary while the drug accumulates, as steady state is achieved after four to five dosing intervals. Fluphenazine decanoate is dosed at 1- to 3-week intervals, but haloperidol decanoate is usually dosed once a month. Conversion from oral to depot dosing and maintenance dosing recommendations are shown in **Table 37–5**. Generally, 12.5 mg (0.5 mL) of fluphenazine decanoate given every 2 weeks is approximately equivalent to 10 mg/day of fluphenazine orally. A maintenance haloperidol decanoate dose of 150 mg every 4 weeks is approximately equivalent to 10 mg/day of oral haloperidol. Initial decanoate injections should be preceded by a small test dose.

## Side Effects of the First-Generation Antipsychotics

In general, the low-potency FGA agents are less likely to cause EPS than the high-potency agents. (See Table 37–4) Of note, high potency and midpotency agents may cause less EPS than once believed and were similar to SGAs in the CATIE trial.[14]

The FGAs are commonly associated with EPS (including akathisia [motor or subjective restlessness], dystonia [muscle spasm], and pseudoparkinsonism [akinesia, tremor, and rigidity]) caused by dopamine antagonism in the nigrostriatal pathways. Akathisia, the most common motor side effect of FGAs occurs in 20% to 40% of people. Roughly half of the cases of akathisia present within 1 month of antipsychotic initiation, though it may present within 5 to 10 days after the first dose or after an increase in dosage. Younger people and those taking high doses of high-potency antipsychotics are at greater risk for development of akathisia.

Acute dystonic reactions are abrupt in onset and are usually seen within 24 to 96 hours after a first dose or increase in dosage. Characteristic signs and symptoms include abnormal positioning or spasm of the muscles of the head, neck, limbs, or trunk. Dystonia may occur in 10% to 20% of patients. There is higher risk for dystonia in young male patients and those taking high-potency FGAs.

Pseudoparkinsonism may be present in 30% to 60% of people treated with FGAs. The onset of symptoms is usually within 1 to 2 weeks after dose initiation or dose increase. Risk factors include older age, female gender, high doses, and possibly those with depressive symptoms.[26]

TD is a movement disorder characterized by abnormal choreiform (rapid, objectively purposeless, irregular, and spontaneous) and athetoid (slow and irregular) movements beginning late in relation to initiation of antipsychotic therapy. It usually develops over several months or after at least 3 months of cumulative exposure to antipsychotics. Severity can range from mild and barely noticeable to severe, causing interference with ambulation. Visible TD symptoms may stigmatize persons taking antipsychotics. The estimated average prevalence of TD is 20% in patients given FGAs with a range of 13% to 36%. The incidence of new cases per treatment year with FGAs is approximately 5%.[27] TD is reversible in one-third to half of cases with the cessation of the antipsychotic.[28] When antipsychotics are tapered or discontinued, there is typically an transient worsening of abnormal movements. Risk factors for TD include older age; longer duration of antipsychotic treatment; and presence of EPS, substance abuse, and mood

### Table 37–5

**Antipsychotic Dosing of Long-Acting Preparations**

| Drug | Starting Dose | Maintenance Dose | Comments |
|---|---|---|---|
| Aripiprazole long-acting injection (Abilify Maintena) | 400 mg monthly and 14 consecutive days of concurrent oral aripiprazole (10–20 mg) or current oral antipsychotic after first injection | 400 mg monthly | Establish tolerability with oral agent first<br>Dosage adjustments for CYP2D6 poor metabolizers, and in persons who take strong CYP2D6 or 3A4 inhibitors; recommend to avoid use if strong 3A4 inducer |
| Haloperidol decanoate | 20 × oral haloperidol daily dose; in the elderly use 10–15 × oral haloperidol daily dose;<br>Generally 100–450 mg/mo<br>Initial dose should not exceed 100 mg regardless of previous dose requirements (if > 100 mg, give 3–7 days apart) | 10–15 × oral haloperidol daily dose, generally 50–300 mg/mo | With initial dosing, oral supplementation may temporarily be necessary; deep IM injection generally with 21-gauge needle; maximum volume per injection site should not exceed 3 mL<br>Available in 50 and 100 mg/mL (5-mL vials and 1-mL ampules) |
| Fluphenazine decanoate | 1.2 × oral fluphenazine daily dose; generally 12.5–mg/2–3 weeks | Based on starting dose and clinical response<br>Generally 12.5–25 mg dosed at 2–4-week intervals (may be up to 6 weeks in some cases) | Can be administered IM or SC; 21-gauge needle, must be dry<br>Should not exceed 100 mg; when dosing above 50 mg, should increase in increments of 12.5 mg<br>Available in 25 mg/mL (5-mL vials) |
| Olanzapine (Zyprexa Relprevv) | **To target oral 10 mg/day dose:** Either 210 mg/2 week or 405 mg/4 week during first 8 weeks<br>**To target oral 15 mg/day dose:** 300 mg/2 week for first 8 weeks<br>**To target 20 mg/day oral dose:** 300 mg/2 week | **To target oral 10 mg/day dose:** after 8 weeks, give 150 mg/2 week or 300 mg/4 week<br>**To target oral 15 mg/day dose:** after 8 weeks, 210 mg/2 week or 405 mg/4 week<br>**To target 20 mg/day oral dose:** continue with 300 mg/2 week | Gluteal injection, 19-gauge needle<br>Do not confuse with rapid-acting IM injection<br>Must reconstitute with included diluent<br>Measure amount to inject from vial (there will be remaining suspension in vial)<br>Zyprexa Relprevv Patient Care Program: 3-hour observation period; patient must be accompanied to destination<br>No refrigeration needed, use within 24 hours, or immediately once suspension is in syringe |
| Paliperidone (Invega Sustenna) | Initiate with 234 mg on day 1 and 156 mg 1 week later, both in deltoid muscle | Recommended monthly maintenance dose is 117 mg (range, 39–234 mg) | First two doses must be given in the deltoid muscle; after that, monthly doses given in either the deltoid or gluteal muscle; available as 39-, 78-, 117-, 156-, and 234-mg prefilled syringes |
| Risperidone long-acting injection (Risperdal Consta) | 25 mg every 2 weeks | 25–50 mg every 2 weeks | Previous antipsychotics should be continued for 3 weeks after initial dose of risperidone long-acting injection<br>Recommended to establish tolerability with oral risperidone prior to initiation of long-acting injection<br>Available in 12.5-, 25-, 37.5-, and 50-mg vial/kit; must use needle supplied with kit, administer IM |

IM, intramuscular; SC, subcutaneous.

disorders. SGAs have a lower risk of TD than FGAs. New-onset TD incidence is approximately 0.8% per year with SGA treatment versus 5.4% per year for FGAs.[16] A subsequent review of studies reports a smaller difference in incidence of TD between agents (3.9% for SGAs and 5.5% for FGAs).[29]

Neuroleptic malignant syndrome (NMS), a life-threatening emergency characterized by severe muscular rigidity, autonomic instability, and altered consciousness, can occur uncommonly with all FGAs and may also occur with SGAs. Rapid dose escalation, use of high-potency FGAs at higher doses, and younger patients have a higher risk of NMS. When NMS is diagnosed or suspected, antipsychotics should be discontinued and supportive, symptomatic treatment begun (eg, antipyretics, cooling blanket, intravenous fluids, oxygen, monitoring of liver enzymes, and complete blood cell count). Dopamine agonists (eg, bromocriptine) should be considered in moderate to severe cases.

| Table 37–6 | | | | | |
| --- | --- | --- | --- | --- | --- |
| **Side Effects of First-Generation Antipsychotics** | | | | | |
| | EPS | Sedation | Anticholinergic Side Effects | Cardiovascular Side Effects | Seizure Effects/QTc Prolongation |

| Thioridazine | ++ | ++++ | ++++ | ++++ | +++ |
| Loxapine | +++ | +++ | ++ | +++ | + |
| Trifluoperazine | +++ | ++ | ++ | ++ | + |
| Perphenazine | +++ | ++ | ++ | ++ | + |
| Thiothixene | +++ | ++ | ++ | ++ | + |
| Fluphenazine | ++++ | ++ | ++ | ++ | + |
| Haloperidol | ++++ | + | + | + | + |

+, very low; ++, low; +++, moderate; ++++, high; EPS, extrapyramidal side effects.

Dermatologic side effects, photosensitivity, and cataracts may occur with the phenothiazine FGAs. Sedation is mediated by $H_1$-receptor antagonism; anticholinergic side effects (constipation, blurred vision, dry mouth, and urinary retention) are caused from $M_1$-receptor antagonism; and $\alpha_1$-receptor blockade is associated with orthostatic hypotension and tachycardia (Table 37–6). QTc prolongation may occur with the lower potency FGAs, and thioridazine has a black-box warning for QTc prolongation.

## Treatment Guidelines and Algorithms

A widely accepted treatment algorithm in the United States is the Texas Implementation of Medication Algorithms (TIMA), developed by a national panel of experts and updated in 2008.[30] Algorithms go beyond guidelines, providing a framework for clinical decision making. According to the TIMA schizophrenia algorithm, the SGAs (except clozapine) should be used as first-line treatment. Choice of SGA is guided by side-effect profiles and patient clinical characteristics. Treatment with a given drug should be continued for 4 to 6 weeks to assess response. If only partial response or nonresponse is noted, a trial of a second SGA should be initiated (Figure 37–1). Other similar guidelines include the APA Practice Guidelines for Schizophrenia,[8] the Expert Consensus Guideline Series,[9] and the 2009 Schizophrenia Patient Outcomes Research Team (PORT) Treatment Recommendations.[31] In contrast to the TIMA guidelines, the PORT recommends use of either FGAs or SGAs as first-line therapy.

## Treatment Adherence

Estimates of nonadherence to antipsychotics range from approximately 24% to 88% with a mean of approximately 50%. Subjects who are nonadherent have about a fourfold greater risk of a relapse than those who are adherent[32]. Neurocognitive deficits and paranoid symptoms may hamper adherence, and identification of nonadherence by caretakers and providers can be challenging. Antipsychotic side effects such as EPS, weight gain, and sexual dysfunction are also major contributing factors to treatment nonadherence. Other factors include delusions, substance abuse, and negative symptoms.[33] For patients who have relapsed several times because of nonadherence, have a history of dangerous behavior, or risk a significant loss of social or vocational gains when relapsed, treatment with long-acting formulations should be encouraged. Risperidone, paliperidone, olanzapine, and aripiprazole are available as long-acting injectable formulations. In general, oral tolerability of these agents should be ensured prior to initiating long-acting injection. Dosing and other information about these formulations is shown in Table 37–5.

## Special Populations

### ▶ Dosing in Renal and Hepatic Impairment

Table 37–7 shows dosing guidance on specific antipsychotic medications.

### ▶ Children and Adolescents

Around 10% to 30% of patients with schizophrenia have psychotic symptoms before their 18th birthday. The diagnosis of schizophrenia in children and adolescents is often challenging, and the differential diagnosis includes autistic spectrum disorders, attention-deficit/hyperactivity disorder, and language or communication disorders. The existence of prominent hallucinations or delusions helps make the diagnosis because they are not prominent in other disorders. Fifty-four percent to 90% of patients developing schizophrenia before age 18 years have premorbid abnormalities such as withdrawal, odd traits, and isolation.[34]

Treatment for psychotic children and adolescents ideally is intensive, comprehensive, and structured. Day treatment, hospitalization, or long-term residential treatment may be necessary. Pharmacologic treatment is indicated if psychotic symptoms cause significant impairments or interfere with other interventions. Children and adolescents are more vulnerable to EPS, particularly dystonias, than are adults. Because of concerns about EPS and TD in children and adolescents, it is recommended that antipsychotic therapy be initiated with SGAs. Aripiprazole, risperidone, quetiapine, olanzapine, and paliperidone are approved by the Food and Drug Administration (FDA) for the treatment of schizophrenia in pediatric and adolescent populations. Initiation and target dosing is lower for adolescents than adults.

Agents with significant sedative and anticholinergic side effects are not preferred because they can interfere with thinking, thus impairing school performance. Compared with adults, children and adolescents tend to gain more weight when taking these agents. Young patients should be started on lower doses than adults and should be titrated at a slower rate. Side effects should be monitored closely initially and throughout therapy.

### ▶ Elderly

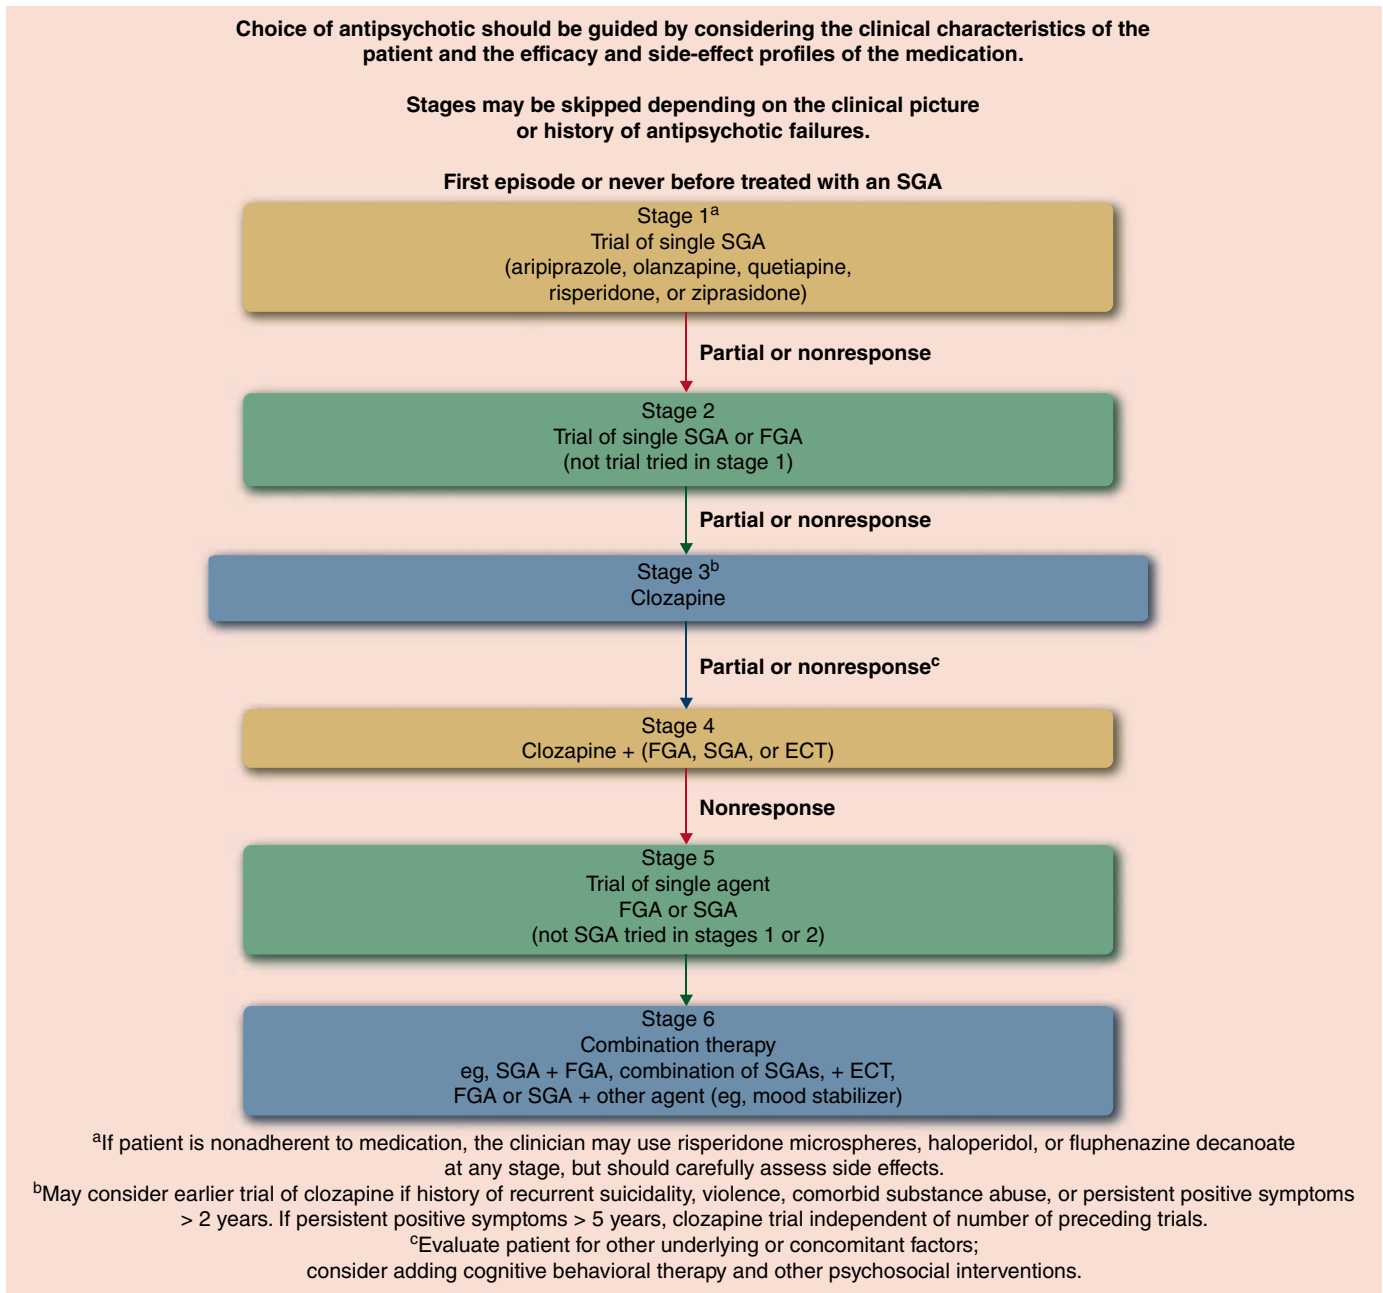
Psychotic symptoms in late life (after 65 years of age) generally result from an ongoing chronic illness; however, a small


**FIGURE 37–1.** Texas Implementation of Medication Algorithms (TIMA) algorithm for antipsychotic treatment in schizophrenia. Choice of antipsychotic should be guided by considering the clinical characteristics of the patient and the efficacy and side effect profiles of the medication. Any stage may be skipped depending on the clinical picture or history of antipsychotic failures. (ECT, electroconvulsive therapy; FGA, first-generation antipsychotic; SGA, second-generation antipsychotic.) (Adapted from the Texas Department of State Health Services, with permission.)

percentage of patients develop psychotic symptoms de novo, defined as late-life schizophrenia. However, other illnesses with psychotic symptoms are common in this population; approximately one-third of patients with Alzheimer disease, Parkinson disease, and vascular dementia experience psychotic symptoms.

Antipsychotics can be safe and effective for the treatment of schizophrenia in the elderly, if used at lower doses than those commonly used in younger adults. Older adults are particularly vulnerable to the side effects of the FGAs. Pseudoparkinsonism reportedly occurs in more than 50% of elderly patients receiving these agents, and the cumulative annual incidence of TD in

middle-aged and elderly patients is greater than 25%. Limited data suggest the risk of TD to be approximately 4% with the SGA and the likelihood of reversing this condition diminishes with age.[35]

Orthostasis, estimated to occur in 5% to 30% of geriatric patients, is a major contributing factor to falls that often lead to injuries and loss of independence. Low-potency antipsychotics and clozapine are more likely to cause significant orthostasis. Antipsychotics may cause or worsen anticholinergic effects, including constipation, dry mouth, urinary retention, and cognitive impairment. Greater antipsychotic-associated impairment

**Table 37–7**

**Second-Generation Antipsychotic Dosing Recommendations for Special Populations**

| Medication | Pediatric | Geriatric | Renal Impairment | Hepatic |
|---|---|---|---|---|
| Aripiprazole | Ages 13–17 years (schizophrenia): Initiate 2 mg every day, increasing to 5 mg daily after 2 days and target of 10 mg after several days, 30 mg/day maximum | No oral adjustment necessary | No adjustment necessary | No adjustment necessary |
| Asenapine | No pediatric FDA indication | No adjustment necessary | No adjustments necessary | No adjustment necessary for mild to moderate impairment, but use not recommended in severe impairment |
| Clozapine | No pediatric FDA indication | Experience is limited; low dose and slow titration | Adjustments may be necessary with significant impairment; no specific recommendations available | Adjustments may be necessary with significant impairment; no specific recommendations available |
| Iloperidone | No pediatric FDA indication | No adjustment necessary | No adjustment information provided, but unlikely necessary | No adjustment needed for mild impairment; exercise caution with moderate impairment; not recommended for severe impairment |
| Lurasidone | No pediatric FDA indication | No adjustment required | With moderate to severe renal impairment, recommended starting dose 20 mg daily; do not exceed 80 mg daily | With moderate impairment, initial dose 20 mg daily; max dose 80 mg daily With severe impairment, initial dose 20 mg daily, max dose 40 mg daily |
| Olanzapine | **Oral:** Ages 13–17 years (schizophrenia): Initial dose, 2.5–5 mg orally every day with target dose of 10 mg/day; maximum dose, 20 mg/day **Long-acting injection:** Not approved in children | **Oral:** 5 mg/day, if escalation needed use caution **Long-acting injection:** Consider starting dose of 150 mg every 4 weeks for elderly or debilitated patients | **Oral:** In renal impairment, no adjustment usually necessary; however, consider a lower initial dose of 5 mg/day **Long-acting injection:** No information given | **Oral:** No dosage adjustment noted in prescribing information except in combination with fluoxetine **Long-acting injection:** No information given |
| Paliperidone | **Oral:** Ages 12–17 years (schizophrenia) Dose by body weight: < 51 kg, initiate 3 mg/day oral, increase at increments of > 5 days; maximum, 6 mg/day At least 51 kg, initiate at 3 mg/day, increase at increments of > 5 days, maximum of 12 mg/day | **Oral:** For patients with normal renal function, no adjustment is required, but if renal impairment guidance is available | **Long-acting injection:** CrCl 50–79 mL/min (0.83–1.32 mL/s); initiate with 156 mg IM day 1, 117 mg IM 1 week later, with maintenance at 78 mg IM monthly CrCl < 50 mL/min (0.83 mL/s): Use not recommended **Oral:** CrCl 50–79 mL/min (0.83–1.32 mL/s): 3 mg once daily initiation, maximum 6 mg/day CrCl between 10 and 49 mL/min (0.17–0.82 mL/s): 1.5 mg once daily initiation; maximum, 3 mg/day CrCl < 10 mL/min (0.17 mL/s): Use is not recommended | **Long-acting injection:** No dosage adjustment needed for mild or moderate impairment; no guidance given for severe impairment **Oral:** No dose adjustment is required for mild or moderate impairment |
| Quetiapine | **Regular-release tablets:** Indicated for schizophrenia (ages 13–17 years): Initiate 25 mg twice daily; recommended target dose 400–800 mg/day; maximum, 800 mg/day **Extended-release tablets:** Initiate 50 mg/day; recommended target dose 400-800 mg | **Regular-release tablets:** Slower dose escalation and a lower target dose **Extended-release tablets:** Initiate at 50 mg/day and increase at 50-mg/ day increments based on response or tolerance | No dosing recommendations for renal dysfunction | **Regular-release tablets:** Lower starting dose (25 mg) and slower titration may be needed **Extended-release tablets:** Should be initiated with 50 mg/day, increasing in 50-mg/day increments |

*(Continued)*

**Table 37–7**

**Second-Generation Antipsychotic Dosing Recommendations for Special Populations (*Continued*)**

| Medication | Pediatric | Geriatric | Renal Impairment | Hepatic |
|---|---|---|---|---|
| Risperidone | **Oral:** Pediatric ages 13 years and older (schizophrenia): Initiate at 0.5 mg orally daily, adjusting at intervals of at least 24 hours and in increments of 0.5–1 mg/day as tolerated Recommended target dose, 3 mg/day | **Long-acting IM:** Initial dose, 25 mg IM every 2 weeks with a 3-week oral crossover; may consider 12.5 mg starting dose **Oral:** Initiate at 0.5 mg twice daily; may increase by 0.5 mg twice daily, increases above 1.5 mg twice daily done at intervals of at least 1 week | **Long-acting IM:** Patients with renal impairment should receive titrated doses of oral risperidone before initiation of IM (more detail in prescribing information) **Oral:** Recommended initial dose in CrCl < 30 ml/min (0.50 mL/s), 0.5 mg twice daily; dose may be increased by 0.5 mg twice daily, but increases above 1.5 mg twice daily should be done at intervals of at least 1 week. Clearance of risperidone is decreased by 60% in patients with moderate-to-severe renal disease (CrCl < 60 ml/min [1.0 mL/s]) | **Long-acting IM:** Titrate with oral risperidone (see renal dosing) **Oral:** Recommended initiation in Child-Pugh Class C (see renal dosing) |
| Ziprasidone | No pediatric indication | No official adjustment recommended; consider starting at lower end of the dosage range | **Oral doses:** No adjustment necessary for mild to moderate renal impairment **IM doses:** Use with caution because of cyclodextrin sodium excipient | No adjustment necessary for mild to moderate hepatic impairment; however, caution is warranted |

CrCl, creatinine clearance; FDA, Food and Drug Administration; IM, intramuscular.

in cognitive functioning may occur in the elderly compared to younger adults. In the elderly, this can lead to decreased independence, a very problematic issue. As a result of data showing a statistically significant increase in mortality in elderly dementia patients taking SGAs, a black-box warning was added to the manufacturer's information for all antipsychotics. Patients and families should be informed of this risk before using these agents in patients with dementia. Dosing in the elderly is initiated lower, and titration is slower than in younger adults. Maximum doses are often half of adult doses (see Table 37–7).

▶ *Dually Diagnosed Patients*

Estimates of the proportion of schizophrenia patients abusing alcohol and/or illicit drugs range from 40% to 60%.[36] Generally, the most common drugs of abuse are cannabis, cocaine, and alcohol. Substance use often worsens the clinical course and complicates treatment. Dually diagnosed patients are more likely to be nonadherent with treatment. They have a poorer response rate to the FGAs, more severe psychosis, and higher rates of relapse and rehospitalization than patients who are not abusing substances. EPS may occur more frequently in substance-abusing patients, and alcohol use is a risk factor for developing TD. SGAs are effective in this population, and they may cause a reduction in the use of drugs and alcohol.[37]

▶ *Treatment-Resistant Patients*

For 20% to 30% of people with schizophrenia, drug treatment is ineffective. A standard definition of treatment resistance is persistent positive symptoms despite treatment with at least two different antipsychotics given at adequate doses (a dose equivalent to at least 600 mg of chlorpromazine) for an adequate duration (4–6 weeks). In addition, patients must have a moderately severe illness as defined by rating instruments, and

have a persistence of illness for at least 5 years.[38] These patients are often highly symptomatic and require extensive periods of hospitalization.

**Clozapine** Clozapine remains the only drug with proven superior efficacy in treatment-resistant patients, and it is the only drug approved for treatment-resistant schizophrenia,[15] with response rates of 30% to 50% in treatment-resistant patients. It is efficacious after nonresponse to other SGAs, in partially responsive patients and patients who have had a poor response to other medication for years. According to published guidelines and recommendations, clozapine should be considered after two failed antipsychotic trials but may be considered sooner if the individual patient situation warrants.[32] Additionally, it has a beneficial effect for aggression and suicidality and is FDA approved for treatment of suicidal behavior in people with psychosis.[39]

It is unknown which pharmacologic properties account for clozapine's superior efficacy. Clozapine has a low affinity for $D_2$ receptors, blocks $D_1$ receptors, and is a $5\text{-HT}_{2A}$ antagonist.

Clozapine's use is limited by the regulatory requirements resulting from the risk for agranulocytosis (0.86%–1% of patients), which is a rare but potentially life-threatening side effect. The required long-term hematologic monitoring (Table 37–8) can be a barrier for both patients and care providers. Other rare side effects include seizures and myocarditis. Other common unpleasant side effects include sedation, dizziness, constipation, enuresis, weight gain, and hypersalivation.

The optimal plasma level of clozapine is a minimum trough level of 300 to 350 ng/mL (300–350 mcg/L; 0.92–1.07 μmol/L; or 918–1071 nmol/L), usually corresponding to a daily dose of 200 to 400 mg, although dosage must be individualized. Males and smokers tend to require higher does to achieve the targeted blood level due to more rapid metabolism.

**Table 37–8**

**Monitoring of White Blood Cell Count and Absolute Neutrophil Count During Clozapine Treatment**

| | Hematologic Values | Frequency of WBC and ANC Monitoring |
|---|---|---|
| Before clozapine initiation | Recommended levels: WBC $\geq 3.5 \times 10^3$/mm³ ($3.5 \times 10^9$/L) and ANC $\geq 2 \times 10^3$/mm³ ($2 \times 10^9$/L)<br>No history of a myeloproliferative disorder or clozapine-induced agranulocytosis | |
| Initiation to 6 months | WBC $\geq 3.5 \times 10^3$/mm³ ($3.5 \times 10^9$/L) and ANC $\geq 2 \times 10^3$/mm³ ($2 \times 10^9$/L) | Weekly for 6 months |
| 6–12 months | WBC $\geq 3.5 \times 10^3$/mm³ ($3.5 \times 10^9$/L) and ANC $\geq 2 \times 10^3$/mm³ ($2 \times 10^9$/L) | Every 2 weeks for 6 months |
| After 12 months of therapy | WBC $\geq 3.5 \times 10^3$/mm³ ($3.5 \times 10^9$/L) and ANC $\geq 2 \times 10^3$/mm³ ($2 \times 10^9$/L) | Every 4 weeks |
| Whenever clozapine is discontinued | | Weekly for at least 4 weeks from day of discontinuation |
| Mild leukopenia or granulocytopenia | WBC value lies between $3 \times 10^3$/mm³ ($3 \times 10^9$/L) and $3.5 \times 10^3$/mm³ ($3.5 \times 10^9$/L) or ANC lies between $1.5 \times 10^3$/mm³ ($1.5 \times 10^9$/L) and $2 \times 10^3$/mm³ ($2 \times 10^9$/L) | Twice weekly until returned to recommended levels |
| Moderate leukopenia or granulocytopenia | WBC value lies between $2 \times 10^3$/mm³ ($2 \times 10^9$/L) and $3 \times 10^3$/mm³ ($3 \times 10^9$/L) or ANC value lies between $1 \times 10^3$/mm³ ($1 \times 10^9$/L) and $1.5 \times 10^3$/mm³ ($1.5 \times 10^9$/L) | Interrupt therapy; monitor daily until WBC $> 3 \times 10^3$/mm³ ($3 \times 10^9$/L) and ANC $> 1.5 \times 10^3$/mm³ ($1.5 \times 10^9$/L); then twice weekly until back to recommended levels |
| Severe leukopenia or granulocytopenia or agranulocytosis | WBC $< 2 \times 10^3$/mm³ ($2 \times 10^9$/L) or ANC $< 1 \times 10^3$/mm³ ($1 \times 10^9$/L)<br>ANC $\leq 0.5 \times 10^3$/mm³ ($0.5 \times 10^9$/L) (agranulocytosis) | Discontinue treatment and do not rechallenge; monitor daily until WBC $> 3 \times 10^3$/mm³ ($3 \times 10^9$/L) and ANC $> 1.5 \times 10^3$/mm³ ($1.5 \times 10^9$/L); then twice weekly until back to recommended levels |

ANC, absolute neutrophil count; WBC, white blood cell count.

### ▶ Acutely Psychotic Patients

Psychiatric emergencies occur in emergency departments, psychiatric units, medical facilities, and outpatient settings. Although verbal interventions are recommended as initial management, most psychiatric emergencies require both pharmacologic and psychological interventions. Safe and effective IM formulations are available for a number of FGAs and three SGAs (aripiprazole, ziprasidone, and olanzapine). These IM SGAs are now recommended as first-line therapy in agitated schizophrenia patients; however, IM benzodiazepines, most often lorazepam with or without concomitant oral antipsychotics are also used. Concomitant IM olanzapine and benzodiazepines may cause cardiorespiratory depression and should be avoided if possible. High doses of FGAs, termed *rapid neuroleptization*, are no longer recommended.

### ▶ Pregnancy and Lactation

When to use antipsychotics in pregnancy and during lactation remains a complicated decision based on a careful analysis of risks and benefits. Women with schizophrenia, even those who are unmedicated, have a significantly greater risk of obstetrical complications (eg, stillbirth, infant death, preterm delivery, low infant birth weight, and infants who are small for gestational age).

Women who have a psychotic relapse during pregnancy are at greatest risk for birth complications.[40] Because psychotic relapse may be more detrimental than antipsychotic treatment to both the mother and baby, antipsychotics are often continued during pregnancy. Women taking antipsychotics who become pregnant should not discontinue them without consulting their health care professionals.

Essentially all antipsychotic medications are distributed to the placenta. Both FGAs and SGAs may be associated with an increased risk of neonatal complications. High-potency FGAs have a low risk for congenital abnormalities; however, limb defects and dyskinesias are reported.[41] Low-potency phenothiazine antipsychotics may increase the risk of congenital abnormalities when used in the first trimester. There appears to be little risk associated with first-line SGAs.[42] Long-term neurobehavioral studies of children exposed to SGAs in utero have not yet been done, however,

---

**Patient Encounter, Part 4**

He is initially reluctant to get "a shot" but finally agrees, as he also does not want to get into power struggles with his mother about whether or not he is taking his medication. His clinician encourages him to exercise regularly and eat a healthy diet that is low in carbohydrates.

Over the next several months, he is more stable on the long-acting intramuscular form of risperidone, and he has not gained further weight. His eating habits are normal. He is less anxious, and his sleep is better. He is still, at times, preoccupied with the "Hollywood stars," and at times, the voice he hears of his father is upsetting to him, particularly when he is falling asleep at night. After 6 months of treatment, his clinician notices slight mouth movements that could be early tardive dyskinesia. After discussion of the risks and benefits, the patient agrees to a trial of clozapine. In a separate phone call to his mom, his clinician reviews the pros and cons of the clozapine trial.

*Why is his clinician considering a clozapine trial?*

*What are the rare serious side effects of clozapine versus the common manageable side effects?*

and certain FGA agents may be preferred in drug-naïve pregnant patients because of availability of more reproductive safety data. If pregnancy occurs during antipsychotic treatment, however, continuation of previous therapy is preferred. On the basis of available data, each case should be weighed individually.

A labeling change for antipsychotic medications has been implemented by the FDA to address the potential risk for EPS and symptoms of withdrawal in newborns whose mothers were treated with antipsychotics in the third trimester. Withdrawal symptoms may include agitation, abnormal muscle tone (increased or decreased), tremor, sleepiness, and difficulty in breathing or feeding, which may last for hours to days after delivery. In some newborns, specific treatment for withdrawal is not needed, whereas in others, longer hospital stays may be required.

Although SGAs are excreted in breast milk, most case reports document a low frequency of deleterious effects on the infant. Women taking prolactin sparing SGAs (SGAs other than risperidone and paliperidone) may have enhanced fertility compared with women taking other antipsychotics because they are less likely to be anovulotory. Therefore, women of childbearing potential taking antipsychotics must be educated about birth control.

## Pharmacokinetics

All antipsychotics are, at least to some extent, metabolized by hepatic CYP450 metabolic enzymes to water-soluble compounds that are excreted by the kidneys (Table 37–9). Unlike the other antipsychotics, ziprasidone is mostly metabolized by aldehyde oxidase, a metabolic system independent of the CYP450 system.

Paliperidone, the 9-OH metabolite of risperidone, is mostly excreted unchanged in the urine, although up to one-third may be metabolized. The transmembrane energy-dependent efflux transporter P-glycoprotein may limit the ability of drugs to penetrate the blood–brain barrier and therefore impact pharmacologic activity in the brain.[43] Antipsychotics currently known to use this pathway include perphenazine, haloperidol, fluphenazine, quetiapine, risperidone, and olanzapine.[44]

Additive side effects may occur with combined drug therapies, and a few clinically significant drug interactions are notable (see Table 37–9). Cigarette smoking decreases serum concentrations of clozapine and olanzapine by induction of CYP1A2. Although antipsychotics are highly protein bound, protein-binding interactions are generally not clinically significant. Absorption of most antipsychotics is not affected by food, with the exception of lurasidone and ziprasidone. The mean maximum concentration of lurasidone increases threefold when administered with food, and ziprasidone's absorption is increased by 60% to 70% when given with meals.

Ziprasidone, iloperidone, and quetiapine have potential to prolong the QTc interval. Using them with other agents that prolong the QTc interval should be undertaken with caution. These other agents include, but are not limited to, quinidine, sotalol, chlorpromazine, droperidol, mesoridazine, pimozide, thioridazine, gatifloxacin, halofantrine, mefloquine, moxifloxacin, and pentamidine. Combining higher doses of ziprasidone, iloperidone or quetiapine with ketoconazole or erythromycin should be undertaken cautiously.

### Table 37–9

**Metabolism and Drug Interactions with Antipsychotics**

| Antipsychotic | Major Metabolic Pathways | Other Metabolic Pathways | Increase Antipsychotic Concentrations | Decrease Antipsychotic Concentrations |
|---|---|---|---|---|
| Aripiprazole | CYP 3A4 | CYP 2D6 | Fluvoxamine, ketoconazole | Carbamazepine |
| Asenapine | Glucuronidation by UGT1A4 and CYP 1A2 | CYP 3A4, CYP 2D6 | Fluvoxamine | |
| Chlorpromazine | CYP 2D6 | CYP 1A2, CYP 3A4 | | |
| Clozapine | CYP 1A2 | CYP 3A4, CYP 2D6, CYP 2C19, CYP 2C9 | Fluvoxamine, ciprofloxacin, paroxetine | Cigarette smoking |
| Fluphenazine | CYP 2D6 | | Paroxetine | |
| Haloperidol | CYP 2D6, CYP 3A4 | CYP 1A2 | Fluvoxamine, fluoxetine, ketoconazole | Carbamazepine |
| Iloperidone | CYP 2D6, CYP 3A4 | 1A2, 2E1 | Ketoconazole, fluoxetine, paroxetine | |
| Loxapine | CYP 1A2, CYP 2D6, CYP 3A4 | | | |
| Lurasidone | CYP 3A4 | | Ketoconazole, diltiazem | Rifampin |
| Olanzapine | CYP 1A2, Glucuronidation by UGT1A4 | CYP 2D6 | Fluvoxamine, ciprofloxacin, paroxetine | Cigarette smoking |
| Paliperidone | CYP 2D6, CYP 3A4 (in vitro, but limited role in vivo) | | Divalproex sodium, paroxetine | Carbamazepine (via increased renal elimination) |
| Perphenazine | CYP 2D6 | | Fluvoxamine, fluoxetine, paroxetine | |
| Pimozide | CYP 3A4 | CYP 1A2 | Strong CYP 2D6 inhibitors, CYP 3A4 inhibitors | CYP 3A4 inducers |
| Quetiapine | CYP 3A4 | 2D6 | Fluvoxamine, ketoconazole | Carbamazepine |
| Risperidone | CYP 2D6 | 3A4 | Fluoxetine, paroxetine | Carbamazepine |
| Thioridazine | CYP 2D6 | 2C19 | Fluvoxamine | Cigarette smoking |
| Thiothixene | CYP 1A2 | | CYP 1A2 inhibitors | CYP 1A2 inducers |
| Trifluoperazine | CYP 1A2 | | CYP 1A2 inhibitors | CYP 1A2 inducers |
| Ziprasidone | Aldehyde oxidase | CYP 1A2, CYP 3A4 | Fluvoxamine, ketoconazole | Carbamazepine |

CYP450, cytochrome P450 isoenzyme.

Added pharmacodynamic effects are possible when combining antipsychotics with others drugs that can cause sedation, hypotension, anticholinergic symptoms, and weight gain or metabolic abnormalities.

### Adjunct Treatments

The judicious use of pharmacologic therapies other than antipsychotics is often necessary for the treatment of motor side effects, anxiety, depression, mood elevation, and possibly residual psychotic symptoms. Anticholinergic medications (eg, benztropine, 1 to 2 mg two times daily; trihexyphenidyl, 1 to 3 mg three times daily; and diphenhydramine, 25 to 50 mg two times daily) are used to treat EPS. They may be prescribed prophylactically with high-$D_2$-binding agents or in patients at risk for EPS or for treatment of EPS. β-Blockers (eg, propranolol 30–120 mg/day) are sometimes effective for patients who develop akathisia. In some situations, such as on an inpatient unit, the concomitant use of benzodiazepines (eg, lorazepam 1–3 mg/day) with the SGAs may be necessary for agitation or insomnia.

Antidepressants may be useful for patients with schizophrenia who have depressive symptoms. Because suicide and depression are linked, aggressive treatment is necessary when depression is present. The selective serotonin reuptake inhibitors (SSRIs) are the preferred agents, but they may inhibit the CYP450 enzymes, thus raising plasma concentrations of clozapine, olanzapine, and haloperidol. Mood stabilizers, such as lithium and the anticonvulsants, have long been used adjunctively with the antipsychotics to treat the affective component of schizoaffective disorder.

Approximately 30% of treatment-resistant patients given clozapine do not respond, and another 30% have only a partial response. Limited treatment options are available for these patients. A number of augmentation strategies have been tried, including FGAs, SGAs, mood stabilizers (eg, lithium, valproate, and topiramate), minocycline, antidepressants, transcranial magnetic stimulation (TMS) and **electroconvulsive therapy** (ECT). Though controlled trial results are mixed, some data support the adjunctive use of risperidone, lamotrigine, or aripiprazole in clozapine-treated patients.[45]

### Psychosocial Treatment

**KEY CONCEPT** *Psychosocial support helps improve functional outcomes.* Residual symptoms often persist such as **avolition,** isolation, and impaired social functioning, limiting participation in social, vocational, and educational endeavors. Psychosocial interventions, as adjuncts to pharmacotherapy, are designed to improve psychosocial functioning, self-esteem, and life satisfaction. These treatments are mainly used as targeted treatments for social and cognitive impairments.[13] In the United States, psychosocial treatments are less standardized than in Europe, but their use is on the rise. There are much data to support family education in decreasing relapse rates and vocational support to improve vocational outcomes. A few of the best-supported and most promising approaches to psychosocial rehabilitation are social skills training (SST), cognitive behavioral therapy (CBT), acceptance commitment therapy, and cognitive remediation (CR). In addition, Assertive Community Treatment (ACT) and Medical Home care models may improve outcomes.[13]

### Patient Education

**KEY CONCEPT** *Education of the patient and family regarding the benefits and risks of antipsychotic medications and the importance of treatment adherence must be ongoing and integrated into pharmacologic*

---

**Patient Encounter, Part 5**

Over the next 6 months, the patient becomes less preoccupied with his psychotic thoughts, though they do not resolve completely. He feels somewhat sad and anxious about the future, unsure of his goals, and preoccupied with all the time he "has wasted being crazy." He continues to be socially withdrawn, not sure how to react to others when they ask him what he has been doing over the last 2 years and what he is doing now. He doesn't know how to interact with his old friends, as they often meet in bars, and he does not feel comfortable there.

*What are the possible underlying causes of his current mental state?*

*How might the clinician consider addressing his concerns?*

---

*management.* Medication management discussions offer an opportunity to provide illness and treatment education including the nature and course of schizophrenia, and can serve as a time to hear the patient's life goals. Key considerations include:

- Involve families in the education and treatment plans because family psychoeducation may decrease relapse, improve symptomatology, and enhance psychosocial and family outcomes.[46]
- Be clear that there is no cure for schizophrenia and that medication can be effective to decrease and improve many symptoms.
- Explain common and rare but dangerous side effects.
- Stress the importance of medication and treatment adherence for improving long-term outcomes.
- Decision making on the best course of treatment should be a shared process.

## OUTCOME EVALUATION

Developing a good working alliance with the patient is essential. In the absence of a solid therapeutic relationship, patients are frequently reluctant to share their beliefs, personal experiences, and life goals.

### Symptom Monitoring

Many assessments are available to objectively rate positive and negative symptoms, level of function, and life satisfaction. The most commonly used scales include:

- Positive and Negative Symptom Scale (PANSS)
- Brief Psychiatric Rating Scale (BPRS)
- Clinical Global Impression (CGI) Scale

Using these scales on a regular basis, particularly when switching medications or changing doses, is a more reliable means of monitoring symptoms. Symptom assessments cannot capture the full range of possible improvements, but they can be useful in deciding whether a medication is having substantial benefit.

### Side-Effect Monitoring

**KEY CONCEPT** *Regularly monitor for side effects and overall health status.*[47,48] Perform orthostatic blood pressure measurements before initiating antipsychotics and regularly throughout treatment. Ask about impaired menstruation, libido, and sexual performance

**Table 37–10**

**Monitoring Protocol for Patients on Second-Generation Antipsychotics**

|  | Baseline | 4 Weeks | 8 Weeks | 12 Weeks | Quarterly | Annually | Every 5 Years |
|---|---|---|---|---|---|---|---|
| Personal or family history[a] | X |  |  |  |  | X |  |
| Weight | X | X | X | X | X |  |  |
| Waist circumference | X |  |  |  |  | X |  |
| Blood pressure | X |  |  | X |  | X |  |
| Fasting plasma glucose | X |  |  | X |  | X |  |
| Fasting plasma lipids | X |  |  | X |  |  | X |

[a]Of obesity, diabetes, dyslipidemia, hypertension, or cardiovascular disease.

regularly. Encourage patients to have annual eye examinations because several antipsychotic medications have been associated with the premature development of cataracts. At baseline check body weight, fasting glucose, glycated hemoglobin, and lipid profile, and repeat these measurements 4 months after initiation of medication and then yearly.[49,50] For patients at higher risk of developing diabetes and those who gain weight, check body weight more often (Table 37–10). Perform baseline electrocardiography for patients with preexisting cardiovascular disease or risk for arrhythmia. With clozapine therapy, there is a risk for the development of agranulocytosis, which is greatest in the first 6 months of treatment. Required monitoring of white blood cell counts is described in Table 37–8.

Commonly used rating scales to monitor for EPS include the Simpson Angus Scale (SAS) and the Extrapyramidal Symptom Rating Scale (ESRS). Akathisia is commonly monitored by the Barnes Akathisia Scale (BAS). The emergence of dyskinesias could represent the emergence of TD. Monitor patients on SGAs for TD at least annually, and patients taking FGAs at each visit. The most commonly used instrument to measure these symptoms is the Abnormal Involuntary Movement Scale (AIMS).

## Patient Care Process

### Patient Assessment:

- Review the patient's chief complaint, presenting symptoms, and history, including family psychiatric history. Assess organization of thoughts and range of affect. Assess presence of mood disturbance, likelihood of harm to self or others, and presence of hallucination, paranoia and/or delusions of control.
- Assess medical records, including laboratory and imaging studies, to rule out medical causes of psychosis.
- Obtain collateral information from family, past medical records and other providers to help clarify the history.
- Elicit the patient's housing arrangements, social and vocational goals.

### Therapy Evaluation:

- Assess current treatments and outcomes of prior treatments.
- Select an antipsychotic based on the side-effect profile that is most appropriate and acceptable to the patient.
- Consider collaboration with other professionals or family members.
- Consider how income and insurance coverage might influence pharmacotherapy choice.

### Care Plan Development:

- Collaboratively, develop a treatment plan that addresses medication adherence and healthy lifestyle goals, including substance and cigarette use.
- Communicate that treatment plan adherence will enhance the likelihood of meeting goals.
- Devise a plan to optimize compliance.
- Educate the patient and, with patient consent, their family about the illness, medication treatments, possible side effects, and goals of treatment.
- Enlist adjunctive treatments, including psychosocial therapies to optimize outcomes.

### Follow-up Evaluation:

- Schedule appointments more frequently initially to assess effectiveness, adverse drug reactions, drug interactions, and allergies.
- Assess the need for adjunctive therapies to enhance progress toward goals.
- Monitor appropriate laboratory measures to prevent or minimize adverse effects, including metabolic abnormalities.
- Assess for emergence of new target symptoms.
- Optimize dosing and consider clozapine if criteria are met for treatment resistance.

# Abbreviations Introduced in This Chapter

| | |
|---|---|
| 5-HT | Serotonin |
| ACT | Assertive Community Treatment |
| AIMS | Abnormal Involuntary Movement Scale |
| ANC | Absolute neutrophil count |
| BAS | Barnes Akathisia Scale |
| BPRS | Brief Psychiatric Rating Scale |
| CATIE | Clinical Antipsychotics Trials of Intervention Effectiveness |
| CBT | Cognitive behavioral therapy |
| CGI | Clinical Global Impression Scale |
| CR | Cognitive remediation |
| CYP450 | Cytochrome P450 isoenzyme |
| D | Dopamine |
| *DSM-5* | *Diagnostic and Statistical Manual of Mental Disorders,* 5th edition |
| ECT | Electroconvulsive therapy |
| EPS | Extrapyramidal side effects |
| ESRS | Extrapyramidal Symptom Rating Scale |
| FDA | Food and Drug Administration |
| FGA | First-generation antipsychotic |

# 38 Major Depressive Disorder

Cherry W. Jackson and Marshall E. Cates

## LEARNING OBJECTIVES

● **Upon completion of this chapter, the reader will be able to:**

1. Explain the etiology and pathophysiology of major depressive disorder (MDD).
2. Identify the signs and symptoms of MDD.
3. Outline the treatment goals for a patient with MDD.
4. Recommend pharmacotherapy given a specific patient with MDD.
5. Develop a monitoring plan for a specific patient with MDD which includes the assessment of efficacy as well as toxicity.
6. Predict, prevent, identify, and resolve potential drug-related problems.
7. Educate patients and caregivers on the proper use of antidepressant therapy.

## INTRODUCTION

**M**ajor depression is a common, seriously disabling, disorder nonresponsive to volitional efforts to feel better. Individuals with major depressive disorder (MDD) experience pervasive symptoms affecting mood, thinking, physical health, work, and relationships. Suicide often results when MDD is inadequately diagnosed and treated.[1]

Over and under detection of MDD is an important consideration. Primary care providers have become increasingly involved in the management of MDD. Studies show that over detection of MDD can outnumber missed cases.[1] Antidepressants account for 15 of the top 200 prescriptions drugs dispensed in the United States.[2] Inadequate treatment remains a serious concern.[3]

### Patient Encounter, Part 1

A 62-year-old man with diabetes, hypertension, and recently diagnosed Parkinson disease presents to the psychiatry clinic. He complains of depressed mood, poor sleep, and appetite. He has lost 25 pounds (11.4 kg) in the last 2 months. He also has been isolating himself from other people, and has had crying spells. He says that he has been thinking about committing suicide, but he does not have a specific plan.

*What symptoms of MDD does he have?*

*What medical or psychiatric issues could be contributing to his symptoms?*

*What additional information do you need to know before creating a treatment plan for this patient?*

## EPIDEMIOLOGY AND ETIOLOGY

The lifetime and 12-month prevalence estimates for MDD are 16.2% and 6.6%, respectively.[4] Women are twice as likely as men to experience MDD. The average age of onset is in the mid-twenties; many patients with MDD have comorbid psychiatric disorders, especially anxiety and substance abuse disorders.[5]

According to the World Health Organization (WHO), depression is the leading cause of disability (based on years lived with disability) and the fourth leading cause of the global burden of disease.[6]

Symptoms of depression are due to a change in the brain neurotransmitters, norepinephrine (NE), serotonin (5-HT), and dopamine (DA).

## PATHOPHYSIOLOGY

● The cause of MDD is unknown but is probably multifactorial. Multiple theories abound, and practitioners suggest that development of depression likely involves a complex interaction of genetic predisposition, psychological stressors, and underlying pathophysiology. There are no currently accepted unifying theories to adequately explain the pathophysiology of depression.

### Genetics

First-degree relatives of MDD patients are about three times more likely to develop MDD compared with controls. Adoption and twin studies also suggest aggregation of MDD is due to genetic influences.[7] Major depression has been associated with four different genes. They include polymorphisms in the glucocorticoid receptor gene NR3C1, the monoamine oxidase A gene, the gene for glycogen synthase kinase-3β, and a group-2 metabotropic glutamate receptor gene (GRM3).[8]

## Stress

Major life stressors do not always cause depression. Nevertheless, there is an undeniable association between life stressors and depression, and there appears to be a significant causative interaction between life stressors and genetic predisposition. Although acute stressors may precipitate depression, chronic stressors cause longer episodes and are more likely to lead to relapse and recurrence.[9]

## Biogenic Amine and Receptor Hypotheses

**KEY CONCEPT** *The primary hypothesis is the biogenic amine hypothesis which states that a deficit of NE, DA, or 5-HT at the synapse is the cause of depression.* Support for this hypothesis is that existing antidepressants increase synaptic monoamine concentrations (see Pharmacologic Therapy). One argument against this hypothesis is that patients with depression do not always have decreased monoamine levels. Additionally, monoamine levels are altered within hours of initiating antidepressant therapy, but response is delayed by 2 to 4 weeks or more.

The receptor hypothesis suggests that depression is related to abnormal functioning of neurotransmitter receptors. In this hypothesis, chronic administration of antidepressants alters receptor sensitivity causing desensitization or down regulation of β-adrenergic and 5-HT receptors leading to therapeutic response. Importantly, the time required for changes in receptor sensitivity correlates with antidepressant onset.[10] These hypotheses are clearly oversimplifications of the pathophysiology of depression. MDD probably involves a complex dysregulation of monoamine systems that modulate and are modulated by other neurobiological systems.

## Other Neurobiological Hypotheses

At least three categories of peripheral hormones are associated with the pathophysiology of depression. They include (1) neurotrophic and other growth factors including brain derived neurotrophic factor (BDNF), vascular endothelial growth factor (VEGF), and insulin-like growth factor, (2) proinflammatory cytokines including interleukin-1β, interleukin-6, and tumor necrosis factor-α; and (3) the hypothalamic pituitary axis (HPA).[8]

Proinflammatory cytokines are increased in individuals with MDD, and antidepressants suppress the synthesis of these cytokines. HPA axis regulation is impaired in depression, and antidepressants can attenuate the neuroendocrine response. BDNF is decreased in patients with MDD, and antidepressants reverse this response.[8]

## CLINICAL PRESENTATION AND DIAGNOSIS

The diagnosis of a major depressive episode (MDE) requires the presence of five depressive symptoms for a minimum of 2 weeks that cause clinically significant effects.[5] The diagnosis of MDD is based on the presence of one or more MDEs during a person's lifetime (Table 38–1).[5]

## Differential Diagnosis

MDEs also occur in bipolar disorder. Individuals with bipolar disorder also experience hypomanic, manic, or mixed episodes (see Chapter 39) during the course of their illness, but individuals with MDD do not.[5]

The anxiety, personality, and substance use disorders are frequently associated with MDD. Several chronic medical conditions have strong correlations with MDD. MDD is associated

---

| Table 38–1 |
| --- |
| **Clinical Presentation of Depression: Diagnostic Criteria for Major Depressive Episode** |
| At least five of the following symptoms have been present during the same 2-week period and represent a change from previous functioning. |
| • Depressed mood[a] |
| • Markedly diminished interest or pleasure in usual activities[a] |
| • Increase of decrease in appetite or weight |
| • Increase or decrease in amount of sleep |
| • Increase or decrease in psychomotor activity |
| • Fatigue or loss of energy |
| • Feelings of worthlessness or guilt |
| • Diminished ability to think, concentrate, or make decisions |
| • Recurrent thoughts of death, suicidal ideation, or suicide attempt |
| The symptoms cause clinically significant distress or impairment in functioning. |
| The symptoms are not due to the direct physiologic effects of a substance or medical condition. |

[a]One of these two symptoms must be present.

Data from American Psychiatric Association. Major Depressive Disorders. Diagnostic and Statistical Manual of Mental Disorders. 5th ed. Washington, DC: American Psychiatric Association; 2013: 160–168.

---

with a 65% increased risk of diabetes in elderly patients.[11] MDD is also strongly correlated with coronary artery disease. Other medical disorders associated with depression include hypothyroidism, cancer, anemia, infections, electrolyte disturbances, folate deficiency, neurologic disorders, and cardiovascular and respiratory disease.[5] Identification and treatment of MDD in patients with chronic medical conditions is important. Inadequate recognition and treatment of depression may increase the mortality associated with these medical disorders.[11] Use of central nervous system (CNS) depressants such as alcohol, benzodiazepines, or narcotics, is associated with an increased incidence of depression.[12] Some drugs that cause depressive symptoms include corticosteroids, contraceptives, levetiracetam, topiramate, vigabatrin, gonadotropin-releasing hormone agonists, interferon-α, interleukin-2, varenicline, mefloquine, isotretinoin, propranolol, clonidine, methyldopa, reserpine, and sotalol.[13]

Persistent depressive disorder (dysthymia) is a chronic form of depression that must be differentiated from MDD. Many symptoms of dysthymia are similar to those of MDD, but they are chronic and milder. Symptoms must be present for at least 2 years and may include sleep and appetite disturbances, lack of energy, poor self-image, and difficulty making decisions. Individuals with dysthymia are more likely to develop MDD than the general population, and when this occurs it is called "double depression."[4]

## COURSE AND PROGNOSIS

Symptoms of a major depressive episode usually develop gradually over days to weeks, but mild depressive and anxiety symptoms may last weeks to months before onset of the full syndrome. Untreated, MDEs last 6 months or more, but a minority of

individuals experience chronic episodes that last at least 2 years. Approximately two-thirds of patients recover and return to normal mood, but one-third have only a partial **remission.**[4]

The course of MDD varies markedly between patients. **KEY CONCEPT** *It is not uncommon for a patient to experience only a single MDE, but most patients with MDD experience multiple episodes.* The number of prior episodes predicts the likelihood of developing subsequent episodes. A patient experiencing a third MDE has a 90% chance of having a fourth one. MDD has a high mortality rate because approximately 15% of patients ultimately complete suicide.[4]

## TREATMENT
### Desired Outcomes

The goal of therapy for patients with MDD is resolution of depressive symptoms, return to **euthymia,** and prevention of relapse and recurrence of symptoms. **KEY CONCEPT** *One extremely important goal is prevention of suicide attempts.* Other desired outcomes include improving quality of life including normalization of functioning in areas such as work and relationships, minimization of adverse effects, and reduction of health care costs.

### Nonpharmacologic Therapy

Evidence supports efficacy of interpersonal and cognitive-behavioral therapy in the treatment of MDD. Psychotherapy alone is an initial treatment option for mild to moderate depression, and it may be useful combined with pharmacotherapy for the treatment of severe depression. This combination can be more effective than either treatment alone in severe or recurrent MDD. Combination treatment may be helpful for patients with psychosocial stressors, interpersonal difficulties, or comorbid personality disorders.[14]

Electroconvulsive therapy (ECT) is a highly efficacious and safe treatment alternative for MDD. The response rate is about 80% to 90%, and it exceeds 50% for patients who have failed pharmacotherapy.[15] ECT may be beneficial for MDD that is complicated with psychotic features, severe suicidality, refusal to eat, pregnancy, or contraindication or nonresponse to pharmacotherapy.[15] Six to 12 treatments are typically necessary with response occurring in 10 to 14 days. When ECT is discontinued, antidepressants are initiated to help maintain response. Side effects after ECT include temporary confusion, retrograde and anterograde amnesia.[14]

Light therapy is an alternative treatment for depression associated with seasonal (eg, winter) exacerbations. Side effects include eye strain, headache, insomnia, and hypomania.[16]

Vagus nerve stimulation (VNS), which was approved by the Food and Drug Administration (FDA) in 2005, may be used for treatment-resistant depression. A pulse generator is surgically implanted under the skin of the left chest, and an electrical lead connects the generator to the left vagus nerve which sends signals to the brain. This therapy is used along with pharmacotherapy and ECT.[17] Adverse effects of VNS include alterations in patients' voice, coughing, pharyngitis, sore throat, hoarseness, headache, nausea, vomiting, dyspnea, and paresthesia.[17]

Transcranial magnetic stimulation is a noninvasive and well-tolerated procedure that is FDA approved for use after one failed trial of an antidepressant.[18] Physical exercise may reduce depressive symptoms, but well-controlled studies are needed to verify this.[19]

### Pharmacologic Therapy

Individual antidepressants, even those within the same class, have important pharmacologic differences (**Tables 38–2** and **38–3**).[10,20] Monoamine oxidase inhibitors (MAOIs) inhibit the enzyme responsible for the breakdown of 5-HT, NE, and DA. There are two main forms of MAO: While both MAO-A and MAO-B have receptors in the brain, MAO-A has more receptors in the gut, and MAO-B is primarily found in the brain. Inhibition of MAO-A impacts the breakdown of 5-HT, dopamine, epinephrine, and NE. MAO-B is primarily involved in the inhibition of DA and phenethylamine. Dietary restrictions are necessary for MAO-A inhibitors, but not usually for MAO-B inhibitors. The tricyclic antidepressants (TCAs) possess both serotonin reuptake inhibition (SRI) and norepinephrine reuptake inhibition (NRI) properties, but they also block other receptors, including $\alpha_1$-adrenergic, histamine-1, and muscarinic cholinergic receptors, which contribute to side effects, not efficacy. The primary action of the specific serotonin reuptake inhibitors (SSRIs) is SRI. Bupropion is a NE and DA reuptake inhibitor (NDRI). Venlafaxine, desvenlafaxine, and duloxetine are 5-HT and NE

---

**Patient Encounter, Part 2: Medical History, Physical Examination, and Diagnostic Tests**

The workup reveals:

**PMH:** Multiple medical problems including insulin-dependent diabetes mellitus, hypertension, and recently diagnosed Parkinson disease. He is followed by a primary care physician

**PPH:** He has multiple psychiatric hospitalizations with the last being 2 years prior to this admission. He has a diagnosis of major depressive episode (MDE). He has also been hospitalized three times for substance abuse. His drug of choice is alcohol

**FH:** Mother had diabetes mellitus and MDD, died at age 58; father had a history of alcoholism and died at age 78; brother is a recovering alcoholic

**SH:** Worked as a movie director. Found out that he had Parkinson disease 2 months ago. Last drink of alcohol was 6 months ago, before his last hospitalization. He denies smoking or illicit substances

**Current Meds:** Sertraline 100 mg daily; trazodone 100 mg at bedtime; nicardipine 20 mg three times daily; novulin 70/30 56 units in the morning, 15 units in the evening; carbidopa/levodopa 25/100 three times daily

**ROS:** Decreased sleep; decreased appetite; weight loss; all others noncontributory

**PE:**

**VS:** Ht 5'11"(180 cm) Wt 183 lbs. (83.2 kg), weight loss of 25 lbs (11.4 kg) over past 8 weeks

**MSE:** Depressed mood, decreased sleep, decreased appetite, isolation, positive suicidal ideation without plan

**Labs:** Within normal limits. Urine drug screen—negative

MAOI, monoamine oxidase inhibitor; SNRI, serotonin norepinephrine reuptake inhibitor; SSRI, selective serotonin reuptake inhibitor; TCA, tricyclic antidepressant; Vilaz, vilazodone; Traz, trazodone; Mirtaz, mirtazapine; Vorti, vortioxetine.

**Table 38–3**

**Efficacy and Adverse Effect Profile Based on Pharmacology**

| Pharmacologic Action | Result |
|---|---|
| SRI | Antidepressant and antianxiety efficacy (via interaction of 5-HT at 5-HT$_{1A}$ receptors) |
| | Anxiety, insomnia, sexual dysfunction (via interaction of 5-HT at 5-HT$_{2A}$ receptors) |
| | Anxiety, anorexia (via interaction of 5-HT$_{2C}$ receptors) |
| | Nausea, GI problems (via interaction of 5-HT at 5-HT$_3$ receptors) |
| NRI | Antidepressant efficacy |
| | Tremor, tachycardia, sweating, jitteriness, increased blood pressure |
| Dopamine reuptake inhibition | Antidepressant efficacy, euphoria, psychomotor activation, aggravation of psychosis |
| $\alpha_2$-Adrenergic receptor blockade | Increase in serotonergic and noradrenergic activity-see actions of SRI and NRI above |
| Serotonin$_{1A}$ receptor agonist | Antianxiety, antidepressant augmentation, decreased blood pressure, |
| Serotonin $_{1A}$ partial agonism | Antianxiety, antidepressant augmentation, decreased blood pressure, decreased heart rate |
| Serotonin$_{2A}$ receptor blockade | Antianxiety efficacy |
| | Increased REM sleep; decreased sexual dysfunction |
| Serotonin$_{2C}$ receptor blockade | Antianxiety efficacy |
| | Increased appetite or weight gain |
| Serotonin$_3$ receptor blockade | Antinauseant, decreased GI problems |
| Serotonin$_7$ receptor blockade | Antidepressant, modulates glutamate |
| $\alpha_1$-Adrenergic receptor blockade | Orthostatic hypotension, dizziness, reflex tachycardia |
| Histamine-1 receptor blockade | Sedation, weight gain |
| Muscarinic cholinergic receptor blockade | Dry mouth, blurred vision, constipation, urinary hesitancy, sinus tachycardia, memory problems |

GI, gastrointestinal; NRI, norepinephrine reuptake inhibition; REM, rapid eye movement; SRI, serotonin reuptake inhibition.

Data from Refs. 8 and 10.

reuptake inhibitors (SNRIs) and weak inhibitors of DA reuptake. Compared with venlafaxine and desvenlafaxine, which have primarily SRI activity, duloxetine has more balanced SRI and NRI activities and has a higher affinity for reuptake sites. Nefazodone and trazodone are 5-HT antagonists. Their SRI activity is not as pronounced as that of the SSRIs, but they potently block 5-HT$_{2A}$ receptors, which allow more 5-HT to interact at postsynaptic 5-HT$_{1A}$ sites. In addition, trazodone blocks histaminergic and α-adrenergic receptors, and nefazodone possesses weak NRI and α-adrenergic blocking properties. Vilazodone, a combination of an SRI and a partial agonist at 5-HT$_{1A}$ receptors, is thought to reduce negative feedback on endogenous serotonin receptors which may improve the medications antidepressant effect.[21] Vortioxetine is an agonist/antagonist/partial agonist at various 5-HT receptors. Vortioxetine has affinity for β-adrenergic receptors which may be associated with side effects and histaminic and acetylcholinergic receptors which may have an effect on memory.[22] Finally, mirtazapine is a noradrenergic and specific serotonergic antidepressant. It blocks presynaptic α$_2$ autoreceptors on noradrenergic neurons and heteroreceptors on serotonergic neurons, resulting in increases in NE and 5-HT synaptic concentrations. Mirtazapine also blocks postsynaptic serotonergic receptors and histamine-1 receptors.[10]

## Complementary and Alternative Treatments

St. John's wort (hypericum perforatum) is an herbal medication that has shown efficacy in mild to moderate depression, but minimal efficacy for moderate to severe depression.[19] It has mild MAO-inhibiting properties. Many patients believe that herbal medications are devoid of adverse effects and drug interactions; however, St. John's wort can cause gastrointestinal (GI) irritation, headache, fatigue, and nervousness, and it triggers drug interactions through induction of CYP3A4 enzymes, and potentially other mechanisms.[23] The safety and efficacy of St. John's wort combined with standard antidepressant medications remains unknown.

S-adenosyl methionine (SAM-e), a naturally occurring compound in the body, tends to be lower in people with major depression. Treatment with SAM-e increases blood levels of both S-adenosyl methionine and hydroxyindolacetic acid. It is sold as a nutritional supplement and lacks the standardization of medications that are FDA approved.[24]

Low folate levels are associated with a greater risk of depression or a lack of response to antidepressants. Because folic acid prevents neural tube defects in pregnancy and causes few to no adverse effects, it can be used in doses of 0.4 to 1 mg/day to improve the efficacy of the antidepressants.[25]

Low doses of omega-3 fatty acids (eicosapentaenoic, docosahexaenoic acid, or both) have been used adjunctively for major depression. More study is needed to establish their role.[26]

## Adverse Effects

The adverse effects of the antidepressants are often a function of their underlying pharmacologic profiles (see Table 38–3). The TCAs cause sedative, anticholinergic, and cardiovascular adverse effects. Although common, they can also be serious in some cases. The tertiary amines (eg, amitriptyline, imipramine) are more sedative and anticholinergic than the secondary amines (eg, desipramine, nortriptyline). The TCAs have a quinidine-like effect on the heart, which makes them toxic in overdose. The average lethal dose in a young adult is 30 mg/kg, which is typically less than a 1-month supply.[20]

The adverse effect profile of the SSRIs includes sexual dysfunction (eg, delayed or absent orgasms), CNS stimulation (eg, nervousness and insomnia), and GI disturbances (eg, nausea and diarrhea).[20,27] **KEY CONCEPT** *Sexual dysfunction, common and challenging to manage, often leads to noncompliance.*[28] Various strategies to deal with antidepressant induced sexual function include waiting for symptoms to subside, reducing the dosage, permitting periodic "drug holidays," prescribing adjunctive therapy, and switching antidepressants.[27] However, waiting for symptoms to subside usually does not work, because sexual dysfunction may very well persist throughout the duration of therapy. Reducing the dose and using drug holidays may weaken the antidepressant effects. Thus, clinicians often prescribe adjunctive therapy such as dopaminergic drugs (eg, bupropion, amantadine), 5-HT$_2$ antagonists (cyproheptadine, nefazodone), and phosphodiesterase inhibitors (eg, sildenafil) or simply switch to antidepressants with less likelihood of causing these effects, such as bupropion, mirtazapine, or nefazodone.[27]

Bupropion causes insomnia, nightmares, decreased appetite, anxiety, and tremors, but the most concerning adverse effect are seizures. Because of the risk for seizures, patients with a CNS lesion, history of seizures, head trauma, or bulimia should not receive the drug. The daily dose of bupropion should not exceed 450 mg/day (immediate release and extended release), and any single dose of the immediate-release formulation should not exceed 150 mg. The maximum dose of sustained release is 200 mg twice daily. Insomnia and/or nightmares often respond to moving the last daily dose from bedtime to late afternoon.[29]

The adverse effects of the SNRIs are similar to those of the SSRIs. Nausea can be troublesome with venlafaxine and desvenlafaxine, which sometimes necessitates using lower starting doses and giving the medication with food. A dose-related elevation in blood pressure can occur at higher doses, and blood pressure monitoring should be conducted for patients receiving venlafaxine or desvenlafaxine. Duloxetine should not be prescribed to patients with moderate to heavy alcohol use or evidence of chronic liver disease owing to the potential for hepatic injury.[30]

Trazodone causes sedation, and it is used more often as an adjunct with other antidepressants for sleep than as an antidepressant. Priapism is a rare but serious adverse effect in men taking trazodone. It is less likely with nefazodone because it has a weaker effect at α-adrenergic receptors and a balancing of adrenergic effects owing to weak NRI activity. Unfortunately, nefazodone has been associated with development of fatal hepatotoxicity, which has led to a black-box warning and significant reduction in its use. It has been discontinued in some countries.[27]

Mirtazapine can cause sedation and weight gain by blocking histamine-1 receptors. Despite being partially a serotonergic drug, it rarely causes serotonergic-related adverse effects because it also blocks the various postsynaptic 5-HT receptors. Although it carries a bolded warning for neutropenia owing to a handful of cases reported during clinical trials, it is questionable whether neutropenia is more problematic with mirtazapine than other antidepressants.[31]

The relative incidence of adverse effects among the newer antidepressants is shown in Table 38–4.

## Pharmacokinetic Parameters

Pharmacokinetic parameters of the newer antidepressants are shown in Table 38–5. Several antidepressants are not highly protein bound, the most notable of these are venlafaxine and desvenlafaxine. The elimination half-lives of nefazodone and venlafaxine are relatively short compared with the other agents.

**Table 38–4**

**Relative Incidence of Adverse Effects of Newer Antidepressants**

Data from Refs. 8, 10, and 27.

Conversely, fluoxetine has a very long half-life (ie, 5–9 days) with chronic dosing, and its active metabolite (norfluoxetine) has an even longer half-life. Because of this, a 5-week washout of fluoxetine is required before starting an MAOI. A 2-week washout is generally considered sufficient for other SSRIs. Sertraline and citalopram also have active metabolites, but these metabolites (desmethylsertraline and desmethylcitalopram, respectively) are only about one-eighth as potent as the parent compounds for SRI activity.[31,32,33]

## Drug Interactions

Antidepressant drug interactions can be pharmacokinetic or pharmacodynamic. The usual pharmacodynamic drug interactions involve the "dirty receptors" blocked by some antidepressants. TCAs can cause significant additive effects with other drugs that cause sedation, hypotension, or anticholinergic effects. Similarly, trazodone and mirtazapine can interact with other drugs that cause hypotensive and sedative effects. By far, the most concerning pharmacodynamic interactions are hypertensive crisis and serotonin syndrome, which are both life-threatening. Hypertensive crisis is characterized by sharply elevated blood pressure, occipital headache, stiff or sore neck, nausea, vomiting, and sweating. It may result during MAOI therapy if the patient takes a sympathomimetic drug, such as ephedrine, pseudoephedrine, phenylephrine, phenylpropanolamine, or stimulants such as amphetamines or methylphenidate or if the patient consumes

**Table 38–5**

**Pharmacokinetic Parameters of Newer Antidepressants**

| Drug | Protein Binding(%) | Elimination Half-Life (hours) | Active Metabolite(s) | Cytochrome P450 Substrate | Cytochrome P450 Inhibitor |

Data from Refs. 8 and 10.

foods rich in tyramine, such as tap beers, aged cheeses, fava beans, yeast extracts, liver, dry sausage, sauerkraut, or tofu.[34] There are extensive lists of foods and drinks that are not permitted during therapy with MAOIs, and these should always be provided to patients. Because many over-the-counter (OTC) products contain sympathomimetics, patients should always be told to consult with their pharmacist or other clinician before using these drugs. Serotonin syndrome is characterized by confusion, restlessness, fever, abnormal muscle movements, hyperreflexia, sweating, diarrhea, and shivering. It may result when a serotonergic agent is added to any other serotonergic agent, but the MAOIs are strongly associated with severe cases of serotonin syndrome. Serotonin syndrome is complicated by (a) an unawareness by clinicians of the diagnosis and (b) the fact that many implicated drugs are not serotonergic in nature, such as dextromethorphan, meperidine, tramadol, linezolid, triptans, and methylene blue.[34]

Many antidepressants inhibit cytochrome P450 isoenzymes, elevating plasma levels of substrates for those isoenzymes and potentially leading to adverse effects or toxicity (see Table 38–5).[31]

### Dosing

Antidepressant dosing is summarized in Table 38–6.[12,20] The extended release formulation of venlafaxine and bupropion allow for once daily dosing. The delayed-release capsule of fluoxetine can be given weekly, which can be started 7 days after the last regular-release capsule or tablet. Selegiline is available as a transdermal patch, and a dose of 6 mg/24 hours can be used without the usual dietary restrictions associated with MAOI use, although patients on the higher doses (9 and 12 mg/24 hours) should follow usual dietary restrictions. Liquid dosage forms and disintegrating tablets of various antidepressants are ideal for patients who have difficulty swallowing tablets or capsules and those who may attempt to "cheek" their medication.

The starting dose is the usual therapeutic dose for most SSRIs, desvenlafaxine, duloxetine, and mirtazapine, but there is usually a need for at least some upward titration of venlafaxine, vilazodone, vortioxetine, bupropion, and nefazodone. An advantage of TCAs is that plasma levels may be used to help guide dosing, especially for those that have well-defined therapeutic plasma level ranges, including nortriptyline (50–150 ng/mL [mcg/L; 190–570 nmol/L]), desipramine (100–160 ng/mL [mcg/L; 375–601 nmol/L]), amitriptyline (75–175 ng/mL [mcg/L; 270–631 nmol/L]), and imipramine (200–300 ng/mL [mcg/L; 713–1070 nmol/L]).

### Efficacy of Pharmacotherapy

KEY CONCEPT *Each antidepressant has a response rate of approximately 60% to 80%, and no antidepressant medication or class has been reliably shown to be more efficacious than another.*[20] MAOIs may be the most effective medication for atypical depression, but MAOI use continues to wane because of adverse effects, dietary and drug restrictions, and the possibility of fatal drug interactions.[20] There is some evidence that dual-action antidepressants, such as TCAs and SNRIs, may be more effective in patients with severe depression than the single action drugs such as the SSRIs,[20] but the more general assertion that multiple mechanisms of action confer efficacy advantages is controversial.[35]

### Selection of Medication

Figure 38–1 depicts a well-known algorithm for the treatment of nonpsychotic MDD-the Texas Medication Algorithm Project

(TMAP).[36] Notable aspects of this algorithm include the preferential use of newer antidepressants in the earlier stages of treatment and sequential trials of antidepressant monotherapy prior to the use of combination therapy (see Managing Partial Response or Nonresponse.) Patients undergoing treatment guided by this algorithm fared better than those who received treatment not guided by the algorithm over a 1-year period. Antipsychotics should be combined with antidepressants in cases of depression with psychotic features.[37]

Various factors must be taken into account when selecting antidepressant therapy for a particular patient. The most reliable predictor of response is the patient's history of response (eg, efficacy, side effects, and overall satisfaction) to antidepressants. To a lesser extent, the history of a first-degree relative's response to antidepressants may be used to predict a patient's response. Adverse effect profiles should be considered, because compliance is influenced by tolerability. The patient is the best source of information regarding acceptability of adverse effects. Patients should be educated about how to deal with side effects (eg, using chewing gum, hard candy, or ice chips for dry mouth). The clinician must anticipate and be vigilant for potential drug–drug interactions and drug-disease interactions. For instance, a patient with a seizure disorder would be an inappropriate candidate for bupropion therapy. The presence of comorbid psychiatric conditions can suggest the best antidepressant to choose. For example, an SSRI can treat both MDD and panic disorder, obviating the need for two separate medications. Fluvoxamine, an SSRI, is marketed for obsessive compulsive disorder, although it also treats depression. The potential for accidental or intentional overdose and affordability of the medication also influence drug selection.[20]

### Time Course of Response

Antidepressants do not produce an immediate clinical response. Improvement in physical symptoms such as sleep, appetite, and energy, can occur within the first or second week of treatment. Although a meta-analysis suggests earlier effects of antidepressant treatment, KEY CONCEPT *it is widely accepted that approximately 2 to 4 weeks of treatment is required before improvement is seen in emotional symptoms such as sadness and anhedonia. As long as 6 to 8 weeks may be required to see full antidepressant effects.*[20,31]

### Managing Partial or No Response

Approximately one-third of patients with MDD do not respond satisfactorily to their first antidepressant medication.[37] In such cases, the clinician must evaluate the adequacy of antidepressant therapy, including dosage, duration, patient compliance, verification of the patient's diagnosis, and reconsideration of clinical factors that could be impeding successful therapy, such as concurrent medical conditions (eg, thyroid disorder), comorbid psychiatric conditions (eg, alcohol abuse), and psychosocial issues (eg, marital stress).[38]

A series of reports from the Sequenced Treatment Alternatives to Relieve Depression (STAR*D) trial revealed that remission is associated with a better overall prognosis than improvement alone. STAR*D also established that in patients with a greater level of nonresponse to treatment, clinicians are less likely to push the patient to achieve remission, and in addition, those patients with the greatest levels of nonresponse had the highest rates of relapse. STAR*D established some successful treatment recommendations.[39] For patients experiencing a partial response, extending the medication trial and/

| Table 38–6 |
|---|

**Dosing of Antidepressants in Adults**

| Generic Name | Brand Name | Generic | Initial Dose (mg/day) | Usual Dosing Range (mg/day) | Usual Dosage Schedule | Renal Dosing Adjustment | Hepatic Dosing Adjustment |
|---|---|---|---|---|---|---|---|
| **MAOIs** | | | | | | | |
| Phenelzine | Nardil | Yes | 15–30 | 15–90 | Twice daily | None | None |
| Selegiline | Emsam | No | 6 | 6–12 | Once daily | None | None |
| Tranylcypromine | Parnate | Yes | 10–20 | 30–60 | Twice daily | None | None |
| Isocarboxazid | Marplan | No | 10–20 | 40–60 mg | Twice daily | None | None |
| **TCAs and Tetracyclics** | | | | | | | |
| Amitriptyline | Elavil[a] | Yes | 25–50 | 100–300 | Once or twice daily | Nondialyzable | Use with caution |
| Amoxapine | Asendin[a] | Yes | 25–50 | 100–400 | Once to twice daily | None | None |
| Clomipramine | Anafranil | Yes | 25 | 100–250 | Once daily | Use with caution | None |
| Desipramine | Norpramin | Yes | 25–50 | 100–300 | Once or twice daily | None | Use with caution |
| Doxepin | Sinequan[a] | Yes | 25–50 | 100–300 | Once or twice daily | Use with caution | Use a lower dose |
| Imipramine | Tofranil | Yes | 25–50 | 100–300 | Once daily | Use with caution | None |
| Maprotiline | Ludiomil[a] | Yes | 50–75 | 100–225 | Once to twice daily | None | None |
| Nortriptyline | Pamelor | Yes | 25 | 50–150 | Once daily | Use with caution | Use a lower dose |
| Protriptyline | Vivactil | No | 5–10 | 15–60 | Once daily | Use with caution | Use with caution |
| Trimipramine | Surmontil | Yes | 25–50 | 100–300 | Once or twice daily | Use with caution | Use with caution |
| **SSRIs** | | | | | | | |
| Citalopram | Celexa | Yes | 20 | 20–40[b] | Once daily | No adjustment for clcr > 20 mL/min (0.33 mL/s); for clcr < 20 mL/min (0.33 mL/s), use with caution | 20 mg/day maximum; may increase to 40 mg in nonresponders |
| Escitalopram | Lexapro | Yes | 10 | 10–20 | Once daily | No adjustment for clcr > 20 mL/min (0.33 mL/s); for clcr < 20 mL/min (0.33 mL/s), use with caution | 10 mg/day |
| Fluoxetine | Prozac | Yes | 10–20 | 20–80 | Once daily | None | Use lower or less frequent dosing |
| | Prozac weekly | Yes | 90 | 90 | Once weekly | None | Use lower or less frequent dosing |
| Fluvoxamine | Luvox | Yes | 50 | 50–300 | Twice daily | None | Reduce dose |
| | Luvox CR | Yes | 100 | 100–300 | Once daily | None | Reduce dose |
| Paroxetine | Paxil | Yes | 10–20 | 20–50 | Once daily | In ClCr < 30 mL/min (0.50 mL/s) 10 mg/day increase weekly to a dose of 40 mg/day or less | Severe impairment, 10 mg daily; increase weekly to dose of 40 mg/day |
| | Paxil CR | Yes | 12.5–25 | 25–62.5 | Once daily | In ClCr < 30 mL/min (0.50 mL/s), 12.5 mg daily initially; may increase weekly to a dose of 50 mg/day or less | Severe impairment, 12.5 mg daily, increase weekly to dose of 40 mg/day or less |
| Sertraline | Zoloft | Yes | 25–50 | 50–200 | Once daily | None | Use a lower dose |
| **NDRI** | | | | | | | |
| Bupropion | Wellbutrin | Yes | 150–200 | 300–450[c] | Twice to thrice daily | Consider lower dose | 75 mg/day |
| | Wellbutrin SR | Yes | 150 | 300–400[c] | Twice daily | Consider lower dose | 100 mg/day or 150 mg every other day |
| | Wellbutrin XL | Yes | 150 | 300–450[c] | Once daily | Consider lower dose | 150 mg every other day |

*(Continued)*

### Table 38–6

**Dosing of Antidepressants in Adults (*Continued*)**

| Generic Name | Brand Name | Generic | Initial Dose (mg/day) | Usual Dosing Range (mg/day) | Usual Dosage Schedule | Renal Dosing Adjustment | Hepatic Dosing Adjustment |
|---|---|---|---|---|---|---|---|
| **SNRIs** | | | | | | | |
| Desvenlafaxine | Pristiq | No | 50 | 50–100 | Once daily | ClCr 30–50 mL/min (0.50 – 0.83 mL/s), 50 mg maximum daily dose, ClCr < 30 mL/min (0.50 mL/s), 50 mg every other day | 50 mg/day, 100 mg/day maximum |
| Duloxetine | Cymbalta | Yes | 40–60 | 40–60 | Once to twice daily | Use lower dose, not recommended for ClCr < 30 mL/min (0.50 mL/s) | Not recommended |
| Venlafaxine | Effexor | Yes | 37.5–75 | 75–375 | Once, twice or three times daily | Reduce dose 25%–50% | Reduce dose by 50% |
| | Effexor XR | Yes | 37.5–75 | 75–225 | Once daily | Reduce dose 25%–50% | Reduce dose by 50% |
| Levomilnacipran | Fetzima | No | 20 mg | 40–120 mg | Once daily | CrCl < 60 mL/min (1.0 mL/s), 80 mg/day maximum dose; CrCl < 30 mL/min (0.50 mL/s), 40 mg/day maximum dose | None |
| **SARIs** | | | | | | | |
| Nefazodone | Serzone[a] | Yes | 100–200 | 300–600 | Twice daily | Use with caution | Discontinue if ALT/AST is more than three times normal |
| Trazodone | Desyrel[a] | Yes | 50–150 | 200–600 | Twice daily | Use with caution | Use with caution |
| | Oleptro | No | 150 | 150–375 | Daily | Use with caution | Use with caution |
| **NaSSA** | | | | | | | |
| Mirtazapine | Remeron | Yes | 15 | 15–45 | Once daily | ClCr < 40 mL/min (0.67 mL/s), 30% decreased clearance ClCr < 10 mL/min (0.17 mL/s), 50% decreased clearance | Clearance decreased by 30%; monitor closely |
| **SRI/5-HT$_{1A}$** | | | | | | | |
| Vilazodone | Viibryd[c] | No | 10 | 20–40 | Once daily | None | Use with caution |
| Vortioxetine | Brintellix | No | 10 | 20 | Once daily | None | None |

[a]Brand no longer available in the United States.

[b]Maximum dose is 40 mg/day.

[c]Upper limit of this range is the maximum dose.

ALT, alanine aminotransferase; AST, aspartate aminotransferase; MAOI, ClCr, creatinine clearance; monoamine oxidase inhibitor; NaSSA, noradrenergic and specific serotonergic antidepressant; NDRI, norepinephrine and dopamine reuptake inhibitor; SARI, serotonin antagonist and reuptake inhibitor; SNRI, serotonin and norepinephrine reuptake inhibitor; SSRI, selective serotonin reuptake inhibitor; SRI/5-HT$_{2A}$, partial agonist-serotonin reuptake inhibitor/serotonin$_{2A}$ partial agonist; TCA, tricyclic antidepressant.

Data from Refs. 12, 19, 21, 33, and 39.

or using higher doses within the recommended dosage range may be helpful. Another option is augmentation therapy, ie, adding another medication that generally is not used as an antidepressant, such as, lithium, buspirone, or triiodothyronine.[40] Second-generationantipsychotics, aripiprazole, and the extended-release formulation of quetiapine, are approved by the FDA for augmenting partial response to antidepressants.[41]

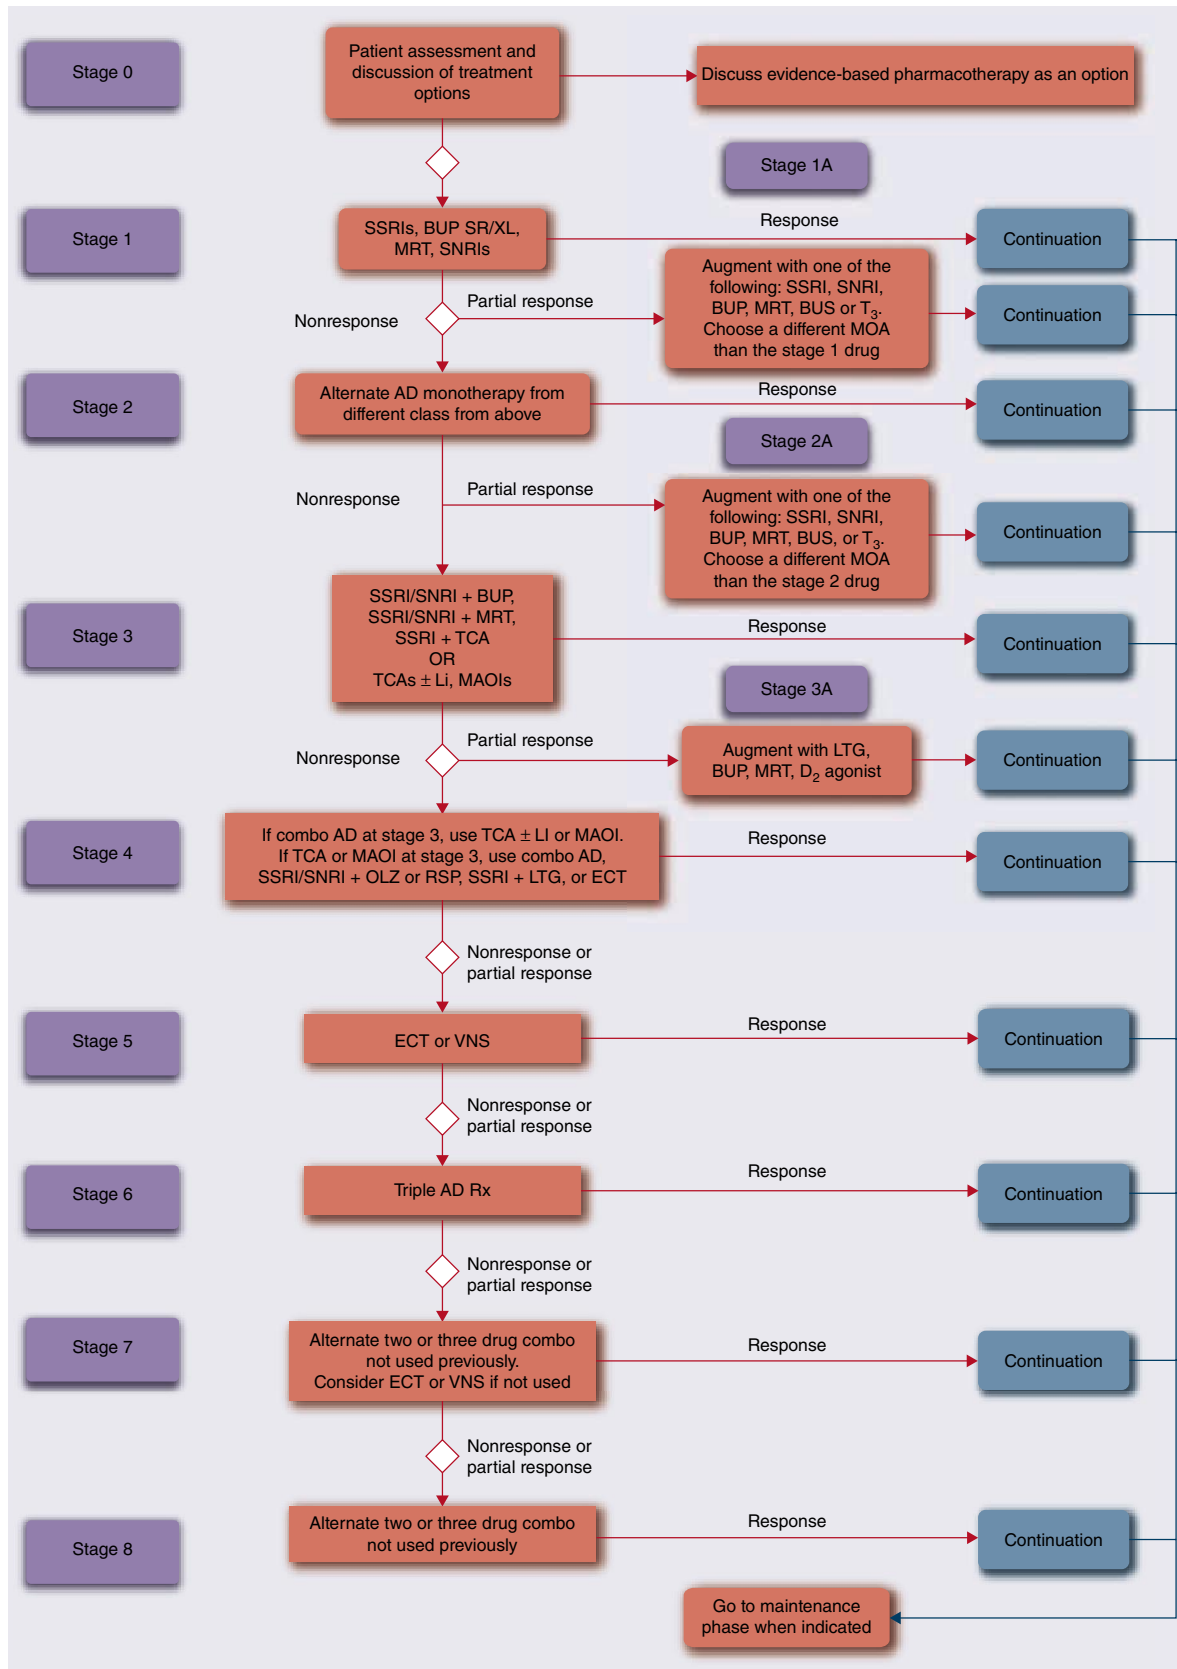
Whereas efficacy has been suggested for dopaminergic drugs (eg, pramipexole) and psychostimulants (eg, methylphenidate), various other medications such as anticonvulsants (eg, valproic acid), modafinil, and estrogen have anecdotal evidence supporting their use as augmenting agents. A third option is combination therapy, whereby another antidepressant, typically from a different pharmacologic class is added to the first


**FIGURE 38–1.** Strategies for the treatment of nonpsychotic major depression. (AD, antidepressant; BUP, bupropion; BUS, buspirone; ECT, electroconvulsive therapy; Li, lithium; $T_3$, liothyronine; LTG, lamotrigine; MAOI, monoamine oxidase inhibitor; MOA, mechanism of action; MRT, mirtazapine; OLZ, olanzapine; RSP, risperidone; Rx, prescription; SNRI, serotonin and norepinephrine reuptake inhibitor; SSRI, selective serotonin reuptake inhibitor; TCA, tricyclic antidepressant; VNS vagus nerve stimulation.) Redrawn with permission from the Texas Medication Algorithm Project.[35]

antidepressant.[42] Examples include combining bupropion and SSRIs or combining TCAs and SSRIs.

Switching to a different antidepressant is a common strategy for patients who have had no response to initial antidepressant therapy, but also is acceptable in cases of partial response. Relative to augmentation or combination therapy, advantages of switching include improved compliance, decreased costs, and less concern over drug–drug interactions. Disadvantages include loss of time, and loss of any improvement seen with the initial drug.[43] When switching from one antidepressant to another, clinicians may choose to stay within the same class (eg, sertraline to fluoxetine) or go outside of the class (eg, paroxetine to venlafaxine). The olanzapine-fluoxetine combination medication Symbyax has been approved for treatment–resistant depression.[43]

Nonpharmacologic interventions in cases of treatment nonresponse include adding or changing to psychotherapy or initiating ECT.

### Duration of Therapy

Treatment of MDD encompasses three phases: acute, continuation, and maintenance (Figure 38–2)[10] The goal of antidepressant therapy is remission of MDE symptoms. This acute phase of treatment typically lasts 6 to 12 weeks. **KEY CONCEPT** *Because the typical MDE lasts 6 months or longer, if antidepressant therapy is interrupted after the acute phase, the patient may relapse into a depressive episode. When treating the first depressive episode, antidepressants must be given for an additional 4 to 9 months in the continuation phase to prevent relapse.*

Maintenance treatment takes place after the normal course of a MDE to prevent recurrence, which is the development of future episodes. This phase can last for years, or for a lifetime. Although patients who have a MDE should receive acute and continuation treatment, not all of them require maintenance treatment, because not all patients experience multiple major depressive episodes. In some patients with multiple episodes, many years may separate the episodes. Therefore, the clinician must consider various factors in determining whether an individual requires maintenance treatment. A major factor is the number of prior episodes experienced by the patient. The more prior episodes experienced, the higher the risk for future episodes. After three or more MDEs, patients are generally given lifelong maintenance treatment because of the high (ie, 90%) chance of experiencing additional episodes. Other factors to consider are the severity

of previous episodes, if suicide attempts were made, whether psychotic features were present, and patient preference. The dose of the antidepressant required in the acute phase of treatment should be sustained during the continuation and maintenance phases.

### Discontinuation of Therapy

When discontinuing therapy, it is best to gradually taper the antidepressant for two reasons. First, almost all antidepressants can produce withdrawal syndromes if discontinued abruptly or tapered too rapidly, especially antidepressants with shorter half-lives (eg, venlafaxine, paroxetine, and fluvoxamine).[37] Withdrawal syndromes can cause sleep disturbances, anxiety, fatigue, mood changes, malaise, GI disturbances, and a host of other symptoms which often are confused with depressive relapse or recurrence.[37] In general, a tapering schedule involving a small dosage decrement (eg, paroxetine 5 mg) every 3 to 5 days should prevent significant withdrawal symptoms.[36] Second, depressive symptoms may return on taper or discontinuation of the antidepressant. So, if the medication is gradually tapered, then early signs of depression can be countered with a return to the original dosage and a potentially quicker response.[37] Depending on the patient's illness and the clinical circumstances, tapering of the antidepressant can be extended for weeks or even months because of the concern over relapse or recurrence.

### Special Considerations

#### ▶ Pregnant or Breastfeeding Patients

Depression is quite common in pregnancy, especially for women with a history of recurrent depression. Both maternal and fetal well-being must be considered when weighing risks and benefits of antidepressant therapy during pregnancy. While somewhat controversial, the prescribing information for paroxetine was changed to reflect findings of an increased risk of congenital malformations, particularly atrial and ventricular septal defects, in infants born to women taking the drug during the first trimester. Sertraline and citalopram have also been associated with septal heart defects when taken during the first trimester. In addition, the incidence of having a baby with a septal heart defect was four times higher for mothers taking more than one SSRI in the first trimester. More recent studies have questioned these results.[43]

**FIGURE 38–2.** The course of depression and phases of treatment. Data from Refs. 10 and 19.

---

**Patient Encounter, Part 3: Creating a Care Plan**

*On the basis of information presented, create a care plan. Your plan should include:*

(a) *A statement of the drug-related needs and/or problems.*

(b) *The goals of therapy.*

(c) *A patient-specific detailed therapeutic plan.*

(d) *A plan for follow-up to determine whether the goals have been achieved.*

---

Antidepressants are reported to occasionally cause perinatal sequelae, such as poor neonatal adaptation, respiratory distress, feeding problems, and jitteriness. Data on the long-term effects of in utero antidepressant exposure are limited. Sertraline, fluoxetine, citalopram, and the TCAs have the greatest reproductive safety data and should be considered first-line treatments when pharmacotherapy is indicated.[44]

There is some drug exposure to the infant from nursing mothers who are taking antidepressants. Although there have been rare anecdotal reports of adverse effects (ie, respiratory depression and seizure-like episodes) in infants exposed to antidepressants through breast milk, no rigorous study has confirmed this, and it is generally accepted that the benefits of breastfeeding outweigh the risks to the infant posed by antidepressant exposure.[44,45] However, the decision needs to be made on an individual basis.

▶ *Geriatric Patients*

Depression in older adults is under recognized and under-treated.[46] Although not uncommon in community samples, MDD is prevalent among those living in long-term care facilities. Barriers to recognition of geriatric depression include "masked" presentations, that is complaints of physical symptoms (eg, pain and GI problems) instead of mood symptoms, the frequent presence of medical illnesses, and the overlap of mood and cognitive symptoms with those of dementia.[46] Age-related pharmacokinetic and pharmacodynamics changes cause geriatric patients to be more sensitive to antidepressant medications. Thus, lower starting doses of antidepressants and slow upward titrations as tolerated are recommended for geriatric patients.[46] The SSRIs are chosen frequently for geriatric depression because of their overall favorable adverse effect profiles and low toxicity; most TCAs are avoided due to problematic anticholinergic, cardiovascular, and sedative properties.[46] The TCAs desipramine and nortriptyline are more tolerable in terms of these adverse effects and may be used in geriatric depression. Other newer antidepressants, such as bupropion, venlafaxine, nefazodone, and mirtazapine, are alternatives for the treatment of geriatric patients.[46]

▶ *Pediatric Patients*

Antidepressant medications appear to be useful for certain children and adolescents, particularly those who have severe or psychotic depression, fail psychotherapy, or experience chronic or recurrent depression. Fluoxetine and escitalopram are the only antidepressants FDA approved for depression in children younger than 18 years.[47] The SSRIs generally are considered the initial antidepressants of choice, but comorbid

conditions may favor alternative agents. "Behavioral activation" can occur with the SSRIs, including such symptoms as impulsivity, silliness, daring conduct, and agitation.[45] Desipramine must be used with caution in this population because of several reports of sudden death, and baseline and follow-up electrocardiography is warranted when using desipramine in pediatric patients.

The FDA warns that antidepressants increase the risk of suicidality (ie, suicidal thinking and behavior) in children and young adults. A large analysis of clinical trials showed the risk of such events was 4% for antidepressants versus 2% for placebo, although no completed suicides occurred in the trials. Because antidepressants carry a black-box warning regarding suicidality, medication guides must be distributed with each prescription or refill of antidepressants. **KEY CONCEPT** *Pediatric patients and young adults should be observed closely for suicidality, worsened depression, agitation, irritability, and unusual changes in behavior, especially during the initial few months of therapy and at times of dosage changes. Furthermore, families and caregivers should be advised to monitor patients for such symptoms.*[48]

▶ *Suicidal Patients*

The FDA has determined that in addition to children and adolescents, there is an increased risk of suicidality in patients between the ages of 18 and 24 years. Similar monitoring for suicidality and clinical worsening that is mandated for pediatric patients should also be followed for these young adult patients.[49]

Whereas the TCAs and MAOIs have narrow therapeutic indices, the SSRIs, SNRIs, nefazodone, and mirtazapine have wide therapeutic indices.

● **Patient Counseling**

Major counseling points are outlined in Table 38–7. **KEY CONCEPT** *Lack of patient understanding concerning optimal antidepressant therapy frequently leads to partial or noncompliance with therapy, thus the primary purpose of antidepressant counseling is to enhance compliance and improve outcomes.*[50]

● **OUTCOME EVALUATION**

**Symptom Assessment**

The patient interview should assess response of target symptoms. Rating scales are useful in this regard. The Hamilton Depression Scale (HAM-D) is a 17-item, clinician administered scale where less than 6 corresponds with normal mood, and greater than 25 is associated with severe depression. The Beck Depression Inventory (BDI) is a patient-rated scale where 9 or less is associated with normal mood, and 20 to 29 corresponds to moderate to severe depression. The Patient Health Questionnaire (PHQ-9) is a 9-item scale which rates 4 or less as normal mood and greater than 20 as severe depression.

**Patient Education**

Patients should be educated that while they may see some improvement in some symptoms like sleep and appetite as early as the first week, generally at least 4 to 8 weeks is required for optimal mood changes to occur. Patients should also recognize common side effects including, how long those side effects might last, and if there are any simple remedies for treatment (eg, using ice chips or sugarless gum for a dry mouth).

## Table 38–7

**Patient Counseling**

| Counseling Point | Clinical Rationale |
|---|---|
| Mechanism of action—The medication works by affecting certain chemicals in the brain | Patient may feel that depression is a character weakness or personality flaw instead of a biological disorder |
| Lack of addiction potential—Although the medication affects certain chemicals in the brain, it is not addicting | Patient may worry that because the antidepressant is psychoactive, it must be addicting |
| Need for routine use—The medication will only work if it is taken as prescribed every day | Patient may try taking the medication on an as-needed basis |
| Delayed onset of action—It may take several weeks to see significant improvement in symptoms | Patient may prematurely discontinue therapy before the onset of beneficial effects |
| Prolonged duration of therapy—The medication should be taken for at least 6–12 months; do not discontinue it without consulting with the prescriber | Patient may prematurely discontinue therapy after symptoms have remitted, which could lead to relapse or recurrence |
| Adverse effects—Mention common and expected adverse effects as well as what to do if they occur | Patient may be more likely to discontinue therapy and distrust the prescriber if adverse effects occur without forewarning |
| Avoidance of alcohol and CNS depressants—Use of alcohol or other CNS depressants could cause worsened depression and additive adverse effects with the medicine | Patient may be unaware of the possible consequences of drinking alcohol or taking other drugs with antidepressants |
| Risk of suicidality—Be alert to symptoms of worsening depression and suicidality | Patient may become suicidal or have suicidal thinking while taking the antidepressant |

CNS, central nervous system.

Data from Refs. 19 and 50.

## Monitoring Adverse Effects

Evaluation for suicidal ideation should be a part of every patient visit. Patients can be taught to manage side effects such as sedation, constipation, and dry mouth. Potential side effects such as weight gain and sexual dysfunction should be discussed with the patient and monitored at each visit. Venlafaxine may increase blood pressure, and patients should have their blood pressure checked at each visit. Patients with cardiovascular risk factors or over the age of 40 should have an electrocardiogram (ECG) completed prior to initiating a TCA. Patients taking TCAs such as amitriptyline, imipramine, nortriptyline, or desipramine should have antidepressant serum levels checked if overdose, side effects, or nonadherence is an issue. Patients should be monitored for serotonin syndrome if they are taking two or more serotonergic medications.

## Patient Care Process

**Patient Assessment:**

- Determine if the patient is experiencing symptoms of depression.
- Review the medical history. Does the patient have any medical problems that might cause the current symptoms?
- Conduct a medication history (including prescriptions, OTC medications, and dietary supplements) to identify possible causes of depression.
- Review available laboratory tests, especially thyroid function tests, renal and hepatic function.

**Therapy Evaluation:**

- Determine if antidepressant therapy is needed.
- Evaluate past history of depression treatment, including response and adverse effects.
- Assess efficacy, safety, and adherence to current pharmacotherapy.

- Ensure that the patient can afford and access prescribed medications.

**Care Plan Development:**

- Choose lifestyle modifications and antidepressant therapy that are safe and effective.
- Determine if the drug dosage is optimal for treatment. Take an algorithmic approach to treatment (see Figure 38–1).
- Address patient concerns.
- Discuss with the patient the importance of medication adherence and lifestyle modifications.

**Follow-up Evaluation:**

- Follow-up to assess effectiveness and safety of therapy.
- Monitor the patient every 3 to 6 months to assess for return of symptoms. Determine if patient is experiencing any adverse effects or drug interactions.

## Abbreviations Introduced in This Chapter

| | |
|---|---|
| BDI | Beck Depression Inventory |
| BDNF | Brain derived neurotrophic factor |
| CNS | Central nervous system |
| DA | Dopamine |
| *DSM-5* | *Diagnostic and Statistical Manual of Mental Disorders, 5th edition* |
| ECG | Electrocardiogram |
| ECT | Electroconvulsive therapy |
| FDA | Food and Drug Administration |
| GI | Gastrointestinal |
| HAM-D | Hamilton Depression Scale |
| HPA | Hypothalamic pituitary axis |
| 5-HT | Serotonin |
| MAOI | Monoamine oxidase inhibitor |
| MDD | Major depressive disorder |
| MDE | Major depressive episode |
| NaSSA | Noradrenergic and specific serotonergic antidepressant |
| NDRI | Norepinephrine and dopamine reuptake inhibitor |
| NE | Norepinephrine |
| NRI | Norepinephrine Reuptake Inhibitor |
| PHQ-9 | Patient Health Questionairre-9 |
| SAM-e | S-adenosyl methionine |
| SARI | Serotonin antagonist and reuptake inhibitor |
| SNRI | Serotonin and norepinephrine reuptake inhibitor |
| SRI | Serotonin reuptake inhibition |
| SSRI | Selective serotonin reuptake inhibitor |
| STAR*D | Sequenced Treatment Alternatives to Relieve Depression |
| TCA | Tricyclic antidepressant |
| TMAP | Texas Medication Algorithm Project |
| VEGF | Vascular endothelial growth factor |
| VNS | Vagus nerve stimulation |
| WHO | World Health Organization |

# 39 Bipolar Disorder

Brian L. Crabtree and Lydia E. Weisser

## LEARNING OBJECTIVES

● **Upon completion of the chapter, the reader will be able to:**

1. Explain the pathophysiologic mechanisms underlying bipolar disorder.
2. Recognize the symptoms of a manic episode and depressive episode in patients with bipolar disorder.
3. Identify common comorbidities of bipolar disorder.
4. Recognize the *Diagnostic and Statistical Manual of Mental Disorders,* 5th edition, criteria for bipolar disorder as well as the subtypes of bipolar I disorder, bipolar II disorder, and cyclothymic disorder.
5. List the desired therapeutic outcomes for patients with bipolar disorder.
6. Explain the use of drugs as first-line therapy in bipolar disorder, including appropriate dosing, expected therapeutic effects, potential adverse effects, and important drug–drug interactions.
7. Recommend individualized drug therapy for acute treatment and relapse prevention based on patient-specific data.
8. Recommend monitoring methods for assessment of therapeutic and adverse effects of drugs used in the treatment of bipolar disorder.
9. Recommend treatment approaches for special populations of patients with bipolar disorder, including pediatric patients, geriatric patients, and pregnant patients.
10. Educate patients with bipolar disorder about their illness, drug therapy required for effective treatment, and the importance of adherence.

## INTRODUCTION

Bipolar disorder is characterized by one or more episodes of mania or **hypomania**, often with a history of one or more major depressive episodes.[1] It is chronic, with relapses and remissions. Mood episodes can be manic, depressed, or mixed. They can be separated by periods of long stability or cycle rapidly. They occur with or without psychosis. Disability and other consequences (eg, increased risk of suicide) can be devastating to patients and families. Correct and early diagnosis and treatment are essential to prevent complications and maximize response to treatment.

## EPIDEMIOLOGY AND ETIOLOGY

### Epidemiology

Bipolar disorders are categorized into bipolar I disorder, bipolar II disorder, and other specified and unspecified bipolar and related disorders. Bipolar I disorder is characterized by one or more manic or **mixed mood episodes**. Bipolar II disorder is characterized by one or more major depressive episodes and at least one hypomanic episode. Hypomania is an abnormally and persistently elevated, expansive, or irritable mood but not of sufficient severity to cause significant impairment and does not require hospitalization. The lifetime prevalence of bipolar I disorder is estimated at 0.6%. The lifetime prevalence of bipolar II disorder is about 0.4%. When including the entire spectrum of bipolar disorders, the prevalence is approximately 3%.[2]

Bipolar I disorder affects men and women equally. Bipolar II is more common in women. Rapid cycling and mixed mood episodes occur more in women. In all, 78% to 85% of individuals with bipolar disorder report having another *Diagnostic and Statistical Manual*, 5th edition (*DSM-5*), diagnosis during their lifetime. The most common comorbid conditions are anxiety, substance abuse, and impulse control disorders. Medical comorbidities are common.[2]

The mean age of onset is 20 years, although onset may occur in early childhood to the mid-40s.[1] If onset occurs after age 60, it is probably due to medical causes. An early onset is associated with greater comorbidities, more mood episodes, a greater proportion of days depressed, and greater lifetime risk of suicide attempts compared with later onset. Substance abuse and anxiety disorders are more common in patients with early onset. Patients with bipolar disorder have higher rates of suicidal thoughts, attempts, and completed suicides than the general population.

### Etiology

The precise etiology is unknown. Thought to be genetically based, bipolar disorder is influenced by a variety of factors that may enhance gene expression. These include trauma, environmental factors, anatomical abnormalities, and exposure to chemicals or drugs.[3,4]

## Patient Encounter, Part 1

**Chief Complaint:** "My family thinks there is something wrong with me."

**HPI:** Joan is a 20-year-old college student who is brought by her family following spring break. The patient states she has only come for the appointment because her family insisted and was concerned because she was "not acting like myself." She denies any physical problems except mild hypertension and recently underwent a complete physical examination by her primary care physician. Screening laboratory studies including metabolic profile, complete blood count, thyroid function, B12 and folate, electrocardiogram, and chest x-ray were generally unremarkable except for an elevated BUN of 24 mg/dL (8.6 mmol/L) and elevated serum creatinine of 2.1 mg/dL (186 μmol/L). Joan was subsequently referred to a psychiatrist for further evaluation.

Joan is a single, well-nourished, well-developed African American woman appearing her stated age. She is attired in a low-cut blouse and short skirt, very high heels, and is wearing bright lipstick, false eyelashes, purple eye shadow,

and an excessive amount of perfume. She seems to have difficulty maintaining an appropriate social distance during the interview and is at times flirtatious and somewhat seductive. Her speech is rapid and difficult to interrupt, and she is quite distractible. Joan says she feels "fantastic" and has lost 8 lb (3.6 kg) over the past 2 weeks without making a conscious effort. She states she is very energetic and enjoyed partying with her friends over spring break, getting approximately 1 to 2 hours of sleep each night but feeling fine the following day. Although Joan has been an excellent student in the past, her grades this semester have been slipping, as she has found it difficult to complete assignments and is now in danger of failing. She states she is not concerned about her classes as she is considering going to New York to become a model. Although Joan has always been a good money manager, recently she has gone on extensive shopping sprees, buying clothing and jewelry she cannot afford.

*What diagnoses are suggested by this patient's presentation?*

*What additional information is needed to clarify the diagnosis?*

## PATHOPHYSIOLOGY

### Neurochemical

The pathophysiology remains incompletely understood. Imaging techniques such as positron emission tomography (PET) scans and functional magnetic resonance imaging (fMRI) are used to elucidate the cause. Historically, research focused on neurotransmitters such as norepinephrine (NE), dopamine (DA), and serotonin. One hypothesis is that bipolar disorder is caused by an imbalance of cholinergic and catecholaminergic activity. Serotonin is suggested to modulate catecholamines. Dysregulation of this relationship could cause mood disturbance. A variety of neurotransmitters are involved that interact with multiple neurochemical and neuroanatomic pathways.[3] The pathophysiology is also hypothesized from the mechanisms of lithium and other drugs. Lithium, valproate, and carbamazepine all have similar effects on neuronal growth that are reversible by inositol, supporting a hypothesis that bipolar disorder may be related to inositol disturbance.[5] Brain-derived neurotrophic factor (BDNF) may play a role in bipolar disorder. Serum BDNF is low in mania and improves with treatment.[6]

### Genetic

Results of family studies suggest a genetic basis.[4] Lifetime risk of bipolar disorder in relatives of a bipolar patient is 40% to 70% for a monozygotic twin and 5% to 10% for other first-degree relatives.

## CLINICAL PRESENTATION AND DIAGNOSIS

### Diagnosis of Bipolar Disorder

**KEY CONCEPT** *Patients presenting with depressive or elevated mood features and a history of abnormal or unusual mood swings should be assessed for bipolar disorder.* Bipolar disorder is categorized into four subtypes: bipolar I (periods of major depressive, manic, and/or mixed episodes); bipolar II (periods of major depression and hypomania), cyclothymic disorder (periods of hypomanic episodes and depressive episodes that do not meet all criteria for diagnosis of a major depressive episode), and other specified and

unspecified bipolar and related disorders. The defining feature of bipolar disorder is one or more manic or hypomanic episodes in addition to depressive episodes that are not caused by a medical condition, substance abuse, or other psychiatric disorder.[1]

Initial and subsequent episodes are mostly depressive.[7] Studies show bipolar I patients spend about 32% of weeks with depressive symptoms compared with 9% of weeks with manic or hypomanic symptoms.[8] Patients with bipolar II disorder spend 50% of weeks symptomatic for depression and only 1% with hypomania.[9] Because patients may present with depression and spend more time depressed than with mood elevation, bipolar disorder is often misdiagnosed or underdiagnosed. It is helpful to use a screening tool such as the mood disorder questionnaire.[10]

*DSM-5* criteria for the diagnosis of bipolar disorder are summarized in Table 39–1.

#### ▶ Bipolar I Disorder

The diagnosis of bipolar I disorder requires at least one episode of mania for at least 1 week with a persistently elevated, expansive, or irritable mood with related symptoms of decreased need for sleep, excessive energy, racing thoughts, a propensity to be involved in high-risk activities, and excessive talkativeness.[1] Bipolar I depression can be misdiagnosed as major depressive disorder (MDD); therefore, it is essential to rule out past episodes of hypomania or mania. If bipolar depression is mistaken for MDD and the patient is treated with antidepressants, it can precipitate a manic episode or induce rapid cycling.

#### ▶ Bipolar II Disorder

The distinguishing feature of bipolar II disorder is a current or past hypomanic episode and a current or past major depressive episode. Irritability and anger are common. There cannot have been a prior full-manic episode.[1]

#### ▶ Cyclothymic Disorder

Cyclothymic disorder is a chronic mood disturbance lasting at least 2 years (1 year in children and adolescents) and characterized

| Table 39–1 | | |
| --- | --- | --- |
| **Evaluation of and Diagnostic Criteria for Mood Episodes** | | |
| Diagnostic workup depends on clinical presentation and findings | | • Mental status examination<br>• Psychiatric, medical, and medication history<br>• Physical and neurologic examination<br>• Basic laboratory tests: CBC, blood chemistry screen, thyroid function, urinalysis, urine drug screen<br>• Psychological testing<br>• Brain imaging: MRI and fMRI; alternative: CT, PET<br>• Lumbar puncture<br>• Electroencephalogram |
| Diagnosis episode | Impairment of functioning or need for hospitalization[a] | *DSM-5* criteria[b] |
| Major depressive | Yes | Greater than or equal to 2-week period of either depressed mood or loss of interest or pleasure in normal activities, associated with at least five of the following symptoms:<br>• Depressed, sad mood (adults); can be irritable mood in children<br>• Decreased interest and pleasure in normal activities<br>• Decreased appetite, weight loss<br>• Insomnia or hypersomnia<br>• Psychomotor retardation or agitation<br>• Decreased energy or fatigue<br>• Feelings of guilt or worthlessness<br>• Impaired concentration and decision making<br>• Suicidal thoughts or attempts |
| Manic | Yes | Greater than or equal to 1-week period of abnormal and persistently elevated mood (expansive or irritable), associated with at least three of the following symptoms (four if the mood is only irritable):<br>• Inflated self-esteem (grandiosity)<br>• Racing thoughts (FOI)<br>• Distractible (poor attention)<br>• Increased activity (either socially, at work, or sexually) or increased motor activity or agitation<br>• Excessive involvement in activities that are pleasurable but have a high risk for serious consequences (buying sprees, sexual indiscretions, poor judgment in business ventures) |
| Hypomanic | No | At least 4 days of abnormal and persistently elevated mood (expansive or irritable); associated with at least three of the following symptoms (four if the mood is only irritable):<br>• Inflated self-esteem (grandiosity)<br>• Decreased need for sleep<br>• Increased talking (pressure of speech)<br>• Racing thoughts (FOI)<br>• Increased activity (either socially, at work, or sexually) or increased motor activity or agitation<br>• Excessive involvement in activities that are pleasurable but have a high risk for serious consequences (buying sprees, sexual indiscretions, poor judgment in business ventures) |
| Mixed | Yes | Criteria for both a major depressive episode and manic episode (except for duration) occur nearly every day for at least a 1-week period |
| Rapid cycling | Yes | At least four mood episodes (depressive, manic, mixed, or hypomanic) in 12 months |

FOI, flight of ideas.

[a]Impairment in social or occupational functioning; need for hospitalization because of potential self-harm, harm to others, or psychotic symptoms.

[b]The disorder is not caused by a medical condition (eg, hypothyroidism) or substance-induced disorder (eg, antidepressant treatment, medications, electroconvulsive therapy).

Data from American Psychiatric Association. Diagnostic and Statistical Manual of Mental Disorders. 5th ed. Washington, DC: American Psychiatric Press; 2013 and Drayton SJ, Pelic CM. Bipolar disorder. In: DiPiro JT, Talbert RL, Yee GC, et al, eds. Pharmacotherapy: A Pathophysiologic Approach. 9th ed. New York, NY: McGraw-Hill. 2014; 1067–1081.

## Patient Encounter, Part 2: Medical History, Physical Exam, Laboratory Exam

Your interview reveals the following information:

**PMH:** No known medical problems except a history of hypertension marginally controlled by hydrochlorothiazide 50 mg/day. Joan also admits to being treated for chlamydia last year

**PPH:** Noncontributory

**FH:** Parents alive and well. The patient's maternal grandmother was hospitalized several times at the state psychiatric hospital for treatment of unspecified mental illness in the remote past. A maternal aunt committed suicide 5 years ago. The patient's father is a recovering alcoholic who regularly attends AA. The patient has one brother and sister in good health

**SH:** Joan admits to numerous sexual partners beginning at the age of 18 when she first went away to college. She states none of her relationships has lasted more than a few weeks, although she would like to eventually get married. She is presently majoring in mathematics and previously aspired to be a high school teacher; however, she has failing grades in most of her classes this semester. Her roommates have complained about her coming in late at night and have also complained about Joan's use of drugs in their apartment. Joan admits to partying several nights each week as well as more on weekends

**SUH:** The patient denies use of tobacco products, hallucinogens, amphetamines, opioids, benzodiazepines, or intravenous drugs. She does admit to smoking marijuana on a daily basis, has experimented with cocaine in the past, and drinks heavily on the weekends. She does not drink coffee but consumes several cans of caffeinated soda each day. She denies use of vitamins or herbal supplements

**Meds:** Hydrochlorothiazide 50 mg by mouth daily

**ROS:** Decreased appetite with recent 8 lb (3.6 kg) weight loss, decreased need for sleep, increased energy, distractibility, pressured speech, hypersexuality. LMP 2 weeks ago

**PE:**

**VS:** BP 150/90, P 94, RR 18, T 98.7°F (37.1°C)

**HEENT:** PERRLA. Extraocular movements intact. Nares patent. Ear canals patent and eardrums easily visualized. Neck supple without JVD, bruits, or lymphadenopathy. Thyroid smooth, symmetric and nontender

**CV:** Heart with regular rate and rhythm; no murmurs, gallops or rubs

**Abdomen:** Soft, nontender, without organomegaly or masses. Positive bowel sounds in all four quadrants

**Exts:** Without clubbing, cyanosis, or edema. Peripheral pulses full and equal bilaterally

**CN:** II-XII intact

**Labs:** Urine drugs screen + for THC; HIV negative; serum β-HCG negative

*Considering this additional information, what is the most likely diagnosis?*

---

by mood swings that include periods of hypomanic symptoms that do not meet the criteria for a hypomanic episode and depressive symptoms that do not meet the criteria for a major depressive episode. Hypomanic symptoms include inflated self-esteem or **grandiosity** (nondelusional), decreased need for sleep, pressured speech, **flight of ideas (FOI)**, distractibility, and increased involvement in goal-directed activities, not causing severe impairment or requiring hospitalization. Psychotic features are not present.[1]

### ▶ Suicide

Patients with bipolar disorder have high risk of suicide. Factors that increase risk are early age at onset, high number of depressive episodes, comorbid alcohol abuse, personal history of antidepressant-induced mania, and family history of suicidal behavior. About one-third of individuals with bipolar disorder report a previous attempt.[11] One of five attempts is fatal, in contrast to one of 10 to one of 20 in the general population.

### ▶ Differential Diagnosis

Schizophrenia and bipolar disorder share certain symptoms, including psychosis in some patients. The prominence of mood symptoms and the history of mood episodes distinguish bipolar disorder and schizophrenia. In addition, psychosis of schizophrenia occurs in the absence of prominent mood symptoms. Schizoaffective disorder may also be considered when developing a differential diagnosis. Schizoaffective disorder is characterized by a period of illness during which there is a major depressive episode or a manic episode, concurrent with symptoms that meet criterion A for schizophrenia (eg, delusions, hallucinations, disorganized speech, grossly disorganized or catatonic behavior, and/or negative symptoms such as affective flattening, alogia, or avolition). During the same period of illness, there have been delusions or hallucinations for at least 2 weeks in the absence of prominent mood symptoms.[1]

Personality disorders are inflexible and maladaptive patterns of behavior that deviate markedly from expectations of society beginning in adolescence or early adulthood.[1] Personality disorders and bipolar disorder may be comorbid, and patients with personality disorders may have mood symptoms. The two diagnoses are distinguished by the predominance of mood symptoms and the episodic course of bipolar disorder in contrast to the stability and persistence of the behavioral patterns of personality disorders.

### ▶ Comorbid Psychiatric and Medical Conditions

Lifetime prevalence rates of comorbidity with bipolar disorder are as high as 58%.[2] Comorbidities, especially substance abuse, make establishing a diagnosis more difficult and complicate treatment. Comorbidities also place the patient at risk for a poorer outcome, high rates of suicidality, onset of depression, and higher costs of treatment.[1] Psychiatric comorbidities include:

- Personality disorders
- Alcohol and substance abuse or dependence
- Anxiety disorders
- Panic disorder

## Clinical Presentation and Diagnosis

Patients presenting with depressive or elevated mood features and a history of abnormal or unusual mood swings should be assessed for bipolar disorder.

### General

The patient may present in a hypomanic, manic, depressed, or mixed state and may or may not be in acute distress.

### Symptoms

*Mood and Affect:*
- Mood elevation
- Expansive mood
- Irritable mood
- Depression
- Hopelessness
- Suicidality

*Physical and Behavioral:*
- Agitation
- Impulsivity
- Aggression
- Rapid, pressured speech
- Insomnia (sometimes for days or weeks)
- Hypersexuality
- Increased physical energy
- Inflated self-esteem, boasting, grandiosity
- Heightened interest in pleasurable activities with a high risk of negative consequences (eg, spending sprees, promiscuity)
- Fatigue
- Hypersomnia

*Thought Processes, Content, and Perceptions:*
- Racing thoughts, FOI, distractibility
- Delusions of grandeur, ideas of reference, persecution, wealth, religion

*Psychosocial*
- Substance use
- Disrupted relationships
- Job loss

### Laboratory and Other Diagnostic Assessments

**KEY CONCEPT** *The diagnosis of bipolar disorder is made based on clinical presentation, a careful diagnostic interview, and a review of the history. There are no laboratory examinations, brain imaging studies, or other procedures that confirm the diagnosis, but such testing can be done to rule out other medical diagnoses.*

- Urinalysis with culture, urine drug toxicology, thyroid function, and complete blood count in elderly patients to rule out infection and anemia
- Mood disorder questionnaire, completed by the patient, asks about common symptoms of bipolar disorder, problems caused by the symptoms, and family history in a "yes" or "no" answer format. It is then scored by the clinician

*Suicidality risk is increased in the presence of:*
- Substance abuse
- Prior suicide attempts and lethality of attempts
- Access to a means of suicide
- Command hallucinations or psychosis
- Severe anxiety
- Family history of attempted or completed suicide

---

Data from Refs. 1 and 3.
FOI, flight of ideas.

- Obsessive-compulsive disorder
- Social phobia
- Eating disorders
- Attention-deficit/hyperactivity disorder

- Medical comorbidities include:
  - Migraine
  - Multiple sclerosis
  - Cushing syndrome
  - Brain tumor
  - Head trauma

## Patient Encounter, Part 3: Creating a Care Plan

*Based on all information presented, create a care plan for this patient's bipolar disorder. Your plan should include (a) a statement of the drug-related needs or problems, (b) the goals of therapy, (c) a patient-specific therapeutic plan, and (d) a plan for follow-up to assess therapeutic response and adverse effects.*

## TREATMENT

### Desired Outcomes

**KEY CONCEPT** *Goals of treatment are to reduce symptoms, induce remission, prevent relapse, improve patient functioning, and minimize adverse effects of drug therapy.*

### General Approach to Treatment

Treatment guidelines for manic and depressive episodes of bipolar disorder are included in Table 39–2.

| Table 39–2 | | | |
|---|---|---|---|
| **Guidelines for the Acute Treatment of Mood Episodes in Patients with Bipolar I Disorder** | | | |

| **Acute Manic or Mixed Episode** | | **Acute Depressive Episode** | |
|---|---|---|---|
| General guidelines<br>Assess for secondary causes of mania or mixed states (eg, alcohol or drug use)<br>Taper off antidepressants, stimulants, and caffeine if possible<br><br>Treat substance abuse<br>Encourage good nutrition (with regular protein and essential fatty acid intake), exercise, adequate sleep, stress reduction, and psychosocial therapy | | General guidelines<br>Assess for secondary causes of depression (eg, alcohol or drug use)<br>Taper off antipsychotics, benzodiazepines or sedative-hypnotic agents if possible<br>Treat substance abuse<br>Encourage good nutrition (with regular protein and essential fatty acid intake), exercise, adequate sleep, stress reduction, and psychosocial therapy | |

| **Hypomania** | **Mania** | **Mild to Moderate Depressive Episode** | **Severe Depressive Episode** |
|---|---|---|---|
| First, optimize current mood stabilizer or initiate mood-stabilizing medication: lithium,[a] valproate,[a] or carbamazepine.[a] Consider adding a benzodiazepine (lorazepam or clonazepam) for short-term adjunctive treatment of agitation or insomnia if needed | First, two- or three-drug combinations: lithium or valproate plus a benzodiazepine (lorazepam or clonazepam) for short-term adjunctive treatment of agitation or insomnia; lorazepam is recommended for catatonia. If psychosis is present, initiate atypical antipsychotic in combination with above | First, initiate and/or optimize mood-stabilizing medication: lithium,[a] lurasidone, olanzapine/ fluoxetine, quetiapine, or lamotrigine[b] | First, two- or three-drug combinations: lithium,[a] lurasidone, quetiapine, olanzapine/ fluoxetine, or lamotrigine[b] plus an antidepressant[c]; lithium plus lamotrigine |
| Alternative medication treatment options: carbamazepine[a]; If patient does not respond or tolerate, consider atypical antipsychotic (eg, olanzapine, quetiapine, risperidone) or oxcarbazepine | Alternative medication treatment options: carbamazepine[a]; If patient does not respond or tolerate, consider oxcarbazepine | Alternative anticonvulsants: valproate,[a] carbamazepine,[a] or oxcarbazepine | Alternative anticonvulsants: valproate;[a] carbamazepine,[a] or oxcarbazepine |
| | | | Second, if response is inadequate, consider adding an atypical antipsychotic (quetiapine, lurasidone) to mood stabilizer |
| | | | Third, if response is inadequate, consider a three-drug combination: |
| Second, if response is inadequate, consider a two-drug combination:<br>• Lithium[a] plus an anticonvulsant or an atypical antipsychotic<br>• Anticonvulsant plus an anticonvulsant or atypical antipsychotic | Second, if response is inadequate, consider a three-drug combination:<br>• Lithium plus antipsychotic plus an antidepressant<br>• Anticonvulsant plus an anticonvulsant plus an atypical antipsychotic<br>Third, if response is inadequate consider ECT for mania with psychosis or catatonia[a]; or add clozapine for treatment-refractory illness | | • Lithium plus lamotrigine[b] plus an antidepressant<br>• Lithium[a] plus an anticonvulsant plus an atypical antipsychotic<br>Fourth, if response is inadequate, consider ECT for treatment-refractory illness and depression with psychosis or catatonia[d] |

ECT, electroconvulsive therapy; MAOI, manoamine oxidase inhibitor; SNRI, serotonin-norepinephrine reuptake inhibitor; SSRI, selective serotonin reuptake inhibitor; TCA, tricyclic antidepressant.

[a]Use standard therapeutic serum concentration ranges if clinically indicated; if partial response or breakthrough episode, adjust dose to achieve higher serum concentrations without causing intolerable adverse effects; valproate is preferred over lithium for mixed episodes and rapid cycling; lithium and/or lamotrigine is preferred over valproate for bipolar depression.

[b]Lamotrigine is not approved for the acute treatment of depression, and the dose must be started low and slowly titrated to decrease adverse effects if used for maintenance therapy of bipolar I disorder. A drug interaction and a severe dermatologic rash can occur when lamotrigine is combined with valproate (ie, lamotrigine doses must be halved from standard dosing titration).

[c]Antidepressant monotherapy is not recommended for bipolar depression. Bupropion, SSRIs (eg, citalopram, escitalopram, or sertraline), and SNRIs (eg, venlafaxine) have shown good efficacy and fewer adverse effects in the treatment of unipolar depression; MAOIs and TCAs have more adverse effects (eg, weight gain) and can have a higher risk of causing antidepressant-induced mania; fluoxetine, fluvoxamine, nefazodone, and paroxetine inhibit liver metabolism and should be used with caution in patients on concomitant medications that require cytochrome P450 clearance; paroxetine and venlafaxine have a higher risk for a discontinuation syndrome.

[d]ECT is used for severe mania or depression during pregnancy and for mixed episodes; prior to treatment, anticonvulsants, lithium, benzodiazepines should be tapered off to maximize therapy and minimize adverse effects.

Data from Refs. 14 and 38.

## Table 39–3

**Secondary Causes of Mania**

**General Medical Conditions**
Alzheimer disease
Cerebral infarction
Cerebral tumors
Closed head injury
Cushing syndrome
Hemodialysis
Hepatic encephalopathy
Huntington disease
Hyperthyroidism
Ictal or postictal mania
Multiple sclerosis
Neurosyphilis
Systemic lupus erythematosus
Vitamin B deficiency

**Medications**
Corticosteroids
Diltiazem
Levodopa
Oral contraceptives
Zidovudine

**Illicit Substances**
Anabolic steroids
Hallucinogens
Stimulants (cocaine, amphetamines)

Data from Drayton SJ, Pelic CM. Bipolar disorder. In: DiPiro JT, Talbert RL, Yee GC, et al, eds. Pharmacotherapy: A Pathophysiologic Approach. 9th ed. New York, NY: McGraw-Hill. 2014;1067–1081.

Although it is a goal of treatment, not all patients achieve remission. The mainstay of drug therapy has been mood-stabilizing drugs but research based on multiple treatments indicates antipsychotic drugs, both first-generation (FGAs) and second-generation (SGAs), may be more effective for acute mania.[15] Antipsychotic drugs may be used as monotherapy or adjunctively with mood-stabilizing drugs. A person entering treatment for a first mood episode in bipolar disorder must have a complete assessment and careful diagnosis to rule out nonpsychiatric causes. A variety of conditions can cause similar symptoms (Table 39–3). Because early and accurate diagnosis is essential to maximizing response to treatment, pharmacologic and nonpharmacologic therapy should begin as soon as possible. Treatment is often lifelong. Comorbid conditions should also be addressed.

▶ **Suicidality Risk**

Patients should be assessed for potential for violence and harm to others. Friends or family can be asked to remove the home guns, caustic chemicals, medications, and objects that patients might use to harm themselves or others. Risk factors for suicide include severity of depression, feelings of hopelessness, comorbid personality disorder, and a history of a previous suicide attempt.[11]

▶ **Nonpharmacologic Therapy**

KEY CONCEPT *Interpersonal, family, or group psychotherapy with a qualified therapist or clinician assists individuals with bipolar disorder to improve functional outcomes and may help treat or prevent mood episodes,* establish a daily routine and sleep schedule, and improve interpersonal relationships.[12]

Cognitive-behavioral therapy (CBT) is a type of psychotherapy that stresses the importance of recognizing patterns of cognition

(thought) and how thoughts influence subsequent feelings and behaviors. Other people, situations, and events external to the individual are not seen as the sources of thoughts and behaviors. With CBT, patients are taught self-management skills to change negative thoughts even if external circumstances do not change.

Electroconvulsive therapy (ECT) is the application of electrical impulses to the brain for the treatment of severe depression, mixed states, psychotic depression, and treatment refractory mania. It also may be used in pregnant women who cannot take carbamazepine, lithium, or divalproex.

Education for patients, families, and groups about chronicity of bipolar disorder and self-management through sleep hygiene, nutrition, exercise, stress reduction, and abstinence from alcohol or drugs is critical to success. The development of a crisis intervention plan is essential.

▶ **Pharmacologic Therapy**

KEY CONCEPT *The primary treatment modality for manic episodes is mood-stabilizing agents or antipsychotic drugs, often in combination.*[13,14]

Mood-stabilizing drugs are first-line treatments and include lithium, divalproex, carbamazepine, and lamotrigine. The SGAs, including risperidone, olanzapine, quetiapine, ziprasidone, aripiprazole, lurasidone, and asenapine, are approved for treatment of acute mania. Lithium, lamotrigine, aripiprazole, olanzapine, and quetiapine are approved for maintenance therapy. Quetiapine's maintenance therapy indication in bipolar I disorder is adjunctive with lithium or divalproex. Drugs used with less research support and without Food and Drug Administration (FDA) approval include topiramate and oxcarbazepine. Benzodiazepines are used adjunctively for mania.

KEY CONCEPT *The primary treatment for depressive episodes in bipolar disorder is mood-stabilizing agents or certain antipsychotics.*

Among antipsychotic drugs, quetiapine as monotherapy, lurasidone as monotherapy or adjunctive to lithium or divalproex, and olanzapine in combination with fluoxetine are approved. Antidepressants can be used but along with a mood stabilizer to reduce risk of a mood switch to mania and after the patient has failed to respond adequately to mood-stabilizing therapy. Evidence of efficacy of antidepressant drugs in bipolar depression is considered controversial.[13,15] Combinations of two mood-stabilizing drugs or a mood-stabilizing drug and either an antipsychotic or antidepressant drug are common, especially in acute mood episodes.

KEY CONCEPT *The primary treatment for relapse prevention is mood-stabilizing agents, often combined with antipsychotic drugs.* Aripiprazole, olanzapine, and quetiapine are approved for maintenance therapy.

Table 39–4 includes a summary of current drug therapy for bipolar disorder. An algorithm for treatment of bipolar mania is shown in Table 39–2.

▶ **Mood-Stabilizing Drugs**

The optimal mood-stabilizing drug is effective in treatment of acute mania and acute bipolar depression and in prevention of manic relapse and bipolar depression relapse. All currently approved mood-stabilizing drugs have demonstrated efficacy over placebo for one or more of these areas, but there are differences among them with regard to specific patient populations. The choice of treatment is dictated by patient characteristics and history. Few studies systematically compare mood stabilizers with each other. Efficacy of individual agents in placebo-controlled trials is similar. Lithium and divalproex are first-choice drugs for the classic presentation of bipolar disorder.

**Table 39–4**

**Product Formulation, Dose, and Clinical Use of Agents Used in Treatment of Bipolar Disorder**

| Generic Name | Brand Names | Formulations | Dosages | Clinical Use | Dosage Adjustment in Renal or Hepatic Impairment |
|---|---|---|---|---|---|
| **Lithium Salts** | | | | | |
| FDA approved in bipolar disorder | | | | | |
| Lithium carbonate | Lithobid | ER tablets: 300 mg | 900–2400 mg/day once daily or in two to four divided doses, preferably with meals. There is wide variation in the dosage needed to achieve therapeutic response and 12-hour serum lithium concentration (ie, 0.6–1.2 mEq/L (mmol/L) for maintenance therapy and 1.0–1.5 mEq/L (mmol/L) for acute mood episodes taken 12 hours after last dose). Single daily dosing is effective and causes fewer renal effects | Monotherapy or in combination with other drugs for the acute treatment of mania and for maintenance treatment | Reduce starting dosage by at least 50% in renal impairment |
| | Generic | ER tablets: 450 mg | | | |
| | Generic | ER tablets: 300 mg | | | |
| | Generic | Tablet: 300 mg | | | |
| | | Capsules: 150, 300, 600 mg | | | |
| Lithium citrate | Generic | 300 mg (8 mmol)/5 mL | | | |
| **Anticonvulsants** | | | | | |
| FDA approved for use in bipolar disorder | | | | | |
| Carbamazepine | Equetro (only the Equetro brand is FDA approved for bipolar disorder) | Capsules: 100 mg, 200 mg, 300 mg SR; may open capsule but do not crush or chew beads; take with food | Start at 100–200 mg bid; increase by 200 mg every 3–4 days to 200–1800 mg/day in two to four divided doses<br><br>Target serum concentration is 4–12 mcg/mL (17–51 µmol/L) | Monotherapy or in combination with other drugs for the acute treatment of mania or mixed episodes for bipolar I disorder | Reduce starting dosage by at least half or avoid in hepatic impairment |
| | Tegretol, generic | Tablets: 200 mg | | | |
| | Tegretol XR | Chewable tablet: 100 mg | | | |
| | Carbatrol | Suspension: 100 mg/5 mL | | | |
| | | ER tablets: 100, 200, 400 mg | | | |
| | | ER capsules: 100, 200, 300 mg | | | |
| Divalproex sodium | Depakote, generic | Enteric-coated, delayed-release tablets: 125, 250, 500 mg | 750–3000 mg/day (20–60 mg/kg/day) in two to three divided doses for delayed-release divalproex or valproic acid | Monotherapy or in combination with other drugs for the acute treatment of mania. Although commonly used for relapse prevention, maintenance treatment is not FDA approved | Reduce starting dosage by half or avoid in hepatic impairment |
| | Depakote ER | Sprinkles: 125 mg | ER divalproex may be given once daily | | |
| | | ER tablets: 250, 500 mg | A loading dose of 20–30 mg/kg/day can be given, then 20 mg/kg/day and titrated to a serum concentration of 50–125 mcg/mL (347–866 µmol/L) | | |
| Valproic acid | Depakene, generic | Capsules: 250 mg | | | |
| Valproic acid syrup | Depakene, generic | 250 mg/5 mL | | | |
| Lamotrigine | Lamictal, generic | Tablets: 25, 100, 150, 200 mg | 50–400 mg/day in divided doses. Dosage should be slowly increased by following prescribing information. If divalproex is added to lamotrigine, the lamotrigine dosage should be reduced by half | Monotherapy or in combination with other drugs for maintenance treatment | |
| | | Chewable tablets: 2, 5, 25 mg | | | |
| | | Orally disintegrating tablets: 25, 50, 100, 200 mg | | | |
| | Lamictal XR (not FDA approved for bipolar disorder) | ER tablets: 25, 50, 100, 200 mg | | | |

**Anticonvulsants and Other Drugs Not FDA Approved for Use in Bipolar Disorder**

| | | | | |
|---|---|---|---|---|
| Clonazepam | Klonopin, generic | Tablets: 0.5, 1, 2 mg<br>Wafers: 0.125, 0.25, 0.5, 1, 2 mg | 0.5–20 mg/day in divided doses or one dose at bedtime<br>Dosage should be slowly adjusted up and down according to response and adverse effects | Use in combination with other drugs for the acute treatment of mania or mixed episodes |
| Lorazepam | Ativan, generic | Tablets: 0.5, 1, 2 mg<br>Oral solution: 2 mg/mL<br>Injection: 2, 4 mg/mL | 2–10 mg/day in divided doses or one dose at bedtime<br>Dosage should be slowly adjusted up and down according to response and adverse effects | |
| Oxcarbazepine | Trileptal, generic | Tablets: 150, 300, 600 mg<br>Suspension: 300 mg/5 mL | 300–1200 mg/day in two divided doses<br>Doses should be slowly adjusted up and down according to response and adverse effects (eg, 150–300 mg twice daily and increase by 300–600 mg/day at weekly intervals) | May cause fewer adverse drug–drug interactions than carbamazepine, but causes more gastrointestinal side effects and hyponatremia. Evidence is limited regarding efficacy |

**Atypical Antipsychotics**

FDA approved for bipolar disorder

| | | | | |
|---|---|---|---|---|
| Aripiprazole | Abilify | Tablets: 2, 5, 10, 15, 20, 30 mg<br>Oral solution: 5 mg/5 mL | 10–30 mg/day once daily | Use as monotherapy or in combination with lithium or valproate for the acute treatment of mania or mixed states for bipolar I disorder and prevention of manic relapse |
| | Abilify Discmelt | Tablets, orally disintegrating: 10, 15 mg | | |
| Asenapine | Saphris | Sublingual tablets: 5, 10 mg | 5–20 mg/day in two divided doses. Must be held under the tongue until dissolved completely, not chewed or swallowed, with no food or liquid for 10 minutes after administering | Use as monotherapy or in combination with lithium or valproate for the acute treatment of mania or mixed states of bipolar I disorder |
| Lurasidone | Latuda | Tablets: 20, 40, 60, 80, 120 mg | 20–120 mg once daily | Use as monotherapy or in combination with lithium or valproate for depression of bipolar I disorder |
| Olanzapine | Zyprexa, generic | Tablets: 2.5, 5, 7.5, 10, 15, 20 mg | 5–20 mg/day in one or two doses | Used as monotherapy or in combination with lithium or valproate for acute treatment of mania or mixed states for bipolar I disorder and prevention of manic relapse. Used in combination with fluoxetine (OFC) for treatment of bipolar depression |
| | Zyprexa Zydis | Tablets, orally disintegrating: 5, 10, 15, 20 mg | | |
| Olanzapine/Fluoxetine combination (OFC) | Symbyax | Capsules: 3/25, 6/25, 6/50, 12/25, 12/50 mg | | |
| Quetiapine | Seroquel | Tablets: 25, 50, 100, 200, 300, 400 mg | 50–800 mg/day in divided doses or once daily when stabilized | Used as monotherapy or in combination with lithium or divalproex for acute treatment of mania, mixed states for bipolar I disorder, and depression of bipolar I and bipolar II disorder. Used adjunctively with lithium or divalproex for relapse prevention of bipolar mania and depression |
| | Seroquel XR | ER tablets: 50, 150, 200, 300, 400 mg | | |
| Risperidone | Risperdal, generic | Tablets: 0.25, 0.5, 1, 2, 3, 4 mg<br>Oral solution: 1 mg/mL | 0.5–6 mg/day in one or two doses | Used as monotherapy or adjunctively with lithium or divalproex for acute mania or mixed episodes of bipolar I disorder |
| | Risperdal M-Tabs | Tablets, orally disintegrating: 0.5, 1, 2, 3, 4 mg | | |
| | Risperdal Consta | Long-acting injectable: 12.5, 25, 37.5, 50 mg | | |
| Ziprasidone | Geodon | Capsules: 20, 40, 60, 80 mg | 40–160 mg/day in divided doses | Used as monotherapy or adjunctively with lithium or divalproex for acute mania or mixed episodes of bipolar I disorder |

DIVALPROEX, divalproex; ER, extended release; FDA, Food and Drug Administration; SR, sustained release; OFC, olanzapine-fluoxetine combination.
Data from Refs. 13, 15, 20–22, 24, 27–29, and 38.

**Lithium** Lithium, the first approved mood-stabilizing drug, remains a first-line agent and sets the standard for efficacy against which other drugs are measured. It is antimanic, prevents relapse, and has modest efficacy for acute bipolar depression. One of the oldest drugs used for psychiatric illness, research continues to support its use.[15] In most studies, lithium's efficacy is equivalent to that of anticonvulsant mood stabilizers and SGAs. It is most effective for patients with few previous episodes, symptom-free interepisode remission, and a family history of bipolar disorder with good response to lithium. Evidence suggests genetic phenotypes that are more responsive to lithium.[16] However, patients with rapid cycling are less responsive to lithium than to other mood-stabilizing drugs such as divalproex. Additionally, its efficacy for bipolar depression is less robust than for mania.[15] It may also be less effective in mixed mood episodes (symptoms of mania and depression occurring simultaneously).

Evidence shows lithium's effect on suicidal behavior is superior to that of other mood-stabilizing drugs.[17] Lithium reduces the risk of deliberate self-harm or suicide by 70%.

**Mechanism of Action** Lithium's mechanism of action is not well understood and is multimodal. Possibilities include altered ion transport, effects on neurotransmitter signaling, blocking adenyl cyclase, effects on inositol, neuroprotection or increased BDNF, and inhibition of second messenger systems.[18]

**Dosing and Monitoring** Lithium is usually initiated at a dosage of 600 to 900 mg/day. Although it is commonly given in a divided dosage, once-daily dosing is recommended, especially with sustained-release formulations. Once-daily dosing can improve adherence and reduce renal side effects. Lithium has a narrow therapeutic index, meaning the toxic dosage is not much greater than the therapeutic dosage. Lithium requires regular serum concentration monitoring as a guide to titration and to minimize adverse effects. At least weekly monitoring is recommended until stabilized; then the frequency can be decreased. Well-maintained patients who tolerate lithium without difficulty can be monitored by serum concentration as infrequently as twice yearly. The dosage is titrated to achieve a serum lithium concentration of 0.6 to 1.4 mEq/L (mmol/L). Higher serum concentrations are required to treat an acute episode than to prevent relapse. Serum lithium above 0.8 mEq/L (mmol/L) may be more effective at preventing relapse than lower serum concentrations. The suggested therapeutic serum concentration range is based on a 12-hour postdose sample collection, usually a morning trough in patients taking more than one dose per day. At least 2 weeks at a suggested therapeutic serum concentration is required for an adequate trial. Table 39–5 shows pharmacokinetic parameters and desired serum concentrations of mood-stabilizing drugs. It is common for lithium to be combined with other mood stabilizers or antipsychotics to achieve more complete remission.

**Adverse Effects** The most common adverse effects are gastrointestinal (GI) upset, tremor, and polyuria,[19] which are dose related. Nausea, dyspepsia, and diarrhea are minimized by coadministration with food, use of the sustained-release formulation, and giving smaller doses more frequently to reduce the amount of drug in the GI tract. Tremor is present in up to 50% of patients. In addition to these approaches, low-dose β-blockers, such as propranolol 20 to 60 mg/day, reduces tremor.

Lithium impairs the kidney's ability to concentrate urine because of its inhibitory effect on vasopressin. This causes an increase in urine volume and frequency of urination and an increase in thirst. Polyuria and polydipsia occur in up to 70% of patients. A severe form of polyuria, when urine volume exceeds 3 L/day,

is termed lithium-induced nephrogenic diabetes insipidus. It can be treated with hydrochlorothiazide or amiloride. If the former is used, the lithium dosage should be reduced by 33% to 50% to account for the drug–drug interaction that increases serum lithium and causes toxicity. Long-term lithium has been associated with structural kidney changes, such as glomerular sclerosis or tubular atrophy. Once-daily dosing of lithium is less likely to cause renal adverse effects than divided-daily dosing.

Lithium is concentrated in the thyroid gland and can impair thyroid hormone synthesis. Although goiter is uncommon, as many as 30% of patients develop at least transiently elevated thyroid-stimulating hormone. Lithium-induced hypothyroidism is not usually an indication to discontinue the drug. Patients can be supplemented with levothyroxine.

Other common adverse effects include poor concentration, acneiform rash, alopecia, worsening of psoriasis, weight gain, metallic taste, impaired glucose regulation, and benign leukocytosis. Lithium causes a flattening of the T wave of the electrocardiogram (ECG), considered benign and not clinically significant. Less commonly, it can cause or worsen arrhythmias.[19]

Lithium and other mood-stabilizing drugs require baseline and routine laboratory monitoring to help determine medical appropriateness for initiation of therapy and monitoring of adverse effects. Guidelines for such monitoring are outlined in Table 39–6.

Acute lithium toxicity, which occurs at serum concentrations over 2 mEq/L (mmol/L), can be severe and life threatening, necessitating emergency treatment. Symptoms include severe vomiting and diarrhea, deterioration in motor coordination, including coarse tremor, ataxia, and dysarthria, and impaired cognition. In its most severe form, seizures, cardiac arrhythmias, coma, and kidney damage are reported. Treatment includes discontinuation of lithium, IV fluids to correct fluid and electrolyte imbalance, and osmotic diuresis or hemodialysis. In case of overdose, gastric lavage is indicated. Clinical symptoms continue after the serum concentration is lowered because clearance from the central nervous system (CNS) is slower than from serum. Factors predisposing to lithium toxicity include fluid and sodium loss from hot weather or exercise or drug interactions that increase serum lithium.[19]

**Drug Interactions** Drug interactions involving lithium are common. Because lithium is not metabolized or protein bound, it is not associated with metabolic drug interactions that occur with other mood-stabilizing drugs. Common and significant drug interactions involve thiazide diuretics, nonsteroidal anti-inflammatory drugs, and angiotensin-converting enzyme (ACE) inhibitor drugs. If a diuretic must be used with lithium and a thiazide is not required, loop diuretics such as furosemide are less likely to increase lithium retention. The ACE inhibitors and angiotensin receptor blockers (ARB) can abruptly increase serum lithium with the potential of acute toxicity, even after months of no change in serum lithium. This combination is strongly discouraged.[19]

**Divalproex Sodium and Valproic Acid** Divalproex sodium is composed of sodium valproate and valproic acid. The delayed-release and extended-release formulations are converted in the intestine into valproic acid (VPA), which is systemically absorbed. It is FDA approved for treatment of the manic phase of bipolar disorder. It is equal in efficacy to lithium and some other drugs for bipolar mania. It has utility in bipolar disorder with rapid cycling, mixed mood features, and substance abuse comorbidity. Although not FDA approved for relapse prevention, studies support its use, and it is widely prescribed for maintenance therapy. Divalproex can be used as monotherapy or in combination with lithium or an antipsychotic.[13]

**Table 39–5**

**Pharmacokinetics and Therapeutic Serum Concentrations of Lithium and Anticonvulsants Used in the Treatment of Bipolar Disorder**

| | Lithium | Carbamazepine | Oxcarbazepine | Divalproex (DIVALPROEX) Sodium/Valproic Acid (VPA) | Lamotrigine |
|---|---|---|---|---|---|
| **_Gastrointestinal Absorption_** | | | | | |
| Regular release | Rapid: 95%–100% within 1–6 hours | Slow and erratic: 85%–90% | Slow and complete: 100% | Rapid and complete (VPA) | Rapid: 98% |
| Syrup, suspension, solution | Faster rate of absorption: 100% | Faster rate of absorption | Unknown | Faster rate of absorption than tablets | NA |
| ER/enteric-coated tablets | Delayed absorption: 60%–90% | Delayed absorption: 89% of the suspension; and less than regular-release tablets | NA | Delayed absorption with delayed-release tablets; valproate is rapidly converted to VPA in the intestine and then is rapidly and almost completely absorbed from the GI tract | Delayed absorption but not significantly different from regular release |
| | | | | ER bioavailability is approximately 15% less than delayed release | |
| Delay in absorption by food | Yes | No; reports of increased rate of absorption with fatty meals (ER capsule) | No | Yes; food slows the rate of absorption but not the extent for DIVALPROEX | Bioavailability not affected by food |
| Time to reach peak serum concentrations | 0.5–3 hours (regular-release) 4–12 hours (ER) 0.25–1 hour (oral solution) | 4–5 hours (regular-release); 1.5 hours (suspension); 3–12 hours (ER tablets); 4.1–7.7 hours (ER capsules); higher peak concentrations with chewable tablets | 4.5 hours (range of 3–13 hours) | 1–4 hours (VPA) 3–5 hours (DIVALPROEX single dose) 7–14 hours (DIVALPROEX ER multiple dosing) | 1–4 hours (regular release), 4–6 hours (ER) |
| **_Distribution_** | | | | | |
| Volume of distribution | Initial: 0.3–0.4 L/kg Steady state: 0.7–1 L/kg | 0.6–2 L/kg (adults) | 10-monohydroxy metabolite: 49 L/kg | 11 L/1.73 m$^2$ (total valproate); 92 L/1.73 m$^2$ (free valproate) | 0.9–1.3 L/kg |
| Crosses the placenta | Yes; pregnancy risk category: D Risk of cardiac defects: 0.1%–0.5% | Yes; pregnancy risk category: D | Yes; pregnancy risk category: C | Yes; pregnancy risk category: D Risk of neural tube defects: 1%–5% | Yes; pregnancy risk category: C |
| Crosses into breast milk | Yes; 35%–50% of mother's serum concentration; breastfeeding not recommended | Yes; ratio of concentration in breast milk to plasma is 0.4 for drug and 0.5 for epoxide metabolite; considered compatible with breastfeeding | Yes; both drug and active metabolite; breastfeeding not recommended | Yes; considered compatible with breastfeeding | Yes; breastfeeding not recommended |
| Protein binding | No | 75%–90% | 40% of active metabolite | 80%–90% (dose dependent) | 55% |

| CYP450 inducer | No | 1A2, 2C9/10, and 3A3/4 | 3A3/4 | No | Unknown |
| ***Therapeutic Serum/Plasma Concentrations*** | | | | | |
| | 1–1.5 mEq/L (mmol/L): for adult, acute mania 0.4–0.6 mEq/L (mmol/L): for elderly or medically ill patients 0.6–1.2 mEq/L (mmol/L): for adult, maintenance; ranges based on 12-hour postdose sample collection | 4–12 mcg/mL (17–51 µmol/L): for adult, acute mania and maintenance 4–8 mcg/mL (17–34 µmol/L): for elderly or medically ill | No established therapeutic range; 12–30 mcg/mL (47–118 µmol/L) for 10-hydroxy metabolite based on epilepsy trials | 50–125 mcg/mL (347–866 µmol/L): adult, acute mania and maintenance 40–75 mcg/mL (277–520 µmol/L) : elderly or medically ill | No established therapeutic range: 4–20 mcg/mL (16–78 µmol/L) based on epilepsy trials |

ER, extended release; GI, gastrointestinal; NA, not applicable.

Data from Refs. 19–22 and 24.

***Mechanism of Action.*** The mechanism is not well understood. It is known to affect ion transport and enhance activity of γ-aminobutyric acid (GABA). Similar to lithium, it has possible neuroprotective effects through enhancement of BDNF.[18]

***Dosing and Monitoring.*** Divalproex is initiated at 500 to 1000 mg/day, but studies indicate a therapeutic serum VPA concentration can be reached more quickly through a loading dose approach of 20 to 30 mg/kg/day. Using this approach, patients may respond with a significant reduction in symptoms within the first few days of treatment. The dosage is then titrated according to response, tolerability, and serum concentration. The most often referenced desired VPA serum concentration is 50 to 125 mcg/mL (347–866 µmoles/L), but it is not unusual for patients to require more than 100 mcg/mL (693 µmoles/L) for optimal efficacy.

| Valproate[n] | X | X | X | X | X | X | X | | | | | | | X | X |

[a]Screen for drug abuse and serum pregnancy.

[b]CBC with differential and platelets.

[c]Fasting glucose, serum lipids, weight.

[d]Lactate dehydrogenase, aspartate aminotransferase, alanine aminotransferase, total bilirubin, alkaline phosphatase.

[e]Serum creatinine, blood urea nitrogen, urinalysis, urine osmolality, specific gravity.

[f] Triiodothyronine, total thyroxine, thyroxine uptake, and thyroid-stimulating hormone.

[g]Serum sodium.

[h]Rashes, hair thinning, alopecia.

[i]Atypical antipsychotic: Monitor for increased appetite with weight gain (primarily in patients with initial low or normal body mass index); monitor closely if rapid or significant weight gain occurs during early therapy; cases of hyperlipidemia and diabetes reported.

[j]Carbamazepine: Manufacturer recommends CBC and platelets (and possibly reticulocyte counts and serum iron) at baseline, and that subsequent monitoring be individualized by the clinician (eg, CBC, platelet counts, and liver function tests every 2 weeks during the first 2 months of treatment, then every 3 months if normal). Monitor more closely if patient exhibits hematologic or hepatic abnormalities or if the patient is receiving a myelotoxic drug; discontinue if platelets are less than 100,000/mm³ (100 × 10⁹/L), if WBC is less than 3000/mm³ (3 × 10⁹/L) or if there is evidence of bone marrow suppression or liver dysfunction. Serum electrolyte levels should be monitored in the elderly or those at risk for hyponatremia. Carbamazepine interferes with some pregnancy tests.

[k]Lamotrigine: If renal or hepatic impairment, monitor closely and adjust dosage according to manufacturer's guidelines. Serious dermatologic reactions have occurred within 2 to 8 weeks of initiating treatment and are more likely to occur in patients receiving concomitant valproate, with rapid dose escalation, or using doses exceeding the recommended titration schedule.

[l]Lithium: Obtain baseline ECG for patients older than 40 years or if preexisting cardiac disease (benign, reversible T-wave depression can occur). Renal function tests should be obtained every 2 to 3 months during the first 6 months, then every 6 to 12 months; if impaired renal function, monitor 24-hour urine volume and creatinine every 3 months; if urine volume more than 3 L/day, monitor urinalysis, osmolality, and specific gravity every 3 months. Thyroid function tests should be obtained once or twice during the first 6 months, then every 6 to 12 months; monitor for signs and symptoms of hypothyroidism; if supplemental thyroid therapy is required, monitor thyroid function tests and adjust thyroid dose every 1 to 2 months until thyroid function indices are within normal range, then monitor every 3 to 6 months.

[m]Oxcarbazepine: Hyponatremia (serum sodium concentrations less than 125 mEq/L [mmol/L]) has been reported and occurs more frequently during the first 3 months of therapy; serum sodium concentrations should be monitored in patients receiving drugs that lower serum sodium concentrations (eg, diuretics or drugs that cause inappropriate antidiuretic hormone secretion) or in patients with symptoms of hyponatremia (eg, confusion, headache, lethargy, and malaise). Hypersensitivity reactions have occurred in approximately 25% to 30% of patients with a history of carbamazepine hypersensitivity and requires immediate discontinuation.

[n]Valproate: Weight gain reported in patients with low or normal body mass index. Monitor platelets and liver function during first 3 to 6 months if evidence of increased bruising or bleeding. Monitor closely if patients exhibit hematologic or hepatic abnormalities or in patients receiving drugs that affect coagulation, such as aspirin or warfarin; discontinue if platelets are less than 100,000/mm³/L (100 × 10⁹/L) or if prolonged bleeding time. Pancreatitis, hyperammonemic encephalopathy, polycystic ovary syndrome, increased testosterone, and menstrual irregularities have been reported; not recommended during first trimester of pregnancy due to risk of neural tube defects.

Data from Refs. 14 and 38.

Some patients require high milligram dosages in order to reach a desired serum concentration. The suggested serum concentration range is based on trough values. Serum concentration monitoring is recommended at least every 2 weeks until stabilized, then less frequently. The extended-release formulation can be taken once daily (see Table 39–4). If the extended-release formulation is administered at night, a morning blood sampling is a peak, not a trough. The drug should be given in the morning so that blood sampling the following morning would be a trough value and more easily interpreted if the typical blood sampling time is in the morning. The systemic bioavailability of extended-release divalproex is about 15% less than that of the delayed-release formulation. Patients who have difficulty swallowing large tablets can use the sprinkle formulation. The immediate-release formulation, either capsules or syrup, is given three or four times per day.[20]

*Adverse Effects.* The most common adverse effects are GI (loss of appetite, nausea, dyspepsia, diarrhea), tremor, and drowsiness. GI distress can be reduced by coadministration with food. The delayed-release and extended-release formulations are less likely to cause gastric distress than immediate-release valproic acid. Dosage reduction can reduce all of the common side effects. As with lithium, a low-dose β-blocker may alleviate tremor. Weight gain is common, occurring in up to 50% of patients.[20]

Other less common adverse effects include alopecia or a change in hair color or texture. Hair loss can be minimized by supplementation with a vitamin containing selenium and zinc. Polycystic ovarian syndrome associated with increased androgen production is reported. Thrombocytopenia is common, and the platelet count should be monitored periodically. It is a dose-related adverse effect and usually asymptomatic, but the drug is usually stopped if the platelet count is less than $100 \times 10^3/mm^3$ ($100 \times 10^9/L$). More rare are hepatic toxicity and pancreatitis, which are not always dose related. Severe GI symptoms of hepatic or pancreatic toxicity include vomiting, pain, and loss of appetite. When these occur, the patient should be evaluated for possible hepatitis or pancreatitis. Divalproex has a wide therapeutic index. Acute toxicity for high dosages or overdosage is not life threatening.

*Drug Interactions.* Drug interactions involving divalproex are common. It is a weak inhibitor of some drug metabolizing liver enzymes and can affect metabolism of other drugs. These include other anticonvulsants and antidepressants. The interaction between divalproex and lamotrigine is significant. The risk of a dangerous rash caused by lamotrigine is increased when given concurrently with divalproex. When lamotrigine is added to divalproex, the initial lamotrigine dosage should be one-half the typical starting dosage, and lamotrigine should be titrated more slowly than usual. When divalproex is added to lamotrigine, the lamotrigine dosage should be reduced by 50%.[21] Conversely, the metabolism of divalproex can be increased by enzyme-inducing drugs such as carbamazepine and phenytoin, but divalproex may simultaneously slow metabolism of the other agents.[20]

**Carbamazepine** Although long used as a mood-stabilizer, only the extended-release formulation is FDA approved for treatment of bipolar disorder. Although it has efficacy for mood stabilization, it is less desirable as a first-line agent because of safety and drug interactions. It is reserved for patients who fail to respond to lithium or for patients with rapid cycling or mixed bipolar disorder. Carbamazepine can be used as monotherapy or in combination with lithium or an antipsychotic drug.[22]

*Mechanism of Action.* The mechanism of action of carbamazepine is not well understood. It blocks ion channels and inhibits sustained repetitive neuronal excitation, but whether this explains its efficacy as a mood stabilizer is not known.[22]

*Dosing and Monitoring.* Carbamazepine is initiated at 400 to 600 mg/day. The sustained-release formulation can be given in two divided doses. In addition to a formulation that is completely sustained release, an additional extended-release formulation contains a matrix of 25% immediate-release, 40% extended-release, and 35% enteric-release beads.[22] The suggested therapeutic serum concentration is 4 to 12 mcg/mL (17-51 µmol/L). As with divalproex, some patients require high dosages to achieve a desired serum concentration and therapeutic effect. The dosage can be increased by 200 to 400 mg/day as often as every 2 to 4 days. Serum concentration monitoring is suggested at least every 2 weeks until stabilized.[22]

*Adverse Effects.* The most common adverse effects are drowsiness, dizziness, ataxia, lethargy, and confusion. At mildly toxic levels, it causes diplopia and dysarthria. These can be minimized through dosage adjustments, use of sustained-release formulations, and giving more of the drug late in the day. GI upset is common. Carbamazepine has an antidiuretic effect similar to the syndrome of inappropriate antidiuretic hormone secretion and can cause hyponatremia. Mild elevations in liver enzymes can occur, but hepatitis is less common. Mild, dose-related leukopenia is not unusual and not an indication for discontinuation. More serious blood count abnormalities such as aplastic anemia and agranulocytosis are rare but life threatening.[22] Suggested baseline and routine laboratory monitoring are reviewed in Table 39–6.

*Drug Interactions.* Carbamazepine induces hepatic metabolism of many drugs, including other anticonvulsants, antipsychotics, some antidepressants, oral contraceptives, and antiretroviral agents. Carbamazepine is an autoinducer (ie, it induces its own metabolism). The dosage may require an increase after 1 month or so of therapy because of this effect. Conversely, the metabolism of carbamazepine can be slowed by enzyme inhibiting drugs such as some antidepressants; macrolide antibiotics, including erythromycin and clarithromycin; azole antifungal drugs, including ketoconazole and itraconazole; and grapefruit juice. Carbamazepine should not be given concurrently with clozapine because of the additive risk of agranulocytosis.[23]

**Lamotrigine** Lamotrigine is effective for maintenance treatment of bipolar disorder. It is more effective for depression relapse prevention than for mania relapse prevention. Its primary limitation as an acute treatment is the time required for titration to an effective dosage. In addition to maintenance monotherapy, it is sometimes used in combination with lithium or divalproex, although combination with divalproex increases the risk of rash, and lamotrigine dosage adjustment is required.[21]

*Mechanism of Action.* The mechanism of action of lamotrigine appears to involve blockage of ion channels and effects on glutamate transmission, although the precise mechanism is not clear.[21]

*Dosing and Monitoring.* Lamotrigine is initiated at 25 mg/day for 1 to 2 weeks, then increased in a dose-doubling manner every 1 to 2 weeks to a target of 200 to 400 mg/day. If lamotrigine is added to divalproex, the starting dosage is 25 mg every other day with a slower titration to reduce risk of rash. If divalproex is added to lamotrigine, the lamotrigine dosage should be reduced by 50% for the same reason. If lamotrigine therapy is interrupted for more than a few days, it should be restarted at the initial dosage and retitrated. Serum concentration monitoring is not recommended.[21]

*Adverse Effects.* The adverse effect of greatest significance is a maculopapular rash, occurring in up to 10% of patients.[21] Although usually benign and temporary, some rashes can progress

to life-threatening Stevens-Johnson syndrome. The risk of rash is greater with a rapid dosage titration and when given concurrently with divalproex or other metabolic enzyme inhibitors. The risk is minimal when the dosage titration schedule is slow. Other side effects include dizziness, drowsiness, headache, blurred vision, and nausea. In contrast to other mood-stabilizing drugs such as lithium and divalproex, lamotrigine does not significantly influence body weight.

*Drug Interactions.* The mechanisms of drug–drug interactions involving lamotrigine are unclear. Lamotrigine's primary route of metabolism is conjugative glucuronidation, although it is known to exhibit metabolic autoinduction. It is not significantly metabolized by CYP P450 enzymes. It does not affect drug metabolizing hepatic enzymes. Divalproex slows the rate of elimination of lamotrigine by about half, necessitating dosage reduction. Conversely, carbamazepine increases the rate of lamotrigine metabolism. Upward adjustment in dosage may be needed.[21]

**Oxcarbazepine** Oxcarbazepine is an analogue of carbamazepine, developed as an anticonvulsant. An advantage over carbamazepine is that routine monitoring of hematology profiles and serum concentrations is not indicated because it is less likely to cause hematologic abnormalities.[24] Additionally, drug interactions are less significant, although it is a mild inducer of certain metabolic pathways. Vigilance for drug interactions is needed, especially with oral contraceptives. Oxcarbazepine appears in the most recent treatment algorithms for bipolar disorder,[13] but clinical trial data are limited.[25]

*Adverse Effects.* Adverse effects include drowsiness, dizziness, GI upset, and hyponatremia, the latter two of which may be more likely than with carbamazepine.[24]

**Others** High-potency benzodiazepine agents such as clonazepam and lorazepam are used as adjunctive therapy, especially during acute mania, to reduce anxiety and improve sleep.[26] As complementary or alternative medicines gain wider usage, omega-3 fatty acids have been used in mood disorders, but do not appear in treatment guidelines.

### ▶ Antipsychotic Drugs

First-generation antipsychotics such as chlorpromazine and haloperidol have long been used in the treatment of acute mania. SGA drugs, including aripiprazole, asenapine, olanzapine, quetiapine, risperidone, and ziprasidone, are approved for the treatment of bipolar mania or mixed mood episodes as monotherapy or in combination with mood stabilizers.[13] Aripiprazole, olanzapine, and quetiapine are approved for maintenance therapy for prevention of manic relapse. The combination of olanzapine and fluoxetine is approved for treatment of acute bipolar depression. Quetiapine is approved as monotherapy for acute bipolar depression and as adjunctive therapy with lithium or divalproex for prevention of bipolar depression relapse. Lurasidone is approved as monotherapy and as adjunctive therapy with lithium or divalproex for acute bipolar depression. Approval of antipsychotic drugs in patients with bipolar disorder applies without regard to presence of psychosis. In comparative studies, SGAs are equivalent or superior in efficacy to lithium and divalproex for treatment of acute mania. Treatment guidelines include antipsychotic drugs as first-line therapy.[13] The combination of mood stabilizers and antipsychotics is more likely to achieve remission than monotherapy. Quetiapine data in relapse prevention of both manic and bipolar depression episodes favored combination therapy over mood-stabilizer monotherapy.[27]

The mechanisms of action, usual dosages, pharmacokinetics, adverse effects, and drug interactions involving antipsychotic drugs are discussed in detail in the chapter on schizophrenia. Dosages in bipolar disorder are similar to those used in schizophrenia. Higher dosages are often required to treat an acute episode. The recommended dosage of aripiprazole for bipolar disorder is 20 to 30 mg/day, somewhat higher than the average dosage used in schizophrenia.[28] The recommended dosage for quetiapine in treatment of acute bipolar depression is 300 mg/day, less than the 600 mg/day recommended in acute mania.[29]

SGAs are less likely than FGAs to cause neurologic side effects, especially movement abnormalities. SGAs are more likely to cause metabolic side effects, such as weight gain, glucose dysregulation, and dyslipidemia.[30] Among SGAs approved for treatment of bipolar disorder, olanzapine is most likely to cause metabolic side effects. Asenapine, lurasidone, quetiapine, and risperidone cause less metabolic effects than olanzapine. Aripiprazole, lurasidone, and ziprasidone are least associated with effects on weight, glucose, and lipids.

### ▶ Antidepressants

Treatment of depressive episodes in patients with bipolar disorder presents a particular challenge because of risk of a drug-induced mood switch to mania. The FDA requires the product label of all antidepressants to contain language about the potential risk of inducing a mood switch to mania. Most research shows no advantage for adjunctive antidepressant use compared with mood-stabilizer therapy alone.[13,15] Treatment guidelines and current FDA approvals indicate lithium and quetiapine as first-line therapy.[13] The approval of lurasidone for acute bipolar depression is recent, thus it is not widely included in first-line recommendations. When usual treatment fails, evidence supports use of antidepressants.[13,15]

Guidelines agree that when antidepressants are used, they should be combined with a mood stabilizer to reduce risk of mood switch. The question of which antidepressant drugs are less likely to cause a mood switch is not resolved, but tricyclic antidepressants are thought to carry greater risk. A comparison of venlafaxine, sertraline, and bupropion as adjunctive therapy to a mood stabilizer showed venlafaxine with highest risk of a mood switch to mania or hypomania and bupropion with the least.[31]

## Special Populations

Assessment and management by appropriate psychiatric specialists is important for special populations, such as pediatric, geriatric, and pregnant patients.

### ▶ Pediatrics

Evidence regarding treatment of bipolar disorder in children and adolescents is more limited than in adults. Children and adolescents are sensitive to medication side effects, including metabolic side effects of SGAs. With these caveats, evidence supports use of mood stabilizers and SGAs in children and adolescents with bipolar disorder. Lithium is FDA approved for treatment of bipolar disorder in children and adolescents as young as age 12. Aripiprazole, olanzapine, quetiapine, and risperidone are FDA approved in children and adolescents as young as age 10.[13,32]

Initial dosages in the pediatric population are lower than in adults. Metabolic elimination rates of many drugs are increased in children, so they may actually require higher dosages on a weight-adjusted basis. Dosages are titrated carefully according to response and tolerability.

Children and adolescents are especially likely to experience weight gain from SGAs.[33] Cognitive toxicity, manifested as confusion, memory or concentration impairment, or impaired

learning, is difficult to detect and is a consideration in the pediatric population so that intellectual and educational development is not hindered.

For comorbid bipolar disorder and attention-deficit/hyperactivity disorder when stimulant therapy is indicated, treatment of mania is recommended before starting the stimulant to avoid exacerbation of mood symptoms.

### ▶ Geriatrics

Treatment of older adults with bipolar disorder requires care because of increased risks associated with medical conditions and drug–drug interactions.[34] General medical conditions, including endocrine, metabolic, or infectious diseases, can mimic mood disorders. Patients should be evaluated for such medical illnesses that cause or worsen mood symptoms. As physiologic systems change with aging, elimination of drugs is slowed. Examples are slowed renal elimination of lithium and slowed hepatic metabolism of carbamazepine and valproic acid. As a result, dosages required for therapeutic effect are lower in geriatric patients. Also, changes in membrane permeability increase risk of CNS side effects. Increased frequency of patient monitoring is required, including serum drug concentration monitoring.

Vigilance for drug–drug interactions is required because of more medications prescribed to older adults and enhanced sensitivity to adverse effects. Pharmacokinetic interactions include metabolic enzyme induction or inhibition and protein binding displacement interactions (eg, divalproex and warfarin). Pharmacodynamic interactions include additive sedation and cognitive toxicity, which increases risk of falls and other impairments.

### ▶ Pregnancy and Postpartum

Treatment of bipolar disorder during pregnancy is fraught with controversy and conflicting recommendations. The key issue is the relative risk of teratogenicity with drug use during pregnancy versus risk of bipolar relapse without treatment with consequent harm to both patient and fetus. Therapeutic judgments depend on the history of the patient and whether the pregnancy is planned or unplanned. Treatment is best managed when pregnancy is planned. Clinicians should discuss the issue with every patient with bipolar disorder who is of childbearing potential. A pregnancy test should be obtained before initiating therapy. For a patient with severe illness, a history of multiple mood episodes, rapid cycling, or suicide attempts, discontinuing treatment, even for a planned pregnancy, is unwise. For a patient with a remote history of a single mood episode with subsequent long stability and contemplating pregnancy, the answer is less clear. Patients should be provided clear and reliable information about risks versus benefits of stopping or continuing therapy so they can make an informed decision. Patients who decide to discontinue medication before pregnancy should taper medication slowly.[13,35]

Lithium administration during the first trimester is associated with Ebstein anomaly, a downward displacement of the tricuspid valve. Although more likely to occur in children of patients who took lithium during pregnancy, the absolute risk is small, around 0.1%. Pharmacokinetic handling of lithium changes as pregnancy progresses. Renal lithium clearance increases, which requires a dosage increase to maintain a therapeutic serum concentration. It is advisable to decrease or discontinue lithium at term or onset of labor to avoid toxicity postpartum when there is a large reduction in fluid volume.[36]

Lithium can cause hypotonicity and cyanosis in the neonate, termed the "floppy baby" syndrome. Most data indicate normal neurobehavioral development when these symptoms resolve.

Lithium is readily transferred via breast milk. Breastfeeding is not advised for patients taking lithium.[19]

Valproic acid and carbamazepine are human teratogens. Neural tube defects such as spina bifida occur in up to 9% of infants exposed during the first trimester. The risk of neural tube defects is related to exposure during the third and fourth weeks of gestation. As such, women with unplanned pregnancies may not know they are pregnant until after the risk of exposure has occurred. Carbamazepine can cause fetal vitamin K deficiency. Vitamin K is important for facial growth and for clotting factors. The risk of facial abnormalities is increased with carbamazepine and VPA, and neonatal bleeding is increased in infants of mothers who are treated with carbamazepine during pregnancy.[37,38]

Fewer data are available on other anticonvulsant mood-stabilizing drugs. Lamotrigine may be associated with an increased risk of oral clefts.[37,38]

The FGAs have been available for many years, and more data are available on their use in pregnancy compared with SGAs, but guidelines for bipolar disorder do not otherwise support FGAs as an initial choice.

Use of antidepressant drugs during pregnancy is discussed in the chapter on depression.

## OUTCOME EVALUATION

### 🔵 Assessment of Therapeutic Effects

Effective interviewing skills and a therapeutic relationship with the patient are essential to assessing response. Understand the particular symptom profile and needs of individual patients. These are the primary therapeutic monitoring parameters. In addition to clinical interview, some clinicians use symptom rating scales such as the Young Mania Rating Scale (YMRS) for mania and the Hamilton Depression Rating Scale (Ham-D, discussed in the chapter on depression). The YMRS is composed of 11 items based on a patient's perception over the preceding 48 hours. Adjunctive information is obtained from clinical observations. The scale takes about 15 to 30 minutes to administer.[39]

---

### Patient Encounter, Part 4: Outcome Evaluation

After an initial assessment, including evaluation of potential suicidality, support systems, and need for inpatient versus outpatient treatment, Joan was hospitalized briefly and then followed in the community on medication as well as psychotherapy. Joan has discontinued her use of alcohol and is now attending Alcoholics Anonymous meetings along with her father. She has also stopped smoking marijuana. Her school performance has returned to normal, and her grades are improving. Joan has responded well to treatment with divalproex 500 mg by mouth twice daily. Recent serum valproic acid levels have stabilized at 80 mcg/mL (554 μmol/L). She now returns to the clinic for routine follow-up. Joan initially complained about mild headaches and nausea which have subsequently resolved, and she has tolerated the divalproex well. However, she now asks how long she must take this medication since she is feeling completely well.

*How would you assess therapeutic and adverse effects of treatment for this patient?*

*How would you educate the patient regarding the need for continued maintenance treatment?*

## Patient Care Process

**Patient Assessment:**

- Assess the patient's symptoms and review the history. Review the family history, including the history of response to treatment by family members.
- Obtain an initial medical evaluation to rule out other causes of mood episodes.
- Evaluate physiologic parameters that may influence pharmacokinetics.

**Therapy Evaluation:**

- Obtain a thorough medication use history, including present and past prescription and nonprescription drugs, the patient's self-assessment of response and side-effects, alcohol, tobacco, caffeine, illicit substances, herbal products, dietary supplements, allergies, and adherence.
- Assess potential drug–disease, drug–drug, and drug–food interactions.

**Care Plan Development:**

- Develop a plan for monitoring therapeutic outcomes, focusing on the individual symptom profile and level of function of the patient. Include a plan for dosage adjustments or alternate therapy if the patient fails to respond adequately. Include serum drug concentration monitoring as appropriate.
- Develop a monitoring plan for drug side effects. Include measures to prevent side effects as well as management if they occur. Include appropriate laboratory measures.
- Determine the role of nonpharmacologic therapy and how it is to be integrated with drug therapy.
- Educate the patient on the nature of bipolar disorder, its treatment, and what to expect with regard to response and side effects, and stress the need for adherence to treatment even when feeling well.
- Encourage a healthy lifestyle, including eliminating or stopping substance abuse, smoking cessation, and encouraging proper nutrition and exercise.

**Follow-Up Evaluation:**

- See the patient daily if hospitalized or weekly if an outpatient to assess efficacy and safety until stabilized. Utilize the clinical interview, physical exam, and lab tests.
- Once stabilized, follow up at decreased frequency, every 3 to 6 months. Use the same parameters and check for new drugs or drug-drug interactions.

Check serum concentrations of mood-stabilizing drugs as a guide to dosage adjustment for optimal efficacy. The frequency of follow-up visits depends on response, tolerability, and adherence.

### Assessment of Adverse Effects

Adverse effects cause more nonadherence than any other factor. Monitor patients regularly for adverse effects and health status, especially because mood stabilizers and antipsychotics commonly cause metabolic side effects such as weight gain. Repeat laboratory tests for renal and thyroid function for patients taking lithium and hematology and liver function for patients taking carbamazepine or divalproex. Annual measurement of serum lipase is advisable for patients taking divalproex. More specific discussion of metabolic side effect monitoring of patients taking SGAs is provided in the chapter on schizophrenia.

### Patient Education

**KEY CONCEPT** *Education of the patient regarding benefits and risks of drug therapy and the importance of adherence to treatment must be integrated into pharmacologic management.* This is important because responsiveness to treatment declines as the number of mood episodes increases. Discuss the nature and chronic course of bipolar disorder and risks of repeated relapses. Help patients understand treatment is not a cure but that many patients enjoy symptom-free or nearly symptom-free function. Make it clear that long-term recovery is dependent on adherence to pharmacologic and nonpharmacologic treatment. Explain the purpose of medication, common side effects to expect, and how to respond to side effects. Provide the patient and family with written information about indications, benefits, and side effects. Discuss less frequent but more dangerous side effects of drugs, and give written instructions on seeking medical attention immediately should they occur.

## Abbreviations Introduced in This Chapter

| | |
|---|---|
| 5-HT | 5-hydroxytryptamine |
| Abd | Abdomen |
| ACE | Angiotensin-converting enzyme |

# Generalized Anxiety Disorder, Panic Disorder, and Social Anxiety Disorder

Sheila R Botts, Sallie Charles, and Douglas A Newton

## LEARNING OBJECTIVES

● **Upon completion of the chapter, the reader will be able to:**

1. Describe pathophysiology of generalized anxiety, panic, and social anxiety disorders (SAD).

2. List common presenting symptoms of generalized anxiety, panic, and SAD.

3. Identify the desired therapeutic outcomes for patients with generalized anxiety, panic, and SAD.

4. Discuss appropriate lifestyle modifications and over-the-counter medication use in these patients.

5. Recommend psychotherapy and pharmacotherapy interventions for patients with generalized anxiety, panic, and SAD.

6. Develop a monitoring plan for anxiety patients placed on specific medications.

7. Educate patients about their disease state and appropriate lifestyle modifications, as well as psychotherapy and pharmacotherapy for effective treatment.

## INTRODUCTION

Anxiety disorders are among the most frequent mental disorders encountered by clinicians. All anxiety disorders share features of fear and anxiety that differ from developmentally normative fear or anxiety by being excessive, persistent, and resulting in behavioral disturbances.

Anxiety disorders are often missed or attributed incorrectly to other medical illnesses, and most patients are treated inadequately.[1] The burden of diagnosis usually falls to primary care clinicians, to whom most patients present in the context of other complaints. Untreated anxiety disorders may result in increased health care utilization, morbidity and mortality, and a poorer quality of life.

## EPIDEMIOLOGY AND ETIOLOGY
### Epidemiology
#### ▶ Prevalence

The lifetime prevalence of anxiety disorders collectively is 28.8% with specific phobia (12.5%) and social anxiety disorder (SAD) (12.1%) being the most common.[2,3] Data from the National Comorbidity Survey, Revised (NCS-R) estimate the lifetime prevalence of generalized anxiety disorder (GAD) for those 18 years of age and older to be 5.7%, and rates for panic disorder (PD), 4.7%.[3,4]

Anxiety disorders are more prevalent among women than men(2:1).[2] Prevalence rates across the anxiety spectrum increase from the younger age group (18–29 years) to older age groups (30–44 and 45–59 years); however, rates are substantially lower for those older than age 59 years.[3]

#### ▶ Course of Illness

PD and GAD have a median age of onset of 24 and 31 years, respectively, whereas SAD develops earlier (median age 13 years).[3] Although GAD and PD may not manifest fully until adulthood, as many as half of adult anxiety patients report subthreshold symptoms during childhood.[5]

Anxiety disorders are chronic, and symptoms tend to wax and wane, with fewer than one-third of patients experiencing spontaneous symptom **remission**.[6] The risk for relapse and recurrence of symptoms is also high for anxiety disorders. In a 12-year follow-up study of anxiety disorder patients, recurrence rates ranged from 58% of PD and GAD patients to 39% of SAD patients.[7]

Remission, if achieved with treatment, is most likely to occur within the first 2 years of an index episode.[6] Similarly, the highest rates of relapse are within the same timeframe. This suggests that many patients need ongoing maintenance treatment. Rates of remission and relapse do not appear to vary by sex[6]; however, one study reported that women with PD without agoraphobia were three times more likely than men to relapse. Patients with anxiety disorders spend a significant portion of time "being ill" during a particular episode, ranging from 41% to 80% of the time.[7] Anxiety disorders are associated with impaired psychosocial functioning and a compromised quality of life.[8] Appropriate treatment improves overall quality of life and psychosocial functioning.[8]

#### ▶ Comorbidity

More than 90% of individuals with an anxiety disorder have a lifetime history of one or more other psychiatric disorders.[9] Depression is the most common comorbidity, followed by

alcohol and substance use disorders, as well as other co-occurring anxiety disorders, especially GAD and PD.[9] Generally, the onset of SAD and GAD symptoms precedes major depressive disorder (MDD), but there is an equal chance of PD onset before, during, or after MDD. Comorbid psychiatric illness is associated with lower rates of remission and higher rates of relapse. Both disorders must be treated appropriately.

## Etiology

Both genetic and psychosocial factors appear to play a role in the initiation and expression of anxiety disorders.[10] Documentation of moderate genetic risk has been identified for all anxiety disorders, although conflicting data exist. No definitive gene or set of genes has been identified as causative for a specific anxiety disorder. Additionally, it is unclear if anxiety disorders share common genetic risk factors. Genetic overlap may exist between GAD and PD and, to a lesser extent, SAD.[10]

Genetics may create a vulnerable phenotype for an anxiety disorder, and an individual's life stressors and means of coping with the stress may play a role in precipitation and continued expression of the anxiety disorder.[11] Some researchers believe that stressful life events may have a strong role in the onset of anxiety disorders, especially in GAD and PD.[10] It has been reported that those experiencing one or more negative life events have a threefold increased chance of developing GAD.[2] Similar findings have been reported with PD.[11]

## PATHOPHYSIOLOGY

The thalamus and amygdala are important in the generation of a normal fear response and play a central role in most anxiety disorders (Figure 40–1). The thalamus provides the first real processing region to organize sensory data obtained from the environment. It passes information to higher cortical centers for finer processing and to the amygdala for rapid assessment of highly charged emotional information. The amygdala provides emotional valence or the emotional importance of the information. This helps the organism to act quickly on ambiguous but

vital events. The cortex then performs a more detailed analysis and sends updates to the amygdala for comparison and any needed course corrections, thus enabling a decision on a course of action.

Anxiety becomes an anxiety disorder when the fear-response system leads to maladaptive behavior or distress. Anxiety can become independent of stimuli as in PD, be associated with benign stimuli as in phobias, or continue beyond the stimulus duration as in GAD.

Direct and indirect connections to the reticular activating system (RAS), a region spanning the medulla, pons, and midbrain, help to regulate arousal, vigilance, and fear. These connections are modulated by serotonin (5-HT) and norepinephrine (NE), which have their primary origins in the RAS.[12] The amygdala sends projections to the hypothalamus, thus influencing the autonomic nervous system to affect heart rate, blood pressure, and stress-associated changes. It also influences the hypothalamic–pituitary–adrenal (HPA) axis, leading to a cascade of stress hormones.[13] One such hormone is cortisol, which, if elevated for prolonged periods, can damage the brain and other organs.

## Noradrenergic System

Norepinephrine-producing cells reside primarily in a region of the brain called the locus ceruleus (LC). Increased activity in this region is associated with an increase in arousal, anxiety, and panic. Drugs such as yohimbine that increase activity in the LC can be anxiogenic; drugs that decrease activity in the LC appear to improve anxiety. Furthermore, dysregulation of this region is implicated by elevated levels of NE or its metabolites in subjects with GAD, PD, and specific phobias.[13]

## Serotonergic System

The raphe nuclei and the resident cell bodies of 5-HT-producing neurons have a complicated role related to anxiety symptoms. Activity of 5-HT cells in the raphe nuclei over time inhibits firing of noradrenergic cells in the LC. Other influences include their ability to regulate cells in the prefrontal cortex and amygdala.

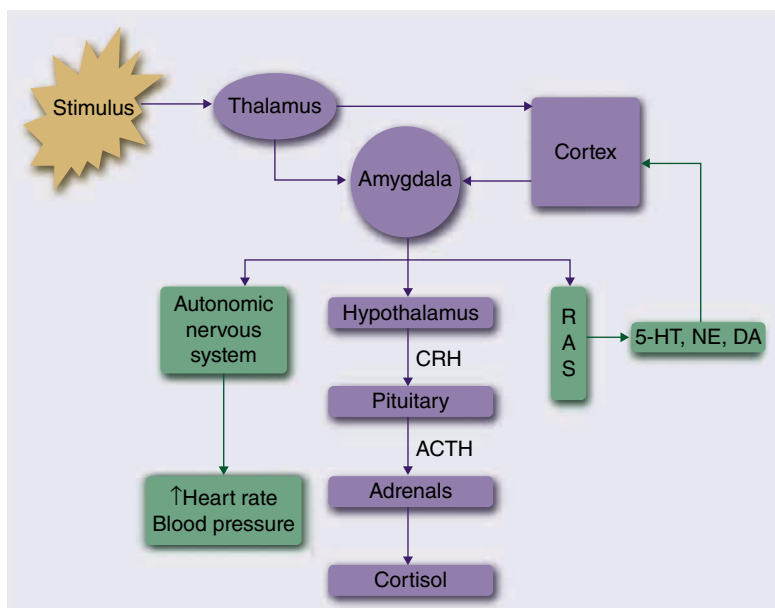

**FIGURE 40–1.** Neurocircuitry and key neurotransmitters involved in mediating anxiety disorders. (ACTH, adrenocorticotrophic hormone; CRH, corticotropin-releasing hormone; DA, dopamine; 5-HT, serotonin; NE, norepinephrine; RAS, reticular activating system.)

Perhaps the strongest evidence for the involvement of the serotonergic system is the success of serotonin reuptake inhibitors in treatment of anxiety disorders.[13]

### γ-Aminobutyric Acid

γ-Aminobutyric acid (GABA) plays a complex role as an inhibitor neurotransmitter with nonspecific effects. GABA-ergic drugs reduce anxiety, but the lack of a specific target for their effect leads to multiple undesirable effects. Current research is focused on defining receptor subtypes that may allow for greater specificity in targeting anxiety symptoms.[14]

### Hypothalamic–Pituitary–Adrenal Axis

The HPA axis provides a critical mechanism for regulation of the stress response and its effects on the brain and other organ systems. Several important hormones, including corticotropin-releasing hormone and cortisol, are involved in this pathway. These hormones regulate the effects of anxiety on the body and provide positive feedback to the brain.[13] A cycle of anxiety and sensitization by such feedback could, if unchecked, result in escalation of symptoms. Neuropeptides may provide one mechanism to balance positive and negative feedback, helping to minimize such escalation.

### Neuropeptides

Several neuropeptides(eg, neuropeptide Y [NPY], substance P, and cholecystokinin) are under investigation for their role in anxiety disorders. NPY appears to reduce the effect of stress hormones and inhibit activity of the LC. Both mechanisms may contribute to the anxiolytic properties seen experimentally. Substance P may have anxiolytic and antidepressant properties partly because of its effects on corticotropin-releasing hormone.[15]

---

### Patient Encounter 1, Part 1

A 24-year-old woman presents to the primary care clinic with complaints of fatigue, joint pain, insomnia, irritability, and daily headaches. She admits to having one to two drinks at night to help with her sleep and "turn her mind off". She states she panicked at the beginning of her economics exam and ran from the room. She states she is overwhelmed with her coursework in an MBA program, and her relationship with her boyfriend has been tumultuous over the past several months. Her medical history is positive for depression and migraine headaches.

**Meds:** Topiramate 50 mg/day

*What manifestations described above are suggestive of an anxiety disorder?*

*What additional information do you need to establish a diagnosis and develop a treatment plan?*

*What other diagnoses should be considered in your differential diagnosis?*

*Could her medication be contributing to her symptoms?*

---

### Clinical Presentation and Diagnosis of GAD

**General**

Onset is typically in early adulthood. Anxiety emerges and dissipates more gradually than in PD. Laboratory evaluation usually is reserved for later onset, atypical presentation, or poor response to treatment.

**Symptoms[2]**

- Excessive anxiety or worry involving multiple events or activities occurring more days than not for at least 6 months
- Difficulty controlling worry
- Anxiety and worry associated with at least three of the following:
  - Restlessness
  - Easily fatigued
  - Poor concentration or mind going blank
  - Irritability
  - Muscle tension
  - Insomnia or unsatisfying sleep
- The anxiety or worry causes significant distress or functional impairment and is NOT attributable to another substance, medical, or psychiatric condition

**Differential Diagnosis**

Rule out underlying medical or psychiatric disorders and medications that may cause anxiety (Tables 40–1 and 40–2)

---

### Table 40–1

**Medical Conditions That Can Cause Anxiety**

**Psychiatric Disorders**
Mood disorders, hypochondriasis, personality disorders, alcohol or substance abuse, alcohol or substance withdrawal, other anxiety disorders

**Neurologic Disorders**
CVA, seizure disorders, dementia, stroke, migraine, encephalitis, vestibular dysfunction

**Cardiovascular Disorders**
Angina, arrhythmias, congestive heart failure, mitral valve prolapse, myocardial infarction

**Endocrine and Metabolic Disorders**
Hypothyroidism or hyperthyroidism, hypoglycemia, Cushing disease, Addison disease, pheochromocytoma, hyperadrenocorticism, hyponatremia, hyperkalemia, vitamin $B_{12}$ deficiency

**Respiratory Disorders**
Asthma, COPD, pulmonary embolism, pneumonia, hyperventilation

**Other**
Carcinoid syndrome, anemias, SLE

COPD, chronic obstructive pulmonary disease; CVA, cerebrovascular accident; SLE, systemic lupus erythematosus.

Data from Refs. 2 and 16.

| Table 40–2 | |
|---|---|
| **Medications Associated with Anxiety Symptoms** | |
| **Category** | **Examples** |
| Anticonvulsants | Carbamazepine, ethosuximide |
| Antidepressants | Bupropion, SSRIs, SNRIs, TCAs |
| Antihypertensives | Felodipine |
| Antimicrobials | Cephalosporins, ofloxacin, isoniazid |
| Antiparkinson drugs | Levodopa |
| Bronchodilators | Albuterol, isoproterenol, theophylline |
| Corticosteroids | Prednisone, methylprednisolone |
| Decongestants | Pseudoephedrine, phenylephrine |
| Herbals | Ma huang, St. John's wort, ginseng, guarana, belladonna |
| NSAIDs | Ibuprofen, indomethacin |
| Stimulants | Amphetamines, caffeine, cocaine, methylphenidate |
| Thyroid hormones | Levothyroxine |
| Toxicity | Anticholinergics, antihistamines, digoxin |
| Withdrawal of CNS depressants (abrupt) | Alcohol, barbiturates, benzodiazepines |

CNS, central nervous system; SNRI serotonin norepinephrine reuptake inhibitor; SSRI, selective serotonin reuptake inhibitor; TCA, tricyclic antidepressant; NSAID, non-steroidal anti-inflammatory drug.

Data from Refs. 2, 16, and 17.

## TREATMENT: GENERALIZED ANXIETY DISORDER

### Desired Outcomes

**KEY CONCEPT** *The goals of therapy for GAD are to acutely reduce the severity and duration of anxiety symptoms and restore overall functioning. The long-term goal is to achieve and maintain remission.* With a positive response to treatment, comorbid depressive symptoms should be minimized.

### General Approach to Treatment

Patients with GAD may be managed with psychotherapy, pharmacotherapy, or both. Treatment should be individualized based on symptom severity, comorbid illnesses, medical status, age, and patient preference. Patients with severe symptoms resulting in functional impairment should receive antianxiety medication.

### Nonpharmacologic Therapy

Nonpharmacologic therapy includes psychoeducation, exercise, stress management, and psychotherapy. Psychoeducation should provide information on GAD and its management. Patients should be instructed to avoid stimulating agents, eg, caffeine, decongestants, diet pills, and excessive alcohol use. Regular exercise is also recommended. Cognitive-behavioral therapy (CBT) is the most effective psychological therapy for GAD patients. It helps patients to recognize and alter patterns of distorted thinking and dysfunctional behavior. Treatment gains with CBT may be maintained for up to 1 year.[18] CBT may be delivered in individual or group settings.[19] Computerized CBT offered over the Internet is effective and may offer an alternative to face-to-face therapy for patients with access barriers.[20] The effect sizes of trials with CBT are comparable to those of pharmacologic therapies. A recent trial in children with GAD suggests the combination of CBT and medication is superior to either treatment alone.[21]

### Patient Encounter 1, Part 2

After a medical workup, she was diagnosed with GAD and unspecified depressive disorder.

**PMH:** Depression, Migraine

**FH:** Mother treated for depression; father, alcohol dependence

**SH:** One to two drinks per night; lives with boyfriend

**Meds:** Topiramate 50 mg/day

*What are first-line treatment options for this patient?*

*What factors should be considered in selecting the patient's treatment?*

*What is the role of benzodiazepines for this patient?*

*How should the patient be monitored when receiving an antidepressant?*

### Pharmacologic Therapy

Antidepressants, benzodiazepines, pregabalin, buspirone, hydroxyzine, and the second-generation antipsychotics (SGAs) have controlled clinical trial data supporting their use in GAD. **KEY CONCEPT** *Antidepressants are the drugs of choice for chronic GAD because of a tolerable side-effect profile; no risk for dependency; and efficacy in common comorbid conditions, including depression, panic, obsessive-compulsive disorder (OCD), and SAD.* Benzodiazepines remain the most effective and commonly used treatment for short-term management of anxiety when immediate relief of symptoms is desired. They are also recommended for intermittent or adjunctive use during GAD exacerbation or for sleep disturbance during the initiation of antidepressant treatment.[18] Buspirone and pregabalin are alternative agents for patients with GAD without depression. Hydroxyzine is usually adjunctive and is less desirable for long-term treatment because of side effects, eg, sedation and anticholinergic effects.

Patients with GAD should be treated to symptom remission. Although supporting data are lacking, recent guidelines recommend continuing treatment for 1 year.[18,19,22,23] Continuation of antidepressant therapy after acute response significantly decreases the risk of relapse (odds ratio, 0.2 [0.15–0.26]).[22] An algorithm for the pharmacologic management of GAD is shown in **Figure 40–2**.

▶ *Antidepressants*

Antidepressants (**Table 40–3**) reduce the psychic symptoms (eg, worry and apprehension) of anxiety with a modest effect on autonomic or somatic symptoms (eg, tremor, rapid heart rate, and/or sweating). All antidepressants evaluated provide a similar degree of anxiety reduction. The onset of antianxiety effect is delayed 2 to 4 weeks. Selective serotonin reuptake inhibitors (SSRIs) or serotonin-norepinephrine reuptake inhibitors (SNRIs) are usually preferred over tricyclic antidepressants (TCAs) because of improved safety and tolerability. Selection of a specific antidepressant generally is based on history of prior **response,** side effect and drug interaction profile (see Chapter 38), cost, or formulary availability.

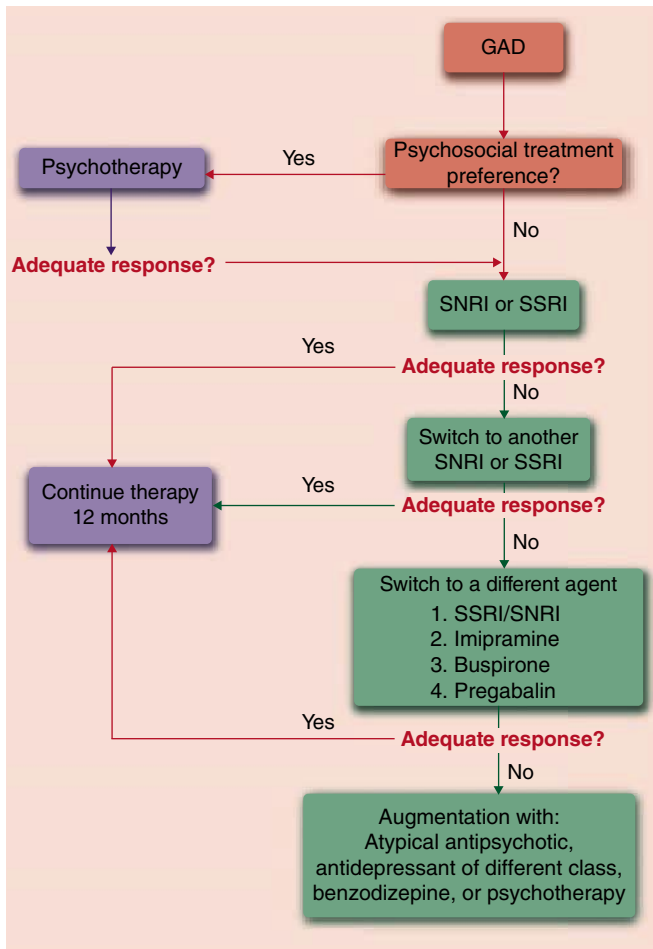
Antidepressants modulate synaptic 5-HT, NE, and/or dopamine (DA) reuptake and receptor-activated neuronal signal transduction. These intracellular changes modify the expression of genes and proteins important in stress response (eg, glucocorticoid


**FIGURE 40–2.** Treatment algorithm for generalized anxiety disorder. (BZ, benzodiazepine; SNRI, serotonin-norepinephrine reuptake inhibitor; SSRI, selective serotonin reuptake inhibitor.) Data from Refs. 17, 18, 23.

receptors, brain-derived neurotrophic factor, corticotropin-releasing hormone).[24] Activation of these "stress-adapting" pathways may improve both somatic and psychic symptoms of anxiety.[24]

**Serotonin Norepinephrine Reuptake Inhibitors** Venlafaxine and duloxetine are approved by the Food and Drug Administration (FDA) for the treatment of GAD. They alleviate anxiety with and without depression and have improved tolerability over TCAs. Venlafaxine is effective at doses 75 to 225 mg/day and maintains response with extended treatment.[18] It is also effective for GAD in children and adolescents.[19] The most common side effects reported in patients with GAD are nausea, somnolence, dry mouth, dizziness, sweating, constipation, and anorexia.[18,25]

Duloxetine is similarly effective and tolerated as venlafaxine.[25] For patients with concurrent pain syndromes, duloxetine has been found to improve anxiety, pain, and functional impairment more than placebo.[26] Newer SNRIs, milnacipran, levomilnacipran, and vortioxetine have not been evaluated in the treatment of GAD.

**Selective Serotonin Reuptake Inhibitors** The SSRIs paroxetine, escitalopram, and sertraline have been shown to be significantly more effective than placebo in reducing anxiety symptoms in adults with GAD. Response rates range from 56% to 68% during acute treatment, with remission achieved in

approximately one-third of patients.[27–30] Common side effects include somnolence, headache, nausea, dry mouth (paroxetine), diarrhea (sertraline), sweating (sertraline), decreased libido, ejaculation disorder, anorgasmia, and asthenia.

SSRI therapy is better tolerated than TCAs, and tolerability is similar to that of venlafaxine. Citalopram is efficacious in the treatment of GAD in the elderly.[31] The SSRIs, sertraline, fluoxetine, and fluvoxamine have demonstrated benefits in children and adolescents with GAD and are the preferred pharmacologic treatment in this population.[19]

**Tricyclic Antidepressants** Imipramine treatment of GAD results in a higher rate of remission of anxiety symptoms than treatment with trazodone or diazepam.[18] Both antidepressants were more effective than diazepam or placebo in reducing psychic symptoms of anxiety. TCA use is limited by bothersome adverse effects (eg, sedation, orthostatic hypotension, anticholinergic effects, and weight gain). TCAs have a narrow therapeutic index and are lethal in overdose because of atrioventricular block.

**Novel Antidepressants** Mirtazapine, an α-2 adrenergic antagonist and postsynaptic serotonin ($5\text{-HT}_2$, $5\text{-HT}_3$) receptor antagonist, is an effective antidepressant but has not been extensively evaluated in anxiety disorders. One open-label study found 12-week treatment of GAD with mirtazapine 30 mg to be efficacious and well tolerated.[18] It is not associated with sexual dysfunction, but does have a propensity to cause sedation and weight gain. Bupropion, a dopamine and norepinephrine reuptake-inhibitor, lacks the common antidepressant side effects of weight gain and sexual dysfunction. Bupropion has not been studied or used extensively in anxiety disorders owing to its stimulating effects that would be expected to worsen anxiety symptoms. However, a small controlled trial comparing bupropion XL with escitalopram found bupropion to have comparable anxiolytic efficacy and tolerability.[18] Vilazodone, a SSRI, and 5-HT 1A receptor partial agonist has not been evaluated in anxiety disorders.

### ▶ Benzodiazepines

**KEY CONCEPT** *Benzodiazepines are recommended for acute treatment of GAD when short-term relief is needed, as an adjunct during initiation of antidepressant therapy, or to improve sleep.*[18] Benzodiazepine treatment results in a significant improvement in 65% to 75% of GAD patients, and most of the improvement occurs in the initial 2 weeks.[18] They are more effective for somatic symptoms than psychic symptoms. Major benzodiazepine disadvantages are lack of effectiveness for depression; risk for dependency and abuse; and potential interdose rebound anxiety, especially with short-acting benzodiazepines. They should be avoided in older adults and patients with current or past chemical dependency.

Benzodiazepines enhance transmission of the inhibitory neurotransmitter GABA through interaction with the $\text{GABA}_A$-receptor complex.[17,18] Only 7 of the 13 currently marketed benzodiazepines are approved by the FDA for the treatment of anxiety disorders (Table 40–4). All benzodiazepines are expected to provide equivalent benefit when given in comparable doses. They differ substantially in their pharmacokinetic properties and potency for the $\text{GABA}_A$-receptor.

Benzodiazepines are metabolized by hepatic oxidation (cytochrome P450 3A4) and glucuronide conjugation. Because lorazepam and oxazepam bypass hepatic oxidation and are conjugated only, they are preferred agents for patients with reduced hepatic function secondary to aging or disease (eg, cirrhosis; hepatitis B or C from intravenous drug use). Many benzodiazepines are metabolized to long-acting metabolites (see Table 40–4) that

**Table 40–3**

**Antidepressants Used in the Treatment of Generalized Anxiety Disorder**

| Medication Class | Recommended Starting Dose (mg/day) | Usual Therapeutic Dosage Range (mg/day) | Hepatic Insufficiency | Renal Insufficiency |
|---|---|---|---|---|
| **SSRIs** | | | | |
| Citalopram[a] (Celexa) | 20 | 20–40 | Maximum, 20 mg/day | |

**Comparison of the Benzodiazepines**

| Drug Name (Brand Name) *Active Metabolites* | Time to Peak Concentration (hours) | Half-Life Range (hours) | Approved Dosage Range (mg/day) | Dose Equivalent (mg) |
|---|---|---|---|---|
| Alprazolam[a,b] (Xanax) | 1–2 | 12–15 | 1–4 (GAD) 1–10 (PD) | 0.5 |
| Chlordiazepoxide[a] (Librium) | 1–4 | 5–30 | 25–100 | 10 |
| *Desmethylchlordiazepoxide* | | 18 | | |
| *Demoxepam* | | 14–95 | | |
| *Desmethyldiazepam* | | 40–120 | | |
| *Oxazepam* | | 5–15 | | |
| Clonazepam[b] (Klonopin) | 1–4 | 18–50 | 1–4 | 0.25 |
| Clorazepate[a] (Tranzene) | 1–2 | | 7.5–60 | 7.5 |
| *Desmethyldiazepam* | | 40–120 | | |
| *Oxazepam* | | 5–15 | | |
| Diazepam[a] (Valium) | 0.5–2 | 20–80 | 2–40 | 5 |
| *Desmethyldiazepam* | | 40–120[c] | | |
| *Temazepam* | | 8–15 | | |
| *Oxazepam* | | 5–15 | | |
| Lorazepam[a] (Ativan) | 2–4 | 10–20 | 0.5–10 | 0.75–1 |
| Oxazepam[a] (Serax) | 2–4 | 5–15 | 30–120 | 15 |

[a]Food and Drug Administration (FDA) approved for use in generalized anxiety disorder.

[b]FDA approved for use in panic disorder.

[c]CYP2C19 genetic polymorphisms resulting in little or no enzyme activity are present in 15% to 20% of Asians and 3% to 5% of blacks and whites, resulting in reduced clearance of desmethyldiazepam.[34]

Data from Refs. 32 and 33.

**Table 40–5**

**Pharmacokinetic Drug Interactions with Benzodiazepines**

| Drug | Effect |
|---|---|
| Alcohol (chronic) | Increased CL of BZs |
| Carbamazepine | Increased CL of alprazolam |
| Cimetidine | Decreased CL of alprazolam, diazepam, chlordiazepoxide, and clorazepate and increased $t_{1/2}$ |
| Disulfiram | Decreased CL of alprazolam and diazepam |
| Erythromycin | Decreased CL of alprazolam |
| Fluoxetine | Decreased CL of alprazolam and diazepam |
| Fluvoxamine | Decreased CL of alprazolam and prolonged $t_{1/2}$ |
| Itraconazole | Potentially decreased CL of alprazolam and diazepam |
| Ketoconazole | Potentially decreased CL of alprazolam |
| Nefazodone | Decreased CL of alprazolam, AUC doubled, and $t_{1/2}$ prolonged |
| Omeprazole | Decreased CL of diazepam |
| Oral contraceptives | Increased free concentration of chlordiazepoxide and slightly decreased CL; decreased CL and increased $t_{1/2}$ of diazepam and alprazolam |
| Paroxetine | Decreased CL of alprazolam |
| Phenobarbital | Increased CL of clonazepam and reduced $t_{1/2}$ |
| Phenytoin | Increased CL of clonazepam and reduced $t_{1/2}$ |
| Probenecid | Decreased CL of lorazepam and prolonged $t_{1/2}$ |
| Propranolol | Decreased CL of diazepam and prolonged $t_{1/2}$ |
| Ranitidine | Decreased absorption of diazepam |
| Rifampin | Increased metabolism of diazepam |
| Theophylline | Decreased alprazolam concentrations |
| Valproate | Decreased CL of lorazepam |

AUC, area under the plasma concentration time curve; BZ, benzodiazepine; CL, clearance; $t_{1/2}$, elimination half-life.

Adapted from Kirkwood CK, Melton ST. Anxiety disorders: I. Generalized anxiety, panic and social anxiety disorders. In: DiPiro JT, Talbert RL, Yee GC, et al., eds. Pharmacotherapy: A Pathophysiologic Approach. 7th ed. New York: McGraw-Hill, 2008:1169, with permission.

provide long-lasting anxiety relief. Drugs that either inhibit or induce CYP450 isozymes or glucuronidation can cause drug interactions (Table 40–5).

The most common side effects of benzodiazepine therapy include central nervous system (CNS) depressive effects (eg, drowsiness, sedation, psychomotor impairment, and ataxia) and cognitive effects (eg, poor recall and anterograde amnesia). Anterograde amnesia is more likely with high-potency benzodiazepines such as alprazolam.[35] Some patients also may be disinhibited and experience confusion, irritability, aggression, and excitement.[17,18] Discontinuation of benzodiazepines may be associated with withdrawal, rebound anxiety, and a high rate of relapse. Higher doses of benzodiazepines and a longer duration of therapy increase the severity of withdrawal and risk of seizures after abrupt or rapid discontinuation. Patients should be tapered rather than discontinued abruptly from benzodiazepine therapy to avoid withdrawal symptoms. The duration of the taper should increase with extended duration of benzodiazepine therapy.[17,18] For example, patients on benzodiazepine therapy for 2 to 6 months should be tapered over 2 to 8 weeks, but patients receiving 12 months of treatment should be tapered over 2 to 4 months. A general approach to the taper is to reduce the dose by 25% every 5 to 7 days until reaching half the original dose and then decreasing by 10% to 12% per week until discontinued. Patients should expect minor withdrawal symptoms and discomfort even when tapering. Rebound symptoms (eg, return of original symptoms at increased intensity) are transient. The patient should be educated that rebound anxiety is not a relapse. Relapse or recurrence of anxiety may occur in as many as 50% of patients discontinuing benzodiazepine treatment.[17,18] It is unclear if this relapse rate represents an inferiority of benzodiazepines or supports the chronic nature of GAD.

### ▶ Pregabalin

Pregabalin is a calcium channel modulator, and its anxiolytic properties are attributed to its selective binding to the α-2-delta subunit of voltage-gated calcium channels. In a 4-week controlled trial versus alprazolam and placebo, pregabalin was effective for both somatic and psychic symptoms of anxiety with onset of effect similar to that of alprazolam.[36] Compared with venlafaxine and placebo, pregabalin was safe, well tolerated, and efficacious in GAD, and results were seen 1 week sooner than with venlafaxine.[37] Pregabalin reduced the risk of relapse versus placebo in a 26-week relapse prevention trial.[38] It has a short elimination half-life and must be dosed two to three times daily. It is excreted renally with a low risk of drug–drug interactions. Pregabalin is a schedule V controlled substance owing to a propensity to cause euphoria, and it may cause withdrawal symptoms if discontinued abruptly. It should be used cautiously in patients with a current or past history of substance abuse. It is not beneficial for depression or other anxiety disorders.

### ▶ Alternative Agents

Hydroxyzine, buspirone, and SGAs are alternative agents. Hydroxyzine may be effective for acute reduction of somatic symptoms of anxiety[18] but not for psychic features of anxiety, depression, or other common comorbid anxiety disorders. Buspirone, a 5-HT$_{1A}$ partial agonist, is thought to exert its anxiolytic effects by reducing presynaptic 5-HT firing.[39] Unlike benzodiazepines, it does not have abuse potential, cause withdrawal reactions, or potentiate alcohol and sedative-hypnotic effects. It has a gradual onset of action (ie, 2 weeks) and does not provide immediate anxiety relief. Data are inconsistent regarding its efficacy in chronic GAD or GAD with comorbid depression.[18]

It may be less effective in patients who have been treated previously (4 weeks–5 years) with benzodiazepines.[18]

Buspirone should be initiated at 7.5 mg twice daily and titrated in 5-mg/day increments (every 2–3 days) to a usual target dose of 20 to 30 mg/day.[18,39] The maximum daily dose is considered to be 60 mg/day. Buspirone is well tolerated and does not cause sedation. The most common side effects include dizziness, nausea, and headaches. Drugs that inhibit CYP3A4 (eg, verapamil, diltiazem, itraconazole, fluvoxamine, and erythromycin) can increase buspirone levels. Enzyme inducers (eg, rifampin) can reduce buspirone levels significantly. Buspirone may increase blood pressure when coadministered with a monoamine oxidase inhibitor (MAOI).

## Clinical Presentation and Diagnosis of PD

### General

Typically presents in late adolescence or early adulthood. Onset in older adults raises suspicion of a relationship to medical disorders or substance use. Laboratory evaluation must be driven by history and physical examination.

### Symptoms[2]

Recurrent, unexpected panic attacks. A panic attack is an abrupt surge of intense fear or discomfort peaking within minutes, and with four or more of the following symptoms:

- Palpitations or rapid heart rate
- Sweating
- Trembling or shaking
- Sensation of shortness of breath or smothering
- Feeling of choking
- Chest pain or discomfort
- Nausea or abdominal distress
- Feeling dizzy or lightheaded
- Chills or hot flushes
- Paresthesias
- Derealization or depersonalization
- Fear of dying
- Fear of losing control or "going crazy"

At least one of the attacks has been followed by 1 month or more of one or both:

- Persistent concern or worry about additional attacks
- Significant maladaptive change in behavior related to the attacks (eg, avoidance)

### Differential Diagnosis

Rule out underlying medical or psychiatric disorders and medications that may cause anxiety (see Tables 40–1 and 40–2).

### Laboratory Evaluation

- Urine drug screen
- Basic metabolic panel (HgbA_{1C}) look at guideline
- Thyroid-stimulating hormone
- Electrocardiogram

The SGAs, quetiapine, olanzapine, and risperidone have demonstrated benefit in GAD. In three large placebo controlled trials, quetiapine in daily doses of 50 to 300 mg resulted in 26% greater likelihood of treatment response (effect size, ~0.3).[40] Quetiapine had similar outcomes to paroxetine 20 mg/day and escitalopram 10 mg/day.[40] Risperidone and olanzapine may improve treatment outcomes in patients with inadequate response to initial pharmacotherapy.[18] SGAs are associated with a risk of weight gain, sedation, fatigue, and extrapyramidal symptoms in anxiety patients.

### Outcome Evaluation

Assess patients for improvement of anxiety symptoms and return to baseline occupational, social, and interpersonal functioning. With effective treatment, patients should have no or minimal symptoms of anxiety or depression. With initiation of drug therapy, evaluate patients frequently for tolerability and response. Monitor for suicidal ideation and behaviors for children, adolescents, and young adults (24 years of age or less) initiated on antidepressants.[41] Increase the dose in patients exhibiting a partial response after 2 to 4 weeks on an antidepressant or 2 weeks on a benzodiazepine. Individualize the duration of treatment as some patients require up to 1 year of treatment.[18]

## TREATMENT: PANIC DISORDER
### Desired Outcomes

The main objectives of treatment are to reduce the severity and frequency of panic attacks, reduce anticipatory anxiety and agoraphobic behavior, and minimize symptoms of depression or other comorbid disorders.[42] The long-term goal is to achieve and sustain remission and restore overall functioning.

### General Approach to Treatment

Treatment options include medication, psychotherapy, or a combination of both. In some cases, pharmacotherapy will follow psychotherapy treatments when full response is not realized. Patients with panic symptoms without agoraphobia may respond to pharmacotherapy alone. Agoraphobic symptoms generally take longer to respond than panic symptoms. **KEY CONCEPT** *The acute*

## Patient Encounter 2

A 14-year-old Hispanic female presents to the pediatric clinic, accompanied by her mother, with complaints of nausea, bloating, and stomach pain. Her mother reports that she is having difficulty adjusting to her new high school and teachers. Mother states "she's always been shy and doesn't like change, and this time she is having significant difficulty adjusting". She has missed 4 days of school over the past 3 weeks with complaints of nausea and stomach pain. She is required to participate in a drama production at the school next week and she is refusing.

Her medical history is positive for ADHD

Meds: methylphenidate ER (24 hour) 36 mg/day

Her medical workup is noncontributory, and she is diagnosed with SAD

*What treatment options should be considered for AD?*

*What are the benefits of using pharmacotherapy versus psychotherapy versus both?*

*phase of PD treatment lasts about 12 weeks and should markedly reduce or eliminate panic attacks and minimize anticipatory anxiety and phobic avoidance. Treatment should be continued to prevent relapse for an additional 12 to 18 months before attempting discontinuation.*[44] For patients who relapse after discontinuation, therapy should be resumed.[42]

## Nonpharmacologic Therapy

Patients with PD should avoid stimulant agents (eg, decongestants, diet pills, and caffeine) that may precipitate a panic attack. CBT generally includes psychoeducation, self-monitoring, countering anxious beliefs, exposure to fear cues, and modification of anxiety-maintaining behaviors.[18,42] Exposure therapy is useful for patients with phobic avoidance. CBT is considered a first-line treatment of PD, with efficacy similar to that of pharmacotherapy. Some studies suggest lower risk of relapse after CBT versus drug therapy.[42] In a trial of PD with or without agoraphobia, SSRI plus CBT was more effective than either therapy alone after 9 months of treatment.[43]

## Pharmacologic Therapy

Patients with PD may be treated with TCAs, SSRIs, SNRIs, or MAOIs, as well as benzodiazepines[18,42] (Table 40–6) with similar effectiveness, but SSRIs have become the treatment of choice. Benzodiazepines often are used concomitantly with antidepressants, especially early in treatment, or as monotherapy to acutely reduce panic symptoms. Benzodiazepines are not preferred for long-term treatment but may be used when patients fail several

antidepressant trials.[18,42] PD patients with comorbid depression should be treated with an antidepressant. An algorithm for pharmacologic management of PD appears in Figure 40–3.

### ▶ *Antidepressants*

Antidepressants typically require 4 weeks for onset of antipanic effect, with optimal response at 6 to 12 weeks. Reduction of anticipatory anxiety and phobic avoidance generally follows improvement in panic symptoms. **KEY CONCEPT** *PD patients are more likely to experience stimulant-like side effects of antidepressants than patients with major depression. Antidepressants should be initiated at lower doses (see* Table 40–6*) in PD patients than in depressed patients.* Target doses are similar to those used for depression. **KEY CONCEPT** *Antidepressants should be tapered when treatment is discontinued to avoid withdrawal symptoms, including irritability, dizziness, headache, and dysphoria.*

**Tricyclic Antidepressants** Treatment with imipramine, leaves 45% to 70% of patients panic free. Desipramine and clomipramine are also effective. However, TCAs are considered second- or third-line pharmacotherapy because of poorer tolerability and toxicity on overdose.[18,42] TCAs are associated with a higher rate of treatment discontinuation than SSRIs.[42] PD patients taking TCAs may experience anticholinergic effects, orthostatic hypotension, sweating, sleep disturbances, dizziness, fatigue, sexual dysfunction, and weight gain. Stimulant-like side effects occur in up to 40% of patients.[42]

**Selective Serotonin Reuptake Inhibitors** SSRIs are the drugs of choice for patients with PD. All SSRIs have demonstrated effectiveness in controlled trials, with 60% to 80% of patients

---

| Table 40–6 | | | | |
|---|---|---|---|---|
| **Antidepressants Used in the Treatment of Panic Disorder**[18,23,42] | | | | |
| **Medication Class** | **Recommended Starting Dose (mg/day)** | **Usual Therapeutic Dosage Range (mg/day)** | **Advantages** | **Disadvantages** |
| **SSRIs/SNRIs** Citalopram | 10 | 20–40 | **SSRIs (in general)** Antidepressant activity; antianxiety activity; single daily dosing (all but fluvoxamine); low toxicity; available in generic | **SSRIs (in general)** Activation; delayed onset of action; may precipitate mania; sexual side effects; GI side effects |
| Escitalopram | 5–10 | 10–20 | | |
| Fluoxetine[a] | 5–10 | 20–60 | | |
| Fluvoxamine | 25 | 100–300 | | |
| Paroxetine[a] | 10 | 20–60 | | |
| Sertraline[a] | 25 | 50–200 | | |
| Venlafaxine XR[a] | 37.5 | 75–225 | | |
| **TCAs** Clomipramine | 25 mg (twice a day) | 75–250 | **TCAs (in general)** Established efficacy; available in generic | **TCAs (in general)** Activation; sedation; anticholinergic effects; cardiovascular effects; delayed onset of action; may precipitate mania; sexual side effects; toxic in overdose; weight gain |
| Imipramine[a] | 10–25 | 75–250 | | |
| **MAOI** Phenelzine | 15 | 45–90 | Antidepressant effects; available in generic | Dietary restrictions; drug interactions; weight gain; orthostasis; may precipitate mania |

[a] Food and Drug Administration approved for use in panic disorder.

GI, gastrointestinal; MAOI, monoamine oxidase inhibitor; SSRI, selective serotonin reuptake inhibitor; TCA, tricyclic antidepressant.

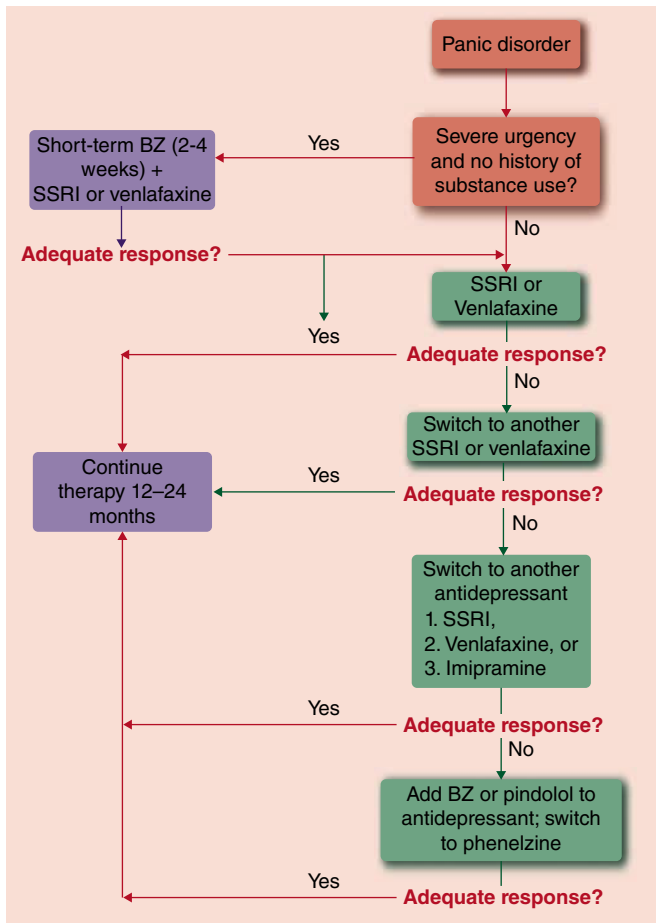
Data from Refs. 18, 23, and 40.


**FIGURE 40–3.** Algorithm for the pharmacotherapy of panic disorder. BZ, benzodiazepine; SSRI, selective serotonin reuptake inhibitor. (Adapted from Young AS, Klap R, Sherbourne CD, Wells KB. The quality of care for depressive and anxiety disorders in the United States. Arch Gen Psychiatry. 2001;58:55–61 and Bruce SE, Yonkers SE, Otto MW, et al. Influence of psychiatric comorbidity on recovery and recurrence in generalized anxiety disorder, social phobia, and panic disorder: A 12-year prospective study. Am J Psychiatry. 2005;162:1179–1187, with permission.)

achieving a panic-free state.[18,40] With similar efficacy reported and no trials comparing different SSRIs, drug selection generally is based on pharmacokinetics, drug interactions, side effects, and cost differences (see Chapter 38). The most common side effects of SSRIs include headaches, irritability, nausea and other gastro-intestinal complaints, insomnia, sexual dysfunction, increased anxiety, drowsiness, and tremor.[42]

**Serotonin Norepinephrine Reuptake Inhibitors** Venlafax-ine, in dosages of 75 to 225 mg/day, reduced panic and antici-patory anxiety in short-term controlled trials and prevented relapse with extended treatment over 6 months.[42,44] The most common side effects include anorexia, dry mouth, constipation, somnolence, tremor, abnormal ejaculation, and sweating. There is insufficient evidence to support the use of other SNRIs.

**Monoamine Oxidase Inhibitors** MAOIs have not been evalu-ated systematically for treatment of PD under the current diag-nostic classification and generally are reserved for patients who are refractory to other treatments.[42] They have significant side effects that limit adherence. Additionally, patients must adhere to dietary restriction of tyramine and avoid sympathomimetic drugs to avoid hypertensive crisis (see Chapter 38).

The reversible inhibitors of monoamine oxidase (RIMAs) (brofaromine and meclobemide,[unavailable in the United States]) have been studied with mixed results.[18,42]

**Other Antidepressants** There is insufficient evidence to support the use of bupropion, trazodone, nefazodone, or mirtazapine for treatment of PD.[18,42]

▶ *Benzodiazepines*

Benzodiazepines are effective antipanic agents with significant effects on anticipatory anxiety and phobic behaviors. Alprazolam, the benzodiazepine most studied, is associated with significant panic reduction after 1 week of therapy (eg, 55%–75% panic free).[42,45] Benzodiazepines achieve outcomes similar to antidepres-sants over extended treatment, but benzodiazepine-treated patients

## Clinical Presentation and Diagnosis of SAD

### General

Individuals have marked fear or anxiety about one or more social situations where they are exposed to possible scrutiny or negative evaluation (eg, common social interactions, conversation, eating, drinking or performing). SAD differs from specific phobia, in which the fear and anxiety are limited to a particular object or situation (eg, insects, heights, public transportation). In children, the anxiety must be present in peer settings, not just in interactions with adults.

### Symptoms[2]

- The individual fears acting in a way or showing anxiety that will be negatively evaluated (ie, humiliating or embarrassing or lead to rejection or offend others)
- Social situations almost always provoke fear or anxiety and are avoided or endured with intense fear or anxiety. Children may express fear or anxiety by crying, tantrums, freezing, clinging or failing to speak in social situations.

*The fear or anxiety is*

- out of proportion to the actual threat posed by the social situation;
- persistent, typically lasting for 6 months or more;
- causes clinically significant distress or impairment in social, occupational, or other area of functioning;
- not attributable to physiological effects of a substance or another medical condition; and
- not better explained by the symptoms of another mental disorder (eg, panic disorder, body dysmorphic disorder, or autism spectrum disorder)

### Differential Diagnosis

Rule out underlying medical or psychiatric disorders and medications that may cause anxiety (see Tables 40–1 and 40–2).

### Laboratory Evaluation

Laboratory investigation is of limited value and should be pursued only in context of other history or physical examination findings.

are more likely to relapse when the drugs are discontinued.[42] The risk for dependence and withdrawal and lack of efficacy for depression are significant concerns for long-term treatment of patients with PD. There is no evidence that tolerance to therapeutic effect occurs. Patients with PD experience greater rebound anxiety and relapse when discontinuing benzodiazepines than do patients with GAD. Tapering should be done at a slower rate and over a more extended period of time than with other anxiety disorders.[18,42]

**KEY CONCEPT** *The dose of benzodiazepine required for improvement generally is higher than that used in other anxiety disorders,* and this may explain why high-potency agents such as alprazolam and clonazepam generally are preferred. Lorazepam and diazepam, when given in equivalent doses, produce similar treatment benefits.[18,42] Doses should be titrated to response (see Table 40–4). The use of extended-release alprazolam or clonazepam may minimize breakthrough panic symptoms that are sometimes observed with immediate-release alprazolam.[45]

The most common side effects of benzodiazepines are sedation, fatigue, and cognitive impairment.[42] Benzodiazepines should be avoided in patients with current or past substance abuse or dependence or sleep apnea. Additionally, caution should be used in older adults because they have more pronounced psychomotor and cognitive side effects.

#### ▶ β-Blockers

Pindolol 25 mg three times a day is an effective adjunctive treatment with an SSRI.[42] Propranolol 120 to 240 mg/day has been found equivalent to alprazolam in reduction of panic attacks.[42] β-blockers are not expected to reduce psychic anxiety or avoidance behavior. Additionally, heart rate and blood pressure reduction are dose-related adverse events that may limit use.

### Outcome Evaluation

Assess patients for symptom improvement frequently (eg, weekly) during the first 4 weeks of therapy. With effective therapy, patients should experience significant reductions in the frequency and intensity of panic attacks, anticipatory anxiety, and phobic avoidance with resumption of normal activities. Rating scales, such as the Panic Disorder Symptom Scale (PDSS) can be useful in measuring symptom change over time. Assess patients for co-morbidities (eg, depression) as well as suicidal ideation. Alter the therapy of patients who do not achieve a significant reduction in panic symptoms after 6 to 8 weeks on an adequate dose of antidepressant or 3 weeks on a benzodiazepine. Regularly evaluate patients for adverse effects and medication adherence, and educate them about appropriate expectations of drug therapy.

When significant response to drug therapy is achieved, continue treatment for at least 1 year. Evaluate for symptom relapse and adverse effects that may emerge with continued treatment (eg, weight gain and sexual dysfunction). During drug discontinuation, monitor frequently for withdrawal, rebound anxiety, and relapse.

### TREATMENT: SOCIAL ANXIETY DISORDER

#### Desired Outcomes

SAD is a chronic disorder that begins in adolescence and occurs with significant functional impairment and high rates of comorbidity. The goal of acute treatment is to reduce physiologic symptoms of anxiety, fear of social situations, and phobic behaviors. Patients with comorbid depression should have a significant reduction in depressive symptoms. The long-term goal is to restore social functioning and improve the patient's quality of life.

### General Approach to Treatment

Patients with SAD may be managed with pharmacotherapy or psychotherapy. There is insufficient evidence to recommend one treatment over the other, and data are lacking on the benefits of combining treatment modalities. Children with SAD should be offered psychotherapy first.[46] Pharmacotherapy often is the first choice of treatment owing to relative greater access and reduced cost compared with psychotherapy.[46] Many patients will not achieve a full response.

### Nonpharmacologic Therapy

Patient education on disease course, treatment options, and expectations is essential. Support groups may be beneficial for some patients. CBT targets avoidance-learning and negative-thinking patterns associated with social anxiety. CBT is effective for reducing anxiety and phobic avoidance and leads to a greater likelihood of maintaining response after treatment discontinuation than does pharmacotherapy.[46]

### Pharmacologic Therapy

Several pharmacologic agents have demonstrated effectiveness in SAD, including the SSRIs, venlafaxine, phenelzine, RIMAs, benzodiazepines, gabapentin, and pregabalin. **KEY CONCEPT** *SSRIs are considered the drugs of choice based on their tolerability and efficacy for SAD and comorbid depression if present.* **KEY CONCEPT** *The onset of response for antidepressants may be as long as 8 to 12 weeks.*[18,47] *Patients responding to medication should be continued on treatment for at least 1 year.* Many patients relapse when medication is discontinued, and there are no clear predictive factors for who will maintain response.[47] Some patients may elect more long-term treatment owing to fear of relapse. A suggested treatment algorithm is shown in Figure 40–4.

#### ▶ Selective Serotonin Reuptake Inhibitors and Venlafaxine

The efficacy of paroxetine, sertraline, escitalopram, fluvoxamine, and venlafaxine was established in large controlled trials.[18,47,48] SSRIs and SNRIs improve social anxiety and phobic avoidance and reduce overall disability. Approximately 50% of patients achieve response during acute treatment. Limited data support the effectiveness of citalopram and fluoxetine in SAD.[47,49]

The initial dose of SSRI is similar to that used in depression. Patients should be titrated as tolerated to response. Many patients require maximum recommended daily doses. Patients with comorbid PD should be started on lower doses (see Table 40–6). When discontinuing SSRIs, the dose should be tapered slowly to avoid withdrawal symptoms. Relapse rates may be as high as 50%, and patients should be monitored closely for several weeks.[46,47] Side effects of SSRIs in SAD are similar to those seen in depression and include nausea, sexual dysfunction, somnolence, and sweating.

Venlafaxine extended release, in doses of 75 to 225 mg/day, has similar efficacy to SSRIs.[18] Doses should be tapered slowly when discontinuing. Common side effects are anorexia, dry mouth, nausea, insomnia, and sexual dysfunction.

#### ▶ Monoamine Oxidase Inhibitors and Reversible Inhibitors of Monoamine Oxidase

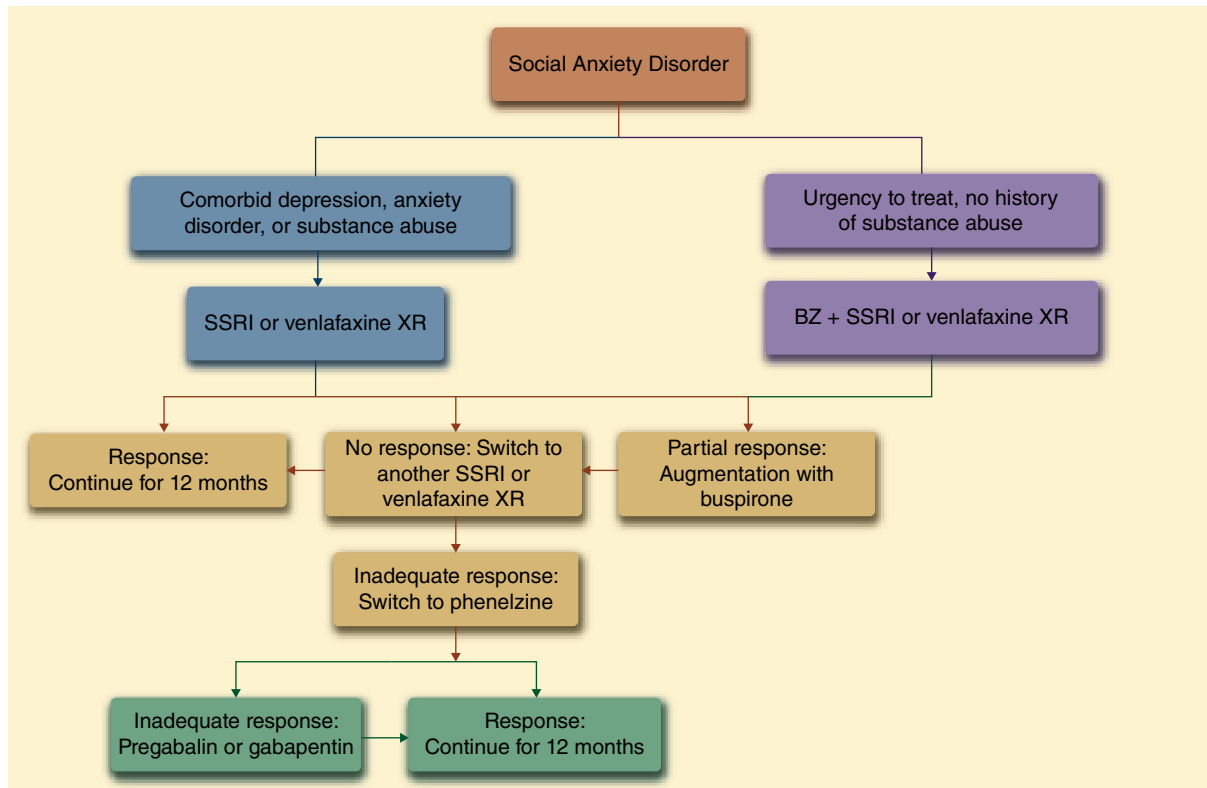
Phenelzine, effective in 64% to 69% of SAD patients,[47] is generally reserved for treatment-refractory patients owing to dietary restrictions,[49] drug interactions, and side effects. The RIMAs brofaramine and meclobemide are also effective.


**FIGURE 40–4.** Algorithm for the pharmacotherapy of social anxiety disorder. BZ, benzodiazepine; SSRI, selective serotonin reuptake inhibitor. (Adapted from Melton ST, Kirkwood CK. Anxiety disorders I: Generalized anxiety, panic and social anxiety disorders. In: DiPiro JT, Talbert RL, Yee GC, et al, eds. Pharmacotherapy: A Pathophysiologic Approach. 8th ed. New York: McGraw-Hill; 2011:1209–1227, with permission.)

## Patient Care Process

**Patient Assessment:**

- Based on clinical presentation and mental status exam, determine whether the patient is experiencing symptoms of sufficient intensity and duration to warrant treatment. Is there functional impairment?

- Based on physical exam and review of systems, does the patient have another condition causing anxiety?

- Determine if the patient has another psychiatric condition, such as depression or a substance use disorder? Is the patient experiencing suicidal ideation?

- Conduct a medication history (including prescriptions, over-the-counter (OTC) medications, and dietary supplements) to identify possible causes of anxiety/panic. Does the patient have any drug allergies? Is the patient experiencing side effects from therapy?

**Therapy Evaluation:**

- Determine whether treatment for the anxiety disorder is needed and if pharmacotherapy is preferred over behavioral interventions based on symptom severity and previous treatment and response.

- If patient is already receiving pharmacotherapy, assess efficacy, safety, and patient adherence. Are there any significant drug interactions?

**Care Plan Development:**

- Select lifestyle modifications and antianxiety therapy that are likely to be effective and safe. Used shared decision making for selection of behavioral and pharmacotherapy intervention(s). Consider comorbid conditions when selecting initial agent.

- Address any patient concerns about anxiety and its management.

- Discuss importance of medication adherence and lifestyle modifications.

**Follow-up Evaluation:**

- Follow-up at monthly intervals or more frequently during acute treatment to assess effectiveness and tolerability.

- Use appropriate rating scales to assess symptom change over time.

- Once anxiety is controlled and baseline function restored, determine the appropriateness of treatment beyond 1 year based on the patient's previous treatment, comorbidities, and ongoing environmental stressors.

▶ *Alternative Agents*

**Benzodiazepines** Benzodiazepines are used commonly in SAD; however, limited data support their use. Clonazepam was shown effective for social anxiety, fear, and phobic avoidance, and it reduced social and work disability during acute treatment.[47] Long-term treatment is not desirable for many SAD patients because of the risk of withdrawal and difficulty with discontinuation, cognitive side effects, and lack of effect on depressive symptoms. Benzodiazepines may be useful for acute relief of physiologic symptoms of anxiety when used concomitantly with antidepressants or psychotherapy. Benzodiazepines are contraindicated in SAD patients with current or past alcohol or substance abuse.

**Anticonvulsants** Gabapentin and pregabalin, structurally similar anticonvulsants, have each demonstrated modest benefit in a randomized, placebo controlled trial.[18,50] Gabapentin was titrated to a maximum dose of 3600 mg/day and pregabalin to 600 mg/day. While both medications have good tolerability, they should be considered for patients with inadequate response to SSRI/SNRIs.

**β-Blockers** β-blockers decrease the physiologic symptoms of anxiety and are useful for reducing performance anxiety. Propranolol or atenolol should be administered 1 hour before a performance situation. β-blockers are not useful in SAD.[47]

### Outcome Evaluation

`KEY CONCEPT` *Pharmacotherapy for patients with SAD should lead to improvement in anxiety and fear, functionality, and overall well-being.*[18] Many patients will experience significant improvement in symptoms but may not achieve full remission. Monitor patients weekly during acute treatment (eg, initiation and titration of pharmacotherapy) and monthly once stabilized. Inquire about adverse effects, SAD symptoms, suicidal ideation, and symptoms of comorbid psychiatric conditions at each visit. Ask patients to keep a diary to record fears, anxiety levels, and behaviors in social situations.[18] Administer the Leibowitz Social Anxiety Scale (LSAS) to rate SAD severity and change, and the Social Phobia Inventory can be used as a "self-assessment" tool. Counsel patients on appropriate expectations of pharmacotherapy in SAD, including gradual onset of effect and the need for extended treatment of at least 6 months following response.

## Abbreviations Introduced in This Chapter

| | |
|---|---|
| CBT | Cognitive-behavioral therapy |
| CNS | Central nervous system |
| DA | Dopamine |
| FDA | Food and Drug Administration |
| GABA | γ-aminobutyric acid |
| GAD | Generalized anxiety disorder |
| HPA | Hypothalamic-pituitary-adrenal |
| 5-HT | Serotonin |
| LC | Locus ceruleus |
| LSAS | Liebowitz Social Anxiety Scale |
| MAOI | Monoamine oxidase inhibitor |
| MDD | Major depressive disorder |
| NCS-R | National Comorbidity Survey, Revised |
| NE | Norepinephrine |
| NPY | Neuropeptide Y |
| OCD | Obsessive-compulsive disorder |
| OTC | Over-the-counter |
| PD | Panic disorder |
| PDSS | Panic Disorder Symptom Scale |
| RAS | Reticular activating system |
| RIMA | Reversible inhibitors of monoamine oxidase A |
| SAD | Social anxiety disorder |
| SGA | Second-generation antipsychotic |
| SNRI | Serotonin-norepinephrine reuptake inhibitor |
| SSRI | Selective serotonin reuptake inhibitor |
| TCA | Tricyclic antidepressant |

# Sleep Disorders

John M. Dopp and Bradley G. Phillips

## LEARNING OBJECTIVES

- **Upon completion of the chapter, the reader will be able to:**

1. List the sequelae of undiagnosed or untreated sleep disorders and appreciate the importance of successful treatment of sleep disorders.

2. State the incidence and prevalence of sleep disorders.

3. Describe the pathophysiology and characteristic features of the sleep disorders covered in this chapter, including insomnia, narcolepsy, restless legs syndrome (RLS), obstructive sleep apnea (OSA), and parasomnias.

4. Assess patient sleep complaints, conduct sleep histories, and evaluate sleep studies to recognize daytime and nighttime symptoms and characteristics of common sleep disorders.

5. Recommend and optimize appropriate sleep hygiene and nonpharmacologic therapies for the management and prevention of sleep disorders.

6. Recommend and optimize appropriate pharmacotherapy for sleep disorders.

7. Describe the components of the patient care process to implement and assess safety and efficacy of pharmacotherapy for common sleep disorders.

8. Educate patients about preventive behavior, appropriate lifestyle modifications, and drug therapy required for effective treatment and control of sleep disorders.

## INTRODUCTION

Individuals with normal sleep patterns sleep up to one-third of their lives and spend more time sleeping than in any other single activity. Despite this, our understanding of the full purpose of sleep and the mechanisms regulating sleep homeostasis remains incomplete. Sleep is necessary to enable one to maintain wakefulness and good health. Disruption of normal sleep is a major cause of societal morbidity, lost productivity, and reduced quality of life.[1] Sleep disturbances may contribute to the development and progression of comorbid medical conditions.[1]

Sleep is governed and paced by the suprachiasmic nucleus in the brain that regulates circadian rhythm. Environmental cues and amount of previous sleep also influence sleep on a daily basis. There are two main types of sleep: **rapid eye movement (REM) sleep**, during which eye movements and dreaming occur but the body is mostly paralyzed, and **non–rapid eye movement (NREM) sleep**, which consists of four substages (stages 1–4). Stage 1 serves as a transition between wake and sleep. Most of the time asleep is spent in stage 2 NREM sleep. Stages 3 and 4 sleep often are grouped together and referred to as *deep sleep*, or *delta sleep*, because prominent delta waves are seen on the electroencephalogram (EEG) during these sleep stages.

## EPIDEMIOLOGY AND ETIOLOGY

Approximately 50% of adults will report a sleep complaint over the course of their lives.[2] In general, sleep disturbances increase with age, and each disorder may have gender differences. The full extent and impact of disordered sleep on our society are not known because many patients' sleep disorders remain undiagnosed. Normal sleep, by definition, is "a reversible behavioral state of perceptual disengagement from and unresponsiveness to the environment."[3] Individuals with sleep disorders exhibit or complain about consequent symptoms (eg, daytime sleepiness) or a bed partner often observes hallmark characteristics of the sleep disorder. Insomnia, RLS, and sleep-related breathing disorders are the most common sleep disorders.

### Insomnia

The prevalence of insomnia increases with age and is nearly 1.5 times greater in women than in men. Approximately one-third of patients older than age 65 years have persistent insomnia.[4,5] About 10% of adults experience chronic insomnia, and slightly more experience short-term insomnia. **KEY CONCEPT** *Insomnia is most frequently a symptom or manifestation of an underlying disorder (comorbid or secondary insomnia) but may occur in the absence of contributing factors (primary insomnia).* Forty percent of patients with psychiatric conditions have accompanying insomnia.[6] Secondary insomnia

may be triggered by acute stress and resolve when the stress resolves. Numerous coexisting medical conditions, such as pain, thyroid abnormalities, asthma, and gastroesophageal reflux, and medications, including selective serotonin reuptake inhibitors (SSRIs), steroids, stimulants, and β-agonists, can cause insomnia.

### Narcolepsy

Although difficult to estimate, the prevalence of narcolepsy is between 0.03% and 0.06%.[7] Significant differences have been reported for various ethnic groups. Narcolepsy has a higher prevalence in Japanese and a lower prevalence in Israeli populations.[8,9] Cataplexy is not required for diagnosis; however, between 50% and 80% of patients with narcolepsy have accompanying cataplexy.[10]

### Restless Legs Syndrome

RLS occurs in 6% to 12% of the population.[11,12] Prevalence increases with age and in various medical conditions, such as end-stage renal disease, pregnancy, and iron deficiency.[13] RLS appears to be more common in women than in men and has a genetic link in a majority of patients.[14]

### Obstructive Sleep Apnea

OSA affects 4% of middle-aged white men and 2% of middle-aged white women.[15] In women, the frequency increases after menopause. Prevalence is the same or higher in African Americans and lower in Asian populations. The risk for OSA increases with age and obesity. Individuals with OSA experience repetitive upper airway collapse during sleep, which decreases or stops airflow, with subsequent arousal from sleep to resume breathing. Severity is determined by nocturnal polysomnography (NPSG) or home sleep study and is graded by the number of episodes of apnea (total cessation of airflow) and hypopnea (partial airway closure with blood oxygen desaturation) experienced during sleep. Severity is expressed as the respiratory disturbance index (RDI), quantified in events per hour.

### Parasomnias

NREM parasomnias have variable prevalence rates depending on patient age and comorbid diagnoses. Sleep talking, bruxism, sleepwalking, sleep terrors, and enuresis occur more frequently in childhood than in adulthood. Nightmares appear to occur with similar frequency in adults and children. REM-sleep behavior disorder (RBD), an REM-sleep parasomnia, has a reported prevalence of 0.5%, is more common in elderly men, and frequently is associated with concomitant neurologic conditions.[16]

## PATHOPHYSIOLOGY

Although the neurophysiology of sleep is complex, certain neurotransmitters promote sleep and wakefulness in different areas of the central nervous system (CNS). Whereas serotonin is thought to control NREM sleep, cholinergic and adrenergic transmitters mediate REM sleep. Dopamine, norepinephrine, hypocretin, substance P, and histamine all play a role in wakefulness. Perturbations of various neurotransmitters are responsible for some sleep disorders and explain why various treatments are beneficial.

### Insomnia

There is no single pathophysiologic explanation for the manifestations of insomnia. Current hypotheses focus on a combination of possible models that incorporate physiologic, cognitive, and cortical arousal. Most models focus on hyperarousal and its interference with the initiation or maintenance of sleep.

### Narcolepsy

The onset of narcolepsy–cataplexy is typically in adolescence, suggesting that the disease may require environmental influence to develop. Currently, it is believed that narcolepsy results from autoimmune insult to the CNS because it is associated with human leukocyte antigen (major histocompatibility complex) DQB10602 and DQ1A1∗0102.[17,18] Concentrations of hypocretin (a wake-promoting neuropeptide) in the cerebrospinal fluid of patients with narcolepsy are reduced significantly, suggesting that the autoimmune attack is against hypocretin-producing cells in the hypothalamus.[19]

### Restless Legs Syndrome and Periodic Limb Movements of Sleep

RLS is a neurologic medical condition characterized by an irresistible desire to move the limbs. It is thought that these abnormal sensations are a result of iron deficiency in the brain and iron-handling abnormalities in the CNS. Iron and H-ferritin concentrations, along with transferrin receptor and iron transporter numbers, are reduced in the substantia nigra of patients with RLS.[20] These iron abnormalities lead to dysfunction of dopaminergic transmission in the substantia nigra. Recently, it has been suggested that local hypoxia in the legs may contribute to pathophysiology of RLS.[21]

### Obstructive Sleep Apnea

At least 20 muscles and soft tissue structures control patency of the upper airway. Patients with OSA may have differences in upper airway muscle activity during sleep and may have smaller airways, predisposing them to upper airway collapse and consequent apneic episodes during sleep. The inability of the upper airway to contend with factors that promote collapse, including fat deposition in the neck, negative pressure in the airway during inspiration, and a smaller lower jawbone, also may play a role in the pathogenesis of OSA.

Poor sleep architecture and fragmented sleep secondary to OSA can cause excessive daytime sleepiness (EDS) and neurocognitive deficits. These sequelae can affect quality of life and work performance and may be linked to occupational and motor vehicle accidents. OSA is also associated with systemic disease such as hypertension, heart failure, and stroke.[22,23] OSA is likely an independent risk factor for the development of hypertension.[24] Furthermore, when hypertension is present, it is often resistant to antihypertensive therapy. Patients with sleep apnea often are obese and may be predisposed to weight gain. Hence, obesity may further contribute to cardiovascular disease in this patient population.

Several factors suggest an association between OSA and systemic disease. Breathing against a closed upper airway during sleep causes intermittent and repetitive episodes of hypoxemia and hypercapnia, dramatic changes in intrathoracic pressure, and activation of the sympathetic nervous system. These responses can produce acute hemodynamic and humoral responses. Blood pressure can increase to 220/120 mm Hg with each apneic episode.[25]

### Parasomnias

The pathogenesis of parasomnias (eg, sleepwalking, enuresis, sleep talking) is variable poorly described, and involves state dissociation, whereby two states of being overlap simultaneously. For example, abnormal activation of the central pattern generator of the spinal cord that produces motor movements is hypothesized to underlie sleepwalking behavior. In RBD, active

## Clinical Presentation and Diagnosis

**KEY CONCEPT** *Patients with sleep complaints should have a careful sleep history performed to assess their possible sleep disorder in order to guide diagnostic and therapeutic decisions.*

Daytime symptoms and associated characteristics: EDS is the primary symptom described by patients with sleep disorders. It is usually described as not waking up refreshed in the morning or falling asleep or fighting the urge to sleep during the day despite a night of sleep. Other daytime characteristics of sleep disorders include:

- Irritability, fatigue, or depression
- Confusion or impaired performance at work or school
- Cataplexy
- Hypertension

Nighttime sleep complaints: Depending on the sleep disorder, patients may exhibit or experience various nocturnal complaints during sleep. Some complaints can be uncovered by clinical history alone (eg, hallucinations, RLS, snoring), but others can be diagnosed during sleep studies (eg, OSA, nighttime awakenings, somnambulism, PLMS, etc). Frequent complaints include:

- Inability to fall asleep, nighttime awakenings
- Sleep walking (somnambulism), sleep talking (somniloquy)
- Cessation of breathing (apnea), snoring
- Sleep paralysis or hallucinations when waking or falling asleep
- Restlessness (PLMS or RLS)

inhibition of motor activity in the perilocus coeruleus region is lost, resulting in loss of paralysis and dream enactment.

## CLINICAL PRESENTATION AND DIAGNOSIS

**KEY CONCEPT** *Although the clinical history guides diagnosis and therapy, only NPSG, home sleep studies, and/or multiple sleep latency tests (MSLTs) can definitively diagnose and guide therapy for OSA, narcolepsy, and periodic limb movements of sleep (PLMS).* All patients presenting with sleep complaints should have a thorough interview and history to inventory their sleep habits and sleep hygiene.

### Insomnia

Insomnia is often characterized by difficulty falling asleep, frequent nocturnal awakenings, early morning awakenings, and nonrestorative sleep, which may result in daytime impairments in concentration and school or work performance. In comorbid (secondary) insomnia, social factors (eg, family difficulties, bereavement), medications (eg, antidepressants, β-agonists, corticosteroids, decongestants), and coexisting medical or psychiatric conditions (eg, depression, bipolar disorder) may help to explain difficulties in initiating and maintaining sleep. Insomnia duration may be described as transient (less than 1 week), acute (1–4 weeks), or chronic (greater than 1 month) in duration.

### Narcolepsy

The hallmark of narcolepsy is EDS and the need for periods of sleep during the day. Patients with narcolepsy may experience repeated nighttime awakenings, terrifying dreams, and difficulty falling asleep. They frequently experience abnormal manifestations of REM sleep, including hallucinations and sleep paralysis that occur on falling asleep and/or awakening. Cataplexy is a weakness or loss of skeletal muscle tone in the jaw, legs, or arms that is elicited by emotion (eg, anger, surprise, laughter, or sadness).

### Obstructive Sleep Apnea

Common characteristics of OSA include snoring, choking, gasping for air, nocturnal reflux symptoms, and morning headaches. A bed partner or roommate may observe these symptoms and witness apneic episodes where the patient stops breathing. Patients with large neck sizes (greater than 45 cm [~18 in] neck circumference) and a body mass index (BMI) of 30 kg/m$^2$ or greater are at higher risk for OSA.

### Periodic Limb Movements of Sleep and Restless Legs Syndrome

Although RLS symptoms can vary, patients commonly report creepy-crawly, burning, tingling, or achy feelings in the legs or arms. These sensations create a desire to move the limbs and may produce motor restlessness. Symptoms are worse in the evening and are worse or exclusively present at rest, with temporary relief with movement. Symptoms also can occur during sleep and often lead to semirhythmic PLMS. PLMS are objective findings during NPSG recorded by leg electrodes. PLMS are present in most patients with RLS but can occur independently.

### Parasomnias

Parasomnias are characterized by undesirable physical or behavioral phenomena that occur during sleep (eg, sleepwalking, sleep eating, sleep talking, bruxism [grinding of teeth], enuresis, night terrors, and RBD). People with RBD act out their dreams during sleep, often in a violent manner.

### Circadian Rhythm Disorders

The most common circadian rhythm disorders (CRDs) include jet lag, shift-work sleep disruption, delayed sleep-phase disorder, and advanced sleep-phase disorder. Jet lag occurs when a person travels across time zones, and the external environmental time is mismatched with the internal circadian clock. Delayed and advanced sleep-phase disorders occur when bed and wake times are delayed or advanced (by 3 or more hours) compared with socially prescribed bed and wake times.

### Sleep Diagnostics

Complete NPSG is the "gold standard" for diagnosing and identifying sleep-disordered breathing, PLMS, parasomnias, and nocturnal sleep irregularities related to narcolepsy. Sleep is observed and monitored in a controlled setting using an EEG, electrooculography, electromyography, electrocardiography, air thermistors, abdominal and thoracic strain belts, and an oxygen saturation monitor. This setup records sleep onset, arousals, sleep stages, eye movements, leg and jaw movements, heart rhythm, airflow, respiratory effort, and oxygen desaturations. Home sleep studies are increasingly used to diagnose sleep apnea due to their reduced cost and increased patient convenience. These devices typically measure nasal airflow, respiratory effort, oxygen saturation, and heart rate to determine if a patient experiences apnea/hypopnea episodes.

The MSLT is a commonly performed test to assess daytime sleepiness. During the MSLT, the patient attempts to take a 20-minute nap every 2 hours during the day beginning 2 hours

after morning awakening (after a normal night's sleep) to evaluate physiologic sleepiness. The patient is instructed not to resist the urge to fall asleep. Sleep latency of less than 5 or 6 minutes is considered pathologically sleepy. The occurrence of an REM onset period during two naps with short sleep latency is indicative of a diagnosis of narcolepsy.

## TREATMENT
### Desired Outcomes

KEY CONCEPT *Treatment goals vary among different sleep disorders but generally include restoration of normal sleep patterns, elimination of daytime sequelae, improved quality of life, and prevention of complications and adverse effects from therapy.*

### General Approach to Treatment

Nonpharmacologic interventions for insomnia are outlined in Table 41–1. Sleep hygiene should be reinforced in all patients, and behavioral, cognitive, and stimulus-control interventions are used mainly for patients with insomnia-type complaints. Both pharmacologic and nonpharmacologic therapies are effective at improving sleep and reducing insomnia complaints. An algorithm for the initial assessment and first treatment step of EDS is provided in Figure 41–1.

### Insomnia

KEY CONCEPT *Early treatment of insomnia may prevent the development of persistent psychophysiologic insomnia.* The ideal hypnotic drug would be effective at reducing sleep latency, increasing total sleep time, and would be free of unwanted side effects. KEY CONCEPT *Benzodiazepine receptor agonists (BZDRAs) (including*

---

### Table 41–1

**Nonpharmacologic Therapies for Insomnia**

**Sleep Hygiene**
- Keep a regular sleep schedule.
- Exercise frequently but not immediately before bedtime.
- Avoid alcohol and stimulants (caffeine, nicotine) in the late afternoon and evening.
- Maintain a comfortable sleeping environment that is dark, quiet, and free of intrusions.
- Avoid consuming large quantities of food or liquids immediately before bedtime.

**Stimulus Control**
- Go to bed only when sleepy.
- Avoid daytime naps.
- If you cannot sleep, get out of bed and go to another room— only return to your bed when you feel the need to sleep.
- Bed is for sleep and intimacy only (no eating or watching TV in bed).
- Always wake up at the same time each day.

**Relaxation Training**
- Reduce somatic arousal (muscle relaxation).
- Reduce mental arousal (eg, attention-focusing procedures, imagery training, meditation).
- Use biofeedback (visual or auditory feedback to reduce tension).

**Cognitive Therapy**
- Alter beliefs, attitudes, and expectations about sleep.

---

*traditional benzodiazepines, zolpidem, zaleplon, and eszopiclone) and ramelteon are approved by the Food and Drug Administration (FDA) for the treatment of insomnia and are first-line therapies.*[2,26,27] Pharmacologic treatment of insomnia is recommended for transient and acute insomnia. Long-term use of hypnotics is not contraindicated unless the patient has another contraindication to their use. Eszopiclone is the only sedative hypnotic approved by the FDA for chronic use up to 6 months.[28] Although not first-line agents for insomnia, sedating antidepressants are also commonly prescribed.

### ▶ Benzodiazepine Receptor Agonists

Pharmacokinetic differences between the eight BZDRAs help to guide selection, depending on patient considerations and specific sleep complaints (Table 41–2). These agents occupy the benzodiazepine site on the γ-aminobutyric acid (GABA) type A receptor complex, resulting in opening of chloride channels that facilitate GABA inhibition and promote sleepiness.[33] BZDRAs have become the first-line agents for treating insomnia and sleep-maintenance problems. They are all efficacious, have wide therapeutic indices, and have a low incidence of abuse.[26,28,29]

Patients should be instructed to take BZDRAs at bedtime and avoid activities requiring alertness after ingestion. Although BZDRAs generally are well tolerated and have good safety profiles, mild to moderate side effects can occur, and precautions are warranted.

**Precautions and Safety** The most common side effects associated with BZDRAs include residual sedation into the waking hours after sleep, grogginess, and psychomotor impairment.[30] Selection of a hypnotic with a duration of action matching the patient's budgeted sleep time can help minimize the risk of residual sedation. BZDRAs should be initiated at low doses, and agents with active metabolites (see Table 41–2) should be avoided in elderly patients. BZDRAs may cause anterograde amnesia, defined as memory loss of activities and interactions after ingestion of the drug. All sedatives can cause anterograde amnesia, and higher doses increase the extent of amnesia.[31,32]

On discontinuation of hypnotic BZDRAs, patients may experience rebound insomnia that may last for a few nights. Rebound insomnia occurs more frequently after discontinuation of shorter duration BZDRAs compared with longer duration BZDRAs. Intermittent hypnotic therapy with the lowest dose possible reduces the likelihood of tolerance, dependence, and withdrawal when therapy is stopped. Patients should be counseled that rebound insomnia is not necessarily a return of their original symptoms, and it may take a few nights for rebound symptoms to subside. In general, eszopiclone, zaleplon, and zolpidem appear to be associated with lower risk of tolerance, rebound insomnia, and withdrawal than traditional benzodiazepines.

### ▶ Sedating Antidepressants

Sedating antidepressants (eg, trazodone, amitriptyline, mirtazapine, nefazodone, doxepin) are commonly used for insomnia and may be an appealing option in patients with concomitant depression. However, at the doses frequently used for sleep, only mirtazapine exhibits significant antidepressant activity. Furthermore, quality clinical studies demonstrating efficacy for insomnia are lacking. Side effects from antidepressants can be frequent, including carryover sedation, grogginess, anticholinergic effects, and weight gain. Tricyclic antidepressants (TCAs) should be used with caution in the elderly and patients with cardiovascular and hepatic impairment. Mirtazapine can cause daytime sedation, dizziness, and weight gain, and trazodone can

**FIGURE 41–1.** Primary assessment and initial treatment for complaint of excessive daytime sleepiness. BZDRA, benzodiazepine receptor agonist; CPAP, continuous positive airway pressure; DA, dopamine agonist; MSLT, multiple sleep latency test; OSA, obstructive sleep apnea; RLS, restless legs syndrome; SNRI, serotonin and norepinephrine reuptake inhibitor; NPSG, nocturnal polysomnography; TCA, tricyclic antidepressant.

cause hypotension and dizziness and should be used with caution in patients with heart disease or hypertension and those taking cardiovascular agents.[33,34] Doxepin is approved for treatment of sleep maintenance insomnia in low doses (3–6 mg).

▶ *Over-the-Counter and Other Miscellaneous Agents*

Over-the-counter antihistamines such as diphenhydramine are frequently used (usual doses, 25–50 mg) for difficulty sleeping. Diphenhydramine is approved by the FDA for the treatment of insomnia and can be effective at reducing sleep latency and increasing sleep time.[35] However, diphenhydramine produces undesirable anticholinergic effects and carryover sedation that limit its use, especially in the elderly. Valerian root is an herb that has inconsistent effects on sleep but may reduce sleep latency and increase efficiency at commonly used doses of 400 to 900 mg valerian extract. Ramelteon, a melatonin receptor agonist, is indicated for insomnia characterized by difficulty with sleep onset. Ramelteon is not a controlled substance and can be a viable option for patients with a history of substance abuse. It has documented efficacy treating sleep onset difficulties in those with mild to moderate chronic obstructive pulmonary disease and OSA.[36–38] Suvorexant (an orexin receptor antagonist) was recently approved for treatment of insomnia. It is the first medication that turns off wakefulness mechanisms instead of

stimulating pathways that induce sleepiness. Suvorexant is indicated for both difficulty initiating and maintaining sleep, and like BZDRAs, it is classified as a schedule IV controlled substance.[39]

**Narcolepsy**

Therapy for narcolepsy involves two key principles: (a) treatment of EDS with scheduled naps and CNS stimulants and (b) suppression of cataplexy and REM-sleep abnormalities with aminergic signaling

**Patient Encounter, Part 1**

An 18-year-old woman with a history of asthma comes to your clinic complaining of excessive daytime sleepiness, disrupted nighttime sleep, and strange weakness when she is surprised. She reports that she falls asleep relatively easily during the day if given a chance. She takes ethinyl estradiol/norethindrone 35 mcg/1 mg, albuterol MDI two puffs as needed shortness of breath, and fluticasone MDI 100 mcg two puffs twice a day.

*What sleep disorders do her symptoms suggest?*

*What additional information do you need to know in your assessment of this patient?*

**Table 41–2**

**Pharmacokinetics and Dosing of Prescription Medications[a] Approved to Treat Insomnia**

| Generic Name | Parent $t_{1/2}$ (hours) | Duration of Action (hours) | Daily Dose Range (mg) | Recommended Daily Dose in Elderly (mg)[b] | Dose or Action in Hepatic Impairment | Comments |
|---|---|---|---|---|---|---|
| Doxepin (Silenor) | 15.3 | Unpublished[c] | 3–6 | 3 | 3 mg | Effective for sleep maintenance difficulties only |
| Estazolam (Prosom) | 2 | 12–15 | 1–2 | 0.5 | Dose ↓ may be needed | Moderate duration |
| Eszopiclone (Lunesta) | 6 | 8 | 2–3 | 1–2 | 1 mg in severe impairment | Can be used up to 6 months for chronic insomnia |
| Flurazepam (Dalmane) | 8 | 10–30 | 15–30 | 15 | No change necessary | High risk of hangover and residual effects |
| Quazepam (Doral) | 2 | 25–41 | 7.5–15 | 7.5–15 | Dose ↓ may be needed | High risk of hangover and residual effects |
| Ramelteon (Rozerem) | 1–2.6 | Unpublished[c] | 8 | No specific recommendations | Do not use in severe hepatic impairment | Noncontrolled substance; may be useful in patients with a history of substance abuse |
| Suvorexant (Belsomra) | 12 | Unpublished[c] | 10–20 | No specific recommendations | No change necessary | Novel mechanism of action—little documented rebound upon discontinuation |
| Temazepam (Restoril) | 10–15 | 7 | 7.5–30 | 7.5 | No change necessary | Moderate duration, well tolerated, inexpensive |
| Triazolam (Halcion) | 2 | 6–7 | 0.125–0.25 | 0.125 | 0.125 mg | Short acting; little residual hangover |
| Zaleplon (Sonata) | 1 | 6 | 5–10 | 5 | 5 mg | Short acting; only for difficulty falling asleep |
| Zolpidem (Ambien) | 2–2.6 | 6–8 | 5–10[d] | 5 | 5 mg | Short to moderate duration; no effects on sleep architecture |
| Zolpidem CR (Ambien CR) | 2.8 | 7–8 | 6.25–12.5[d] | 6.25 | 6.25 mg | Longer duration of action than regular release zolpidem |
| Zolpidem sublingual (Intermezzo) | 2.5 | < 4 | 1.75–3.5[d] | 1.75 | 1.75 mg | Approved for middle-of-the-night insomnia taken > 4 hours before awakening |

[a]In 2007, the Food and Drug Administration required additional information added to the safety labeling of sedative–hypnotic drugs concerning potential risks, including severe allergic reactions and complex sleep-related behaviors, which may include sleep driving. Sleep driving is defined as driving while not fully awake after ingestion of a sedative–hypnotic product with no memory of the event.

[b]If a dosing range is displayed, the first dose listed should be the starting dose.

[c]Data not available.

[d]For zolpidem, recommended dose for women is 5 mg, 6.25 mg for zolpidem CR, and 1.75 mg for sublingual zolpidem.

Adapted, with permission, from DiPiro JT, Talbert RL, Yee GC, et al (eds). Pharmacotherapy: A Pathophysiologic Approach. 9th ed. New York: McGraw-Hill; 2014:1118.

drugs. Modafinil (Provigil), armodafinil (Nuvigil), methylphenidate, and amphetamines are effective FDA-approved drugs for the treatment of EDS with narcolepsy.[40] Modafinil and armodafinil (the active R-isomer of modafinil) are Schedule IV medications, and these drugs may have fewer peripheral and cardiovascular effects than traditional stimulants. Selegiline, a selective monoamine oxidase B enzyme inhibitor, is metabolized to amphetamines and can reduce daytime sleepiness. In an individual patient, one wake-promoting agent may work better than another, and if the first drug selected is not successful at adequate doses, a trial with another agent should be attempted. **KEY CONCEPT** *Treatment of EDS in narcolepsy and other sleep disorders may require sustained- and immediate-release stimulants to promote wakefulness throughout the day and at key times that require alertness.* One potential treatment regimen includes a sustained-release stimulant preparation first thing in the morning and again at noon followed by an immediate-release stimulant preparation as needed in the late afternoon or before driving to maintain wakefulness. One advantage of

traditional CNS stimulants over modafinil is their ability to help control cataplexy and REM-sleep abnormalities.

Traditional CNS stimulants have the potential to increase blood pressure and heart rate when used long term. In addition, excessive CNS stimulation can cause tremors and tics and can carry over into evening hours, disrupting normal nighttime sleep. Caution should be used in patients with underlying cardiovascular or cerebrovascular disease and in patients with a history of seizures because stimulants may lower the seizure threshold.

▶ *Cataplexy*

Traditionally, aminergic signaling antidepressants have been used effectively to control symptoms of cataplexy, sleep paralysis, and other REM-sleep manifestations of narcolepsy.[40] These include TCAs and certain selective serotonin and serotonin/norepinephrine reuptake inhibitors (SSRIs and SNRIs). Clomipramine, protriptyline, imipramine, venlafaxine, and fluoxetine are the agents that have been used most frequently. In addition, low-dose selegiline

## Patient Encounter, Part 2: Medical History, Physical Examination, and Diagnostic Test

The patient undergoes further workup for her sleep complaint, which includes an overnight sleep study (in-lab) and a daytime nap study (MSLT).

**PMH:** Asthma × 8 years

**FH:** Noncontributory

**SH:** College freshman, has never smoked, does not drink alcohol

**Meds:** Ethinyl estradiol/norethindrone 35 mcg/1 mg, albuterol MDI two puffs Q 4–6 hours as needed, fluticasone MDI two puffs twice a day

**ROS:** (+) daytime sleepiness (Epworth sleepiness score: 18 out of 24); (–) symptoms of RLS

**PE:**

**VS:** BP 122/68, P 72, RR 16, T 37°C (98.6°F); BMI 21 kg/m$^2$

**Labs:** TSH 1.6 μIU/mL (mIU/L)

**Overnight Polysomnogram:** Bedtime at 10 PM; awake at 7 AM. No snoring or apneas observed, shortened REM sleep latency (15 minutes), frequent awakenings (13), 63 minutes awake after sleep onset.

- RDI 1 events/hour
- No significant leg movements

**MSLT Test:** Mean sleep latency = 3.5 minutes, 2 out of 5 sleep-onset REM periods

*Given this additional information, summarize the patient's diagnosis.*

*What nonpharmacologic and pharmacologic alternatives are available for this patient if the prescribed therapy is not successful or not tolerated?*

may be effective at reducing cataplexy. Although not approved by the FDA for treatment of cataplexy, these drugs suppress REM sleep and have been the mainstay of anticataplectic therapy for years. Sodium oxybate, a potent sedative with a very short duration of action, is FDA approved for the treatment of narcolepsy with cataplexy. Its mechanism of action is not entirely known. Two doses per night are taken, one at bedtime and one follow-up dose taken 2½ to 4 hours later. Sodium oxybate is tightly regulated and is available from only one central pharmacy because of its high abuse potential.

### Restless Legs Syndrome

**KEY CONCEPT** *RLS treatment involves suppression of abnormal sensations and leg movements and consolidation of sleep. Dopaminergic and sedative–hypnotic medications are prescribed commonly.* Dopamine agonists (DAs) successfully treat RLS symptoms and offer many advantages over levodopa–carbidopa, including longer half-lives to cover overnight symptoms, flexible dosing, and a reduced incidence of symptom augmentation. Up to 80% of patients who take levodopa–carbidopa eventually will experience symptom augmentation: RLS symptoms appear earlier in the day, previously unaffected body parts become involved, duration

of relief gets shorter, and higher doses of medication are required to control symptoms.[41] Augmentation may be reduced by use of longer-duration DAs.[42] Ropinirole (Requip), pramipexole (Mirapex), and rotigotine (Neupro) are FDA approved for the treatment of RLS and are available in sustained-release products.[43] Gabapentin is an effective treatment for RLS, particularly in patients with painful symptoms.[44] The gabapentin prodrug (gabapentin enacarbil) is FDA approved for RLS at a recommended dose of 600 mg taken with food at about 5 pm.[45] BZDRAs such as temazepam, clonazepam, zolpidem, and zaleplon reduce arousals in patients with RLS.[46] Their main benefit is derived from improving sleep continuity in patients with RLS, particularly as adjunct treatment with other pharmacologic therapies. Opioids are effective in some patients with RLS symptoms, with oxycodone, hydrocodone, and codeine being used most frequently. For both BZDRAs and opioids, caution should be used in the elderly, in patients who are at risk for sleep apnea, and in patients with a history of substance abuse. Low iron levels frequently exacerbate RLS symptoms. Iron supplementation should be prescribed in patients who are iron deficient. Iron supplementation in patients with serum ferritin concentrations of less than 50 to 75 mcg/L (ng/mL; 112–169 pmol/L) improves RLS symptoms. Medications frequently used for RLS are shown in Table 41–3.

### Obstructive Sleep Apnea

**KEY CONCEPT** *The main therapy for OSA is nasal continuous positive airway pressure (CPAP) therapy,* which alleviates sleep-disordered breathing by producing a positive pressure column in the upper airway using room air. A flexible tube connects the CPAP machine to a mask that covers the nose. CPAP therapy has a favorable impact on blood pressure and attenuates some of the potential hemodynamic and neurohumoral responses that may link OSA to systemic disease.

Not all individuals tolerate CPAP therapy, in part because it requires wearing a mask during sleep, and therapy can dry and irritate the upper airway. In some individuals, these barriers for adherence may be lessened or eliminated by properly fitting the mask, adding humidity to therapy, or using bilevel positive airway pressure (BiPAP) or auto titrating continuous positive airway pressure (AutoPAP) therapy. BiPAP therapy applies a variable pressure into the airway during the inspiratory phase of respiration but, unlike CPAP, reduces the applied pressure during the expiratory phase. AutoPAP machines are set for a pressure range and individualizes the pressure based on breath-to-breath analysis of the necessary pressure to keep the airway open.

Obesity can worsen sleep apnea, and weight management should be implemented for all overweight patients with OSA. In obese patients with mild OSA, weight loss alone can be effective, and studies have reported reduced severity of OSA with gastric stapling. For patients who cannot tolerate CPAP, oral appliances can be used to advance the lower jawbone and to keep the tongue forward to enlarge the upper airway. For individuals who have OSA only when on their backs during sleep, positional therapies may be effective. Surgical therapy (uvulopalatopharyngoplasty) is not a first-line option because of its invasiveness and relatively low long-term effectiveness.

There is no drug therapy for OSA. Drug therapy for symptoms of OSA may be considered in selected patients. Modafinil and armodafinil are wake-promoting medications that are approved by the FDA to treat residual daytime sleepiness despite CPAP therapy. Initiation of these medications should be attempted only after patients are using optimal CPAP therapy to alleviate

|---|---|---|---|
| **Frequently Used Medications for Restless Legs Syndrome** | | | |
| **Generic Name (Brand Name)** | **Half-Life (Hours)** | **Dose Range (mg/day)[a]** | **Potential Side Effect or Disadvantage** |
| **Dopaminergic Agents[b]** | | | |
| Levodopa–carbidopa (Sinemet) | 1.5–2 | 100–200 of levodopa | Nausea or vomiting; high incidence of symptom augmentation |
| Pramipexole (Mirapex) | 8–12[c] | 0.125–0.5 | Nausea or vomiting; risk of compulsive behaviors[d] |
| Ropinirole (Requip) | 6[e] | 0.25–3 | Nausea or vomiting; risk of compulsive behaviors[d] |
| Rotigotine (Neupro) | 5–7 | 1–3 | Application site reactions with patch |
| **Anticonvulsants** | | | |
| Gabapentin (Neurontin, Horizant) | 5–7[c] | 300–3600 | Dizziness, ataxia |
| Pregabalin (Lyrica) | 5–6.5 | 50–300 | Weight gain, daytime sedation |
| **Hypnotic Agents** | | | |
| Clonazepam (Klonopin) | 30–40 | 0.5–2 | Tolerance, carryover sedation |
| Temazepam (Restoril) | 10–15 | 7.5–30 | Tolerance, carryover sedation |
| Zolpidem (Ambien) | 2–2.6[e] | 5–10 | Tolerance |
| Zaleplon (Sonata) | 1[e] | 5–10 | Tolerance; may not last entire night |
| **Opioids** | | | |
| Hydrocodone | 3.8–4.5[e] | 5–10 | Constipation, nausea, sedation |
| Codeine | 2.5–3.5[e] | 30–60 | Constipation, nausea, sedation |
| Methadone | 22[e] | 5–20 | Constipation, nausea, sedation |
| Oxycodone | 3.2–12[c,e] | 5–30 | Constipation, nausea, sedation |

[a]Usual range; all medications (other than dopaminergic agents) are dosed at bedtime.

[b]Dopaminergic agents are frequently given at bedtime or 2 hours before bedtime or the anticipated onset of RLS symptoms.

[c]May be longer in patients with renal dysfunction.

[d]Compulsive behaviors such as gambling, shopping, sexual behaviors, and eating have been reported in patients taking dopamine agonists.

[e]May be longer in patients with hepatic dysfunction.

Data from Earley CJ. Restless legs syndrome. N Engl J Med. 2003;348:2103–2109.

sleep-disordered breathing. The need for treating residual sleepiness in this population is not clear because it may not be related to the OSA and is similar to sleepiness in the general population.[47] OSA should always be considered and evaluated in hypertensive patients who are resistant to therapy.

## Parasomnias

NREM parasomnias usually do not require treatment. If needed, low-dose BZDRAs such as clonazepam can be prescribed for bothersome episodes. Clonazepam reduces the amount of sleep time spent in stages 3 and 4 of NREM sleep, when most NREM parasomnias occur. For treating RBD, clonazepam 0.5 to 2 mg at bedtime is the drug of choice, although melatonin 3 to 12 mg at bedtime also may be effective. Patients with RBD also should have dangerous objects removed from the bedroom and environmental accommodations made to reduce the chance of injury from breakthrough episodes.

## Circadian Rhythm Disorders

Melatonin, 0.5 to 5 mg taken at appropriate target bedtimes for east or west travel, is the drug of choice for jet lag. Melatonin significantly reduces jet lag and shortens sleep latency in travelers.[48] Hypnotic agents with relatively short durations of action (3–5 hours) may also be used to sustain sleep during the initial adaptation to the new time zone.

## Drug–Disease and Drug–Drug Interactions

KEY CONCEPT *It is important to review medication profiles for drugs that may aggravate sleep disorders. Patients should be monitored for adverse drug reactions and potential drug–drug interactions*

*and assessed for treatment adherence.* Pharmacotherapy for sleep disorders should be individualized. Often medications can treat several concomitant sleep disorders. Conversely, drug therapy may be effective for one sleep disorder and exacerbate another. For example, antidepressants may alleviate depressive symptoms but exacerbate symptoms of RLS. Medications that

### Patient Encounter, Part 3: Modifying the Treatment Plan

The patient returns to the clinic 3 months later. The physician previously diagnosed her with narcolepsy and cataplexy. She received a prescription for methylphenidate 20-mg tablets and was instructed to take one tablet twice daily (7 AM and noon). She reports today that the methylphenidate has made her feel more awake and slightly reduced her cataplexy. She still is somewhat sleepy during the day and has cataplexy more often than she would like. Her Epworth Sleepiness Scale (ESS) score today is 13 out of 24. She would like a medication that lasts longer and provides better control of her cataplexy.

*Based on the information presented, recommend therapy for the patient.*

*What narcolepsy medications would you not want to use for this patient?*

*What medication-related precautions would you want to counsel the patient on?*

## Patient Care Process

### Patient Assessment:

- Perform a detailed history of prescription, nonprescription, and complementary or alternative medication use.
- Based on patient nighttime and daytime complaints and bed partner report, determine the suspected sleep problem and its consequences.
- Review objective and subjective data regarding sleepiness, nighttime sleep quality, and limb movements, sleep disordered breathing, and parasomnias.
- Evaluate concomitant sleep and medical conditions that influence therapy decisions.

### Therapy Evaluation:

- Evaluate effectiveness, safety, adherence, and side effects of therapy.
- Determine whether the patient has insurance coverage for prescribed medications.

### Care Plan Development:

- For treatment of insomnia, try to ensure the lowest possible doses are prescribed and used for the shortest time period possible.
- If patient complaints are not entirely improved, consider increasing dose or adding a complementary agent.
- Ensure sleep hygiene (see Table 41–1) and drug therapy are appropriate for each sleep complaint.
- Determine if medication doses are optimal for treatment of various sleep disorders (see Tables 41–2 and 41–3).
- For insomnia select medications whose duration of action matches the timing of the difficulty sleeping (eg, difficulty initiating or maintaining sleep).

### Follow-up Evaluation:

- Evaluate improvement in the specific sleep complaint (eg, how has therapy affected sleep latency or sleep maintenance?).
- Monitor daytime sleepiness, sleep diaries, and diaries of sleep events (PLMS, hallucinations, snoring, apneas, etc) and monitor cataplexy and other daytime symptoms to determine if therapy is effective.
- Make appropriate changes to therapy to address inadequately controlled symptoms and reported adverse effects.

## OUTCOME EVALUATION

Evaluate whether the treatment plan restored normal sleep patterns, reduced daytime sequelae, and improved quality of life without causing adverse effects. Schedule patients for follow-up within 3 weeks for insomnia and within 3 months for other sleep disorders. Perform a detailed clinical history to determine the patient's perception of treatment progress and symptoms along with medication effectiveness and side effects.

Instruct patients to keep sleep diaries (number of hours, number of awakenings, and worsening or improved sleep) and daytime symptoms, along with documentation of episodes such as cataplexy or RBD. Increase medication to effective doses, and if necessary, start additional therapy to control symptoms. Patients with sleep disorders should experience relief of symptoms the first night of drug therapy but may not receive maximal benefit (effect on daytime symptoms) for a few weeks. Perform a detailed history of prescription, nonprescription, and complementary or alternative medications and review the patient's sleep diary, daytime symptoms, and nonpharmacologic therapies on a regular basis.

## Abbreviations Introduced in This Chapter

| | |
|---|---|
| AutoPAP | Auto-titrating continuous positive airway pressure |
| BiPAP | Bilevel positive airway pressure |
| BMI | Body mass index |
| BZDRA | Benzodiazepine receptor agonist |
| CNS | Central nervous system |
| CPAP | Continuous positive airway pressure |
| CRD | Circadian rhythm disorder |
| DA | Dopamine agonist |
| EDS | Excessive daytime sleepiness |
| EEG | Electroencephalogram |
| ESS | Epworth Sleepiness Scale |
| FDA | Food and Drug Administration |
| GABA | γ-Aminobutyric acid |
| MSLT | Multiple sleep latency test |
| MWT | Maintenance of wakefulness test |
| NPSG | Nocturnal polysomnography |
| NREM | Non–rapid eye movement |
| OSA | Obstructive sleep apnea |
| PLMS | Periodic limb movements of sleep |
| RBD | REM-sleep behavior disorder |
| RDI | Respiratory disturbance index |
| REM | Rapid eye movement |
| RLS | Restless legs syndrome |
| SNRI | Serotonin/norepinephrine reuptake inhibitor |
| SSRI | Selective serotonin reuptake inhibitor |
| TCA | Tricyclic antidepressant |

block dopaminergic transmission may worsen RLS symptoms. Alcohol and CNS depressants, including opiates, sedatives, and muscle relaxants, can worsen OSA, even in small doses, by reducing respiratory drive and relaxing the upper airway muscles responsible for maintaining patency. CNS depressants should be avoided, and if they are necessary, they should not be administered before sleep. Drug therapy for sleep disorders should be patient specific, and careful consideration should be given to coexisting diseases, concomitant medications, and potential drug–drug and drug–disease interactions to optimize patient care and treatment.

# 42 Attention-Deficit/ Hyperactivity Disorder

Kevin W. Cleveland and John Erramouspe

## LEARNING OBJECTIVES

**Upon completion of the chapter, the reader will be able to:**

1. Explain accepted criteria necessary for the diagnosis of attention-deficit/hyperactivity disorder (ADHD).
2. Recommend a therapeutic plan, including drug selection, initial doses, dosage forms, and monitoring parameters, for a patient with ADHD.
3. Differentiate among the available pharmacologic agents used for ADHD with respect to pharmacology and pharmaceutical formulation.
4. Recommend second-line and/or adjunctive agents that can be effective alternatives in the treatment of ADHD when stimulant therapy is less than adequate.
5. Address potential cost–benefit issues associated with pharmacotherapy of ADHD.
6. Recommend strategies for minimizing adverse effects of ADHD medications.

Attention-deficit/hyperactivity disorder is characterized by a persistent pattern of inattention and/or hyperactivity-impulsivity. It can have a severe impact on a patient's ability to function in both academic and social environments. Early diagnosis and appropriate treatment are essential to compensate for areas of deficit.

## EPIDEMIOLOGY AND ETIOLOGY

**KEY CONCEPT** *This disorder usually begins by 3 years of age but must occur before 12 years of age to meet current diagnostic criteria.* In the United States, ADHD is the most common neurobehavioral disorder that affects children.[1–4] ADHD has been estimated to occur in 4.3% to 9.5% of school-aged children.[4,5] ADHD occurs more than twice as often in school-aged boys than girls.[5]

Although ADHD generally is considered a childhood disorder, symptoms can persist into adolescence and adulthood. The prevalence of adult ADHD is estimated to be 2.5 %; however, 60% of adults with ADHD have symptoms that manifested in childhood.[6,7,8] Furthermore, problems associated with ADHD (eg, social, marital, academic, career, anxiety, depression, smoking, and substance abuse problems) increase with the transition of patients into adulthood.

## PATHOPHYSIOLOGY

**KEY CONCEPT** *The exact pathologic cause of ADHD has not been identified.* ADHD is generally thought of as a disorder of self-regulation or response inhibition. Patients who meet the criteria for ADHD have difficulty maintaining self-control, resisting distractions, and concentrating on ideas.[4,9,10] Furthermore, children with ADHD often alternate between inattentiveness to monotonous tasks and overexcitement. Multiple brain studies have failed to elucidate any pathophysiologic basis for ADHD.

**KEY CONCEPT** *Dysfunction of the neurotransmitters norepineph-rine and dopamine is thought to be key in the pathology of ADHD.* Whereas norepinephrine is responsible for maintaining alertness and attention, dopamine is responsible for regulating learning, motivation, goal setting, and memory. Both of these neurotransmitters predominate in the frontal subcortical system, an area of the brain responsible for maintaining attention and memory. Genetics appears to play a role because a child who has a parent with ADHD has a 50% chance of developing ADHD. An association has been made between the development of ADHD and fetal alcohol syndrome, lead poisoning, maternal smoking, and hypoxia.[4,10]

## CLINICAL PRESENTATION AND DIAGNOSIS

**KEY CONCEPT** *ADHD is rarely encountered without comorbid conditions and often is undiagnosed.* Between 50% and 60% of patients with ADHD will have one or more comorbidities (eg, learning disabilities, oppositional defiant, conduct, anxiety, or depressive disorders).[2] It is important to identify and appropriately treat coexisting conditions in patients with ADHD.

According to newer diagnostic and treatment guidelines, all patients 4 to 18 years of age presenting with inattention, hyperactivity, impulsivity, academic, and/or behavioral problems should be evaluated for ADHD. Additional information about behavior in various settings should be gathered from the patient, family, and teachers, or supervisors. The age of onset, frequency, severity, and duration of symptoms should be documented.[6,11]

The most useful diagnostic criteria for ADHD is the *Diagnostic and Statistical Manual of Mental Disorders*, 5th edition (*DSM-5*).[6] The *DSM-5* defines three presentations of ADHD: (a) predominately inattentive; (b) predominantly hyperactive-impulsive; and (c) combined, in which both inattentive and hyperactive or impulsive symptoms are evident.[11] Neuroimaging,

electroencephalograms, and continuous performance examinations are investigational and not used clinically for diagnosis. It is recommended that parents and teachers complete a standardized rating scale based on the *DSM-5* criteria.[6] These rating scales are not by themselves diagnostic but are diagnostic aids when added to a careful history and interview.[12]

Although ADHD is considered a childhood disorder, signs and symptoms persist into adolescence in 40% to 80% of cases and into adulthood in approximately 60% of cases.[1,7] Adult ADHD is difficult to assess, and diagnosis is always suspect in patients failing to display clear symptoms before 12 years of age.[10,11] Untreated adults with ADHD have higher rates of psychopathology, substance abuse, social dysfunction, and occupational underachievement than adults without ADHD.

## TREATMENT
### Desired Outcomes

**KEY CONCEPT** *The primary therapeutic objectives in ADHD are to improve behavior and increase attention or response inhibition; secondary goals of treatment are to:*

- Improve relationships with family, teachers, and peers
- Decrease disruptive behavior in academic and social settings
- Improve academic performance
- Increase independence in activities
- Minimize undesirable adverse effects of therapy

---

### Clinical Presentation and Diagnosis of ADHD

**General**

Patients with ADHD can present with inattention, hyperactivity–impulsivity, or both. ADHD is typically encountered with comorbid conditions.

**Symptoms**

- Inattentive type: difficulty paying attention to details in school, work, and social activities; difficulty completing tasks that require a lot of mental effort; easily distracted; forgetful
- Hyperactive–impulsive type: difficulty sitting still, fidgets; has trouble playing quietly and waiting turns; frequently interrupts
- Combined: exhibits both inattention and hyperactivity–impulsivity

**Diagnostic Criteria**

- Must exhibit 6 of 9 symptoms before 12 years of age that persist for at least 6 months
- Symptoms must be present in two or more settings and adversely affect functioning in social situations, school, or work
- Must meet the diagnostic criteria in *DSM-5* for ADHD
- Symptoms cannot be better explained by another mental disorder (eg, autism)

## Nonpharmacologic (Behavioral) Therapy

Behavioral therapy can be useful; however, it is generally not recommended as first-line monotherapy except in preschool-aged children (4–5 years of age).[6,11] **KEY CONCEPT** *Several studies have demonstrated that treatment with medication alone is superior to behavioral intervention alone in improving attention. However, behavioral therapy in combination with* stimulant *therapy is better at improving oppositional and aggressive behaviors.*[13] Behavioral modification involves training parents, teachers, and caregivers to change the physical and social environment and establish a reward or consequence system.[10,11] Success of behavioral modifications depends on the cooperation and involvement of the patient's parents and teachers.

## Pharmacologic Therapy

The proposed mechanism of ADHD pharmacotherapy is to modulate neurotransmitter function in order to improve academic and social functioning. Pharmacologic therapy can be divided into two categories—stimulants and nonstimulants. Stimulants include methylphenidate, dexmethylphenidate, dextroamphetamine–amphetamine (amphetamine salts), dextroamphetamine, and lisdexamfetamine, and nonstimulant medications include atomoxetine, bupropion, clonidine, and guanfacine.

### ▶ Stimulants

**KEY CONCEPT** *Psychostimulants (eg, methylphenidate and dextroamphetamine with or without amphetamine) are the most effective agents in treating ADHD. Following diagnosis of ADHD, a stimulant medication should be considered first-line therapy in patients 6 years of age or older.* In preschool-aged children, methylphenidate can be added to the patient's treatment if behavioral

---

### Patient Encounter, Part 1

The single mother of a rowdy 8-year-old boy comes to your clinic. The mother is upset due to a recent altercation with her grandfather over her son's behavior. Her grandfather claims her son swears, is careless, violent, and has destructive tendencies such as pulling and flicking the hair and head of other family members, especially his 5-year-old brother. She had been living with her parents in an effort to save money since she has a minimum wage job as a room cleaner for a local motel, but recently she has moved her two sons and herself to their own apartment. During the visit, her son is easily distracted, all over the examination room investigating and getting into everything. He even launches a paper airplane twice during the visit which hits both his mother and you. His performance at school on the few assignments he has completed has consistently been failing. During his physical education class, he frequently pushes and shoves others in order to not have to wait for his turn. On two occasions, he has been sent home from school for unruly behavior.

*Which of the patient's symptoms are suggestive of ADHD?*

*What other comorbid conditions should the child be evaluated for before starting therapy for ADHD?*

*What other information do you need to assess for ADHD?*

*What help or suggestions could you offer to his parents?*

modification monotherapy is not sufficient in managing ADHD symptoms.[10] Stimulants are safe and effective and have a response rate of 70% to 90%.[3,11,14] Generally, a trial of at least 3 months on a stimulant is appropriate, and this includes dose titration to response while balancing side effects.[8,10,11] **KEY CONCEPT** *If treatment with the first stimulant formulation fails, it is recommended to switch to a different stimulant formulation.*[6,10] For example, if the patient was started on methylphenidate but could not tolerate the side effects, switching to dextroamphetamine with or without amphetamine is appropriate. Most patients who fail one stimulant will respond to an alternative stimulant.[10,11] **KEY CONCEPT** *If the patient fails two adequate trials of different stimulant medications, a third stimulant formulation or second-line nonstimulant such as bupropion, atomoxetine, guanfacine, or clonidine can be considered.* The diagnosis of ADHD should be revalidated as well.

Stimulants theoretically exert their primary effect by blocking the reuptake of dopamine and norepinephrine. They have been shown to decrease fidgeting and finger tapping, increase on-task classroom behavior and positive interactions at home and in social environments, and ameliorate conduct and anxiety disorders.[14]

Stimulants should be initiated at recommended starting doses and titrated up with a consistent dosing schedule to the appropriate response while minimizing side effects (Table 42–1). Generally, stimulants should not be used in patients who have glaucoma, severe hypertension or cardiovascular disease, hyperthyroidism, severe anxiety, or previous illicit or stimulant drug abuse. Stimulants can be used, albeit cautiously, in patients with seizure disorders, Tourette syndrome, and motor tics.[14]

Stimulant drug formulations can be divided into short-, intermediate-, and extended-acting preparations (see Table 42–1). Initial response to short-acting stimulant formulations (eg, methylphenidate and dextroamphetamine) is seen within 30 minutes and can last for 4 to 6 hours.[6,10,14] Thus short-acting stimulant formulations must frequently be dosed at least twice daily, increasing the chance of missed doses and noncompliance. Patients using any stimulant formulation, but especially short-acting formulations, can experience a rebound effect of ADHD symptoms as the stimulant wears off.[14]

Most intermediate-acting stimulants release the medication in a slow, continuous fashion without any early release (except Dexedrine Spansules). The onset of action for this category of stimulants (typically 60–90 minutes) may be inadequate for some patients. Some practitioners prescribe a short-acting stimulant concurrently with an intermediate-acting stimulant to curtail the delay in onset of action of the intermediate-acting stimulant. However, this practice can increase patient copay costs.

To minimize rebound symptoms associated with short-acting formulations and still achieve early stimulant release, extended-acting formulations with rapid onsets have been developed. These formulations have an early release of medication and deliver a delayed release of stimulant in either a pulsed (Adderall XR, Focalin XR, Metadate CD, Quillivant XR and Ritalin LA) or continuous manner (Concerta). Formulations available as capsules contain coated beads that can be opened and sprinkled on semisolid food. Concerta tablets have an immediate-release overcoat and an oral osmotic controlled-release that delivers methylphenidate in an extended manner. Patients should be counseled that the empty tablet shell of Concerta can be seen in the stool.

Two extended-acting stimulants, Daytrana and Vyvanse, have slower onsets of action than the other extended-acting stimulants with a rapid release. Daytrana transdermal patches are to be applied for only 9 hours per day and have a delayed onset of 2 hours, and their effects persist for 3 hours after being removed. Some patients report skin sensitization and irritation. Vyvanse is a prodrug that is hydrolyzed to its active form, dextroamphetamine, after oral ingestion. Inhalation or injection abuse potential is minimized because of impeded hydrolysis by these routes. Onset of action for Vyvanse has been reported to be 2 hours.[15]

Adverse effects of stimulants can be generalized to the whole class (Table 42–2). Most side effects can be managed by changing the dosing routine (ie, giving with food, dividing daily dose, or giving the dose earlier in the day). Serious side effects (eg, hallucinations and abnormal movements) require discontinuation of medication.[6,10,14] To avoid potential drug–food interactions and absorption issues, stimulants should be given 30 to 60 minutes before eating.

Growth suppression or delay is a major concern for parents of children taking stimulants. Growth delay appears to be transient and to resolve by midadolescence, but more data are needed to resolve this issue. Another concern is risk of substance abuse with stimulant use. A diagnosis of ADHD alone increases the risk of substance abuse in adolescents and adults. However, stimulant use has not been shown to further increase this risk but actually may decrease this risk, provided ADHD is treated adequately.[16]

The choice of ADHD medication should be made based on the patient's condition, prescriber's familiarity with the medications, ease of administration, and cost. Stimulants should be used as first-line agents in most ADHD patients, although studies in groups of patients have shown no clear advantage of one stimulant over another.[17]

## ▶ Nonstimulants

**Atomoxetine** Atomoxetine is approved for the treatment of ADHD in both children and adults. In clinical studies, it demonstrated superior efficacy over placebo and either equivalent efficacy compared with a suboptimal immediate-release methylphenidate dose or inferior to Concerta.[18–23] **KEY CONCEPT** *Atomoxetine may be used as a second- or third-line medication for ADHD.*

Atomoxetine selectively inhibits the reuptake of adrenergic neurotransmitters, principally norepinephrine.[18–21] Atomoxetine is metabolized through the cytochrome P450 (CYP) 2D6 pathway. Concurrent use of certain antidepressants (ie, fluoxetine, paroxetine) may inhibit this enzyme and necessitate slower dose titration of atomoxetine. Approximately 5% to 10% of the population are CYP2D6 poor metabolizers, and atomoxetine's half-life is increased significantly in this population.[24] The recommended dosing for atomoxetine depends on patient weight and is given once or twice daily[24] (see Table 42–1). In poor metabolizers, atomoxetine should be dosed once daily at 25% to 50% of the dose typically used in normal metabolizers.[24] The maximum therapeutic effect of atomoxetine may take up to 4 weeks, significantly longer than with stimulants. Common side effects of atomoxetine are similar to those of stimulants. Some studies have reported an increase in blood pressure and heart rate.[19–21] It can slow growth rate and cause weight loss; thus, height and weight should be monitored routinely in children[19–21] (see Table 42–2). Atomoxetine's labeling includes warnings about severe hepatotoxicity and increased association with suicidal thinking.

Atomoxetine can be given once daily in many patients. It appears to lack any abuse potential and is not a controlled substance.[25] One big disadvantage of atomoxetine is cost compared with other ADHD medications (Table 42–3).

**Table 42–1**

**Selected Medications for ADHD[a]**

| Drug, Generic (Brand Name) | Initial Dose | Titration Schedule Increments | Typical Dosing Range (Maximum Dose) |
|---|---|---|---|
| **Stimulants** | | | |
| *Short Acting* | | | |
| Methylphenidate[b] (Methylin, Ritalin) | 5 mg twice daily | 5–10 mg/day in weekly intervals | 5–20 mg two to three times daily (60 mg/day) |
| Dexmethylphenidate[b] (Focalin) | 2.5 mg twice daily | 2.5–5 mg/day in weekly intervals | 5–10 mg twice daily (20 mg/day) |
| Dextroamphetamine[b] (Dexedrine) | 2.5–5 mg every morning | 2.5–5 mg/day in weekly intervals | 5–20 mg twice daily (40 mg/day) |
| *Intermediate Acting* | | | |
| Methylphenidate[b] (Ritalin SR, Metadate ER, Methylin ER) | 10 mg once daily | 10 mg/day in weekly intervals | 20–40 mg daily in the morning (60 mg/day) |
| Dextroamphetamine–amphetamine[b] (Adderall) | 2.5–5 mg once to twice daily | 2.5–5 mg/day in weekly intervals | 10–30 mg every morning or 5–20 mg twice daily (40 mg/day) |
| Dextroamphetamine[b] (Dexedrine Spansule) | 5 mg every morning | 5 mg/day in weekly intervals | 5–30 mg daily or 5–15 mg twice daily (40 mg/day) |
| *Extended Acting* | | | |
| Methylphenidate[b] | | | |
| (Concerta) | 18 mg every morning | 9–18 mg/day in weekly intervals | 18–54 mg every morning (54 mg/day in children) |
| (Metadate CD) | 20 mg every morning | 10–20 mg/day in weekly intervals | 20–40 mg daily in the morning (60 mg/day) |
| (Ritalin LA) | 20 mg every morning | 10 mg/day in weekly intervals | 20–40 mg daily in the morning (60 mg/day) |
| (Quillivant XR)[c] | 20 mg every morning | 10-20 mg/day in weekly intervals | 20-40 mg daily in the morning (60 mg/day) |
| Dextroamphetamine/amphetamine[b] (Adderall XR) | 5–10 mg every morning (children); 20 mg once daily (adults) | 5–10 mg/day in weekly intervals | 10–30 mg every morning or 5–15 mg twice daily (30 mg/day, children) (60 mg/day, adult) |
| Dexmethylphenidate[b] (Focalin XR) | 5 mg every morning (children); 10 mg every morning (adults) | 5 mg/day in weekly intervals | 10–20 mg daily in the morning (20 mg/day) |
| Lisdexamfetamine[b] (Vyvanse) | 30 mg every morning (children and adults) | 10–20 mg/day in weekly intervals | 30–70 mg daily in the morning (70 mg/day) |
| **Nonstimulants** | | | |
| Atomoxetine[b,d] (Strattera) | ≤ 70 kg: 0.5 mg/kg/day divided once to twice daily | To target dose of 1.2 mg/kg/day after 3 days | 40–60 mg/day (1.4 mg/kg or 100 mg/day, whichever is less) |
| | > 70 kg: 40 mg once daily | 40 mg/day after 3 days (may ↑ to total of 100 mg/day after 2–3 weeks) | 40–80 mg/day divided once to twice daily (100 mg/day) |
| Clonidine (Catapres) | 0.05 mg once daily | 0.05 mg/day every 3–7 days | 0.1 mg 1 to 4 times daily (0.4 mg/day) |
| (Kapvay)[b] | 0.1 mg at bedtime | 0.1 mg/day in weekly intervals | 0.1–0.2 mg twice daily (0.4 mg/day) |
| Guanfacine (Tenex) | 0.5 mg at bedtime | 0.5 mg every 3–14 days | 1.5–3 mg/day divided into 2–3 doses (4 mg/day) |
| (Intuniv)[b] | 1 mg once daily | No more than 1 mg/week | 1–4 mg daily (4 mg/day) |
| Bupropion (Wellbutrin, Wellbutrin SR, Wellbutrin XL) | 3 mg/kg/day for 7 days (children); 150 mg once daily of SR or XL (adults) | 3 mg/kg/day in weekly intervals (children); increase 150–300 mg/day in weekly intervals (adults) | 6 mg/kg/day or 400 mg/day—whichever is smaller (children); 150–450 mg/day (400 mg/day SR; 450 mg/day XL—adults) |

[a]Pediatric dosing except when adult dosing specified.

[b]Approved by the US FDA for the treatment of ADHD.

[c]Oral extended-release suspension.

[d]Dose adjustment required in patients with hepatic insufficiency.

CD, extended release (biphasic immediate release with extended release); ER, extended release; LA, long acting; SR, sustained release; XL, extended release.

| Table 42–2 | | | |
|---|---|---|---|
| **Patient Monitoring and Management of Selected Adverse Effects of ADHD Medications** | | | |
| **Drug** | **Adverse Effects** | **Management** | **Monitoring** |
| **Stimulants** | | | |
| Methylphenidate dexmethylphenidate dextroamphetamine with or without amphetamine lisdexamfetamine | GI upset, nausea, decreased appetite, potential growth delay | Administer after breakfast and lunch<br>Encourage high-calorie meals/beverages and snacks after dinner<br>Divide dose<br>Change to shorter-acting stimulant<br>Discontinue on weekends and during holidays | Height, weight, blood pressure, pulse<br>ECG if warranted<br>Eating and sleeping patterns<br>Evaluate every 2–4 weeks until stable dose is achieved; then evaluate every 3 months |
| | Insomnia | Move dose(s) earlier in the day and discontinue later day dose if problem persists<br>Change to a shorter-acting stimulant<br>Consider adjunct hypnotic (eg, melatonin) or alternate medication (eg, guanfacine, bupropion) | |
| | Headache | Decrease dose<br>Change to longer-acting stimulant or nonstimulant (eg, atomoxetine)<br>Consider analgesic (eg, acetaminophen) | |
| | Irritability, dysphoria, agitation | Early onset (peak related): Decrease dose or change to longer-acting stimulant<br>Late onset (withdrawal related): Change to longer-acting stimulant<br>Evaluate for comorbidity and treat if present | |
| | Tics | Decrease dose<br>Change to a different stimulant or a nonstimulant (eg, guanfacine, atomoxetine)<br>Add an antipsychotic (eg, risperidone) | |
| **Nonstimulants** | | | |
| Atomoxetine | Increased blood pressure and pulse, nausea, vomiting, fatigue, and insomnia | Decrease dose or change to another medication (eg, guanfacine, bupropion) | Same as above but with baseline and routine liver function tests for hepatotoxicity |
| | Hepatotoxicity, suicidal thoughts | Discontinue or change to another medication | |
| Clonidine and guanfacine | Sedation | Decrease dose<br>Administer closer to bedtime | Same as above |
| Bupropion | GI upset, restlessness, sleep disturbances, tremor | Decrease dose or change to another medication (eg, guanfacine) | Height, weight, blood pressure, pulse every month |
| | Tics, rash, seizures | discontinue medication | Eating and sleeping patterns |

ECG, electrocardiography; GI, gastointestinal.

Because of the high cost, lack of long-term efficacy data, and few comparison studies with stimulants, atomoxetine should be advocated only if the patient has failed or is intolerant to stimulant therapy.

**Bupropion** Bupropion is a monocyclic antidepressant that weakly inhibits the reuptake of norepinephrine and dopamine. It is effective for symptoms of ADHD in children, and preliminary results suggest it may be as effective as methylphenidate.[26,27] Similar results have been shown in adults.[26] Bupropion is well tolerated with minimal side effects (eg, insomnia, headache, nausea, and tremor) which typically disappear with continuation of therapy and with slow titration of dose. Bupropion can worsen tics and movement disorders. It is a rational choice in an ADHD patient with comorbid depression.[26] However, seizures have

been associated with bupropion doses greater than 6 mg/kg/day.[28] Seizures related to high doses can be minimized by reducing the dose or switching to a longer-acting formulation. Bupropion can increase the risk of suicidal ideation and is contraindicated in patients with seizure and eating disorders.

**Clonidine and Guanfacine** Clonidine and guanfacine are central $\alpha_2$-adrenergic agonists that inhibit the release of norepinephrine presynaptically. Both of these agents are less effective than stimulants in treating ADHD but typically are used as adjuncts to stimulants to control disruptive or aggressive behavior and alleviate insomnia.[29] The effects of immediate-release guanfacine typically last 3 to 4 hours longer than immediate-release clonidine, and the drug requires less frequent dosing. Extended-release formulations of guanfacine (Intuniv) and clonidine

^aCost based on brand regimen specified without a dispensing fee or discount for a 30-day supply. (From PrescriptionBlueBook.com or various online State Maximum Allowable Costs [SMAC].)

^bAscending release (early then gradual/continuous).

^cBimodal release (early then late; mimics twice daily dosing of shorter-acting stimulant counterpart).

$, less than $40; $$, $40–$79; $$$, $80–$120; $$$$, greater than $120.

CD, controlled release (biphasic immediate release with extended release); ER, extended release; LA, long-acting; SR, sustain release; XL, extended release.

(Kapvay) were developed to minimize dosing frequency and improve treatment of anger, hostility, and irritability in patients with ADHD. Similar to other nonstimulants, these two dosage forms can also be used in patients who are intolerant to stimulants. However, use of these dosage forms is limited because of a lack of comparative trials to stimulants and high cost. Common side effects with clonidine and guanfacine are low blood pressure and sedation. Sedation generally subsides after 2 to 3 weeks of therapy.[29,30] Rarely, severe side effects such as bradycardia, rebound hypertension, irregular heart beats, and sudden death have been reported.

## Pharmacoeconomic and Treatment Adherence Considerations

- Annual health care costs of patients with ADHD are more than double those of patients without ADHD.[31,32] The financial burden

of ADHD is attributed to the direct cost of pharmacotherapy, office visits, diagnostic measurements, therapy monitoring, and indirect costs (eg, lost work time and productivity). When selecting a treatment, the cost burden to the patient's family should be considered. Short-acting stimulants may be more cost effective in many patients compared with longer-acting stimulant formulations (see Table 42–3), but in certain circumstances, longer-acting stimulant formulations may provide a greater benefit owing to increased adherence to the medication and prolonged control of symptoms of ADHD. All intermediate-acting and various extended-acting (Concerta, Ritalin LA, Metadate CD, Focalin XR, and Adderall XR) stimulant formulations are now available as generic products, making them potentially more affordable. In addition, some nonstimulant ADHD medications (eg, bupropion and immediate-release $\alpha_2$-adrenergic agonists) appear to be less costly than many stimulant formulations; however, these agents have not been consistently proven to have superior efficacy over stimulants. Decisions on selection of specific ADHD medications should not be based solely on cost but also on efficacy and safety along with adherence to the prescribed regimen.

## OUTCOME EVALUATION

Carefully document core ADHD symptoms at baseline to provide a reference point from which to evaluate effectiveness of treatment. Improvement in individualized patient outcomes are desired, such as (a) family and social relationships, (b) disruptive behavior, (c) completing required tasks, (d) self-motivation, (e) appearance, and (f) self-esteem. Elicit evaluations of the patient's behavior from family, school, and social environments in order to assess these outcomes. Using standardized rating scales (eg, Conners Rating Scales—Revised, Brown Attention-Deficit Disorder Scale, and Inattentive-Overactive with Aggression [IOWA] Conners Scale) in both children and adults with ADHD helps to minimize variability in evaluation.[33] After initiation of pharmacotherapy, evaluate every 2 to 4 weeks to determine

### Patient Encounter Part 2: Additional Historical and Physical Examination Findings

**Wt:** 25.7 kg (56.5 lb)

**Allergies:** None known

**Ht:** 3'10" (119 cm)

**BP:** 99/59 mm Hg

**P:** 92 beats/min

The family does not qualify for medical assistance, and they can hardly afford their monthly expenses

*What stimulants and nonstimulants are available that might control this child's symptoms?*

*Which ADHD medications should you be concerned about using?*

*What medications will maximize efficacy, facilitate adherence, minimize potential side effects, and offer an acceptable cost?*

*What baseline assessment do you need before starting stimulant therapy?*

*What are important counseling points to discuss with the parents before starting any ADHD medication?*

---

### Patient Care Process

**Patient Assessment:**

- Suspected ADHD: evaluate patient for signs and symptoms of hyperactivity-impulsivity and/or inattentiveness.
- Utilize patient symptoms and parent-teacher evaluation to determine if the patient meets the *DSM-5* criteria for ADHD.
- Perform a complete medical history, home assessment, physical, and neurological examination. Include blood pressure, pulse, and height and weight measurements. A baseline ECGs may be obtained in children when known or suspected cardiac disease exists. What is the patient's age?

**Therapy Evaluation:**

- Evaluate current and past medications for effectiveness and side effects. Does the patient have clear indications or any contraindications for therapy?
- Evaluate the cost effectiveness/burden of current therapy and the patient's ability to remain adherent to therapy.
- Assess for adherence and drug interactions.

**Care Plan Development:**

- If patient is younger than 6 years, initiate behavioral modification therapy before starting low-dose methylphenidate (see Table 42–1). Start older patients on low-dose stimulant therapy (see Table 42–1).
- Continuously stress the importance of adherence.
- Consider switching to a different stimulant formulation if initial stimulant is not effective (see Table 42–1).
- A trial of at least two stimulants should be attempted before a nonstimulant is considered.
- Reevaluate the diagnosis if all treatment attempts fail.
- Educate the patient's parents and/or caregivers that behavioral therapy is not as effective as stimulant therapy and about the growth delay and substance abuse risks with stimulants.

**Follow-up Evaluation:**

- Perform a general physical examination yearly and monitor blood pressure quarterly in adults.
- Evaluate for improvement in behavioral modification therapy patients every 3 months. Obtain information from parent/teacher rating scales.
- Measure effectiveness and safety (side effect profile) of stimulant therapy monthly for the first 3 months. Has the patient's behavior improved? Is the patient experiencing any adverse effects?

Review medical history and obtain height, weight, heart rate, and blood pressure at each visit.

---

efficacy of treatment and potential effects on height, weight, pulse, and blood pressure. Use physical examinations or liver function tests as appropriate to monitor for adverse effects. In children being considered for ADHD pharmacotherapy, obtain baseline electrocardiograms (ECGs) when known or suspected cardiac disease exists or the clinician judges it necessary.[34–36] Typically,

therapeutic benefits will be seen within days of initiating stimulants and within 1 or 2 months of starting bupropion and atomoxetine. When a maintenance dose has been achieved, schedule follow-up visits every 3 months. At these visits, assess height and weight, and screen for possible adverse drug effects. If a patient has failed to respond to multiple agents, reevaluate for other possible causes of behavior dysfunction. Counsel patients and their families that treatment generally is long term. Typically, appropriately treated patients learn to better control their ADHD symptoms as adults.

## Abbreviations Introduced in This Chapter

ADHD    Attention deficit hyperactivity disorder

# Diabetes Mellitus

Julie Sease and Kayce Shealy

## LEARNING OBJECTIVES

**Upon completion of the chapter, the reader will be able to:**

1. Discuss the incidence and economic impact of diabetes.
2. Distinguish clinical differences in type 1, type 2, and gestational diabetes.
3. List screening and diagnostic criteria for diabetes.
4. Discuss therapeutic goals for blood glucose and blood pressure for a patient with diabetes.
5. Recommend nonpharmacologic therapies, including meal planning and physical activity, for patients with diabetes.
6. Compare oral agents used in treating diabetes by their mechanisms of action, time of action, side effects, contraindications, and effectiveness.
7. Select appropriate insulin therapy based on onset, peak, and duration of action.
8. Discuss the signs, symptoms, and treatment of hypoglycemia.
9. Define *diabetic ketoacidosis* and discuss treatment goals.
10. Develop a comprehensive therapeutic monitoring plan for a patient with diabetes based on patient-specific factors.

## INTRODUCTION

**KEY CONCEPT** *D**iabetes mellitus (DM) describes a group of chronic metabolic disorders characterized by hyperglycemia that may result in long-term* microvascular *and neuropathic complications. These complications contribute to diabetes being the leading cause of (a) new cases of blindness among adults, (b) end-stage renal disease, and (c) nontraumatic lower limb amputations.* Macrovascular *complications (coronary artery disease, peripheral vascular disease, and stroke) are also associated with DM.*

## EPIDEMIOLOGY AND ETIOLOGY

DM affects an estimated 29.1 million persons in the United States, or 9.3% of the population.[1] Although an estimated 21 million persons have been diagnosed, another 8.1 million have DM but are unaware they have the disease. The total financial impact of DM in 2012 was approximately $245 billion, with direct medical costs equaling $176 billion (2.3 times higher than what expenditures would be in the absence of diabetes) and indirect costs secondary to disability, work loss, and premature mortality equaling $69 billion.

DM is characterized by a complete lack of insulin, a relative lack of insulin, or **insulin resistance** as well as disorders of other hormones. These defects result in an inability to use glucose for energy. The increasing prevalence of DM is partly caused by three influences: lifestyle, ethnicity, and age.

### Lifestyle

A sedentary lifestyle coupled with greater consumption of high-fat, high-carbohydrate foods, and larger portion sizes have resulted in increasing rates of persons being obese. Current estimates indicate that 34.9% of the US population is obese when obesity is defined as a body mass index (BMI) of greater than 30 $kg/m^2$.[2] In a 2008 survey, the Centers for Disease Control and Prevention (CDC) found that 25.4% of American adults spent none of their free time being physically active.[3]

### Ethnicity

In addition to current lifestyle trends and increased body weight, certain ethnic groups are at a disproportionately high risk for developing DM. The risk of diabetes is 18% higher among Asian Americans, 68% higher among Hispanics, and 74% higher among non-Hispanic Blacks compared with non-Hispanic White adults.[1] New cases of DM are diagnosed at a higher rate among United States minority populations than in non-Hispanic Whites.

### Age

The third factor contributing to the increased prevalence of type 2 DM (T2DM) is age. In 2012, 11.2 million people in the United States who were 65 years of age or older had diabetes compared with only 208,000 younger than age 20 years.[1] As the population ages, the incidence of T2DM is expected to increase.

**KEY CONCEPT** *Type 1 DM (T1DM) is usually diagnosed before age 30 years but can develop at any age. Autoimmune destruction of the β cells causes insulin deficiency. T2DM accounts for approximately 90% to 95% of all diagnosed cases of DM, is progressive in its development, and is often preceded by an increased risk for diabetes (previously known as prediabetes). A combination of insulin deficiency, insulin resistance, and other hormonal irregularities, primarily involving glucagon, are key problems with T2DM. The majority of people with T2DM are overweight, and an increasing number of cases in children have been observed.*

T1DM is an autoimmune disease in which insulin-producing β cells in the pancreas are destroyed, leaving the individual insulin deficient.[4] Individuals with T1DM may develop islet cell antibodies, insulin autoantibodies, glutamic acid decarboxylase autoantibodies, protein tyrosine phosphatase autoantibodies, or zinc transporter protein autoantibodies, though most laboratories do not have reliably sensitive or specific assays to measure all five. As more β cells are destroyed, glucose metabolism becomes compromised because of reduced insulin release after a glucose load. At the time of diagnosis of T1DM, it is commonly believed that most patients have an 80% to 95% loss of β-cell function.[5] The remaining β-cell function at diagnosis creates a "honeymoon period" during which smaller amounts of insulin are required to control glucose levels. After this, remaining β-cell function is lost, and patients become completely insulin deficient and require more exogenous insulin.

Latent autoimmune diabetes in adults (LADA), slow-onset type 1, or type 1.5 DM, is a form of autoimmune T1DM that occurs in individuals older than the usual age of T1DM onset.[6] Patients often are mistakenly thought to have T2DM because the person is older and may respond initially to treatment with oral blood glucose–lowering agents. These patients do not have insulin resistance, but antibodies are present in the blood that are known to destroy pancreatic β cells. C-peptide, a surrogate marker for insulin secretion, may be used to establish or verify a diagnosis of T1DM.[4] When C-peptide levels are drawn, a simultaneous blood glucose level should also be taken.

Categories of increased risk for diabetes (commonly referred to as prediabetes) include impaired fasting glucose (IFG), impaired glucose tolerance (IGT), or hemoglobin $A_{1c}$ ($A_{1c}$) between 5.7% and 6.4% (0.057 and 0.064; 39 and 46 mmol/mol hemoglobin [Hgb]).[7] IFG is defined as having a fasting blood glucose (FBG) level between 100 and 125 mg/dL (5.6 and 6.9 mmol/L). IGT is defined by a postprandial blood glucose level between 140 and 199 mg/dL (7.8 and 11.0 mmol/L). The development of IFG, IGT, or $A_{1c}$ between 5.7% and 6.4% (0.057 and 0.064; 39 and 46 mmol/mol) places the individual at high risk of eventually developing diabetes.

T2DM is usually slow and progressive in its development. Risk factors for T2DM include:

- First-degree family history of DM (ie, parents or siblings)
- Overweight or obese
- Habitual physical inactivity
- Race or ethnicity (Native American, Latino or Hispanic American, Asian American, African American, and Pacific Islanders)
- Previously identified IFG, IGT, or $A_{1c}$ between 5.7% and 6.4% (0.057 and 0.064 or 39 and 46 mmol/mol Hgb)
- Hypertension (greater than or equal to 140/90 mm Hg or on therapy for hypertension)
- High-density lipoprotein (HDL) cholesterol less than 35 mg/dL (0.91 mmol/L) and/or a triglyceride level greater than 250 mg/dL (2.83 mmol/L)
- History of gestational diabetes or delivery of a baby weighing greater than 4 kg (9 lb)
- History of cardiovascular disease
- History of polycystic ovarian syndrome
- Other conditions associated with insulin resistance (eg, acanthosis nigricans)

Gestational diabetes mellitus (GDM) is defined as glucose intolerance in women during pregnancy. Clinical detection of and therapy for GDM are important because blood sugar control produces significant reductions in adverse maternal, fetal, and neonatal outcomes.

Diabetes from other causes includes genetic defects in β-cell function, genetic defects in insulin action, diseases of the exocrine pancreas such as cystic fibrosis, and drug- or chemical-induced diabetes. Drugs that may cause increased blood glucose include glucocorticoids, pentamidine, nicotinic acid, β-adrenergic agonists, thiazides, phenytoin, clozapine, olanzapine, and γ-interferon.[8] Although the use of these medications is not contraindicated in persons with DM, caution and awareness of the effects on blood glucose should be taken into account when managing these patients.

## PATHOPHYSIOLOGY
### Normal Carbohydrate Metabolism

The body's main fuel source is glucose. Cells metabolize glucose completely through glycolysis and the Krebs cycle, producing adenosine triphosphate (ATP) as energy.[9] Glucose is stored in the liver and muscles as glycogen. Glycogenolysis converts stored glycogen back to glucose.[10] Glucose also may be stored in adipose tissue, which may subsequently undergo lipolysis yielding free fatty acids.[9] In the fasting state, free fatty acids supply much of the energy needs for the body except for the central nervous system, which requires glucose to function normally.[10] Proteins also can be converted to glucose through gluconeogenesis.[9] Homeostasis is achieved through a balance of the metabolism of glucose, free fatty acids, and amino acids to maintain a blood glucose level sufficient to provide an uninterrupted supply of glucose to the brain.[10]

Insulin and glucagon are produced in the pancreas by cells in the islets of Langerhans. β cells make up 70% to 90% of the islets and produce insulin and amylin, whereas α cells produce glucagon.[9] The main function of insulin is to decrease blood glucose levels. Glucagon, along with other counterregulatory hormones such as growth factor, cortisol, and epinephrine, increases blood glucose levels.[10] Although blood glucose levels vary, the opposing actions of insulin and glucagon, along with the counterregulatory hormones, normally maintain fasting values between 79 and 99 mg/dL (4.4–5.5 mmol/L).

▶ *Normal Insulin Action*

Fasting insulin levels in the circulation average from 43 to 186 pmol/L (6–26 μIU/mL).[9] After food is consumed, blood glucose levels rise, and the insulin-secretion response occurs in two phases. An initial burst, known as *first phase insulin response,* lasts approximately 5 to 10 minutes and serves to suppress hepatic glucose production and cause insulin-mediated glucose disposal in adipose tissue. This bolus of insulin minimizes hyperglycemia during meals and during the postprandial period.

The *second phase of insulin response* is characterized by a gradual increase in insulin secretion, which lasts 60 to 120 minutes and stimulates glucose uptake by peripheral insulin-dependent tissues, namely muscle. Slower release of insulin allows the body to respond to the new glucose entering from digestion while maintaining blood glucose levels.

Amylin is a naturally occurring hormone that is cosecreted from β cells with insulin. People with diabetes have either a relative or complete lack of amylin. Amylin has three major mechanisms of action: suppression of postmeal glucagon secretion; regulation of the rate of gastric emptying from the stomach to the small intestine, which increases satiety; and regulation of plasma glucose concentrations in the bloodstream.

### ▶ Impaired Insulin Secretion

A pancreas with normal β-cell function is able to adjust insulin production to maintain normal blood glucose levels.[10] In T2DM, more insulin is secreted to maintain normal blood glucose levels until eventually the pancreas can no longer produce sufficient insulin.[9] The resulting hyperglycemia is enhanced by extremely high insulin resistance, pancreatic burnout in which β cells lose functional capacity, or both. Impaired β-cell function results in a reduced ability to produce a first-phase insulin response sufficient to signal the liver to stop producing glucose after a meal.[11] Over time, patients with T2DM experience progressive β-cell death and many require exogenous insulin to maintain blood glucose control.

### ▶ Insulin Resistance

Insulin resistance is the primary factor that differentiates T2DM from other forms of diabetes. Insulin resistance may be present for several years prior to the diagnosis of DM and can continue to progress throughout the course of the disease.[9] Resistance to insulin occurs in adipose tissue, skeletal muscle and the liver.[8] Insulin resistance in the liver poses a double threat because the liver becomes nonresponsive to insulin for glucose uptake, and hepatic production of glucose after a meal does not cease, leading to elevated fasting and postmeal blood glucose levels.

### ▶ Metabolic Syndrome

Insulin resistance has been associated with a number of other cardiovascular risks, including abdominal obesity, hypertension, dyslipidemia, hypercoagulation, and hyperinsulinemia.[12] The clustering of these risk factors has been termed **metabolic syndrome**. Criteria defining the metabolic syndrome as established by the International Diabetes Federation are summarized in **Table 43–1**.[12] Patients having these additional risk factors have been found to be at much higher cardiovascular risk than would be expected from the individual components of the syndrome.

### ▶ Incretin Effect

When nutrients enter the stomach and intestines, incretin hormones are released, which stimulate insulin secretion.[13] This so-called **incretin effect** is mediated by two hormones, glucagon-like peptide-1 (GLP-1) and glucose-dependent insulinotropic peptide (GIP), with GLP-1 being studied the most. GLP-1 is secreted by the L cells of the ileum and colon primarily, and GIP is secreted by the K cells. GLP-1 secretion is caused by endocrine and neural signals started when nutrients enter the gastrointestinal (GI) tract. Within minutes of food ingestion, GLP-1 levels rise rapidly. A glucose-dependent release of insulin occurs, and the dipeptidyl peptidase-4 (DPP-4) enzyme cleaves GLP-1

---

**Table 43–1**

**Five Components of Metabolic Syndrome[12]**

| Risk Factor | Defining Level |
|---|---|
| 1. Abdominal obesity | |
| • Men | Waist circumference > 102 cm (40 in)[a] |
| • Women | Waist circumference > 88 cm (35 in)[a] |
| 2. Triglycerides | ≥ 150 mg/dL (1.70 mmol/L) |
| 3. HDL cholesterol | |
| • Men | < 40 mg/dL (1.03 mmol/L) |
| • Women | < 50 mg/dL (1.29 mmol/L) |
| 4. Blood pressure | ≥ 130/85 mm Hg |
| 5. Fasting glucose | ≥ 100 mg/dL (5.6 mmol/L) |

Individuals having at least three of the five above criteria meet the diagnostic criteria for metabolic syndrome. HDL, high-density lipoprotein.

[a]These values are most likely to continue being used clinically in the United States, though the International Diabetes Federation advocates for use of waist circumference measurements based on ethnic group.

---

rapidly to an inactive metabolite. Much of the research on glucose-lowering products involves prolonging the action of GLP-1. Other glucose-lowering effects of GLP-1 include suppression of glucagon, slowing gastric emptying, and increasing satiety.

## CLINICAL PRESENTATION AND DIAGNOSIS
### Screening

Currently, the American Diabetes Association (ADA) recommends routine screening for T2DM every 3 years in all adults starting at 45 years of age.[7] Testing for T2DM should be considered, regardless of age, in adults who have a BMI greater than or equal to 25 kg/m$^2$ (or BMI greater than or equal to 23 kg/m$^2$ for

---

### Clinical Presentation and Diagnosis of Diabetes Mellitus

| Characteristic | T1DM | T2DM |
|---|---|---|
| Usual age of onset | Childhood or adolescence | Adult |
| Speed of onset | Abrupt | Gradual |
| Family history | Negative | Positive |
| Body type | Thin | Obese or history of obesity |
| Metabolic syndrome | No | Often |
| Autoantibodies | Present | Rare |
| Symptoms | Polyuria, polydipsia, polyphagia, rapid weight loss | Asymptomatic |
| Ketones at diagnosis | Present | Uncommon |
| Acute complications | Diabetic ketoacidosis (DKA) | Rare |
| Microvascular complications at diagnosis | Rare | Common |
| Macrovascular complications at or before diagnosis | Rare | Common |

---

**Table 43–2**

**American Diabetes Association Screening Recommendations for Diabetes[7]**

**Asymptomatic Type 1**
The ADA does not recommend screening for T1DM because of the low incidence in the general population and due to the acute presentation of symptoms

**Asymptomatic Type 2**
1. The ADA recommends screening for T2DM every 3 years in all adults beginning at 45 years of age, particularly in those with a BMI ≥ 25 kg/m$^2$ (or BMI ≥ 23 kg/m$^2$ for Asian Americans)
2. Testing should be considered for persons younger than 45 years of age or more frequently in individuals who are overweight (BMI ≥ 25 kg/m$^2$ (for the general population and ≥ 23 kg/m$^2$ for Asian Americans) and have additional risk factors:
   • Habitually inactive
   • First-degree relative with diabetes
   • Member of a high-risk ethnic population (eg, African American, Latino, Native American, Asian American, Pacific Islander)
   • Delivered a baby weighing > 4.1 kg (9 lb) or previous diagnosis of GDM
   • Hypertensive (≥ 140/90 mm Hg)
   • HDL cholesterol level less than 35 mg/dL (0.91 mmol/L) and/or triglyceride level > 250 mg/dL (2.83 mmol/L)
   • Polycystic ovary syndrome
   • Previous IGT or IFG
   • Other clinical conditions associated with insulin resistance (eg, acanthosis nigricans)
   • History of cardiovascular disease

**Type 2 in Children and Adolescents**
Criteria:
   • Overweight (BMI > 85th percentile for age and sex, weight for height > 85th percentile, or weight > 120% of ideal for height)
Plus any two of the following risk factors:
   • Family history of T2DM in first- or second-degree relatives
   • Race or ethnicity (Native American, African American, Latino or Hispanic American, Asian American, Pacific Islander)
   • Signs of insulin resistance or conditions associated with insulin resistance (acanthosis nigricans, hypertension, dyslipidemia, or polycystic ovary disease)
   • Maternal history of diabetes or GDM during child's gestation

**Age of initiation**
Age 10 years or at onset of puberty, if puberty occurs at a younger age
Frequency of testing:
   Every 3 years
   Test method: FPG or OGTT possibly more suitable than A$_{1c}$

**Gestational diabetes**
1. Screen for undiagnosed T2DM at first prenatal visit in those with risk factors using standard criteria
2. All women should be screened with an OGTT between weeks 24 and 28 of gestation

A$_{1c}$, hemoglobin A$_{1c}$; ADA, American Diabetes Association; BMI, body mass index; FPG, fasting plasma glucose; GDM, gestational diabetes mellitus; HDL, high-density lipoprotein; IFG, impaired fasting glucose; IGT, impaired glucose tolerance; OGTT, oral glucose tolerance test; T1DM, type 1 diabetes mellitus; T2DM, type 2 diabetes mellitus.

---

Asian Americans) and one or more additional risk factors. The ADA does not currently recommend widespread screening for T1DM, although measurement of islet autoantibodies may be appropriate for high-risk individuals, including those who have relatives with T1DM. See **Table 43–2**[7] for complete screening guidelines.

## Gestational Diabetes

All pregnant women who have risk factors for T2DM should be screened for undiagnosed T2DM at their first prenatal visit using standard diagnostic criteria. Any woman found to have diabetes at that early point in pregnancy is considered to have T2DM, not GDM. All other pregnant women, not currently known to have DM should be screened for GDM. Two possible strategies exist for GDM screening. They are a "one-step" 2-hour 75-gram **oral glucose tolerance test** (OGTT) and a "two-step" process which includes a 1-hour 50-gram nonfasting screen followed by a 3-hour 100-gram OGTT for those with a 1-hour screening glucose of greater than or equal to 140 mg/dL (7.8 mmol/L). The diagnostic criteria for the "one-step" 2-hour 75-gram OGTT are

listed in **Table 43–3**.[7] Any woman diagnosed with GDM should be retested at 6 to 12 weeks postpartum using the OGTT with nonpregnant diagnostic criteria.

**Table 43–3**

**Diagnosis of Gestational Diabetes Mellitus With a 75-g Glucose Load[7]**

| Time | Plasma Glucose | |
|---|---|---|
| | mg/dL | mmol/L |
| **75-g glucose load** | | |
| Fasting | 92 or more | 5.1 or more |
| 1 hour | 180 or more | 10.0 or more |
| 2 hours | 153 or more | 8.5 or more |

A positive diagnosis of diabetes is made when any of the listed glucose values are exceeded. The test should be done in the morning after an 8-hour fast.

Note: these values are based on American Diabetes Association guidelines.

## Table 43–4

**ADA Criteria for Diagnosis of Diabetes[7]**

Symptoms of diabetes plus a casual plasma glucose concentration ≥ 200 mg/dL (11.1 mmol/L). *Casual* is defined as any time of day without regard to time since the last meal. The classic symptoms of diabetes include polyuria, polydipsia, and unexplained weight loss.

*or*

FPG ≥ 126 mg/dL (7.0 mmol/L). *Fasting* is defined as no caloric intake for at least 8 hours.

*or*

Two-hour postload glucose ≥ 200 mg/dL (11.1 mmol/L) during an OGTT. The test should be performed as described by the WHO using a glucose load containing the equivalent of 75 g of anhydrous glucose dissolved in water.

*or*

$A_{1c}$ ≥ 6.5% (0.065; 48 mmol/mol Hgb). The test should be performed in a laboratory using a method that is NGSP certified to the DCCT assay.

ADA, American Diabetes Association; $A_{1c}$, hemoglobin $A_{1c}$; DCCT, Diabetes Control and Complications Trial; FPG, fasting plasma glucose; Hgb, hemoglobin; NGSP, National Glycohemoglobin Standardization Program; OGTT, oral glucose tolerance test; WHO, World Health Organization.

In the absence of unequivocal hyperglycemia, these criteria should be confirmed by repeat testing on a different day. The OGTT is not recommended for routine clinical use.

### Diagnostic Criteria

The diagnosis of DM includes glycemic outcomes exceeding threshold values with one of three testing options (**Table 43–4**).[7] Confirmation of abnormal values must be made on a subsequent day for diagnosis unless unequivocal symptoms of hyperglycemia exist, such as polydipsia, polyuria, and polyphagia. Either $A_{1c}$, fasting plasma glucose (FPG), or OGTT are appropriate tests for detecting DM.

The ADA categorizes patients demonstrating $A_{1c}$ between 5.7% and 6.4% (0.057 and 0.064 or 39 and 46 mmol/mol Hgb), IFG, or IGT as having increased risk for future diabetes. The categorization thresholds of glucose status for FPG determination and the OGTT are listed in **Table 43–5**.[7] IFG and IGT may coexist or may be identified independently. FPG level represents hepatic glucose production during the fasting state, whereas

## Table 43–5

**ADA Categorization of Glucose Status[7]**

| | mg/dL | mmol/L |
|---|---|---|
| **FPG** | | |
| • Normal | < 100 | < 5.6 |
| • IFG (prediabetes) | 100–125 | 5.6–6.9 |
| • Diabetes | ≥ 126 | ≥ 7.0 |
| **2-hour postload plasma glucose** (OGTT) | | |
| • Normal | < 140 | < 7.8 |
| • IGT (prediabetes) | 140–199 | 7.8–11.0 |
| • Diabetes | ≥ 200 | ≥ 11.1 |

ADA, American Diabetes Association; FPG, fasting plasma glucose; IFG, impaired fasting glucose; IGT, impaired glucose tolerance; OGTT, oral glucose tolerance test.

## Patient Encounter, Part 1

A 42-year-old African American woman presents to her physician for a follow-up appointment for her recent pregnancy. Upon questioning, she states that she was diagnosed with gestational diabetes during the pregnancy, and that two of her previous three children weighed greater than 9 pounds (~4 kg) at birth. She is currently 12 weeks postpartum and is without complaint.

**PMH:** Allergic rhinitis, gestational diabetes

**FH:** Father has diabetes, hypertension, and a history of myocardial infarction at age 54 years; mother has diabetes and a history of stroke at age 70 years; brother has hypercholesterolemia

**SH:** Smokes half pack per day for 10 years, but quit during her pregnancy; denies alcohol or illicit drug use; denies physical activity

**Allergies:** Sulfa and penicillin

**Meds:** Fluticasone nasal spray, one spray each nostril daily

**VS:** BP 114/85 mm Hg, P 82 beats/min, RR 20 breaths/min, T 37°C (98.6°F), Ht 5′3″ (160 cm), Wt 165 lb (75 kg)

**ROS:** (+) Fatigue, (–) N/V/D, HA, SOB, chest pain

*What risk factors does this patient have for diabetes?*

*Which type of diabetes do her characteristics suggest?*

*What additional information is needed to diagnose this patient with diabetes?*

postprandial glucose levels in the OGTT may reflect glucose uptake in peripheral tissues, insulin sensitivity, or a decreased first-phase insulin response. The OGTT identifies people with either IFG or IGT and therefore potentially more people at increased risk for DM and cardiovascular disease. The OGTT is a more cumbersome test to perform than either the $A_{1c}$ or FPG; however, the efficacy of interventions for primary prevention of T2DM have been demonstrated among patients with IGT, not among those with IFG or specific $A_{1c}$ levels.

## TREATMENT
### Goals of Therapy

**KEY CONCEPT** *DM treatment goals include reducing, controlling, and managing long-term microvascular, macrovascular, and neuropathic complications; preserving β-cell function; preventing acute complications from high blood glucose levels; minimizing hypoglycemic episodes; and maintaining the patient's overall quality of life. To achieve the majority of these goals, near-normal blood glucose levels are fundamental; thus, glycemic control remains a primary objective in diabetes management.* Two landmark trials, the Diabetes Control and Complications Trial (DCCT)[14] and the United Kingdom Prospective Diabetes Study (UKPDS),[15] showed that lowering blood glucose levels decreased the risk of developing chronic complications. A near-normal blood glucose level can be achieved with appropriate patient education, lifestyle modification, and medications.

Proper care of DM requires goal setting and assessment for glycemic control, self-monitoring of blood glucose (SMBG), monitoring of blood pressure and lipid levels, regular monitoring for the development of complications, dietary and exercise lifestyle modifications, and proper medication use. The complexity

of proper DM self-care principles has a dramatic impact on a patient's lifestyle and requires a highly disciplined and dedicated person to maintain long-term control.

▶ *Setting and Assessing Glycemic Targets*

**KEY CONCEPT** *Patients and clinicians can evaluate disease state control of the patient's diabetes by monitoring daily blood glucose values, $A_{1c}$ or estimated average glucose (eAG) values, and blood pressure.* SMBG enables patients to obtain their current blood glucose level at any time easily and relatively inexpensively. The $A_{1c}$ test provides a weighted-mean blood glucose level from approximately the previous 3 months.

**Self-Monitoring of Blood Glucose** SMBG is the standard method for routinely checking blood glucose levels. Each reading provides a point-in-time evaluation of glucose control that can vary widely depending on numerous factors, including food, exercise, stress, and time of day.

By examining multiple individual points of data, patterns of control can be established. Therapy can be evaluated from these patterns, and adjustments can be made to improve overall blood glucose control. The ADA premeal plasma glucose goals are 80 to 130 mg/dL (4.4–7.2 mmol/L) and peak postprandial plasma glucose goals are less than 180 mg/dL (10.0 mmol/L).[7] The American Association of Clinical Endocrinologists (AACE) supports tighter SMBG controls, with premeal goals of less than 110 mg/dL (6.1 mmol/L) and peak postmeal goals of less than 140 mg/dL (7.8 mmol/L).[16] For patients using multiple daily insulin injections or insulin pump therapy, SMBG may need to be performed six to eight times per day.[7] The optimal frequency of testing in patients using less frequent insulin injections, noninsulin therapies, or medical nutrition therapy (MNT) is less clear. Each patient should be educated regarding how often and when to perform SMBG, and these measurements should be evaluated and used by both the patient and his or her health care providers to help the patient gain and maintain blood glucose control.

Typically, in SMBG, a drop of blood from the fingertip is placed on a test strip that is then read by a blood glucose monitor. Recent technological advancements have decreased the blood sample size required to as small as 0.3 μL, provided the capability of alternate-site testing (abdomen, arm, leg, palm), and allowed for the delivery of readings in as few as 5 seconds. Many SMBG devices can download or transfer information to a computer program that can summarize and produce graphs of the data. Identifying patterns in the patient's blood glucose data can aid practitioners in modifying treatment for better glucose control. Specific therapy adjustments can be made for patterns found at certain times of the day, on certain days, or with large day-to-day variances.

In choosing a glucose meter for a patient, several additional factors may aid in the best selection for the patient. Larger display areas or units with audible instructions and results may be better suited for older individuals and those with visual impairment. Patients with arthritis or other conditions that decrease dexterity may prefer larger meters with little or no handling of glucose strips. Younger patients or busy professionals may prefer smaller meters with features such as faster results, larger memories, reminder alarms, and downloading capabilities. Continuous glucose sensors are now available that work with or independently of insulin pumps. These monitors provide blood glucose readings, primarily through interstitial fluid (ISF). A small sterile disposable glucose-sensing device called a sensor is inserted into the subcutaneous tissues. This sensor measures the change in glucose in ISF and sends the information to a monitor, which stores the results.

**Hemoglobin $A_{1c}$** Glucose interacts spontaneously with Hgb in red blood cells to form glycated derivatives. The most prevalent derivative is $A_{1c}$. Greater amounts of glycation occur when blood glucose levels increase. Because Hgb has a life span of approximately 3 months, levels of $A_{1c}$ provide a marker reflecting the average glucose levels over this timeframe.[7] The ADA goal for persons with DM is less than 7% (0.07; 53 mmol/mol Hgb), whereas the AACE supports a goal of less than or equal to 6.5% (0.065; 48 mmol/mol Hgb).[7,16] Testing $A_{1c}$ levels should occur at least twice a year for patients who are meeting treatment goals and four times per year for patients not meeting goals or those who have had recent changes in therapy.

**Estimated Average Glucose** The eAG is used to correlate $A_{1c}$ values with readings that patients obtain from their home glucose monitors.[7] The equation to convert from $A_{1c}$ to eAG is: eAG (mg/dL) = 28.7 × $A_{1c}$ – 46.7 (or eAG [mmol/L] = 1.59 × $A_{1c}$ – 2.59 for $A_{1c}$ expressed as a percentage).[17] The goal eAG is 154 mg/dL (8.5 mmol/L), which corresponds with an $A_{1c}$ of less than 7% (0.07; 53 mmol/mol Hgb).

**Ketone Monitoring** Urine and blood ketone testing is important in people with T1DM, in pregnancy with preexisting diabetes, and in GDM. People with T2DM may have positive ketones and develop diabetic ketoacidosis (DKA) if they are ill.

The presence of ketones may indicate a lack of insulin or ketoacidosis, a condition that requires immediate medical attention. When there is a lack of insulin, peripheral tissues cannot take up and store glucose. This causes the body to think it is starving, and because of excessive lipolysis, ketones, primarily β-hydroxybutyric acid and acetoacetic acid, are produced as byproducts of free fatty acid metabolism in the liver. Glucose and ketones are osmotically active, and when an excessive amount of ketones is formed, the body gets rid of them through urine, leading to dehydration. Patients with T1DM should test for ketones during acute illness or stress or when blood glucose levels are consistently elevated above 300 mg/dL (16.7 mmol/L). This commonly occurs when insulin is omitted or when diabetes is poorly controlled due to nonadherence, illness, or other reasons. Women with preexisting diabetes before pregnancy or with GDM should check ketones using their first morning urine sample or when any symptoms of ketoacidosis such as nausea, vomiting, or abdominal pain are present. Blood ketone testing methods that quantify β-hydroxybutyric acid, the predominant ketone body, are available and are the preferred way to diagnose and monitor ketoacidosis. Home tests for β-hydroxybutyric acid are available. The specific treatment of DKA may include rehydration, correction of electrolyte imbalances, and insulin administration.

▶ *Blood Pressure and Monitoring for Complications*

The ADA standards of medical care address many of the common comorbid conditions, as well as complications that result from the progression of DM. Table 43–6 presents goals for blood pressure measurements and monitoring parameters for complications associated with diabetes.[7]

## General Approach to Therapy

▶ *Type 1 Diabetes Mellitus*

Treatment of T1DM requires providing exogenous insulin to replace the endogenous loss of insulin from the nonfunctional pancreas. Ideally, insulin therapy mimics normal insulin physiology. The basal-bolus approach attempts to reproduce basal

| Table 43–6 |
| :-- |

**ADA Recommended Goals of Therapy[7]**

| Area | Goals |
| :-- | :-- |
| **Glycemia** | |
| $A_{1c}$ | < 7% (0.07; 53 mmol/mol Hgb) |
| | Evaluate every 3 months until in goal; then every 6 months |
| eAG | < 154 mg/dL (8.6 mmol/L) |
| Preprandial plasma glucose | 80–130 mg/dL (4.4–7.2 mmol/L) |
| Peak postprandial plasma glucose[a] | < 180 mg/dL (10.0 mmol/L) |
| **Blood Pressure** | < 140/90 mm Hg |
| | Evaluate at every visit |
| **Lipids** | Evaluate at diagnosis and/or age 40, then every 1-2 years thereafter |
| **Monitoring for Complications** | |
| Eyes | Dilated eye exam yearly |
| Feet | Feet should be examined at every visit |
| Urinary microalbumin | Yearly |

$A_{1c}$, hemoglobin $A_{1c}$; ADA, American Diabetes Association; eAG, estimated average glucose; Hgb, hemoglobin.

[a]Peak postprandial glucose measurements should be made 1 to 2 hours after the beginning of the meal.

insulin response using intermediate- or long-acting insulin, whereas short- or rapid-acting insulin replicates bolus release of insulin physiologically seen around a meal in nondiabetics. A number of different regimens have been used through the years to more closely follow natural insulin patterns. As a rule, basal insulin makes up approximately 50% of the total daily dose. The remaining half is provided with bolus doses around three daily meals.

Exact doses are individualized to the patient and the amount of food consumed. T1DM patients frequently are started on about 0.6 unit/kg/day, and then doses are titrated until glycemic goals are reached. Most people with T1DM use between 0.6 and 1 unit/kg/day.

Currently, the most advanced form of insulin delivery is the insulin pump, also referred to as continuous subcutaneous insulin infusion (CSII). See Figure 43–1. Using rapid-acting insulin only, these pumps are programmed to provide a slow release of small amounts of insulin as the basal portion of therapy, and larger boluses of insulin are injected by the patient to account for the consumption of food. Pramlintide, a synthetic analog of the naturally occurring hormone amylin, is another injectable blood glucose–lowering medication that can be used in people with T1DM or in people with T2DM using insulin for treatment.

### ▶ Type 2 Diabetes Mellitus

Treatment of patients with T2DM has changed dramatically over the past decade with the addition of a number of new drugs and recommendations to maintain tighter glycemic control.[16,18,19] However, lifestyle modifications including education, nutrition, and exercise are paramount to managing the disease successfully.

### ▶ Gestational Diabetes

An individualized meal plan consisting of three meals and three snacks per day is commonly recommended in GDM. Preventing ketosis, promoting adequate growth of the fetus, maintaining satisfactory blood glucose levels, and preventing nausea and other undesired GI side effects are desired goals in these patients. An abundance of glucose causes excessive insulin production by the fetus, which if left uncontrolled, can lead to the development of an abnormally large fetus. Infant hypoglycemia at delivery, hyperbilirubinemia, and complications associated with delivery of a large baby also may occur when blood glucose levels are not controlled adequately. Insulin should be used when blood glucose levels are not maintained adequately by diet and physical activity. Insulin detemir, insulin aspart, lispro, and regular insulin carry Category B safety ratings.

## Nonpharmacologic Therapy

### ▶ Medical Nutrition Therapy

MNT is considered an integral component of diabetes management and diabetes self-management education. People with DM

Dosage instructions are entered into the pump's small computer and the appropriate amount of insulin is then injected into the body in a calculated, controlled manner
**FIGURE 43–1.** Insulin pump and placement.

should receive individualized MNT, preferably by a registered dietitian. MNT should be provided as an ongoing dialog customized to take into account cultural, lifestyle, and financial considerations.

The primary focus of MNT for patients with T1DM is matching optimal insulin dosing to carbohydrate consumption. In T2DM, the primary focus is portion control and controlling blood glucose, blood pressure, and lipids through individualizing limits of carbohydrates, saturated fats, sodium, and calories. Carbohydrates are the primary contributor to postmeal glucose levels. The percentages of fat, protein, and carbohydrate included in each meal should be individualized based on the specific goals of each patient.[7]

### ▶ Dietary Supplements

There is insufficient evidence of efficacy for improved blood glucose control for any individual herb or supplement.[7] Herbs and supplements commonly touted to improve glucose control include chromium, magnesium, vitamin D, and cinnamon. Patients will inquire about and use dietary supplements. It is important that clinicians respect the patient's health beliefs, address their questions and concerns, and educate them on the differences between dietary supplements and prescribed therapies.

### ▶ Weight Management

Moderate weight loss in patients with T2DM has been shown to reduce cardiovascular risk, as well as delay or prevent the onset of DM in those with prediabetes.[7,20] The recommended primary approach to weight loss is therapeutic lifestyle change (TLC), which integrates a 7% reduction in body weight and an increase in physical activity.[7] A slow but progressive weight loss of 0.45 to 0.91 kg (1–2 lb) per week is preferred.[21] Although individual target caloric goals should be set, a general rule for weight loss diets is that they should supply at least 1000 to 1200 kcal/day (about 4200–5000 kJ/day) for women and 1200 to 1600 kcal/day (about 5000–6700 kJ/day) for men. Gastric reduction surgeries (gastric banding or procedures that bypass, transpose, or resect portions of the small intestine), when used as a part of a comprehensive approach to weight loss, are recommended for consideration in patients with T2DM and a BMI that exceeds 35 kg/m². [7] Two drug therapy options were recently approved, lorcaserin and phentermine/topiramate extended release, to aid weight loss in obese patients and in overweight patients with concomitant disease states such as T2DM, hypertension and dyslipidemia.[16]

### ▶ Physical Activity

Regular physical activity has been shown to improve blood glucose control and reduce cardiovascular risk factors such as hypertension and elevated serum lipid levels.[20] Physical activity is also a primary factor associated with long-term maintenance of weight loss and overall weight control. Regular physical activity also may prevent the onset of T2DM in high-risk persons.

Before initiating a physical activity program, patients should undergo a detailed physical examination, including screening for microvascular or macrovascular complications that may be worsened by a particular activity. Initiation of physical activities in an individual with a history of a sedentary lifestyle should begin with a modest increase in activity. Walking, swimming, and cycling are examples of low-impact exercises that could be encouraged. At the same time, gardening and usual housecleaning tasks are good exercises as well. Recommended physical activity goals for patients with T2DM include 150 minutes per week of moderate to vigorous aerobic exercise spread out during at least 3 days of the week with no more than two consecutive days between bouts of aerobic activity and moderate to vigorous resistance training at least 2 to 3 days per week.[7]

### ▶ Psychological Assessment and Care

Mental health and social state have been shown to have an impact on a patient's ability to carry out DM management care tasks.[7] Clinicians should incorporate psychological assessment and treatment into routine care. The ADA guidelines recommend ongoing psychological screening, including determining the patient's attitudes regarding DM; expectations of medical management and outcomes; mood and affect; general and diabetes-related quality of life; and financial, social, and emotional resources. Patients demonstrating poor self-management should be screened for diabetes-related distress, depression, anxiety, an eating disorder, and/or cognitive impairment.

### ▶ Immunizations

Influenza and pneumonia are common preventable infectious diseases that increase mortality and morbidity in persons with chronic diseases, including DM. Yearly influenza vaccinations, commonly called flu shots, are recommended for all patients with DM 6 months of age or older.[7] Pneumococcal vaccination with the polysaccharide vaccine 23 is also recommended for patients with DM who are 2 years of age or older as a one-time vaccination. Adults aged greater than or equal to 65 years of age who have not previously been vaccinated should receive the pneumococcal conjugate vaccine 13 followed by the polysaccharide vaccine 6 to 12 months later. Adults who have received the polysaccharide vaccine should receive the conjugate vaccine after greater than or equal to 12 months. The hepatitis B vaccine series should also be administered as per the CDC's recommendations in patients with diabetes.

## Pharmacotherapy

Figures 43–2 and 43–3 summarize treatment algorithms for T2DM.[16,18] While similar, these treatment algorithms differ in that, at this time, the ADA guidelines do not advocate for the use of several treatment options that the AACE guidelines include; namely, colesevelam, α-glucosidase inhibitors, and bromocriptine. Also, the AACE guidelines take a more aggressive approach, including consideration for starting a patient on two drugs if their presenting $A_{1c}$ is greater than or equal to 7.5% (0.075; 58 mmol/mol Hgb). While the ADA guidelines include metformin alone as the first-line therapy option for T2DM, the AACE guidelines include six other noninsulin initial therapy options as possibilities. As noted earlier, the AACE guidelines also advocate for lower $A_{1c}$ and SMBG goals. Because T2DM generally tends to be a progressive disease, blood glucose levels will eventually increase, making insulin therapy the eventual required therapy in many patients. Recently, the ADA added selective sodium-dependent glucose cotransporter-2 (SGLT-2) inhibitors as second and third line add-on options.[7] The addition of GLP-1 receptor agonists is now recognized by the ADA as an alternative to mealtime insulin in those requiring more complex injectable regimens. Figure 43–4 is one illustration of a way to start insulin therapy while keeping the patient on some oral medications.[19] This is usually done when several oral agents have been used with inadequate glucose-lowering results.

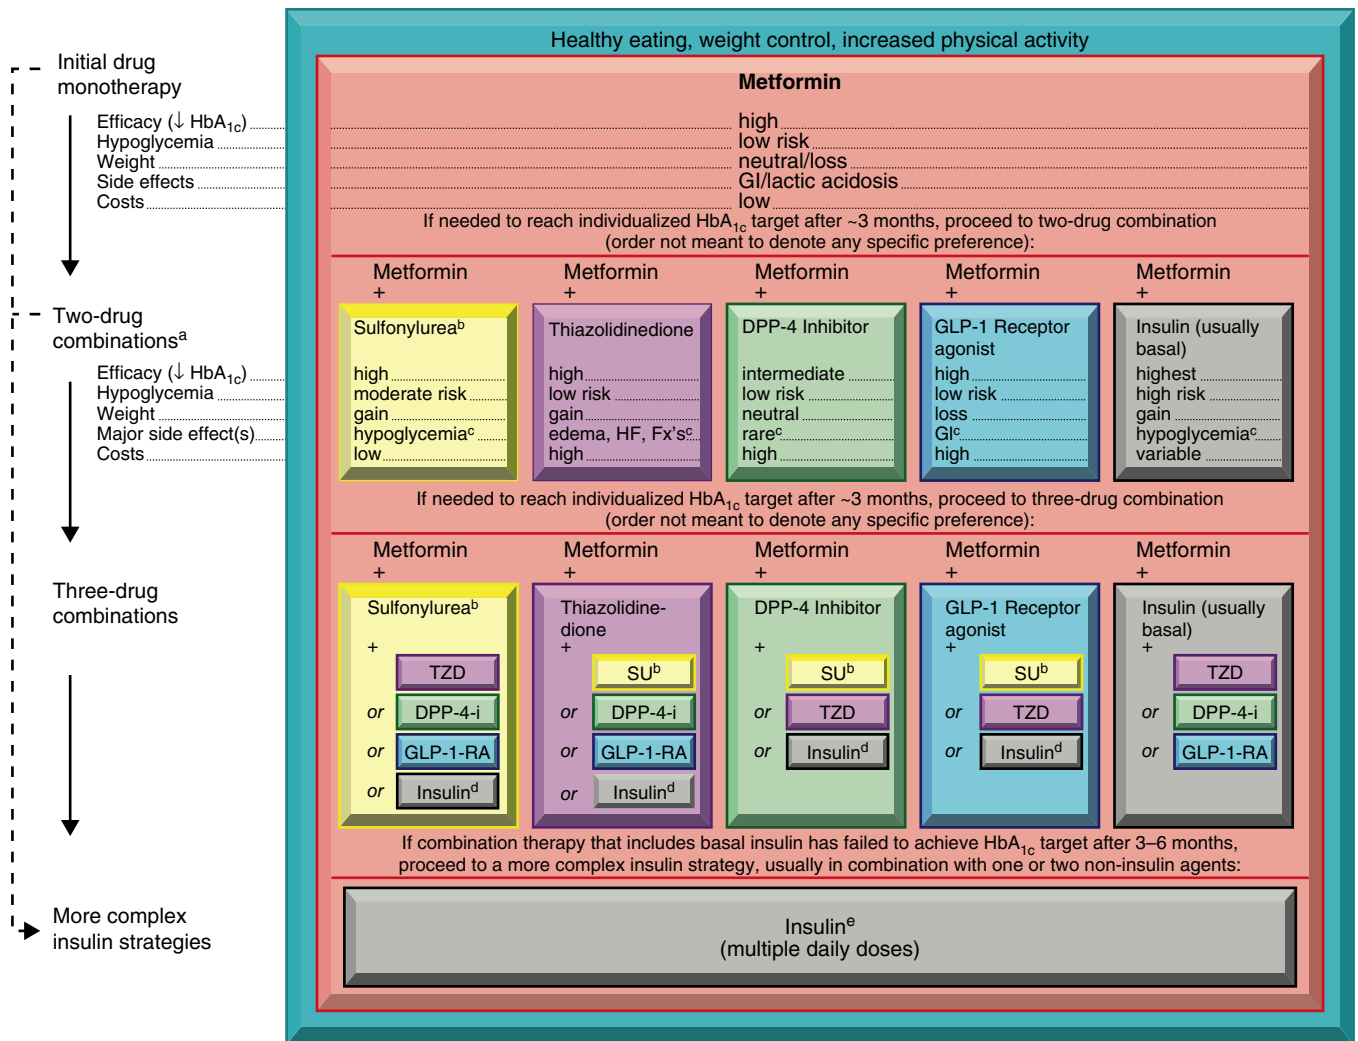
**KEY CONCEPT** *Oral and injectable agents are available to treat patients with T2DM who are unable to achieve glycemic control*


**FIGURE 43–2.** Patient centered approach to antihyperglycemic therapy in type 2 diabetes as per the American Diabetes Association/ European Association for the Study of Diabetes. Begin with lifestyle changes and add metformin monotherapy at, or soon after, diagnosis. If HbA$_{1c}$ target is not achieved after 3 months, consider one of five treatment options combined with metformin: a SU, TZD, DPP-4 i, GLP-1 RA, or basal insulin. Choice is based on patient and drug characteristics. [a]Consider beginning at this stage in patients with HbA$_{1c}$ greater than 9% (0.09; 75 mmol/mol Hgb). [b]Consider meglitinides in patients with irregular meal schedules or who develop postprandial hypoglycemia on sulfonylureas. [c]Consider additional potential adverse effects. [d]Usually a basal insulin in combination with noninsulin agents. [e]Some noninsulin agents may be continued with insulin. Consider beginning at this stage if patient presents with glucose greater than 300 mg/dL (16.7 mmol/L). (DPP-4, dipeptidyl peptidase-4; DPP-4 i, dipeptidyl peptidase-4 inhibitor; Fx, fractures; GI, gastrointestinal; GLP-1, glucagon-like peptide-1; GLP-1 RA, glucagon-like peptide-1 receptor agonist; HbA$_{1c}$, hemoglobin A$_{1c}$; HF, heart failure; SU, sulfonylurea; TZD, thiazolidinedione.) (From Inzucchi SE, Bergenstal RM, Buse JB, et al. Management of hyperglycemia in type 2 diabetes: A patient-centered approach. Diabetes Care. 2012;35:1364–1379, with permission.)

*through meal planning and physical activity.* Table 43–7[16,18,22] lists the oral agents and Table 43–8 lists each noninsulin drug class with site of action and mechanism of action. The various classes of blood glucose–lowering agents target different organs and have different mechanisms of action. Each of these agents may be used individually or in combination with other medications that target different organs for synergistic effects. In addition to single agent products, there are many combination products marketed as well.

▶ **Sulfonylureas**

Sulfonylureas enhance insulin secretion by blocking ATP-sensitive potassium channels in the cell membranes of pancreatic β cells. This action results in membrane depolarization, allowing an influx of calcium to cause the translocation of secretory granules of insulin to the cell surface, and enhances insulin secretion in a non–glucose-dependent manner. Insulin is then transported through the portal vein to the liver, suppressing hepatic glucose production. These drugs are classified as being either first- or second-generation agents. Both classes of sulfonylureas are equally effective when given at equipotent doses. Today, the vast majority of patients receiving a sulfonylurea are prescribed a second-generation agent.

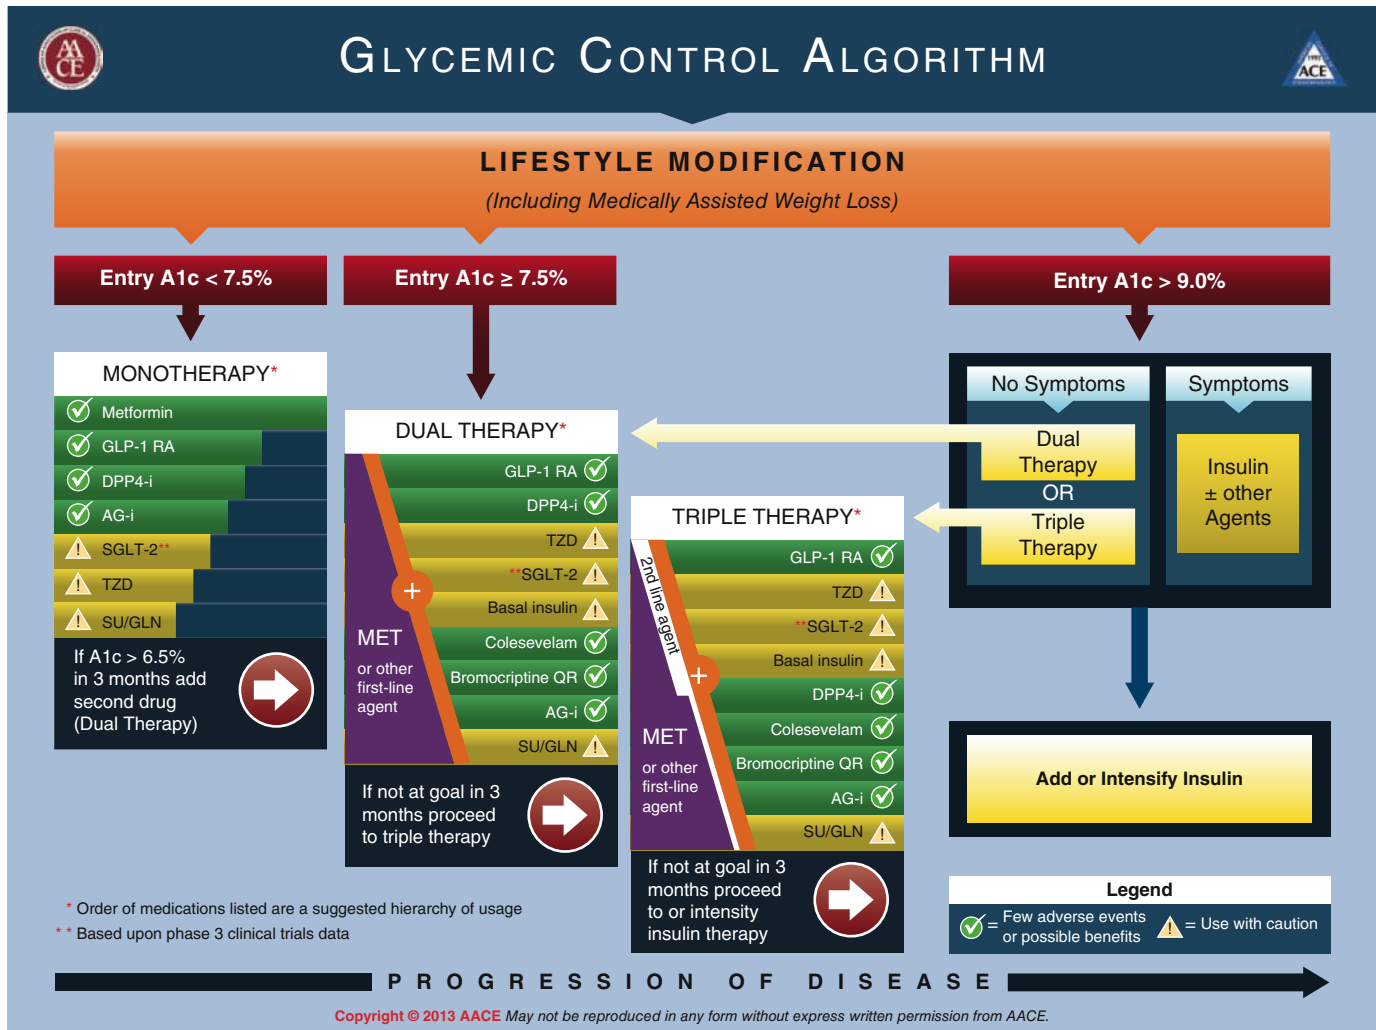
All sulfonylureas undergo hepatic biotransformation, with most agents being metabolized by the cytochrome P450 2C9 pathway. The first-generation sulfonylureas are more likely to cause drug interactions than second-generation agents. All sulfonylureas, except tolbutamide, require a dosage adjustment or are


**FIGURE 43–3.** Algorithm for the metabolic management of type 2 diabetes as per AACE. (AACE, American Association of Clinical Endocrinologists; A$_{1c}$, hemoglobin A$_{1c}$; AG-i, alpha glucosidase inhibitor; DPP4-i, dipeptidyl peptidase-4 inhibitor; GLN, meglitinides; GLP-1 RA, glucagon-like peptide-1 receptor agonist; MET, metformin; QR, quick release; SGLT-2, sodium-dependent glucose cotransporter-2; SU, sulfonylurea; TZD, thiazolidinedione.) (From Garber AJ, Abrahamson MJ, Barzilay JI, et al. American Association of Clinical Endocrinologists' comprehensive diabetes management algorithm 2013 consensus statement. Endocr Pract. 2013;19[Suppl 1]: 1–48, with permission.)

not recommended in renal impairment.[22] In elderly patients or those with compromised renal or hepatic function, lower starting dosages are necessary.

Sulfonylureas' blood glucose–lowering effects can be observed in both fasting and postprandial levels. Monotherapy with these agents generally produces a 1.5% to 2% (0.015–0.02 or 17–22 mmol/mol Hgb) decline in A$_{1c}$ concentrations and a 60 to 70 mg/dL (3.3–3.9 mmol/L) reduction in FBG levels.[8] Secondary failure with these drugs occurs as a result of continued pancreatic β-cell destruction. One limitation of sulfonylurea therapy is the inability of these products to stimulate insulin release from β cells at extremely high glucose levels, a phenomenon called glucose toxicity. Common adverse effects include hypoglycemia and weight gain. There may be some cross-sensitivity in patients with sulfa allergy.

▶ **Nonsulfonylurea Secretagogues (Glinides)**

Although producing the same effect as sulfonylureas, nonsulfonylurea secretagogues, also referred to as meglitinides, have a much shorter onset and duration of action. Meglitinides produce a pharmacologic effect by interacting with ATP-sensitive potassium channels on the β cells; however, this binding is to a receptor adjacent to those to which sulfonylureas bind.

The primary benefit of nonsulfonylurea secretagogues is in reducing postmeal glucose levels. These agents have demonstrated a reduction in A$_{1c}$ levels between 0.8% and 1% (0.008 and 0.01; 9–11 mmol/mol Hgb).[8] Because they have a rapid onset and short duration of action, they are to be taken 15 to 30 minutes before a meal.

▶ **Biguanides**

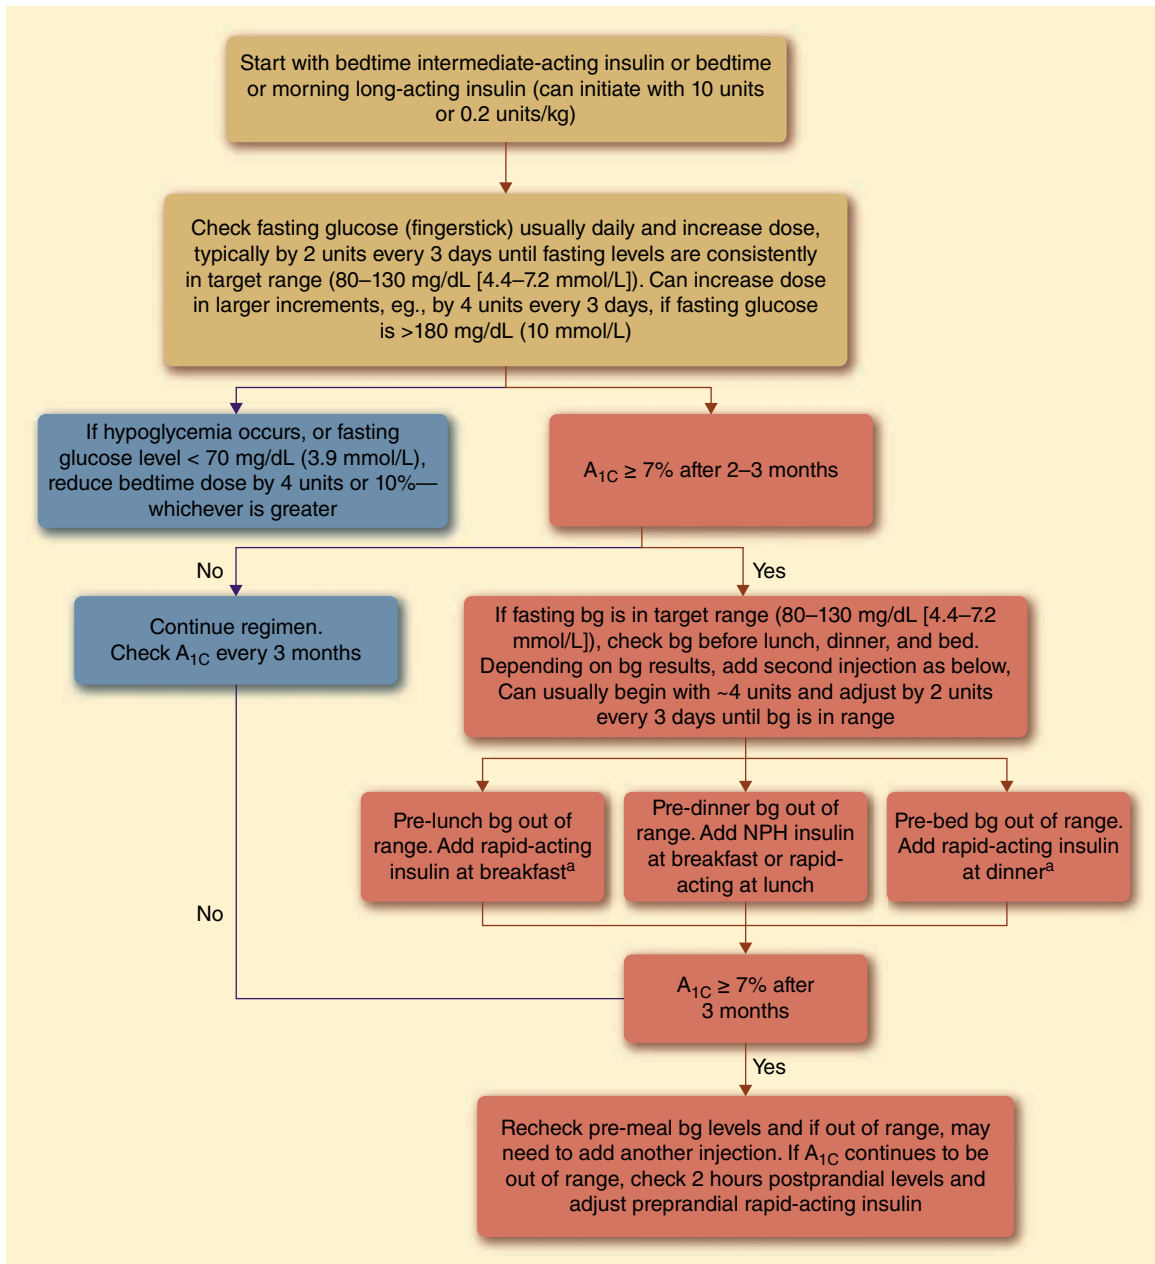
The only biguanide approved by the Food and Drug Administration (FDA) and currently available in the United States is metformin. This agent is thought to lower blood glucose by decreasing hepatic glucose production and increasing insulin sensitivity in both hepatic and peripheral muscle tissues; however, the exact mechanism of action remains unknown. It has been shown to reduce A$_{1c}$ levels by 1.5% to 2% (0.015–0.02; 17–22 mmol/mol


**FIGURE 43–4.** Initiation and adjustment of insulin regimens. Insulin regimens should be designed taking lifestyle and meal schedule into account. The algorithm can only provide basic guidelines for initiation and adjustment of insulin. [a]Premixed insulins not recommended during adjustment of doses; however, they can be used conveniently, usually before breakfast and/or dinner, if proportion of rapid- and intermediate-acting insulins is similar to the fixed proportions available. $A_{1c}$ of 7% is equivalent to 0.07 or 53 mmol/mol Hgb. ($A_{1c}$, hemoglobin $A_{1c}$; bg, blood glucose; NPH, neutral protamine Hagedorn.) (From Nathan DM, Buse JB, Davidson MB, et al. Medical management of hyperglycemia in type 2 diabetes: A consensus algorithm for the initiation and adjustment of therapy: A consensus statement from the American Diabetes Association and the European Association for the Study of Diabetes. Diabetes Care. 2009;32:193–203, with permission.)

Hgb) and FPG levels by 60 to 80 mg/dL (3.3–4.4 mmol/L) when used as monotherapy.[8] Unlike the sulfonylureas, metformin retains the ability to reduce fasting glucose levels when they are over 300 mg/dL (16.7 mmol/L). Metformin does not affect insulin release from β cells of the pancreas, so hypoglycemia is not a common side effect.[22]

Metformin significantly reduced all-cause mortality and the risk of stroke in overweight patients with T2DM compared with

intensive therapy with sulfonylurea or insulin in the UKPDS.[23] It also reduced diabetes-related death and myocardial infarction compared with a conventional therapy arm. Given that metformin is the only oral antihyperglycemic medication proven to reduce mortality and is available generically, metformin is considered foundational therapy along with lifestyle modification for T2DM and is often used in combination with other antihyperglycemics for synergistic effects.[7]

Table 43–7

**Oral Agents for the Treatment of T2DM[16,18,22]**

| Drug Class | Trade | Drugs Generic/ Commercially Available | Target Area | Blood Glucose Affected | Dosing Strategy (All Agents Are Taken Orally) | Adjustment for Renal Impairment CrCl 30–50 mL/ min (0.50–0.83 mL/s) | Adjustment for Renal Impairment CrCl < 30 mL/ min (0.50 mL/s) | Adjustment for Hepatic Impairment | Common Adverse Drug Reactions |
|---|---|---|---|---|---|---|---|---|---|
| α-Glucosidase Inhibitors | Precose | Acarbose/Y | Brush border of small intestine | Postprandial | 25 mg three times daily with first bite of each main meal<br><br>Advance at 4–8 week intervals to a maximum of 100 mg three times daily | SCr > 2 mg/ dL (177 μmol/L): Not recommended | SCr > 2 mg/dL (177 μmol/L): Not recommended | No specific dose adjustment recommended | GI (flatulence, diarrhea) |

| Kidney | SGLT-2 inhibitors | Inhibits glucose reabsorption in the kidney's proximal tubule |

GLP-1, glucagon-like peptide-1; SGLT-2, sodium-dependent glucose cotransporter-2.

Per US labeling, metformin is contraindicated in patients with abnormal creatinine clearance for any cause and in patients with a serum creatinine level greater than or equal to 1.4 mg/dL (124 μmol/L) in women and 1.5 mg/dL (133 μmol/L) in men.[22] It should not be initiated in patients 80 years of age or older unless normal renal function has been established. Additionally, therapy with metformin should be withheld in patients undergoing surgery or radiographic procedures in which a nephrotoxic dye is used. Therapy should be withheld the day of the radiographic procedure, and renal function should be assessed 48 hours after the procedure. If renal function is normal, therapy may be resumed.

Primary side effects associated with metformin therapy are GI in nature, including decreased appetite, nausea, and diarrhea. These side effects can be minimized through slow titration of the dose and often subside within 2 weeks.[19] Interference with vitamin $B_{12}$ absorption has also been reported.[8] Metformin is thought to inhibit mitochondrial oxidation of lactic acid, thereby increasing the chance of lactic acidosis, a condition which rarely occurs. Patients at greatest risk for developing lactic acidosis include those with renal impairment and those who are of advanced age.[22] Metformin should be withheld promptly in cases of hypoxemia, sepsis, or dehydration. Patients should avoid consumption of excessive amounts of alcohol while taking metformin, and use of the drug should be avoided in patients with liver disease.

▶ *Thiazolidinediones*

Thiazolidinediones (TZDs) are known to increase insulin sensitivity by stimulating peroxisome proliferator-activated receptor gamma (PPAR-γ) which increases insulin sensitivity and decreases plasma fatty acids. As monotherapy, TZDs reduce FPG levels by around 60 to 70 mg/dL (3.3–3.9 mmol/L), and the effect on $A_{1c}$ is an up to 1.5% (0.015; 17 mmol/mol Hgb) reduction.[8] The onset of action for TZDs is delayed for several weeks and may require up to 12 weeks before maximum effects are observed.

Both pioglitazone and rosiglitazone minimally increase HDL cholesterol, 2.4 to 5.2 mg/dL (0.06–0.13 mmol/L) on average.[24] Pioglitazone has been shown to decrease serum triglycerides (TG) 51.9 mg/dL (0.59 mmol/L) on average, but an increase in TG has been observed with rosiglitazone. Low-density lipoprotein (LDL) cholesterol concentrations increase by 12.3 mg/dL (0.32 mmol/L) and 21.3 mg/dL (0.55 mmol/L) on average with pioglitazone and rosiglitazone, respectively.

The TZDs may produce fluid retention and edema. Thus, these drugs are contraindicated in situations in which an increased fluid volume is detrimental such as heart failure. Fluid retention appears to be dose related and increases when combined with insulin therapy.

A few cases of hepatotoxicity have been reported with rosiglitazone and pioglitazone. Patients with a baseline elevated alanine aminotransferase (ALT) level should be started on TZD therapy with caution. Therapy should be stopped if ALT levels exceed three times the upper limit of normal while on therapy and remain there, especially if the patient's total bilirubin is also elevated.[8]

Increased rates of upper and lower limb fractures are known to occur with TZD therapy. Premenopausal anovulatory women may begin to ovulate on TZD therapy, and therefore counseling regarding this should be provided to all women capable of becoming pregnant. A slight increased risk for bladder cancer has been noted with pioglitazone therapy, especially among men and smokers.

A 2007 meta-analysis conducted by Nissen and colleagues reported a significantly greater risk of myocardial infarction with rosiglitazone compared with other oral agents.[25] A subsequent prospective study found rosiglitazone use to be associated with a nonsignificant increase in myocardial infarction risk and a nonsignificant reduction in stroke, but a trend toward increased cardiovascular risk in those patients with a history of ischemic heart disease.[26] In May 2011, the FDA chose to restrict access and distribution of rosiglitazone to the Avandia-Rosiglitazone Medicines Access Program.[22] Following receipt of subsequent data that showed the risk of heart attack with rosiglitazone was not increased as compared with metformin and sulfonylureas, the FDA lifted their restrictions on the drug in November 2013.

▶ *α-Glucosidase Inhibitors*

Acarbose and miglitol are α-glucosidase inhibitors which compete with the enzymes of the small intestines that break down complex carbohydrates. These drugs delay absorption of carbohydrates and reduce postprandial blood glucose concentrations as much as 40 to 50 mg/dL (2.2 to 2.8 mmol/L); however, $A_{1c}$ reductions range only from 0.3% to 1% (0.003–0.01; 3–11 mmol/mol Hgb).[8] High incidences of GI side effects, including flatulence (42%–74%), abdominal discomfort (12%–19%), and diarrhea (29%–31%), have limited their use.[22] Low initial doses followed by gradual titration may minimize GI side effects.

The α-glucosidase inhibitors are contraindicated in patients with chronic intestinal diseases including inflammatory bowel disease. In addition, neither drug in this class is recommended for patients with a serum creatinine greater than 2 mg/dL (177 μmol/L).[8]

#### ▶ Dipeptidyl Peptidase-4 Inhibitors (Gliptins)

The dipeptidyl peptidase-4 (DPP-4) inhibitors (sitagliptin, saxagliptin, linagliptin, and alogliptin) are approved as adjunct to diet and exercise to improve glycemic control in adults with T2DM. They lower blood glucose concentrations by inhibiting DPP-4, the enzyme that degrades endogenous GLP-1, thereby increasing the amount of endogenous GLP-1. The blood glucose–lowering effect of the gliptins is primarily on postprandial levels. Typical $A_{1c}$ reductions are 0.7% to 1% (0.007–0.01; 8–11 mmol/mol Hgb).[8] Common adverse effects include headache and nasopharyngitis. Hypoglycemia is not a common adverse effect with these agents because insulin secretion results from GLP-1 activation caused by meal-related glucose detection and not from direct pancreatic β-cell stimulation. Acute pancreatitis, including hemorrhagic and necrotizing pancreatitis, has been reported in patients taking glipitins.[22]

#### ▶ Selective Sodium-Dependent Glucose Cotransporter-2 (SGLT-2) Inhibitors

Canagliflozin, dapagliflozin, and empagliflozin, SGLT-2 inhibitors, are approved as adjunct to diet and exercise to improve glycemic control in adults with T2DM. The SGLT-2 receptor is responsible for 90% of the active glucose reabsorption of the kidney's proximal tubule.[8] By inhibiting this receptor, glucose reabsorption is decreased. Glucose passes into the urine, serum glucose is lowered and modest weight loss is promoted. Typical $A_{1c}$ reductions are 0.7% to 1.3% (0.007–0.013; 8–14.3 mmol/mol Hgb).[22] Possible adverse reactions include urinary tract infections, genital mycotic infections, increased urination, hypotension, and increased serum creatinine.

#### ▶ Central-Acting Dopamine Agonist

A quick release formulation of the central-acting dopamine agonist, bromocriptine, is approved for the treatment of T2DM. The mechanism of action for how bromocriptine regulates glycemic control is unknown, but data indicate that bromocriptine administered in the morning improves insulin sensitivity, and this is likely a result of its affect on dopamine oscillations.[8] When used to treat patients with T2DM, bromocriptine should be taken 2 hours after waking in the morning with food.[22] A modest $A_{1c}$ reduction of 0.3% to 0.6% (0.003–0.006; 3–7 mmol/mol Hgb) can be expected from this drug.[8] Main side effects include rhinitis, dizziness, asthenia, headache, sinusitis, constipation, and nausea. Contraindications include syncopal migraine and women who are nursing.[22]

#### ▶ Bile Acid Sequestrants

Colesevelam is the only bile acid sequestrant currently approved as an adjunctive therapy to improve glycemic control in conjunction with diet, exercise, and insulin or oral agents for the treatment of T2DM. It acts on the intestinal lumen to bind bile acid, but the drug's exact mechanism that results in plasma glucose lowering is unknown. An $A_{1c}$ reduction of approximately 0.4% (0.004; 5 mmol/mol Hgb) and a FPG reduction of about 5 to 10 mg/dL (0.3–0.6 mmol/L) can be expected when colesevelam is added.[8] Common adverse effects include constipation

and dyspepsia. Drug–drug interactions are possible because of absorption and can be particularly important in patients who are taking levothyroxine, glyburide, oral contraceptives, phenytoin, warfarin, and digoxin. These medications should not be taken together, and they should be separated by at least 4 hours before dosing colesevelam. Malabsorption of fat-soluble vitamins (A, D, E, and K) is also a concern.

#### ▶ Insulin

Insulin is the one agent that can be used in all types of DM and has no specific maximum dose, meaning it can be titrated to suit each individual patient's needs. **KEY CONCEPT** *Insulin is the primary treatment to lower blood glucose levels for patients with T1DM, and injected amylin can be added to decrease fluctuations in blood glucose levels.* An insulin treatment algorithm for T2DM is found in Figure 43–2.[19]

Insulin can be divided into two main classes, basal and bolus, based on their length of action to mimic endogenous insulin physiology. Most formulations are available as U-100, indicating a concentration of 100 unit/mL. Insulin is typically refrigerated, though most vials are good for 28 days at room temperature.[22] Specific details of insulin products are listed in Table 43–9.[22,27]

The most common route of administration for insulin is subcutaneous injection using a syringe or pen device. Patients should be educated to rotate their injection sites to minimize lipohypertrophy, a buildup of fat that decreases or prevents proper insulin absorption. Additionally, patients should understand that the absorption rate may vary among injection sites (abdomen, thigh, arm, and buttocks) because of differences in blood flow, with absorption occurring fastest in the abdomen and slowest in the buttocks.

Insulin syringes are distinguished according to the syringe capacity, syringe markings, and needle gauge and length. Insulin pens are self-contained systems of insulin delivery. The primary advantage of the pen system is the patient does not have to draw up the dose from the insulin vial. Both insulin syringes and pens are now available with shorter needles (4–6 mm, compared to traditional lengths of 8–12.7 mm) which do not require the patient to pinch up their skin before injecting. With the no pinch technique, the needle is injected straight in at a 90-degree angle until flush with the skin. However, these products require a 10 second count to allow enough time for the insulin to be injected. This technique makes injections easier, especially the traditionally more difficult sites such as arms and buttocks.

#### Bolus Insulins

*Regular Insulin.* Regular insulin is unmodified crystalline insulin commonly referred to as natural or human insulin. It is a clear solution that has a relatively short onset and duration of action and is designed to cover insulin response to meals. On subcutaneous injection, regular insulin forms small aggregates called hexamers that undergo conversion to dimers followed by monomers before systemic absorption can occur. Patients should be counseled to inject regular insulin subcutaneously 30 minutes before consuming a meal. Regular insulin is the only insulin that can be administered intravenously (IV).

*Rapid-Acting Insulin.* Three rapid-acting injectable insulins have been approved in the United States: aspart, glulisine, and lispro. Substitution of one or two amino acids in regular insulin results in the unique pharmacokinetic properties characteristic of these agents. The onset of action of injectable rapid-acting insulins varies from 15 to 30 minutes, with peak effects occurring one to two hours after administration and is dosed before

**Table 43–9**

**Insulin Agents for the Treatment of T1DM and T2DM[22,27,28]**

| Generic Name (Insulin) | Brand/Rx Status | Manufacturer | Strength | Onset (minutes) | Peak (hours) | Duration (hours) | Administration Options |
|---|---|---|---|---|---|---|---|
| **Rapid-Acting Insulin** | | | | | | | |
| Lispro | Humalog/Rx | Eli Lilly | U-100 | 15–30 | 0.5–2.5 | 3–4 | SC; 10-mL vial, 3-mL cartridge, and disposable pen |
| Aspart | Novolog/Rx | Novo-Nordisk | U-100 | 15–30 | 1–3 | 3–5 | SC; 10-mL vial, 3-mL cartridge, and disposable pen |
| Glulisine | Apidra/Rx | Aventis | U-100 | 15–30 | 1–2 | 3–4 | SC; 10-mL vial, 3-mL cartridge, and disposable pen |
| Recombinant human insulin regular | Afrezza/Rx | MannKind | Not applicable | 12–15 | 1 | 2.5–3 | Inh; Technosphere insulin particles for oral inhalation |
| **Short-Acting Insulin** | | | | | | | |
| Regular | Humulin R/OTC | Eli Lilly | U-100, U-500 | 30–60 | 2–3 | 3–6 | IV, SC; U-100 10-mL vial; U-500 20-mL vial |
| | Novolin R/OTC | Novo-Nordisk | U-100 | | | | IV, SC; 10-mL vial, 3-mL cartridge, 3-mL *Innolet* |

| Glargine | Lantus/Rx | Sanofi-Aventis | U-100 | 4–5 hours | Flat | 22–24 | SC; 10-mL vial, 3-mL cartridge for *Opticlik* (available in SoloSTAR disposable pen) |
| | Toujeo/Rx | | U-300 | | | | SC;1.5-mL SoloSTAR disposable pen |
| Detemir | Levemir/Rx | Novo-Nordisk | U-100 | 3–4 hours | Flat | Up to 24 | SC; 10-mL vial, 3-mL cartridge, 3-mL *Innolet*, 3-mL disposable *FlexPen* |
| **Combination Insulin Products** | | | | | | | |
| Neutral protamine Hagedorn and regular | Humulin 70/30/OTC | Eli Lilly | U-100 | 30–60 | 1.5–16 | 10–16 | SC: 10-mL vial, 3-mL disposable pen |
| | Novolin 70/30/OTC | Novo-Nordisk | U-100 | 30–60 | 2–12 | 10–16 | SC; 10-mL vial, 3-mL cartridge, 3-mL *Innolet* |
| | Humulin 50/50/OTC | Eli Lilly | U-100 | 30–60 | 2–5.5 | 10–16 | SC; 10-mL vial |
| Neutral protamine lispro and lispro | Humalog Mix 75/25/Rx | Eli Lilly | U-100 | 15–30 | 1–6.5 | 15–18 | SC; 10-mL vial, 3-mL disposable pen |
| Neutral protamine aspart and aspart | Novolog Mix 70/30/Rx | Novo-Nordisk | U-100 | 15–30 | 1–4 | Up to 24 | SC; 10-mL vial, 3-mL cartridge, 3-mL disposable *FlexPen* |

Inh, inhalation; IV, intravenous; OTC, over-the-counter; Rx, prescription required; SC, subcutaneous; T1DM, type 1 diabetes mellitus; T2DM, type 2 diabetes mellitus.

or with meals. An inhaled rapid-acting insulin was also recently approved. Its peak effect is expected to occur around 15 to 20 minutes following a dose with a duration of action of only two to three hours.[28]

**Basal Insulins**

*Intermediate-Duration Insulin.* Neutral Protamine Hagedorn, better known as NPH insulin, is prepared by a process in which protamine is conjugated with regular insulin, rendering a product with a delayed onset but extended duration of action, and is designed to cover insulin requirements in between meals and/or overnight. With the advent of the long-acting insulins, NPH insulin use has declined because of (a) an inability to predict accurately when peak effects occur and (b) a duration of action of less than 24 hours. Additionally, protamine is a foreign protein that may increase the possibility of an allergic reaction.

NPH insulin can be mixed with regular insulin and used immediately or stored for future use. NPH insulin can be mixed with either aspart or lispro insulins, but it must be injected immediately after mixing. Whenever mixing insulin products

with NPH insulin, the shorter acting insulin should be drawn into the syringe first.

*Long-Duration Insulin.* Glargine and detemir are designed as once-daily-dosing basal insulins which provide a relatively constant insulin concentration over 24 hours.[22,27] Insulin glargine differs from regular insulin by three amino acids, resulting in a low solubility at physiologic pH. The clear solution is supplied at a pH of 4, which precipitates on subcutaneous administration. Detemir binds to albumin in the plasma, which gives it sustained action. Neither glargine nor detemir can be administered IV or mixed with other insulin products. Although detemir is recommended for dosing in the evening if being used as a once-daily dose, it stands to reason that both glargine and detemir could be administered irrespective of meals or time of day. Another long-duration insulin, insulin degludec, developed to offer an even more consistent insulin concentration throughout the day, is currently under FDA review.

*Combination Insulin Products.* A number of combination insulin products are available commercially. NPH is available in combinations of 70/30 (70% NPH and 30% regular insulin) and 50/50 (50% NPH and 50% regular insulin). Two short-acting insulin analog mixtures are also available. Humalog mix 75/25 contains 75% insulin lispro protamine suspension and 25% insulin lispro. Novolog mix 70/30 contains 70% insulin aspart protamine suspension and 30% insulin aspart. The lispro and aspart insulin protamine suspensions were developed specifically for these mixture products and are not commercially available separately.

### ▶ Insulin Pump Therapy

Insulin pump therapy consists of a programmable infusion device that allows for basal infusion of insulin 24 hours daily (see Figure 43–1), as well as bolus administration before meals and snacks. Regular or rapid-acting insulin is delivered from a reservoir either by infusion set tubing or through a small canula. Most pump infusion sets are inserted in the abdomen, arm, or other infusion site by a small needle. Most patients prefer insertion in abdominal tissue because this site provides optimal insulin absorption. Infusion sets should be changed every 2 to 3 days to reduce the possibility of infection.

Patients use a carbohydrate-to-insulin ratio to determine how many units of insulin are required. More specifically, an individual's ratio is calculated to determine how many units of the specific insulin being used in the pump "covers" for a certain amount of carbohydrates to be ingested at a particular meal. The 450 rule (for regular insulin) or the 500 rule (for rapid-acting insulin) is commonly used. To calculate the ratio using the 500 rule, the patient would divide 500 by his or her total daily dose of insulin. Once this ratio is determined, patients can eat more or fewer carbohydrates at a given meal and adjust the bolus dose accordingly.

In addition to mealtime boluses, correction doses based on premeal glucose readings are also used. The amount of additional insulin for the correction is based on either the 1500 rule for regular insulin or the 1800 rule for rapid-acting insulin. If using rapid-acting insulin, divide 1800 by the patient's total daily insulin dose. The resulting value will represent the reduction in glucose (mg/dL) produced by one unit of insulin. The correction dose would be given in addition to the bolus dose needed based on the patient's carbohydrate-to-insulin ratio and the amount of carbohydrates present in the meal he or she is about to consume.

Insulin pump therapy may be used to lower blood glucose levels in any type of DM; however, patients with T1DM are the most likely candidates to use these devices. Use of an insulin pump may improve blood glucose control, reduce wide fluctuations in blood glucose levels, and allow individuals to have more flexibility in timing and content of meals and exercise schedules.

### ▶ Noninsulin Injectable Agents

**Glucagon-Like Peptide 1 Agonists** Exenatide, liraglutide, albiglutide, and dulaglutide are indicated for the treatment of T2DM to improve glycemic control. These agents are part of the group of drugs known as incretins (**Table 43–10**).[8,22,29]

GLP-1 agonists lower blood glucose levels by: (a) producing glucose-dependent insulin secretion; (b) reducing postmeal glucagon secretion, which decreases postmeal glucose output; (c) increasing satiety which decreases food intake; and (d) regulating gastric emptying, which allows nutrients to be absorbed into the circulation more smoothly. Typical $A_{1c}$ reductions vary between GLP-1 agonists. Exenatide immediate release lowers $A_{1c}$ around 0.9% (0.009; 10 mmol/mol Hgb), exenatide extended-release lowers $A_{1c}$ around 1.6% (0.016; 18 mmol/mol Hgb), liraglutide reduces $A_{1c}$ around 1.1% (0.011; 12 mmol/mol Hgb), and albiglutide reduces $A_{1c}$ around 0.78% (0.0078; 8.8 mmol/mol Hgb).[8,30] GLP-1 agonists typically produce moderate weight loss of around 1 to 3 kg (2.2–6.6 lbs) depending on the drug chosen.[8] Exenatide is eliminated renally and is not recommended in patients with a creatinine clearance of less than 30 mL/min (0.50 mL/s).[22] No specific dose adjustments are recommended for liraglutide or albiglutide in renal impairment. An increased risk of hypoglycemia occurs when GLP-1 agonists are used in combination with a sulfonylurea or insulin.[8] The main side effects of GLP-1 agonist therapy include nausea, vomiting, and diarrhea. These GI adverse effects tend to lessen over time. GLP-1 agonists have been associated with cases of acute pancreatitis. Any patient presenting with symptoms of acute pancreatitis, including abdominal pain, nausea, and vomiting, should have GLP-1 agonist therapy discontinued until pancreatitis can be ruled out. Albiglutide, liraglutide, exenatide extended-release, and dulaglutide packagings contain a black-box warning about thyroid C-cell tumors.[22] They are contraindicated in patients with a personal or family history of medullary thyroid cancer and in those with a history of multiple endocrine tumors.

**Amylin** Pramlintide acetate is a synthetic analog of human amylin, which is a naturally occurring neuroendocrine peptide that is cosecreted with insulin by the β cells of the pancreas in response to food. Amylin secretion is very low or completely deficient in patients with T1DM and lower than normal in patients with T2DM who require insulin. Pramlintide slows gastric emptying without altering absorption of nutrients, suppresses glucagon secretion, and leads to a reduction in food intake by increasing satiety. By slowing gastric emptying, the normal initial postmeal spike in blood glucose is reduced.

Pramlintide is given by subcutaneous injection before meals to lower postprandial blood glucose elevations in patients with types 1 or 2 DM. Pramlintide generally results in an additional $A_{1c}$ reduction of 0.4% to 0.5% (0.004–0.005; 5–6 mmol/mol Hgb) and an average weight loss of 1 to 2 kg (2.2–4.4 lb).[8] Hypoglycemia, nausea, and vomiting are the most common side effects encountered with pramlintide therapy, although pramlintide itself does not produce hypoglycemia. To decrease the risk of hypoglycemia, doses of short-acting, rapid-acting, or premixed insulins should be reduced by 30% to 50% before pramlintide is initiated. Primarily, the kidneys metabolize pramlintide, but dosage adjustments in liver or kidney impairment are not required.

Table 43–10

**Noninsulin Injectable Agents for the Treatment of Diabetes[8,22,29]**

| Generic Name (Brand) | Type of Diabetes | Dosage Strengths[a] | Starting Dosage | Doses/Day | Titration Interval | Maximum Dose | Time to Effect (minutes) | Comments and Cautions |
|---|---|---|---|---|---|---|---|---|
| Pramlintide[b] (Symlin) | T1DM | 15, 30, 45, 60 mcg | 15 mcg | 3 | 3–7 days | 60 mcg | 20 | Take just before major meals; reduce insulin by 50%<br>Maintenance dose 30–60 mcg |
| | T2DM | 60, 120 mcg | 60 mcg | 3 | 3–7 days | 120 mcg | 20 | Side effects: Hypoglycemia, nausea, vomiting<br>Available in SymlinPen 60 and 120 |
| Exenatide[b] (Byetta, Bydureon) | T2DM | Immediate-release: 5 mcg, 10 mcg; extended-release: 2 mg | Immediate-release: 5 mcg, extended-release: 2 mg | Immediate-release: 2, extended-release: N/A; once-weekly | Immediate-release: 1 month, extended-release: N/A | Immediate-release: 10 mcg, extended-release: 2 mg | Immediate-release: 15–30 | Inject immediate-release formulation 15–20 minutes before two meals of the day with 6 hours separating the meals; prefilled disposable pen; may delay absorption of oral drugs; separate doses by 1 hour<br>Extended-release formulation can be administered regardless of meals<br>Side effects: Nausea, vomiting, diarrhea, increased hypoglycemia with sulfonylureas |
| Liraglutide[b] (Victoza) | T2DM | 6 mg/3 mL pen | 0.6 mg | 1 | 1 week | 1.8 mg | Not applicable | Can be dosed at any time of day regardless of meals; may delay absorption of oral drugs; separate doses by 1 hour<br>Side effects: Nausea, vomiting, increased hypoglycemia with sulfonylureas |
| Albiglutide[b] (Tanzeum) | T2DM | 30 mg single-dose pen; 50-mg single-dose pen | 30 mg | N/A; once weekly | 6 weeks | 50 mg | Not applicable | If missed dose occurs within 3 days of the regularly scheduled dose, dose should be administered at that time. If missed dose occurs more than 3 days past scheduled dose, wait until next regularly scheduled dose to administer next dose<br>Side effects: upper respiratory infection, diarrhea, nausea, injection site reaction |
| Dulaglutide[b] (Trulicity) | T2DM | 0.75 mg single-dose pen and prefilled syringe; 1.5-mg single-dose pen and prefilled syringe | 0.75 mg | N/A; once weekly | Not specified | 1.5 mg | Not applicable | If missed dose occurs within 3 days of the regularly scheduled dose, dose should be administered at that time. If missed dose occurs more than 3 days past scheduled dose, wait until next regularly scheduled dose to administer next dose<br>Side effects: nausea, diarrhea, vomiting, abdominal pain, decreased appetite, dyspepsia, fatigue. |

[a]Pramlintide supplied as 0.6 mg/mL in 5-mL vials. Exenatide immediate-release supplied as 250 mcg/mL, 1.2 mL for the 5-mcg prefilled pen, and 2.4 mL for the 10-mcg per dose prefilled pen. Exenatide extended-release supplied as 2 mg sterile powder plus 0.65 mL diluent in single use trays. Liraglutide supplied in 6 mg/3 mL prefilled pen, which can be dialed to the desired dose of 0.6, 1.2, or 1.8 mg. Albiglutide supplied in a 30-mg and a 50-mg single-dose pen. Dulaglutide supplied in a 0.75-mg and 1.5-mg single-dose pen and prefilled syringe.

[b]Generic not available in United States.

T1DM, type 1 diabetes mellitus; T2DM, type 2 diabetes mellitus

Pramlintide has the potential to delay the absorption of orally administered medications. When rapid absorption is needed for the efficacy of an agent, pramlintide should be administered 1 hour after or 3 hours before the drug. Pramlintide should not be used in patients receiving medications that alter GI motility. A disposable pen formulation is now on the market and available as SymlinPen 60 for patients with T1DM and SymlinPen 120 for people with T2DM.

## Treatment of Concomitant Conditions

### ▶ Cardiovascular Health

Cardiovascular disease is the major cause of morbidity and mortality for patients with DM. Interventions targeting smoking cessation, blood pressure control, lipid management, antiplatelet therapy, and lifestyle changes (including diet and exercise) can reduce the risk of cardiovascular events and should be considered as important as glycemic control in the management of a patient with DM. All patients with a history of cardiovascular disease should be prescribed aspirin 75 to 162 mg/day as a secondary prevention strategy.[7] For those with aspirin allergy, another antiplatelet option such as clopidogrel 75 mg/day should be used. The ADA currently recommends that antiplatelet therapy should also be considered for patients with DM and no history of heart disease if that patient's risk of cardiovascular event is calculated to be greater than 10% over 10 years. This includes most men older than 50 years of age and most women older than 60 years of age who have at least one additional cardiovascular risk factor.

The results of a number of trials, including the Action to Control Cardiovascular Risk in Diabetes (ACCORD),[31] Action in Diabetes and Vascular Disease (ADVANCE),[32] and Veterans Affairs Diabetes Trial (VADT,)[33] taken together with long-term follow-up information from the UKPDS[34] and DCCT [35,36] trials, have been used to formulate conclusions regarding the effect of glucose lowering on cardiovascular health. Those conclusions are: (1) short-term (3–5 years) intensive glycemic control does not improve the risk of macrovascular complications in patients with long-standing T2DM; and (2) a decrease in macrovascular risk from improved glycemic control may take more than a decade to be realized. Because of the results of these trials, the $A_{1c}$ goal used for most patients with T2DM is less than 7% (0.07; 53 mmol/mol Hgb), whereas a goal of less than or equal to 6.5% (0.065; 48 mmol/mol Hgb) may be used for otherwise healthy individuals who are thought to be early in the course of their diabetes.[7,16] More relaxed $A_{1c}$ targets may be employed for those patients who are older, have numerous medical conditions limiting their life expectancy, are at increased risk for hypoglycemia, or who have had T2DM for a long period of time.

### ▶ Dyslipidemia

The 2013 American College of Cardiology/American Heart Association Guideline on the Treatment of Blood Cholesterol to Reduce Atherosclerotic Cardiovascular Risk in Adults recommends statin therapy be considered if a patient falls into one of four statin benefit groups.[37] The groups are:

1. Patients with clinical atherosclerotic cardiovascular disease (ASCVD);

2. Patients with no prior history of ASCVD but a LDL level of 190 mg/dL (4.91 mmol/L) or higher;

3. Patients with diabetes and no history of clinical ASCVD who are between the ages of 40 and 75 years with a LDL level between 70 and 189 mg/dL (1.81 and 4.89 mmol/L); and

4. Patients ages 40 to 75 years with no prior history of ASCVD or diabetes who have a LDL level between 70 and 189 mg/dL (1.81 and 4.89 mmol/L) and a 10-year estimated ASCVD risk of 7.5% or higher.

Severe hypertriglyceridemia may warrant therapy with niacin, a fibrate, and/or fish oil. Although it was common practice in the past to add niacin or a fibrate onto statin therapy to augment triglyceride and HDL once LDL goals were met, cardiovascular outcome benefit has not been proven when these drugs are added to statin therapy over statin therapy alone.[38,39] Refer to Chapter 12, Dyslipidemias, for more information on managing cardiovascular risk through the optimal use of antihyperlipidemic therapies.

### ▶ Hypertension

**KEY CONCEPT** *Uncontrolled blood pressure plays a major role in the development of macrovascular events as well as microvascular complications, including retinopathy and nephropathy, in patients with DM. The ADA recommends that systolic blood pressure goals for patients with DM be individualized but generally set at less than 140 mm Hg.[7] The diastolic blood pressure goal for patients with DM is less than 90 mm Hg.* In addition, there are several general principles regarding the treatment of hypertension in diabetes patients. Angiotensin-converting enzyme (ACE) inhibitors or angiotensin II receptor blockers are recommended as initial therapy because of their beneficial effects on renal function. It can be expected that most patients will require more than one agent to reach blood pressure goal. Renal function and serum potassium levels should be monitored closely in all patients taking an ACE inhibitor, angiotensin II receptor blocker, and/or diuretic. ACE inhibitors and angiotensin II receptor blockers are contraindicated in patients who are pregnant and in those with bilateral renal artery stenosis.

---

## Patient Encounter, Part 2: Follow-Up Visit

The patient returns a week later with results from her fasting blood work. The physician also requests a fasting glucose, $A_{1c}$ and vitals at today's visit. The results are listed below.

**VS:** BP 122/76 mm Hg, P 70 beats/min, RR 19 breaths/min, T 38°C (100°F)

**$A_{1c}$ (today):** 8.2% (0.082; 66 mmol/mol Hgb)

**FPG (today):** 189 mg/dL (10.5 mmol/L)

**Labs (2 days ago):** Na 136 mEq/L (136 mmol/L); K 3.6 mEq/L (3.6 mmol/L); Cl 98 mEq/L (98 mmol/L); $CO_2$ 24 mEq/L (24 mmol/L); BUN 15 mg/dL (5.4 mmol/L); SCr 0.9 mg/dL (80 μmol/L); Glu 172 mg/dL (9.5 mmol/L)

*The patient is diagnosed with type 2 diabetes. Identify the goals of treatment for this patient.*

*What nonpharmacologic alternatives are available for this patient for her diabetes?*

*What are the three general categories of pharmacologic alternatives used to lower blood glucose?*

*What is the most appropriate initial therapy for this patient in regards to her diabetes?*

*What additional interventions are recommended for this patient today?*

### ▶ Human Immunodeficiency Virus (HIV) and Acquired Immune Deficiency Syndrome (AIDS)

Patients with risk factors for diabetes are more likely to develop diabetes when exposed to highly active antiretroviral therapy.[40] Universal screening of all HIV patients for diabetes is controversial, but most clinicians support screening for those with risk factors, especially if those risk factors include positive family history and central adiposity. Disturbances in glucose homeostasis are a known side effect of protease inhibitor therapy. Indinavir and ritonavir block insulin-mediated glucose disposal, causing insulin resistance, but amprenavir and atazanzvir have no effect on this pathway. Indinavir also increases hepatic glucose production and release and causes insulin to lose its ability to suppress hepatic glucose production. Nelfinavir, lopinavir, and saquinavir cause a 25% reduction in β-cell function, reducing first-phase insulin release. Drug selection for treating protease inhibitor–induced hyperglycemia should address the mechanism behind the adverse effect. Protease inhibitor therapy avoidance should be considered in patients with preexisting glucose abnormalities and in those with a first-degree relative with diabetes. Metformin should be used with caution in patients taking the nucleoside reverse transcriptase inhibitors stavudine, zidovudine, and didanosine because of an increased risk for lactic acidemia.

### ▶ Antipsychotic Drug Therapy

An association has been recognized between second-generation antipsychotics and the development of diabetes.[41] Risk seems to be highest with clozapine and olanzapine, but data are conflicting for risperidone and quetiapine. Aripiprazole and ziprasione have not, as of yet, shown an increased risk for diabetes with their use. Nutrition and physical activity counseling is recommended for all patients with mental illness who are overweight or obese, especially if they are beginning second-generation antipsychotic therapy. After therapy initiation, the patient's weight should be assessed at weeks 4, 8, and 12 and then every 3 months. In the event of weight gain greater than or equal to 5% of the patient's baseline weight, a therapeutic adjustment should be considered. For patients who develop worsening glycemia or dyslipidemia while on antipsychotic therapy, it is recommended that a switch to a second-generation antipsychotic with less weight gain or diabetes potential be considered.

## Treatment of Acute Complications

### ▶ Hypoglycemia

Hypoglycemia, or low blood sugar, can be defined clinically as a blood glucose level of less than or equal to 70 mg/dL (3.9 mmol/L).[42] Individuals with DM can experience symptoms of hypoglycemia at varying blood glucose levels. Those with uncontrolled glucose can experience pseudohypoglycemia which is when symptoms of hypoglycemia occur even at normal glucose levels. Those with recent low blood glucose levels may have no symptoms even at glucose values below the hypoglycemia threshold and, therefore, patients with recurrent hypoglycemia may benefit from a period of more relaxed glycemic targets.[7] Typical symptoms of hypoglycemia include shakiness, sweating, fatigue, hunger, headaches, and confusion.

Common causes of hypoglycemia include delayed or inadequate amounts of food intake, especially carbohydrates, excessive doses of medications (eg, sulfonylureas and insulin), exercising when insulin doses are reaching peak effect, or inadequately

adjusted drug therapy in patients with impaired renal or hepatic function. Patients experiencing symptoms of hypoglycemia should check their blood glucose level, consume 15 g of carbohydrate, wait 15 minutes for symptom resolution, and retest.[42] Examples of acceptable treatments may include a small box of raisins, 4 oz (~120 mL) of orange juice, 8 oz (~240 mL) of skim milk, or three to six glucose tablets. In patients receiving an α-glucosidase inhibitor in combination with a sulfonylurea or insulin, hypoglycemia should be treated with glucose tablets or skim milk owing to the mechanism of action of the α-glucosidase inhibitors. For patients with hypoglycemia experiencing a loss of consciousness, a glucagon emergency kit should be administered by the intramuscular or subcutaneous route. It is important to contact emergency medical personnel in this particular situation. The patient should be rolled onto his or her side to prevent aspiration because many patients receiving the glucagon injection vomit.

### ▶ Diabetic Ketoacidosis

Diabetic ketoacidosis is a reversible but potentially life-threatening medical emergency that results from a relative or absolute deficiency in insulin. Without insulin, the body cannot use glucose as an energy source and must obtain energy via lipolysis. This process produces ketones and leads to acidosis. Although DKA occurs frequently in young patients with T1DM on initial presentation, it can occur in adults as well. Often, precipitating factors such as infection, omission, or inadequate administration of insulin can cause DKA. Signs and symptoms develop rapidly within 1 day or so and commonly include fruity or acetone breath; nausea; vomiting; dehydration; polydipsia; polyuria; and deep, rapid breathing.

Hallmark diagnostic criteria for DKA include hyperglycemia (greater than 250 mg/dL [13.9 mmol/L]), ketosis (anion gap greater than 12 mEq/L [12 mmol/L]), and acidosis (arterial pH less than or equal to 7.3).[43] Typical fluid deficit is 5 to 7 L or more, and major deficits of serum sodium and potassium are common.

The severity of DKA depends on the magnitude of the decrease in arterial pH, serum bicarbonate levels, and the mental state rather than the magnitude of the hyperglycemia. Treatment goals of DKA consist of reversing the underlying metabolic abnormalities, rehydrating the patient, and normalizing the serum glucose. Fluid replacement with normal saline at 1 to 1.5 L/hour for the first hour is recommended to rehydrate the patient and to ensure the kidneys are perfused.

Potassium and other electrolytes are supplemented as indicated by laboratory assessment. The use of sodium bicarbonate in DKA is controversial and generally only recommended when the pH is less than 7. Regular insulin at 0.1 unit/kg/hour by continuous IV infusion is the preferred treatment in DKA to regain metabolic control rapidly. When plasma glucose values drop below 250 mg/dL (13.9 mmol/L), dextrose 5% should be added to the IV fluids. During the recovery period, it is recommended to continue administering insulin and to allow patients to eat as soon as possible. Dietary carbohydrates combined with insulin assist in the clearance of ketones. See Table 43–11 for the management of DKA.[43]

### ▶ Hyperosmolar Hyperglycemic State

Hyperosmolar hyperglycemic state (HHS) is a life-threatening condition similar to DKA that also arises from inadequate

## Patient Encounter, Part 3: Follow-Up

The patient returns in 3 months for a follow-up visit. She brings her blood glucose readings from the past week for review in addition to more fasting blood work. Blood glucose readings are in units of mg/dL (mmol/L). Her most recent medication list is below. There are no changes to her health record from previous visits.

**Allergies:** Sulfa and penicillin

**Meds:** Fluticasone nasal spray, one spray each nostril daily if needed during allergy season; metformin 1000 mg by mouth twice daily

**VS:** BP 154/96 mm Hg, P 78 beats/min, RR 18 breaths/min, T 37°C (98.6°F)

**Labs:** Total cholesterol 240 mg/dL (6.21 mmol/L); HDL 41 mg/dL (1.06 mmol/L); LDL 163 mg/dL (4.22 mmol/L); TG 183 mg/dL (2.07 mmol/L); AST 28 U/L (0.47 μKat/L); ALT 31 U/L (0.52 μKat/L)

| Day | FPG | PPG |
|---|---|---|
| Monday | 118 (6.5) | 168 (9.3) |
| Tuesday | 122 (6.8) | 187 (10.4) |
| Wednesday | 134 (7.4) | 140 (7.8) |
| Thursday | 110 (6.1) | 244 (13.5) |
| Friday | 98 (5.4) | 257 (14.3) |
| Saturday | 128 (7.1) | 297 (16.5) |
| Sunday | 116 (6.4) | 240 (13.3) |

*Are this patient's blood glucose levels within target? What pattern seems to be established?*

*Which classes of antidiabetic drugs act in a manner that would specifically correct the undesirable glucose pattern?*

*Based on the information available from this encounter and previous encounters, develop a care plan for this patient. The plan should include (a) identification and assessment of all drug-related needs and/or problems, (b) a detailed therapeutic plan to address each need and problem, and (c) monitoring parameters to assess safety and efficacy.*

---

### Table 43–11

**Management of Diabetic Ketoacidosis[41]**

1. Confirm diagnosis (increased plasma glucose, positive serum ketones, metabolic acidosis).

2. Admit to hospital; intensive care setting may be necessary for frequent monitoring or if pH < 7 or unconscious.

3. Asses serum electrolytes ($K^+$, $Na^+$, $Mg^{2+}$, $Cl^-$, bicarbonate, phosphate), acid–base status—pH, $HCO_3^-$, $P_{CO_2}$, β-hydroxybutyrate, and renal function (creatinine, urine output).

4. Replace fluids: 0.9% saline 1 L/hour over first 1–3 hours; subsequently, 0.45% saline at 4–14 mL/kg/hour; change to 5% dextrose with 0.45% saline when plasma glucose reaches 250 mg/dL (13.9 mmol/L).

5. Administer regular insulin: IV (0.15 U/kg bolus followed by 0.1 unit/kg/hour infusion); check glucose hourly and double insulin infusion until glucose level falls at steady hourly rate of 50–70 mg/dL (2.8–3.9 mmol/L). Alternatively, could use SC or IM routes, although dosing regimen different. If initial serum potassium is less than 3.3 mEq/L (3.3 mmol/L), do not administer insulin until the potassium is corrected to > 3.3 mEq/L (3.3 mmol/L).

6. Assess patient: What precipitated the episode (eg, nonadherence, infection, trauma, infarction, cocaine)? Initiate appropriate workup for precipitating event (cultures, chest x-ray, ECG).

7. Measure chemistry (especially $K^+$, bicarbonate, phosphate and anion gap) every 2–4 hours until stable.

8. Replace $K^+$: If $K^+$ is < 3.3 mEq/L (3.3 mmol/L), hold insulin and give 40 mEq (40 mmol) of $K^+$ per liter of IV fluid. If $K^+$ is > 5 mEq/L (5 mmol/L), do not give $K^+$ but check level every 2 hours. When $K^+$ > 3.3 mEq/L (3.3 mmol/L) but < 5 mEq/L (5.5 mmol/L), ECG normal, urine flow and normal creatinine documented, administer 20–30 mEq/L (20–30 mmol/L) of IV fluid to maintain $K^+$ at 4–5 mEq/L (4–5 mmol/L).

9. Continue above until patient is stable, glucose goal is 150–250 mg/dL (8.3–13.9 mmol/L), and acidosis is resolved. Insulin infusion may be decreased to 0.05–0.1 unit/kg/hour.

10. Administer intermediate- or long-acting insulin as soon as patient is eating. Allow for overlap in insulin infusion and subcutaneous insulin injection.

Cl, chloride; ECG, electrocardiogram; $HCO_3$, serum bicarbonate; IM, intramuscular; IV, intravenous; K, potassium; Mg, magnesium; Na, sodium; $P_{CO_2}$, partial pressure of carbon dioxide in the arterial blood; SC, subcutaneous.

---

insulin, but HHS occurs primarily in older patients with T2DM. DKA and HHS also differ in that HHS lacks the ketonemia and acidosis associated with DKA. Patients with hyperglycemia and dehydration lasting several days to weeks are at the greatest risk of developing HHS. Infection, silent myocardial infarction, cerebrovascular accident, mesenteric ischemia, acute pancreatitis, and the use of medications that affect carbohydrate metabolism including steroids and thiazide diuretics are known precipitating causes of HHS. Two main diagnostic criteria for HHS are a plasma glucose value of greater than 600 mg/dL (33.3 mmol/L) and a serum osmolality of greater than 320 mOsm/kg (320 mmol/kg).[43] The extreme hyperglycemia and large fluid deficits resulting from osmotic diuresis are major challenges to overcome with this condition. Similar to DKA, the treatment of HHS consists of aggressive rehydration, correction of electrolyte imbalances, and continuous insulin infusion to normalize serum glucose. Blood glucose levels should be reduced gradually to minimize the risk of cerebral edema.

## Treatment of Long-Term Complications

### ▶ Retinopathy

Diabetic retinopathy occurs when the microvasculature that supplies blood to the retina becomes damaged. This damage permits leakage of blood components through the vessel walls. Diabetic retinopathy is the leading cause of blindness in adults 20 to 74 years of age in the United States.[7] The risk of retinopathy is increased in patients with long-standing DM, chronic hyperglycemia, hypertension, and nephropathy. Other eye disorders, including glaucoma and cataracts, are more likely to occur in patients with diabetes as well.

The ADA recommends that patients with T2DM receive a dilated eye examination at the time of diagnosis by an ophthalmologist or optometrist.[7] Examinations should begin within 5 years

of diagnosis of T1DM. Once one or more normal examinations occur, the dilated eye exam is recommended to be repeated at least every two years. But, in patients with documented retinopathy, an annual dilated eye exam is recommended. Glucose and blood pressure control are the best strategies for decreasing the risk and slowing the progression of retinopathy.

### ▶ Neuropathy

**KEY CONCEPT** *Peripheral neuropathy is a possible complication of diabetes. The most common types of peripheral neuropathy include chronic sensorimotor distal peripheral neuropathy, which can cause pain, tingling, and numbness in the feet and hands, and autonomic neuropathy, which can lead to hypotension, gastroparesis, sexual dysfunction, and autonomic failure in response to hypoglycemia.*[7] Two drugs, pregabalin and duloxetine, have been approved for the relief of distal peripheral neuropathy pain. A number of other drugs are also sometimes used including venlafaxine, amitriptyline, valproate, and opioids.

### ▶ Microalbuminuria and Nephropathy

DM is a leading contributor to end-stage renal disease. Early evidence of nephropathy is the presence of albumin in the urine. Therefore, as the disease progresses, larger amounts of protein spill into the urine. The ADA recommends urine protein tests annually in T2DM patients.[7] For patients with T1DM, annual urine protein testing should begin 5 years after the diagnosis of diabetes. The most common form of screening for protein in the urine is a random collection for measurement of the urine albumin-to-creatinine ratio. The desirable value is less than 30 mcg of albumin per milligram of creatinine (3.4 mg/mmol creatinine). The terms microalbuminuria and macroalbuminuria are being replaced by the term "persistent albuminuria," with the level of albuminuria further defined as either being between 30 and less than 299 mcg of albumin per milligram of creatinine (3.4–34 mg/mmol creatinine; previously referred to as microalbuminuria) or greater than or equal to 300 mcg of albumin per milligram of creatinine (greater than or equal to 34 mg/mmol creatinine; previously known as macroalbuminuria).

Glycemic control and blood pressure control are primary measures for the prevention of progression of nephropathy. ACE inhibitors and angiotensin II receptor blockers prevent the progression of renal disease in patients with T2DM. Treatment of advanced nephropathy includes dialysis and kidney transplantation.

### ▶ Foot Ulcers

**KEY CONCEPT** *Lower extremity amputations are one of the most feared and disabling sequelae of long-term uncontrolled DM. A foot ulcer is an open sore that develops and penetrates to the subcutaneous tissues. Complications of the feet develop primarily as a result of peripheral vascular disease, neuropathies, and foot deformations.*

Peripheral arterial disease causes ischemia to the lower limbs. This decreased blood flow deprives the tissues of oxygen and nutrients and impairs the ability of the immune system to function adequately. Symptoms of peripheral arterial disease include intermittent claudication, cold feet, pain at rest, and loss of hair on the feet and toes. Smoking cessation is the single most important treatment for peripheral arterial disease. In addition, exercising by walking to the point of pain and then resting and resuming can be a vital therapy to maintain or improve the symptoms of peripheral arterial disease.

Pharmacologic intervention with antiplatelet therapy (aspirin 160–325 mg/day or clopidogrel 75 mg/day) is indicated in patients with peripheral arterial disease.[44] For those that remain symptomatic, cilostazol 100 mg twice daily may be useful to improve blood flow and reduce the symptoms of peripheral vascular disease.

Neuropathies play a large part in the development of foot ulcers. Loss of sensation in the feet allows trauma to go unnoticed. Autonomic neuropathy can cause changes in blood flow, perspiration, skin hydration, and possibly, bone composition of the foot. Motor neuropathy can lead to muscle atrophy, resulting in weakness and changes in the shape of the foot. To prevent foot complications, the ADA recommends daily visual examination of the feet and a foot check performed at every physician visit.[7] Sensory testing with a 10-gauge monofilament can detect areas of neuropathy. Treatment consists of glycemic control, preventing infection, debriding dead tissues, applying dressings, treating edema, and limiting ambulation. Additionally, diabetics should wear properly fitted, cushioned footwear and padded socks.

## Special Situations

### ▶ Hospitalized Care

The NICE-SUGAR (intensive versus conventional glucose in critically ill patients) trial compared intensive (81–108 mg/dL [4.5–6.0 mmol/L]) with conventional (less than 180 mg/dL [10.0 mmol/L]) glucose control using IV insulin in intensive care unit patients.[45] At 90 days, intensively controlled patients had an increased absolute risk of death. Significantly more hypoglycemia was observed in the intensively controlled group.

Current recommendations call for critically ill patients to be started on IV insulin therapy at a threshold of 180 mg/dL (10.0 mmol/L).[7] A goal range of 140 to 180 mg/dL (7.8–10.0 mmol/L) is recommended for the majority of patients. More stringent goals may be considered for selected critically ill patients, but only if hypoglycemia can be avoided. Scheduled subcutaneous insulin regimens with basal, nutritional, and correction components are recommended for patients who are not critically ill. Goals of less than 140 mg/dL (7.8 mmol/L) for fasting glucose and less than 180 mg/dL (10.0 mmol/L) for random glucose are recommended for noncritically ill patients.

### ▶ Sick Days

Patients should monitor their blood glucose levels more frequently during sick days because it is common for illness to increase blood glucose values.[46] Patients with T1DM should check their glucose and urine for ketones every 4 hours when sick. Patients with T2DM may also need to check for ketones when their blood glucose levels are greater than 300 mg/dL (16.7 mmol/L). Patients should continue to take their medications while sick. T1DM patients may require additional insulin coverage, and some with T2DM who are currently on oral medication regimens may require insulin during an acute illness. Patients should be advised to maintain their normal caloric and carbohydrate intake while ill as well as to drink plenty of noncaloric beverages to avoid dehydration. When having difficulty eating a normal diet, patients may be advised to use nondiet beverages, sports drinks, broths, crackers, soups, and nondiet gelatins to provide normal caloric and carbohydrate intake and avoid hypoglycemia. With proper management, patients can decrease their chance of illness-induced hospitalization, particularly DKA and HHS.

## Patient Encounter, Part 4: Insulin Therapy

The patient returns to the office for her annual checkup. It has been 5 years since she was first diagnosed with diabetes. Her updated information is below. Her past medical and family histories are unchanged. She states that she has been adherent to medications and lifestyle changes. She complains that she has burning and tingling constantly in both of her feet.

**SH:** Smokes half pack cigarettes per day for 15 years; drinks bottle of wine on the weekends; denies illicit drug use

**Allergies:** Sulfa and penicillin

**Meds:** Lisinopril 20 mg by mouth once daily; atorvastatin 20 mg by mouth once daily; fluticasone nasal spray, one spray each nostril daily if needed during allergy season; metformin 1000 mg by mouth twice daily; liraglutide 1.2 mg subcutaneously once daily; multivitamin by mouth once daily

**Meal History:** Has been consuming approximately 30 to 45 g of carbohydrates per meal three times a day; saturated fat is limited to 12 g/day, and sodium is 2000 mg/day

**Physical Activity:** Was walking 4 or 5 days per week for 30 minutes at moderate intensity but has not done so recently due to tingling in feet

**VS:** BP 135/82 mm Hg, P 85 beats/min, RR 20 breaths/min, T 38°C (100°F), Ht 5′3″ (160 cm), Wt 155 lb (70.5 kg)

**Labs:** Na 139 mEq/L (139 mmol/L); K 5 mEq/L (5 mmol/L); Cl 103 mEq/L (103 mmol/L); $CO_2$ 23 mEq/L (23 mmol/L); BUN 16 mg/dL (5.7 mmol/L); SCr 0.9 mg/dL (80 μmol/L); FPG 180 mg/dL (10.0 mmol/L); $A_{1c}$ 9.7% (0.097; 83 mmol/mol Hgb); AST 28 U/L (0.47 μKat/L); ALT 31 U/L (0.52 μKat/L)

- Fasting lipid profile:
  - Total cholesterol: 202 mg/dL (5.22 mmol/L)
  - LDL: 108 mg/dL (2.79 mmol/L)
  - HDL: 43 mg/dL (1.11 mmol/L)
  - TG: 205 mg/dL (2.32 mmol/L)

*What additional pharmacologic options are available for this patient to lower her blood glucose to goal?*

*Which insulin and starting dose would be most appropriate for this patient?*

*What additional medications, screenings, labs, and/or referrals are recommended for the patient at this point?*

*What is an important lifestyle modification this patient still needs to make?*

## Patient Care Process

**Patient Assessment:**
- Assess patient for development or progression of DM and complications (see Tables 43–4 and 43–5).
- Evaluate SMBG for glycemic control, including FPG and postprandial levels (see Table 43–6).
  - Are the blood glucose values too high or low?
  - Are there specific times of day or specific days not in control?
  - Is hypoglycemia occurring?
- Review laboratory data for attainment of goals (see Table 43–6). What goals are not being met? What tests or referrals to other health care team members are needed?
- Assess patient for quality-of-life measures such as physical, psychological, and social functioning and well-being.

**Therapy Evaluation:**
- Perform medication history of prescription, over-the-counter, and herbal product use.
- Are there any medication problems, including presence of adverse drug reactions, drug allergies, and drug interactions?
- If patient is already receiving treatment for DM, has he/she been adherent to recommended lifestyle modifications and drug therapies? Is the patient having difficulty affording their therapies?

- Determine if patient has prescription coverage.
- Is the patient taking medications that may affect glucose control?

**Care Plan Development:**
- Recommend appropriate therapy and develop a plan to assess effectiveness (see Tables 43–7, 43–9, and 43–10).
- Stress adherence to prescribed lifestyle and medication regimen.
- Provide education on diabetes, lifestyle modifications, appropriate monitoring, and drug therapy:
  - Causes of DM complications and how to prevent them.
  - How diet and exercise can affect diabetes.
  - How to perform SMBG and what to do with the results.
  - When to take medications and what to expect, including adverse effects.
  - What warning sign(s) should be reported to the physician.

**Follow-up Evaluation:**
- Set follow up for SMBG and tolerability/presence of adverse effects based on therapy chosen.
- Follow up $A_{1c}$ every 3 months until patient reaches goal, then every 6 months. See Table 43–6 for other monitoring parameters and frequency.

## OUTCOME EVALUATION

- The success of therapy for DM is measured by the ability of the patient to manage his or her disease appropriately between health care provider visits.

- Appropriate therapy necessitates adequate patient education about the disease, development of a meal plan to which patients can comply, and integration of a regular exercise program.

- Patient care plans should include a number of daily evaluations to be performed by the patient, such as examining the feet for any sores, cuts, or abrasions; checking the skin for dryness to prevent cracking and chafing; and monitoring blood glucose values as directed. Weekly appraisals of weight and blood pressure are also advised.

- Until $A_{1c}$ levels are at goal, quarterly visits with the patient's primary health care provider are recommended. Table 43–6 summarizes the specific ADA goals for therapy. The practitioner should review SMBG data and a current $A_{1c}$ level for progress and address any therapeutic or educational issues.

- At a minimum, yearly laboratory evaluation of serum lipids, urinary microalbumin, and serum creatinine should be performed.

# Thyroid Disorders

Michael D. Katz

## LEARNING OBJECTIVES

**Upon completion of the chapter, the reader will be able to:**

1. Discuss the prevalence of common thyroid disorders, including mild and overt hypothyroidism and hyperthyroidism.

2. Explain the major components of the hypothalamic–pituitary–thyroid axis and interaction among these components.

3. Discuss the relationship between serum thyroid-stimulating hormone (TSH) levels and primary thyroid disease, and the advantages for use of TSH levels over other tests such as serum $T_4$ (thyroxine) and $T_3$ (triiodothyronine) levels.

4. Identify typical signs and symptoms of hypothyroidism and the consequences of suboptimal treatment.

5. Describe clinical use of levothyroxine ($LT_4$) in the treatment of hypothyroidism.

6. Discuss the issues regarding $LT_4$ product bioequivalence and reasons for maintaining patients on the same product.

7. Describe the management of hypothyroidism and hyperthyroidism in pregnant women.

8. Identify typical signs and symptoms of Graves disease and consequences of inadequate treatment.

9. Discuss the pharmacotherapy of Graves disease, including advantages and disadvantages of antithyroid drugs versus radioactive iodine, adverse effects, and patient monitoring.

10. Describe the potential effects of selected drugs, including amiodarone, lithium interferon-α, and tyrosine kinase inhibitors on thyroid function.

## INTRODUCTION

Thyroid disorders are common. More than 2 billion people, or 38% of the world's population, have iodine deficiency, resulting in 74 million people with **goiters**. Although overt iodine deficiency is not a significant problem in developed countries, a number of common thyroid conditions exist. The most common are **hypothyroidism** and **hyperthyroidism**, which often require long-term pharmacotherapy. Undetected or improperly treated thyroid disease can result in long-term adverse sequelae, including increased mortality. It is important that clinicians are aware of the prevalence of thyroid disorders, methods of identifying thyroid disorders, and appropriate therapy. This chapter focuses on the most common pharmacologically treated thyroid disorders.

## EPIDEMIOLOGY OF THYROID DISEASE

Among 4392 people 12 years of age and older in a sample representing the geographic and ethnic distribution of the US population, hypothyroidism was found in 3.7% (3.4% mild) and hyperthyroidism in 0.5%.[1] The prevalence of hypothyroidism was higher in older age groups and in whites and Hispanics; blacks had a lower prevalence of hypothyroidism. The prevalence of hypothyroidism correlated with age. Compared with the total population, people aged 50 to 79 years had an almost twofold higher prevalence, and those aged 80 years and older had a fivefold higher prevalence. Pregnant women also had a higher prevalence of hypothyroidism. The Colorado Thyroid Health Survey assessed thyroid function in 25,862 subjects attending a health fair.[2] Overall prevalence of an abnormal TSH level was 11.7% of the study population, with 9.4% hypothyroid (9% subclinical) and 2.2% hyperthyroid (2.1% subclinical). Of the 916 subjects taking thyroid medication, 60% were **euthyroid**, with an equal distribution between subclinical hypothyroidism and hyperthyroidism. The National Health and Nutrition Examination Survey (NHANES) study also found that many patients receiving thyroid medications had an abnormal TSH level. These findings imply that many patients who are receiving thyroid medications are not being managed successfully.

## THYROID HORMONE PHYSIOLOGY AND BIOSYNTHESIS[1]

**KEY CONCEPT** *The thyroid gland is the largest endocrine gland in the body, residing in the neck anterior to the trachea between the cricoid cartilage and suprasternal notch. The thyroid gland produces two biologically active hormones, thyroxine ($T_4$) and triiodothyronine ($T_3$). Thyroid hormones are essential for proper fetal growth*

and development, particularly of the central nervous system (CNS). After delivery, the primary role of thyroid hormone is in regulation of energy metabolism. These hormones can affect the function of virtually every organ in the body. **KEY CONCEPT** *The parafollicular C cells of the thyroid gland produce calcitonin.* The function of calcitonin and its therapeutic use are discussed in other chapters in this book.

$T_4$ and $T_3$ are produced by the organification of iodine in the thyroid gland. Iodine is actively transported into the thyroid follicular cells. This inorganic iodine is oxidized by thyroid peroxidase and covalently bound to tyrosine residues of thyroglobulin. These iodinated tyrosine residues, monoiodotyrosine and diiodotyrosine, couple to form $T_4$ and $T_3$. Eighty percent of thyroid hormone is synthesized as $T_4$ and is stored in the thyroid bound to thyroglobulin. Thyroid hormones are released from the gland when needed, primarily under the influence of TSH (thyrotropin from the anterior pituitary). $T_4$ and $T_3$ are transported in the blood by three proteins, 70% bound to thyroid-binding globulin (TBG), 15% to transthyretin (thyroid-binding prealbumin), and 15% to albumin. $T_4$ is 99.97% protein bound, and $T_3$ is 99.7% protein bound, with only the unbound or free fractions physiologically active. The high degree of protein binding results in a long half-life of these hormones: approximately 7 to 10 days for $T_4$ and 24 hours for $T_3$.

Most of the physiologic activity of thyroid hormones is from the actions of $T_3$. $T_4$ can be thought of primarily as a prohormone. Eighty percent of needed $T_3$ is derived from conversion of $T_4$ to $T_3$ in peripheral tissue under the influence of tissue deiodinases. These deiodinases allow end organs to produce the amount of $T_3$ needed to control local metabolic functions. These enzymes also catabolize $T_3$ and $T_4$ to biologically inactive metabolites.

The production and release of thyroid hormones are regulated by the hypothalamic–pituitary–thyroid axis (**Figure 44–1**). Hypothalamic thyrotropin-releasing hormone (TRH) stimulates the release of TSH when there are physiologically inadequate levels of thyroid hormones. TSH promotes production and release of thyroid hormones. As circulating thyroid hormone levels rise to needed levels, negative feedback results in decreased release of TSH and TRH. Release of TRH is also inhibited by somatostatin and its analogs, and release of TSH can also be inhibited by dopamine, dopamine agonists, and high levels of glucocorticoids.

## SPECTRUM OF THYROID DISEASE

There are two general modes of presentation for thyroid disorders: changes in the size or shape of the gland and changes in secretion of hormone from the gland. In some cases, structural changes can result in changes in hormone secretion. Thyroid nodules and goiters in euthyroid patients are common problems. Patients with a goiter who are biochemically euthyroid often require no specific pharmacotherapy unless the goiter is caused by iodine deficiency. In developing countries, iodized salt is the primary therapy in treating goiter. Thyroid nodules, seen in 4% to 7% of adults, may be malignant or may autonomously secrete thyroid hormones. A discussion of thyroid nodules is beyond the scope of this chapter; however, thyroid cancer is discussed briefly in the context of levothyroxine ($LT_4$) suppressive therapy. Refer to other resources for a more extensive review of thyroid cancer management.

Changes in hormone secretion, often due to an underlying inflammatory disorder (thyroiditis), can result in hormone deficiency or excess. Although patients with overt hypothyroidism and hyperthyroidism may have dramatic signs and symptoms, most patients have subtle signs and symptoms that

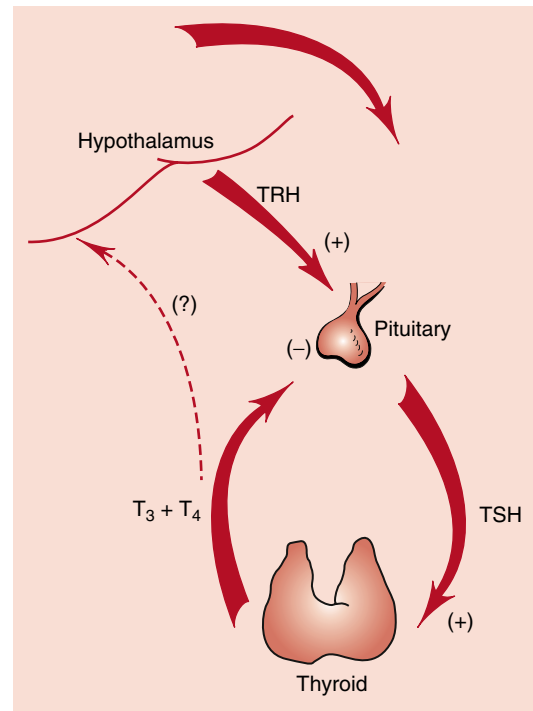

**FIGURE 44–1.** Hypothalamic–pituitary–thyroid axis. Thyrotropin-releasing hormone (TRH) is synthesized in the neurons within the paraventricular nucleus of the hypothalamus. TRH is released into the hypothalamic–pituitary portal circulation and carried to the pituitary, where it activates the pituitary to synthesize and release thyrotropin (TSH). TSH activates the thyroid to stimulate the synthesis and secretion of thyroxine ($T_4$) and triiodothyronine ($T_3$). $T_4$ and $T_3$ inhibit TSH secretion, closing the feedback loop. Negative feedback from $T_4$ and $T_3$ to hypothalamic TRH is less certain, hence the question mark.

progress slowly over time. The availability of sensitive and specific biochemical tests for diagnosis of thyroid hormone disorders has facilitated screening and earlier case-finding and diagnosis, including in those with mild or subclinical thyroid disorders. Screening of newborns for congenital hypothyroidism has reduced the incidence of mental retardation and neonatal hypothyroidism (cretinism) dramatically in the United States. However, congenital hypothyroidism owing to iodine deficiency remains a significant worldwide public health problem.

## PATIENT ASSESSMENT AND MONITORING

Assessment of patients for thyroid disorders entails a history and physical examination. In many patients with mild or subclinical thyroid disease, there may be an absence of specific signs and symptoms, and physical examination findings may be normal. Various diagnostic tests can be used, including serum thyroid hormone(s), TSH, thyroid antibody levels, and imaging techniques (Table 44–1). Laboratory assessment of patients with suspected thyroid disorders must be based on the continuum of disease from subclinical or mild to overt (Figure 44–2).

### TSH Levels

**KEY CONCEPT** *In most patients with thyroid hormone disorders, measurement of a serum TSH level is adequate for initial screening and diagnosis of hypothyroidism and hyperthyroidism. Serum free thyroxine*

### Table 44–1

**Selected Thyroid Tests for Adults**

| Test | Reference Range | Comments |
|------|-----------------|----------|
| TSH | 0.5–4.5 mIU/L (μIU/mL) | Gold standard; may be lowered by dopamine, dopamine agonists, glucocorticoids, octreotide, recovery from severe nonthyroidal illness |
| FT$_4$ | 0.7–1.9 ng/dL (9.0–24.5 pmol/L) | May be normal in mild thyroid disease |
| Anti-TPOAb, Anti-TGAb | Variable[a] | Present in autoimmune hypothyroidism; predicts more rapid progression from subclinical to overt hypothyroidism |
| TSI (TSHR-SAb) | Undetectable | Confirms Graves disease |

Anti-TPOAb, antithyroid peroxidase antibody; FT$_4$, free T$_4$ (thyroxine); Anti-TGAb, antithyroglobulin antibodies; TSH, thyroid-stimulating hormone; TSHR-SAb, TSH receptor-stimulating antibodies; TSI, thyroid-stimulating immunoglobulin

[a]Anti-TPOAb reference ranges are highly variable from one laboratory to another depending on the method used. Results greater than the upper cutoff are considered abnormal and are consistent with increased risk for autoimmune thyroid disease.

(FT$_4$) and triiodothyronine (FT$_3$) levels may be helpful in distinguishing mild (subclinical) thyroid disease from overt disease. TSH for most patients being treated for thyroid disorders should be the mean normal value of 1.5 milli international units/L (mIU/L) or 1.5 micro international units/mL (μIU/mL) (target range, 0.5–4 mIU/L or μIU/mL), although patients must be individually titrated based on resolution of signs and symptoms as well as biochemical tests. Target TSH may be different in the elderly and in patients being treated with LT$_4$ for thyroid cancer.

TSH is a highly sensitive bioassay of the thyroid axis. A twofold change in serum-free T$_4$ levels will result in a 100-fold change in TSH levels. This biologic magnification by TSH allows it to be used in early diagnosis as well as in closely titrating therapy in hypothyroidism and hyperthyroidism. In patients with primary hypothyroidism or hyperthyroidism resulting from gland dysfunction, there is an inverse relationship between the TSH level

**FIGURE 44–2.** The continuum of thyroid disorders. (FT$_4$, free T$_4$; TSH, thyroid-stimulating hormone.)

and thyroid function. High TSH signifies hypothyroidism (or iatrogenic underreplacement), and low TSH signifies hyperthyroidism (or iatrogenic overreplacement). There is controversy regarding the normal or laboratory reference ranges for TSH.[3] NHANES showed the mean TSH level in a normal population was 1.46 mIU/L (μIU/mL) (clinical laboratories use either unit of measurement, usually expressed as mIU/L or μIU/mL), but the values were not normally distributed. Although most laboratories quote the upper limit of normal for TSH between 4 and 5 mIU/L (μIU/mL), 95% of subjects had a TSH level of between 0.5 and 2.5 mIU/L (μIU/mL). The population of subjects whose TSH level was 2.5 to 4.5 mIU/L (μIU/mL) may have had mild hypothyroidism, or the non-normal distribution may reflect different normal ranges in a heterogeneous (age, sex, race) population. The mean normal TSH appears to be higher in the elderly with no clinical evidence of hypothyroidism,[4] and there is some evidence that normal TSH ranges are sex and ethnicity specific.[1] The target TSH for most patients being treated for thyroid disorders is not the same as the reference range. Ideally, TSH should be the mean normal value of 1.5 mIU/L (μIU/mL; target range, 0.5–4 mIU/L or μIU/mL).[3] The upper limit of the target range may be higher in the elderly. Therapy may be titrated within the target TSH range to maximally improve patient signs and symptoms without causing adverse effects of overtreatment or undertreatment.

### Serum T$_4$ and T$_3$ Levels

Serum T$_4$ and T$_3$ levels are used commonly to assess thyroid function. Older screening tests of thyroid function measure total serum T$_4$ or T$_3$ levels. Because of the high degree of protein binding of these hormones, the free fraction can be altered by changes in the levels of binding proteins or the degree of protein binding. Since a number of factors can alter protein binding, these older assays are very insensitive and should no longer be used routinely even with protein-binding adjustment factors such as the free T$_4$ index. Free or unbound T$_4$ (FT$_4$) and T$_3$ (FT$_3$) assays are readily available and are more sensitive in identifying thyroid dysfunction than the older total assays.[4] However, patients with mild hypothyroidism or hyperthyroidism have normal FT$_4$ levels despite abnormal TSH levels.

### Other Diagnostic Tests

Global tests of thyroid gland function can be performed to assess the rate of hormone synthesis. The radioactive iodine uptake (RAIU) is elevated in those with hyperthyroidism and can aid in identifying **thyrotoxicosis** owing to nonthyroid gland sources. Radionuclide thyroid scans are used in the evaluation of thyroid nodules. Because many thyroid disorders are autoimmune, measurement of various serum antithyroid antibodies can be performed. Antithyroid peroxidase antibodies (anti-TPOAb) and antithyroglobulin antibodies (anti-TGAb) are present in many patients with hypothyroidism. Most patients with Graves disease have TSH receptor-stimulating antibodies (TSHR-SAb) as well as elevated anti-TPOAb and antimicrosomal antibodies.

### HYPOTHYROIDISM

Hypothyroidism is the most common clinical disorder of thyroid function. It is the clinical syndrome that results from inadequate secretion of thyroid hormones from the thyroid gland. The vast majority of hypothyroid patients have primary gland failure, but occasional patients have pituitary or hypothalamic failure. Most studies define hypothyroidism based on a serum TSH

level above the upper limit of the laboratory reference range. In adults, 1.4% of women and 0.1% of men are biochemically hypothyroid. However, incidence is highly age dependent. In the Colorado Thyroid Health Study, by age 64 years, 12% of women and 5% of men were hypothyroid, and in the over 74 years age group, incidence in men approached that of women.[2] Most epidemiologic studies of hypothyroidism in the elderly show a prevalence of 6% to 12%.[4] There is a strong correlation between the presence of anti-TPOAb or anti-TGAb and the risk of developing hypothyroidism. In patients with subclinical hypothyroidism and positive anti-TPOAb, 5% per year will progress to overt hypothyroidism.[5] Other risk factors for development of hypothyroidism include the postpartum state, family history of autoimmune thyroid disorders, a previous history of head and neck or thyroid surgery, head and neck irradiation, other autoimmune endocrine disorders such as type 1 diabetes and Addison disease, other nonendocrine autoimmune diseases such as celiac disease and pernicious anemia, history of treatment for hyperthyroidism, treatment with amiodarone or lithium, and an iodine-deficient diet.[3,6]

## Screening for Hypothyroidism

Because prevalence of hypothyroidism is high in certain populations, screening may be useful. Screening for hypothyroidism in women older than age 35 years may be cost-effective, though some organizations recommend screening of adults after age 50 or 60 years.[7] Others advocate a case-finding approach, defined as performing a TSH determination in patients based on risk factors or presence of signs and symptoms.[3]

## Causes of Hypothyroidism

The most common causes of hypothyroidism are listed in Table 44–2.[3,8–11] Up to 90% of patients with autoimmune thyroiditis (Hashimoto disease) have circulating anti-TPOAbs. The autoimmune inflammatory response results in a lymphocytic infiltration of the thyroid gland and its eventual destruction.

Iatrogenic hypothyroidism can occur after thyroid irradiation or surgery and excessive doses of antithyroid drugs. Several drugs can cause hypothyroidism, including iodine-containing drugs such as amiodarone and iodinated radiocontrast media, lithium, interferon-α, multikinase and tyrosine kinase inhibitors (imatinib, sunitinib, sorafenib), *p*-aminosalicylic acid, ethionamide, sulfonylureas, valproic acid and other antiepileptic drugs, and aminoglutethimide.[3,11,12] Iodine deficiency is a common worldwide cause of hypothyroidism, including congenital hypothyroidism in newborns. Patients with hypothalamic or pituitary

---

**Table 44–2**

**Common Causes of Hypothyroidism[3,8–11]**

**Primary Hypothyroidism**
Autoimmune thyroiditis (Hashimoto disease)
Iatrogenic (irradiation, surgery)
Drugs (amiodarone, radiocontrast media, lithium, interferon-α, tyrosine kinase inhibitors)
Silent thyroiditis (including postpartum)
Iodine deficiency and excess

**Secondary Hypothyroidism**
Pituitary disease
Hypothalamic disease

---

## Clinical Presentation and Diagnosis of Hypothyroidism[3,6,8–10]

**Symptoms**

| | |
|---|---|
| Fatigue | Cold intolerance |
| Lethargy | Hoarseness |
| Sleepiness | Dry skin |
| Mental impairment | Decreased perspiration |
| Depression | Decreased appetite |
| Weight gain | Constipation |
| Menstrual disturbances | Arthralgia |
| Paresthesia | |

**Signs**

| | |
|---|---|
| Slow movements | Dry skin |
| Slow speech | Nonpitting edema (myxedema) |
| Hoarseness | Hyporeflexia |
| Bradycardia | Delayed relaxation of reflexes |

**Screening/Diagnosis**

- A TSH level of 4.5 to 10 mIU/L (μIU/mL) may constitute mild or subclinical hypothyroidism.
- A TSH level greater than 10 mIU/L (μIU/mL) signifies overt hypothyroidism.
- The free $T_4$ level will be normal (0.7–1.9 ng/dL or 9.0–24.5 pmol/L) in mild or subclinical hypothyroidism and low (less than 0.7 ng/dL or 9.0 pmol/L) in patients with obvious signs and/or symptoms.

---

disease often have other signs of pituitary disease, such as hypogonadism, and their TSH levels are low.

## Signs and Symptoms of Hypothyroidism

**KEY CONCEPT** *Hypothyroidism can affect virtually any tissue or organ in the body. The most common symptoms, such as fatigue, lethargy, sleepiness, cold intolerance, and dry skin, are nonspecific and can be seen with many other disorders. The classic overt signs, such as myxedema and delayed deep tendon reflexes, are seen uncommonly now because more patients are screened or seek medical attention earlier. Patients with mild (also known as subclinical) hypothyroidism may have subtle symptoms that progress so slowly that they are not noticed easily by the patient or family. The lack of overt or specific signs and symptoms emphasizes the importance of using serum TSH level to identify patients with hypothyroidism.*

## Mild (Subclinical) Hypothyroidism

Mild or subclinical hypothyroidism is present when a patient has a TSH above the upper limit of the laboratory reference range but usually below 10 mIU/L or μIU/mL, normal $FT_4$, and no overt hypothyroid signs and symptoms.[4,13,14] Many of these patients have autoimmune thyroiditis and anti-TPOAbs and some will progress to overt hypothyroidism. Although patients may not express the typical symptoms of hypothyroidism, many patients do have mild, nonspecific symptoms (eg, fatigue, cold intolerance, constipation). Recent studies have shown subclinical hypothyroidism to be a risk factor for cardiovascular mortality and to be associated with decreased myocardial contractility, decreased exercise tolerance, elevated low-density lipoprotein (LDL) cholesterol, and neuropsychiatric symptoms.[13–16]

## Sequelae of Hypothyroidism

Hypothyroidism is a chronic disease that may result in significant long-term sequelae. Hypercholesterolemia is associated with hypothyroidism, increasing the long-term risk of cardiovascular disease and cardiovascular mortality. Between 4% and 14% of patients with hypercholesterolemia are found to be hypothyroid. The Colorado Thyroid Health Study showed a direct correlation between degree of TSH elevation and rise in serum cholesterol.[2] Hypothyroidism also may result in increased systemic vascular resistance, decreased cardiac output, and increased diastolic blood pressure. Hypothyroidism can cause significant neuropsychiatric problems, including a dementia-like state in the elderly that is reversible with $LT_4$ therapy. Maternal hypothyroidism can have dire consequences for developing fetuses. Fetuses are almost completely dependent on maternal thyroid hormones during the first trimester, a time crucial for development of the CNS. Inadequately treated maternal hypothyroidism results in increased risk of miscarriage and developmental impairment in the child.[17]

Myxedema coma is seen in advanced hypothyroidism. These patients develop CNS depression, respiratory depression, cardiovascular instability, and fluid and electrolyte disturbances. Myxedema coma often is triggered by an underlying acute medical condition such as infection, stroke, trauma, or administration of CNS depressant drugs.

## Treatment of Hypothyroidism

**KEY CONCEPT** *There are three major goals in the treatment of hypothyroidism: replace the missing hormones, relieve signs and symptoms, and achieve a stable biochemical euthyroid state.* Although these goals should not be difficult to achieve, 20% to 40% of treated patients are not receiving optimal pharmacotherapy.

### ▶ Thyroid Hormone Products

A number of thyroid hormone products are marketed in the United States (Table 44–3). These products include synthetic $LT_4$ and $T_3$, combinations of synthetic $LT_4$ and $T_3$, and animal-derived products. **KEY CONCEPT** *Despite the availability of a wide array of thyroid hormone products, it is clear that synthetic $LT_4$ is the treatment of choice for almost all patients with hypothyroidism.[3] $LT_4$ mimics the normal physiology of the thyroid gland, which secretes mostly $T_4$ as a prohormone. Peripheral tissues convert $T_4$ to $T_3$ as needed based on metabolic demands. If $T_3$ is used to treat hypothyroidism, the peripheral tissues lose their ability to control local metabolic rates. $LT_4$ also has distinct pharmacokinetic advantages over $T_3$. With a 7- to 10-day half-life, $LT_4$ provides a very smooth dose-response curve with little peak and trough effect. In a small number of patients who have impairment of conversion of $T_4$ to $T_3$, addition of $T_3$ may be warranted.* $T_3$, with a 24-hour half-life, provides a significant peak and trough effect, and many patients have symptoms of thyrotoxicosis after each dose is administered. The use of compounded $T_3$ products that have not been approved by the Food and Drug Administration (FDA) or dietary supplements marketed for "thyroid health" should be strongly discouraged. For patients who have difficulty adhering to a once-daily regimen, a once-weekly $LT_4$ regimen is safe and effective.[3]

Animal-derived products such as desiccated thyroid are obtained from pig thyroid and have various degrees of purity. These products contain both $LT_4$ and $T_3$, but the amount of $T_3$ is much higher ($T_4$:$T_3$ = 4:1) than what would be found in the human thyroid gland ($T_4$:$T_3$ = 14:1). With the desiccated thyroid products, there are concerns about standardizing the amount of hormone and lot-to-lot variability. Although some patients want to use desiccated thyroid because it is "natural," the products are in no way natural for humans. With the strong evidence supporting the safety and efficacy of $LT_4$ in the treatment of hypothyroidism, there is no rationale for the use of these animal-derived products. Patients who are being treated with these agents should be strongly encouraged to switch to synthetic $LT_4$. Additionally, patients should be encouraged to not purchase thyroid hormone- or iodine-containing products from health food stores or internet sites.

Several studies have been published that evaluate use of $LT_4$ and $T_3$ combinations in ratios that mimic human physiology.

---

### Table 44–3

**Thyroid Preparations**

| Drug (Brand Name) | Content | Relative Dose | Comments |
|---|---|---|---|
| Levothyroxine, (Synthroid, Levoxyl, Unithroid), other brands, and generics | Synthetic $LT_4$; 25-, 50-, 75-, 88-, 100-, 112-, 125-, 137-, 150-, 175-, 200-, and 300-mcg tablets; 100-, 200-, and 500-mcg vial for injection | 60 mcg | Gold standard for treating hypothyroidism; products not therapeutically equivalent; full replacement dose, 1–1.6 mcg/kg/day; when switching from animal product, lower calculated daily dose by 25–50 mcg; IV form rarely needed |
| Liothyronine (Cytomel) | Synthetic $T_3$; 5-, 25-, and 50-mcg tablets | 15 mcg | Rarely needed in treatment of hypothyroidism; rapid absorption and pharmacologic effect; increased toxicity versus $LT_4$; no outcome benefit to combining with $LT_4$ |
| Thyroid (desiccated) USP (Armour, others) | Desiccated pork thyroid glands; contains $T_3$ and $T_4$; 15-, 16.25-, 30-, 32.5-, 48.75-, 60-, 65-, 90-, 97.5-, 120-, 130-, 162.5-, 180-, 195-, 240-, 260-, 300-, and 325-mg tablets | 65 mg | Nonphysiologic $T_4$:$T_3$ ratio; unpredictable hormone content and stability; $T_3$ content may cause toxicity; no role in modern therapy |
| Liotrix (Thyrolar) | Synthetic $T_4$, $T_3$ in fixed 4:1 ratio; ¼-, ½-, 1-, 2-, 3-strength tablets | 12.5/50 mcg $T_3$:$T_4$ (1 strength) | Nonphysiologic $T_4$:$T_3$ ratio; $T_3$ content may cause toxicity; no role in modern therapy |

IV, intravenous; $LT_4$, levothyroxine; $T_3$, triiodothyronine; $T_4$, thyroxine.

A meta-analysis of randomized, controlled clinical trials comparing $LT_4$ and $T_3$ combinations with $LT_4$ monotherapy show no outcome benefit with combination therapy.[18] Except in rare circumstances (eg, patients with impaired $T_4$-to-$T_3$ conversion as evidenced by adequate $LT_4$ dose, continued symptoms and low $FT_3$ level), there is no rationale for using combinations of $LT_4$ and $T_3$ to treat hypothyroidism.

### ▶ Bioequivalence and LT₄ Product Selection

$LT_4$ products have a long history of bioavailability problems.[3,19] Over the years, $LT_4$ bioavailability has increased, so maintenance doses today are significantly lower than those seen before the early 1980s. Currently, the average bioavailability of $LT_4$ products is about 80%. Because of long-standing concerns about $LT_4$ bioequivalence and because $LT_4$ products had never undergone formal approval by the FDA under the 1938 Food, Drug, and Cosmetics Act, the FDA mandated that all manufacturers of $LT_4$ products submit an Abbreviated New Drug Application (ANDA) to keep their products on the US market after 2001.[20] Products approved under this process would have to comply with FDA manufacturing and bioequivalence standards. This action has resulted in many changes in the United States $LT_4$ market, as well as renewed interest in $LT_4$ bioequivalence. Since 2001, a variety of brand and generic products have been approved by the FDA. Some marketed products carry AB ratings (bioequivalence) to certain other products, using a complex AB1, AB2, AB3, and AB4 system.[21]

For many years, there have been concerns regarding the FDA bioequivalence methodology for $LT_4$ products. FDA bioequivalence standards allow a −20% to +25% variance in single-dose pharmacokinetic parameters between the test and reference products. Many people believe this degree of allowed variance is not appropriate for a narrow-therapeutic-index (NTI) drug such as $LT_4$. Furthermore, there are unique challenges to performing bioequivalence studies with an endogenous hormone such as $LT_4$. Because these single-dose pharmacokinetic studies are done in healthy volunteers, the pharmacokinetic data are a combination of endogenous and exogenous $LT_4$. Seventy percent of the area under the curve (AUC) in these studies consists of the subjects' endogenous $T_4$. Blakesley and colleagues showed the standard FDA bioequivalence methodology would rate 600-, 450-, and 400-mcg $LT_4$ doses as bioequivalent.[22] This study also showed that mathematically removing the subjects' endogenous $T_4$ level (baseline correction) improves the sensitivity of the analysis. Based on these data, since 2003, the FDA has required that $LT_4$ bioequivalence data undergo baseline correction. Although this method has improved the ability to identify large differences in $LT_4$ bioequivalence, small but clinically significant differences will not be identified. In 2008, the FDA adopted stricter criteria for $LT_4$ tablet shelf-life potency (95%–105% of stated potency vs standard 90%–110%), which may reduce the intrapatient variability seen during long-term $LT_4$ therapy.

More important than bioequivalence is the therapeutic equivalence of $LT_4$ products. Will patients have the same outcomes if bioequivalent products are used? A study by Dong and colleagues helps to answer this question.[23] Twenty-two well-controlled hypothyroid women were randomly switched to the same dose of four different products every 6 weeks. Nonbaseline corrected bioequivalence data showed these products to be bioequivalent. However, as each product switch occurred, more of the subjects had an abnormal TSH level.[24] By the end of the third product switch, 52% had an abnormal TSH level. This is strong evidence that $LT_4$ products are not therapeutically equivalent even if they are rated as bioequivalent by the FDA.

Evidence does exist that small differences in $LT_4$ dose can result in large changes in TSH. In one study, when the daily dose was reduced by 25 mcg, 78% had an elevated TSH level.[25] When the daily dose was increased by 25 mcg, 55% had a low TSH level. Clearly, differences in $LT_4$ dose or bioavailability within the FDA-allowed variance for bioequivalent products can cause significant changes in TSH.

**KEY CONCEPT** *There is no evidence that one $LT_4$ product is better than another. However, given the evidence that these products do have differences in bioavailability, patients should be maintained on the same $LT_4$ product. Given the generic substitution regulations of most states, this is best accomplished by prescribing a brand-name product or otherwise ensuring the product remains constant and not allowing substitution.* Although practitioners are pressured by insurance companies and employers to substitute $LT_4$ products as a cost-saving measure, such switching is not in the best interest of the patient and should not be allowed. If patients are switched to a different product, the prescriber should be notified, and a TSH determination should be done in 6 to 8 weeks to allow dose retitration. The economic impact of retitration must be considered when formularies are changed to reduce drug acquisition cost.

### ▶ Therapeutic Use of LT₄

$LT_4$ replacement is indicated for patients with overt hypothyroidism.[3,6,8–10] However, the need for treatment is controversial in patients with mild or subclinical disease. There are no prospective clinical trials that show an outcome benefit with treating these patients. A retrospective study from the United Kingdom showed that $LT_4$ therapy in patients with mild hypothyroidism reduced ischemic heart disease events in patients 70 years and younger.[26] In patients without symptoms who have underlying heart disease, high cardiovascular risk, goiter, positive anti-TPOAb and/or are infertile or pregnant, $LT_4$ replacement should be considered.[3,27] Patients with mild or subclinical hypothyroidism do not need to be started on the full $LT_4$ replacement dose because they still have some endogenous hormone production. Start these patients on 25 to 50 mcg/day and titrate every 6 to 8 weeks based on TSH levels. Over time, it is likely the $LT_4$ dose will need to be increased slowly as the patient's thyroid gland loses residual function.

In patients younger than age 65 years with overt hypothyroidism, the average $LT_4$ replacement dose is 1.6 mcg/kg/day (use ideal body weight in obese patients[3]). However, there is wide interpatient variability in the optimal replacement dose, so individual dose titration is necessary. If there is no history of cardiac disease, these patients may be started on the full replacement dose.

The full replacement dose in patients older than age 75 years is lower, about 1 mcg/kg/day.[4,5] In the elderly, the starting dose should be 25 to 50 mcg/day, and the dose should then be titrated to the target TSH value. In patients with ischemic heart disease, start with 12.5 to 25 mcg/day and slowly titrate. If the patient develops angina or other forms of myocardial ischemia, lower the dose and titrate more slowly. At the start of therapy and with each change in dose, recheck the TSH in 6- to 8-week intervals. If the TSH is not in the target range (0.5–4 mIU/L or μIU/mL), change the dose by 10% to 20% and then recheck the TSH 6 to 8 weeks later. As the dose is titrated, assess the patient's symptoms. Many patients will improve quickly, and younger patients will feel best if the TSH is titrated to low-normal to middle-normal levels (0.5–1.5 mIU/L or μIU/mL).

## Patient Encounter 1, Part 1

A 36-year-old woman comes to the clinic complaining of fatigue, lethargy, heavy periods, dry skin, and constipation for the past 6 months. She thought it was because she was "working too hard and was not eating right," but the symptoms have not improved despite her primary care provider giving her a vitamin with iron. She noticed a 2.5-kg (5.5-lb) weight gain over the past 4 months. Her friend gave her some sertraline, but she did not take it. She takes no medications other than a hormonal contraceptive, occasional acetaminophen for headache and MiraLAX for constipation. Her vital signs and physical examination, including her most recent pelvic examination findings several months ago, are normal.

### Labs

Serum Cholesterol: 205 mg/dL (5.30 mmol/L; normal, less than 200 mg/dL, or 5.17 mmol/L); LDL cholesterol 96 mg/dL (2.48 mmol/L; normal less than 130 mg/dL or 3.36 mmol/L)

TSH: 7.8 mIU/L (μIU/mL; reference range, 0.5–4.5 mIU/L or μIU/mL)

Free T$_4$: 0.96 ng/dL (12.4 pmol/L; reference range, 0.7–1.9 ng/dL, or 9.0–24.5 pmol/L)

### PE:

VS: Wt 68 kg (150 lb); Ht 5'5" (165 cm); BMI 25 kg/m$^2$

*Should the patient receive LT$_4$ therapy? Why or why not?*

*If you feel treatment is indicated, what initial dose of LT$_4$ would you choose?*

*If you feel treatment is not indicated, how would you monitor the patient?*

*What would you tell the patient regarding the significance of her symptoms, elevated TSH level, and risk versus benefits of LT$_4$ therapy?*

### ▶ Risks of Overtreatment and Undertreatment

Patients receiving LT$_4$ therapy who are not maintained in a euthyroid state are at risk for long-term adverse sequelae. In general, overtreatment and a suppressed TSH are more common than undertreatment with an elevated TSH.[27] Patients with long-term overtreatment are at higher risk for atrial fibrillation and other cardiovascular morbidities, depression or mental status changes, and osteoporosis. Elderly patients being treated with LT$_4$ have a dose-related risk of fractures even if the TSH is not suppressed below normal values.[28] Although studies have not defined a specific TSH target range for the elderly, these patients should receive close monitoring and dose adjustments to prevent overtreatment. Patients who are undertreated are at higher risk for hypercholesterolemia and other cardiovascular problems, depression or mental status changes, and obstetric complications.

### ▶ Alterations in LT$_4$ Dose Requirements

A number of factors can alter LT$_4$ dose requirements (Table 44–4), including time of administration and drug–drug and

### Table 44–4

**Factors That Alter LT$_4$ Dose Requirements[3,9]**

| Increased Dose Requirement | Decreased Dose Requirement |
|---|---|
| **Decreased LT$_4$ Absorption** | Aging |
| Malabsorption syndromes | Delivery of pregnancy |
| **Drugs or Diet** | Withdrawal of interacting substance |
| Bile acid binders | |
| Caffeine | |
| Calcium | |
| Charcoal | |
| Chromium picolinate | |
| Ciprofloxacin | |
| Fiber | |
| Grapefruit juice | |
| H$_2$-blockers | |
| Iron | |
| Malabsorption syndromes | |
| Oral bisphosphonates | |
| Orlistat | |
| Phosphate binders (sevelamer, aluminum) | |
| Proton pump inhibitors | |
| Sodium polystyrene sulfonate | |
| Soy | |
| Sucralfate | |
| Tube feeding | |
| **Increased TBG** | |
| Cirrhosis | |
| Estrogen therapy | |
| Hereditary | |
| Pregnancy | |
| Tamoxifen, raloxifene therapy | |
| **Increased Clearance** | |
| Carbamazepine | |
| Growth hormone | |
| Nevirapine | |
| Oxcarbazepine | |
| Phenobarbital | |
| Phenytoin | |
| Primidone | |
| Quetiapine | |
| Rifampin | |
| Sertraline | |
| Stavudine | |
| Tyrosine kinase inhibitors | |
| Valproic acid | |
| **Impaired Deiodination** | |
| Amiodarone | |
| **Mechanism Unknown** | |
| Critical illness | |

LT$_4$, levothyroxine; TBG, thyroxine-binding globulin.

drug–food interactions.[3,9] LT$_4$ has the greatest and most consistent bioavailability when taken in the evening on an empty stomach.[29] The most common cause of increased dose requirement is coadministration of LT$_4$ with calcium or iron supplements (including prenatal vitamins). Counsel patients that they should take the LT$_4$ dose at least 2 hours before or 6 hours after the calcium or iron dose. The most common cause of decreased dose requirement is aging.

| Table 44–5 |
|---|

**Monitoring LT$_4$ Therapy**

- Serum TSH
  - Every 6–12 months or if change in clinical status
  - 6–8 weeks after any dose or product change
  - As soon as possible in pregnancy; then monthly
- Same product prescribed and dispensed with every refill
- Watch for mg/mcg dosing errors
- Assess patient's understanding of disease, therapy, and need for adherence and tight control
- Assess for signs and symptoms of over- and undertreatment
- Identify potential interactions between LT$_4$, and foods and/or drugs

LT$_4$, levothyroxine; TSH, thyroid-stimulating hormone.

### ▶ Patient Monitoring

Patients on stable LT$_4$ therapy do not need frequent monitoring. In most patients, measuring TSH every 6 to 12 months along with an assessment of clinical status is adequate (Table 44–5). If the patient's clinical status changes (eg, pregnancy), more frequent monitoring may be necessary. LT$_4$ prescriptions should be written as microgram doses to avoid potential errors when written as milligram doses.

Patient education is an important component of care. Treatment adherence rates (at least 80% of doses taken) in hypothyroid patients are 68%, slightly less than adherence rates seen in hypertensive patients.[30] Educate patients about the benefits of proper therapy, importance of adherence, consistency in time and method of administration, and importance of receiving a consistent LT$_4$ product. Some patients take excessive amounts of LT$_4$ in an effort to "feel better" or as a weight loss treatment. Explain to patients that excessive amounts of LT$_4$ will not improve symptoms more than therapeutic doses, can cause serious problems, and is not an effective treatment for obesity.

### ▶ Special Populations and Conditions

**Hypothyroidism and Pregnancy** Hypothyroidism during pregnancy has a variety of maternal and fetal adverse effects.[3,17,31] During pregnancy, β-human chorionic gonadotropin (β-hCG)

acts as a TSH receptor agonist, increasing the amount of thyroid hormone available for fetal growth and development.

Maternal hypothyroidism results in an increased rate of miscarriage and decreased intellectual capacity of the child. Endocrinologists recommend a TSH measurement as soon as the pregnancy is confirmed. Most hypothyroid women who become pregnant will quickly need an increased dose of LT$_4$, typically 20% to 50% above the prepregnancy dose.[31] The increased dose should be maintained throughout the pregnancy, with monthly TSH monitoring to keep the TSH in the middle- to low-normal range. After delivery, the LT$_4$ dose usually can be reduced to prepregnancy levels, although patients with preexisting autoimmune thyroiditis may have increased postpartum dose requirements. Because prenatal vitamins contain significant amounts of calcium and iron, remind these patients to take the LT$_4$ dose at least 2 hours before or 6 hours after the vitamin.

**Children** Congenital hypothyroidism is uncommon in the United States, and all newborns in the United States undergo screening with a TSH level. As soon as the hypothyroid state is identified, the newborn should receive the full LT$_4$ replacement dose. The replacement dose of LT$_4$ in children is age dependent. In newborns, the usual dose is 10 to 17 mcg/kg/day. LT$_4$ tablets may be crushed and mixed with breast milk or formula, but it is best to administer LT$_4$ to infants and children on an empty stomach.[32] Serum FT$_4$ levels (target, 1.6–2.2 ng/dL or 20.6–28.3 pmol/L) are used for dose titration in infants because the TSH level may not respond to treatment as it does in older children and adults. By 6 months of age, the required dose is reduced to 5 to 7 mcg/kg/day, and from ages 1 to 10 years, the dose is 3 to 6 mcg/kg/day. After age 12 years, adult doses can be given.

**Myxedema Coma** This is a life-threatening condition owing to severe, long-standing hypothyroidism and has a mortality rate of 60% to 70%. These patients are given 300 to 500 mcg LT$_4$ intravenously initially, using caution in patients with underlying cardiac disease. Although administration of T$_3$ would provide a more rapid onset of action, there is no evidence that T$_3$ improves outcomes in patients with myxedema coma. Historically, glucocorticoids, such as hydrocortisone 50 to 100 mg every 6 hours, are administered owing to concern about simultaneous adrenal insufficiency. Although there is no strong evidence for an outcome benefit, the use of glucocorticoids is reasonable because such treatment may be lifesaving, and the risks of a short course of corticosteroids at this dose are low. As patients improve, the LT$_4$ dose can be given orally in a typical full replacement dose.

## HYPERTHYROIDISM AND THYROTOXICOSIS

Hyperthyroidism is much less common than hypothyroidism. Refer to the Epidemiology of Thyroid Disease section.

### Causes of Thyrotoxicosis and Hyperthyroidism

Hyperthyroidism is related to excess thyroid hormone secreted by the thyroid gland. Thyrotoxicosis is any syndrome caused by excess thyroid hormone and can be related to excess hormone production (hyperthyroidism). The common causes of thyrotoxicosis are shown in Table 44–6.[33–35] Graves disease is the most common cause of hyperthyroidism. Thyrotoxicosis in the elderly is more likely caused by toxic thyroid nodules or multinodular goiter than by Graves disease. Excessive intake of thyroid hormone may be caused by overtreatment with prescribed therapy or as a self-remedy for obesity, as thyroid hormones can be obtained easily without a prescription from health food stores or internet sources.

---

**Patient Encounter 1, Part 2**

One year later, the patient comes to you for routine follow-up stating that she has felt progressively worse since her last visit. She feels more fatigued, and gained 4 more kg and her periods are even heavier now (which she ascribes to stopping her contraceptive). Several months ago she elected to "go natural," and stopped taking all medications except for supplements purchased at a health food store. Her most recent TSH determination, obtained 2 days ago, was 12.8 mIU/L (μIU/mL; reference range, 0.5–4.5 mIU/L or μIU/mL).

*Why is LT$_4$ therapy indicated now?*

*What would you recommend regarding her LT$_4$ dose and monitoring?*

*What instructions would you give the patient regarding her LT$_4$ therapy?*

## Patient Care Process: Hypothyroidism

**Patient Assessment:**

- Evaluate for signs and symptoms of hypothyroidism (see Clinical Presentation and Diagnosis of Hypothyroidism). As signs and symptoms of hypothyroidism are nonspecific, clinicians should have a high index of suspicion in higher risk patients including women and the elderly.
- Use serum TSH to identify patients with hypothyroidism (see Clinical Presentation and Diagnosis of Hypothyroidism), and check TSH in pregnant women as soon as pregnancy is determined.

**Therapy Evaluation:**

- If patient has been or is already receiving pharmacotherapy to treat thyroid disease, assess efficacy, safety, $LT_4$ product received (eg, any recent changes in product) and patient adherence. Are there any significant drug interactions?
- If patient is not at desired TSH level and not on therapy, determine if pharmacotherapy is indicated.

**Care Plan Development:**

- Provide synthetic $LT_4$ replacement to patients with overt hypothyroidism.
- Consider replacement therapy in patients with TSH level of greater than 4.5 but less than 10 mIU/L (µIU/mL) who have nonspecific or subtle symptoms (eg, mild fatigue, lethargy), an elevated cholesterol level, underlying heart disease, or positive anti-TPOAbs.
- Patients with mild hypothyroidism may be started at 25 to 50 mcg/day of $LT_4$.
- Patients with overt hypothyroidism who are older than 12 and younger than 65 years and do not have cardiac disease

may receive the calculated full replacement $LT_4$ dose of 1.6 mcg/kg/day (based on ideal body weight if obese).

- Elderly patients or those with cardiac disease should be started at a lower $LT_4$ dose (eg, 12.5–25 mcg/day).
- Provide a brand-name $LT_4$ product, and do not allow product switches. If the product is switched, check TSH in 6 weeks and retitrate the dose.
- Provide $LT_4$ prescriptions as microgram, not milligram, doses to avoid errors.
- Make sure patients understand importance of adherence and risks of overuse and underuse of $LT_4$.
- In pregnant patients, expect to increase $LT_4$ dose early in first trimester. Maintain TSH in low to middle normal range. After delivery, consider reducing $LT_4$ dose to prepregnancy level, if appropriate.

**Follow-up Evaluation:**

- Measure serum TSH 6 to 8 weeks after starting or after any dose change. If TSH level is not in target range, alter dose by 10% to 20% increments. Target TSH for patients on $LT_4$ replacement therapy for hypothyroidism is 0.5 to 2.5 mIU/L (µIU/mL). Younger patients often feel best at a TSH level in the low- to middle-normal range (ie, 0.5–1.5 mIU/L or µIU/mL).
- Check TSH every 6 to 12 months in stable patients receiving $LT_4$ replacement.
- Monitor for drug interactions, such as $LT_4$ absorption problems caused by calcium and iron.
- At each visit, assess for signs and symptoms of overtreatment and undertreatment.
- In pregnant patients, check TSH monthly.

---

| Table 44–6 |
|---|

**Causes of Thyrotoxicosis[33–35]**

**Primary Hyperthyroidism**
Graves disease
Toxic multinodular goiter
Toxic adenoma
Thyroid cancer
Struma ovarii
Iodine excess (including radiocontrast, amiodarone)

**Thyrotoxicosis without Hyperthyroidism**
Subacute thyroiditis
Silent (painless) thyroiditis
Excess thyroid hormone intake (thyrotoxicosis factitia)
Drug-induced (amiodarone, iodine, lithium, interferons)

**Secondary Hyperthyroidism**
TSH-secreting pituitary tumors
Trophoblastic (hCG-secreting) tumors
Gestational thyrotoxicosis

hCG, human chorionic gonadotropin; TSH, thyroid-stimulating hormone.

## Clinical Manifestations of Thyrotoxicosis

Many of the signs and symptoms seem to be related to autonomic hyperactivity. The clinical manifestations of hyperthyroidism may be subtle and slowly progressive. Screening of patients for thyroid disease may identify patients with subclinical or mild thyrotoxicosis. Patients may seek medical attention only after a long period of thyrotoxicosis or owing to an acute complication such as atrial fibrillation. Clinical manifestations of thyrotoxicosis in the elderly may be blunted or atypical. These patients may present only with atrial fibrillation, depression, or altered mental status or cognition.

### Mild (Subclinical) Hyperthyroidism

Mild (subclinical) hyperthyroidism is defined as a low TSH level with a normal $FT_4$ level.[13,26] Although there may be few or no symptoms in these patients, there are several areas of concern.[14,33] Some patients progress to overt thyrotoxicosis. Patients with subclinical hyperthyroidism have been shown to experience long-term cardiovascular[33,36] and bone sequelae.[37] Mild hyperthyroidism appears to increase cardiovascular morbidity and mortality.[36] Prolonged subclinical thyrotoxicosis speeds

---

**Clinical Presentation and Diagnosis of Hyperthyroidism[33–35]**

**Symptoms**

- Nervousness
- Fatigue
- Weakness
- Increased perspiration
- Heat intolerance
- Tremor
- Hyperactivity, irritability
- Palpitations
- Appetite change (usually increased)
- Weight change (usually weight loss)
- Menstrual disturbances (often oligomenorrhea)
- Diarrhea

**Signs**

- Hyperactivity
- Tachycardia

- Atrial fibrillation (especially in elderly adults)
- Hyperreflexia
- Warm, moist skin
- Ophthalmopathy, dermopathy (Graves disease)
- Goiter
- Muscle weakness

**Screening/Diagnosis**

- Low TSH level (less than 0.5 mIU/L or μIU/mL) signifies thyrotoxicosis.
- $FT_4$ is elevated in overt hyperthyroidism but may be normal in mild hyperthyroidism.
- Increased radioiodine uptake in the thyroid indicates increased hormone production by the thyroid gland.
- Almost all patients with Graves disease will have positive TSHR-SAbs and positive anti-TPOAbs.

---

the loss of bone mineral density and increases fracture rates in postmenopausal women.[33,37] Treatment of patients with mild hyperthyroidism is controversial but should be considered in patients with TSH levels less than 0.1 mIU/L (μIU/mL), Graves disease, postmenopausal women, and patients with underlying cardiovascular disease.[33] Patients who do not have a fully suppressed (below the lower limit of detection) TSH or other risk factors for hyperthyroid complications (eg, osteoporosis, cardiac arrhythmias) may just undergo observation, with TSH testing every 6 months to identify progression of the hyperthyroid state.

### Graves Disease

Graves disease is an autoimmune syndrome that includes hyperthyroidism, diffuse thyroid enlargement, exophthalmos and other eye findings, and skin findings.[33–35] The prevalence of Graves disease in the United States is approximately 0.4% in women and 0.1% in men. The peak age of incidence is 20 to 49 years, with a second peak after 80 years of age. Hyperthyroidism results from the production of TSHR-SAbs in at least 80% of patients with clinical Graves disease. These antibodies have TSH agonist activity, thereby stimulating hormone synthesis and release. These antibodies cross-react with orbital and fibroblastic tissue, resulting in ophthalmopathy and dermopathy. Although the underlying cause of Graves disease is not known, heredity seems to play a role. Subclinical Graves disease may become acutely overt in the presence of iodine excess, infection, stress, parturition, smoking, and lithium and cytokine therapy.

Several features of Graves disease are distinct from other forms of thyrotoxicosis. Clinically apparent ophthalmopathic changes are seen in 20% to 40% of patients[34,35,38] and include exophthalmos, proptosis, chemosis, conjunctival injection, and periorbital edema. Eyelid retraction causes a typical staring or startled appearance (Figure 44–3). Patients may complain of vague eye discomfort and excess tearing. In severe cases, the eyelids are unable to close completely, resulting in corneal damage. In very severe cases, the optic nerve can be compressed, resulting

in permanent vision loss. All patients with suspected or known Graves disease must be evaluated and monitored by an ophthalmologist. Treatment of the underlying hyperthyroid state often, but not always, improves the ophthalmopathy.

Dermopathy occurs in 5% to 10% of patients with Graves disease and usually is associated with severe ophthalmopathy. Skin findings include hyperpigmented, nonpitting induration of the skin, typically over the pretibial area (pretibial myxedema), the dorsa of the feet, and the shoulder areas. Clubbing of the digits (thyroid acropachy) is associated with long-standing thyrotoxicosis.

### Treatment of Hyperthyroidism

Treatment of thyrotoxicosis caused by hyperthyroidism is similar regardless of the underlying cause.[33–35] **KEY CONCEPT** *The goals of treating hyperthyroidism are to relieve signs and symptoms, reduce thyroid hormone production to normal levels and achieve biochemical euthyroidism, and prevent long-term adverse sequelae.*

#### ▶ β-Blockers

Because many of the manifestations of hyperthyroidism appear to be mediated by the β-adrenergic system, β-adrenergic blockers are used to rapidly relieve palpitations, tremor, anxiety, and heat intolerance. Because β-blockers do not reduce the synthesis of thyroid hormones, they are used only until more specific antithyroid therapy is effective. Because nonselective agents can impair the conversion of $T_4$ to $T_3$, propranolol and nadolol are preferred. An initial propranolol dose of 20 to 40 mg four times daily should be titrated to relieve signs (target resting heart rate less than 90 beats/min) and symptoms. β-Blockers should not be used in patients with decompensated heart failure or asthma. A more β-1 specific blocker (eg, metoprolol, atenolol) may be used when a relative contraindication to a β-blocker exists; however, when an absolute contraindication to β-blockers exists, clonidine, verapamil or diltiazem may be used for rate control.

**FIGURE 44–3.** Features of Graves disease. (**A**) Facial appearance: exophthalmos, eyelid retraction, periorbital edema, and proptosis. (**B**) Thyroid dermopathy over lateral aspects of the shins (*arrow*). (**C**) Thyroid clubbing or acropachy (*arrow*). (From Jameson JL, Weetman AP. Disorders of the thyroid gland. ### ▶ Methods to Reduce Thyroid Hormone Synthesis

Excess production of thyroid hormone can be reduced in four ways: iodides, antithyroid drugs, radioactive iodine, and surgery.

**Iodide** Large doses of iodide inhibit the synthesis and release of thyroid hormones. Serum $T_4$ levels may be reduced within 24 hours, and the effects may last for 2 to 3 weeks. Iodides are used most commonly in Graves disease patients before surgery and to quickly reduce hormone release in patients with thyroid storm. Potassium iodide is administered either as a saturated solution (SSKI) that contains 38 mg iodide per drop or as Lugol solution, which contains 6.3 mg iodide per drop. The typical starting dose is 120 to 400 mg/day. Iodide therapy should start 7 to 14 days before surgery. Iodide should not be given before radioactive iodine treatment because the iodide will inhibit concentration of the radioactivity in the thyroid. Iodides also are used to protect the thyroid from radioactive iodine fallout after a nuclear accident or attack. Daily administration of 30 to 100 mg iodide markedly reduces thyroid gland uptake of radioactive iodine. The most frequent toxic effects with iodide therapy are hypersensitivity reactions, "iodism" (characterized by palpitations, depression, weight loss, and pustular skin eruptions), and gynecomastia.

**Antithyroid Drugs** The thionamide agents propylthiouracil (PTU) and methimazole (MMI) are used in the United States to treat hyperthyroidism.[39] Carbimazole, an MMI prodrug, is used in some countries (10 mg carbimazole = 6 mg MMI). These drugs inhibit thyroid hormone synthesis by interfering with thyroid peroxidase–mediated iodination of tyrosine residues in thyroglobulin. PTU has the added effect of inhibiting the conversion of $T_4$ to $T_3$. The thionamides also have immunosuppressant effects. In patients with Graves disease treated with thionamides, TSHR-SAb levels and other immune mediators decrease over time. Both drugs are well absorbed from the gastrointestinal (GI) tract. PTU has a half-life of 1 to 2.5 hours, whereas the half-life of MMI is 6 to 9 hours.

Antithyroid drugs are used as primary therapy for Graves disease or as preparative therapy before surgery or radioactive iodine administration. The decision to use antithyroid drugs as primary therapy must be weighed against the risks and benefits of radioiodine or surgery. Patient preference must be considered.

In most patients, there is no clear efficacy advantage of one thionamide over the other, but in the United States, MMI use has increased dramatically since the mid-1990s in lieu of PTU.[40] Although PTU has the advantage of inhibiting $T_4$-to-$T_3$ conversion, MMI can be given as a single daily dose and may have a better overall safety profile, particularly less hepatotoxicity. MMI is preferred to normalize thyroid function before radioactive iodine therapy, although both thionamides increase the failure rate of radioactive iodine therapy.[41] The usual starting dose of MMI is 10 to 20 mg/day, and the usual starting dose of PTU is 50 to 150 mg three times daily. Thyroid hormone levels drop in 2 to 3 weeks, and after 6 weeks, 90% of patients with Graves disease will be euthyroid. Thyroid function testing should be performed every 4 to 6 weeks until stable. After the patient becomes euthyroid, the antithyroid drug dose often can be decreased (5–10 mg/day MMI, 100–200 mg/day PTU) to maintain the euthyroid state. Excessive doses of antithyroid drugs will result in hypothyroidism.

Remission of Graves disease occurs in 40% to 60% of patients after 1 to 2 years of therapy. Antithyroid therapy may be stopped or tapered after 12 to 24 months. Relapse usually occurs in the first 3 to 6 months after stopping antithyroid therapy. Levels of TSHR-SAb after a course of treatment may have predictive value for the risk of relapse in that antibody-positive patients almost always relapse. However, antibody-negative patients also may relapse after therapy is stopped. About 75% of women in remission who become pregnant will have a postpartum relapse. When therapy is discontinued, a therapeutic strategy should be in place in the event of relapse. Many patients will opt for radioactive iodine as a long-term solution.

Antithyroid drugs are associated with an overall low rate of adverse effects, although serious adverse effects can occur. In

2010, the FDA released a new boxed warning on severe liver injury with PTU.[42] The warning states that PTU should only be used in patients who cannot tolerate MMI. Skin rash, arthralgias, and GI upset are seen in 5% of patients. Although the drug can be continued in the presence of a minor skin rash, the development of arthralgia warrants discontinuation. Hepatotoxicity is an uncommon but potentially serious or fatal adverse effect, occurring in 0.1% to 0.2% of patients. However, transient rises in aminotransferase enzyme levels are seen in up to 30% of patients treated with PTU. Severe hepatocellular damage can occur from PTU, whereas MMI can cause cholestatic jaundice. Antineutrophil cytoplasmic antibody (ANCA) vasculitis is another potentially serious but uncommon reaction that is more common with PTU, and patients may develop a drug-induced lupus syndrome.

**KEY CONCEPT** *Agranulocytosis is one of the most serious adverse effects of antithyroid drug therapy.* Agranulocytosis must be distinguished from a transient decrease in white blood cell count seen in up to 12% of adults and 25% of children with Graves disease. Agranulocytosis occurs in 0.3% of patients, and the incidence may be the same with PTU and MMI therapy. Lower doses of MMI may be associated with a lower incidence of agranulocytosis.[33] Agranulocytosis, thought to be autoimmune, almost always occurs within the first 3 months of therapy, and it occurs suddenly and unpredictably. Patients will present with fever, malaise, and a sore throat, and the absolute neutrophil count will be less than 1000/mm³ ($1 \times 10^9$/L). Patients may develop sepsis and die rapidly. If agranulocytosis occurs, discontinue the antithyroid drug immediately, administer broad-spectrum antibiotics if the patient is febrile, and consider administration of filgrastim. The white blood cell count should recover in 1 or 2 weeks. Patients who develop agranulocytosis should not be switched to another thionamide drug. Monitoring for agranulocytosis is controversial owing to its sudden and unpredictable nature. Most do not recommend routine monitoring of the complete blood count (CBC), although early detection could improve patient outcomes. Patients initiating thionamide therapy must be informed about the signs and symptoms of agranulocytosis and other serious side effects. Patients should be counseled to report signs and symptoms suggestive of infection, such as fever and sore throat lasting more than 2 or 3 days, bruising, pruritic rash, jaundice, dark urine, arthralgias, abdominal pain, nausea, or fatigue.

**Radioactive Iodine** Radioactive iodine, typically ¹³¹I, produces thyroid ablation without surgery. ¹³¹I is well absorbed after oral administration. The iodine is concentrated in the thyroid gland and has a half-life of 8 days. Over a period of weeks, thyroid cells that have taken up the ¹³¹I begin to develop abnormalities and necrosis. Eventually, thyroid cells are destroyed, and hormone production is reduced. After a single dose, 40% to 70% of patients will be euthyroid in 6 to 8 weeks, and 80% will be cured. In most patients, hypothyroidism will develop, and long-term LT$_4$ replacement will be necessary. Because ¹³¹I has a slow onset of action, most patients are treated initially with β-blockers and antithyroid drugs to prevent ¹³¹I-induced thyroid storm. MMI is the preferred agent before the administration of ¹³¹I. MMI is discontinued 3 to 5 days before the administration of ¹³¹I and is restarted 3 to 7 days later. MMI is then slowly tapered over the next 4 to 6 weeks as thyroid function normalizes. β-Blockers can be continued during ¹³¹I therapy. The dose of ¹³¹I is based on the estimated weight of the patient's thyroid gland (typical dose, 10–15 mCi [370–555 MBq]). Radioactive iodine therapy is contraindicated during pregnancy and breast-feeding. Radioactive iodine therapy may acutely worsen Graves ophthalmopathy. Patients with prominent eye disease may be started on prednisone 40 mg/day, with the dose tapered over 2 to 3 months. Radioactive iodine also may cause a painful thyroiditis, which may necessitate anti-inflammatory therapy. No long-term carcinogenic effect of ¹³¹I has been demonstrated in clinical trials.

**Surgery** Subtotal thyroidectomy is indicated in patients with very large goiters and thyroid malignancies and those who do not respond or cannot tolerate other therapies. Patients must be euthyroid before surgery, and they are often administered iodide preoperatively to reduce gland vascularity. The overall surgical complication rate is 2.7%. Postoperative hypothyroidism occurs in 10% of patients who undergo subtotal thyroidectomy. After thyroidectomy, serum calcium and intact parathyroid hormone levels should be monitored for early identification of postoperative hypoparathyroidism.

Postoperative administration of 1250 to 2500 mg/day of calcium and 0.5 mcg/day of calcitriol may be given and then tapered over 1 to 2 weeks if the patient does not develop hypoparathyroidism.

▶ *Special Conditions and Populations*

**Graves Disease and Pregnancy** Pregnancy may worsen or precipitate thyrotoxicosis in women with underlying Graves disease owing to the TSH agonist effect of β-hCG.[31,43] Untreated maternal thyrotoxicosis may result in increased rates of miscarriage, premature delivery, eclampsia, and low-birth-weight infants. Fetal and neonatal hyperthyroidism may occur as a result of transplacental passage of TSHR-SAbs. Because radioactive iodine is contraindicated and surgery is best avoided during pregnancy, most patients are treated with antithyroid drugs. PTU is considered the treatment of choice, particularly in the first trimester. While MMI is thought to have greater teratogenic potential versus PTU, the relative safety of these medications in pregnancy is not clear.[44] Patients receiving prepregnancy MMI should be switched to PTU as soon as the pregnancy is confirmed. The lowest possible dose of PTU to maintain maternal euthyroidism should be used. Given the potential maternal adverse effects of PTU (eg, hepatotoxicity), it may be preferable to switch from PTU to MMI for the second and third trimesters.[42] Antithyroid therapy in excessive doses may suppress fetal thyroid function. Although PTU and MMI are found in breast milk, nursing mothers should be switched to MMI after delivery because of the risk of hepatotoxicity from PTU in the mother and infant.

**Pediatric Hyperthyroidism** β-Blockers are administered to children who are symptomatic or have a heart rate greater than 100 beats/min.[33] MMI is the preferred antithyroid drug therapy in children at a dose of 0.2 to 0.5 mg/kg/day.[33] Once a euthyroid state is achieved, the MMI dose can be reduced by 50% or more to maintain euthyroidism. As in adults, antithyroid drugs are administered to children with Graves disease for 1 to 2 years. If remission does not occur in that time, long-term antithyroid drug therapy, radioactive iodine, or surgical therapy is offered. Long-term studies with ¹³¹I use in children show no increased risk of thyroid cancer or leukemia.

**Thyroid Storm** Thyroid storm is a life-threatening condition caused by severe thyrotoxicosis.[33,45] Signs and symptoms include high fever, tachycardia, tachypnea, dehydration, delirium, coma, and GI disturbances. Thyroid storm is precipitated in a previously hyperthyroid patient by infection, trauma, surgery, radioactive iodine treatment, and sudden withdrawal from antithyroid drugs. Patients are treated with a short-acting β-blocker such as intravenous (IV) esmolol, IV or oral iodide, and large doses of

## Patient Encounter 2

A 19-year-old woman comes to the clinic stating, "I'm so jumpy and sweaty and hungry, and I'm losing weight. I think I'm losing my mind. What is wrong with me?" She first noticed these symptoms 3 months ago, and they have worsened steadily. She feels anxious for no reason and has trouble sleeping. She has noticed that her appetite has increased, although she has lost about 2 kg (4.4 lb) over the past 3 months. Sometimes she can feel her heart beating in her chest, but she denies chest pain or syncope. Her only medications are a vitamin product, occasional naproxen for headaches, and a hormonal contraceptive. She thinks that her mother had some kind of thyroid problem when she was pregnant with her.

**PE:**

**VS:** Pulse 122 beats/min, BP 106/71 mm Hg, RR 12 breaths/min, T 37.8°C (100.1°F)

**HEENT:** Diffusely enlarged thyroid; mild exophthalmos

**CV:** Tachycardic, RRR

**Exts:** Fine tremor

**Skin:** Warm, moist, and soft

**ECG:** Sinus tachycardia

**Labs:** Electrolytes, CBC normal. TSH less than 0.1 mIU/L (μIU/mL; reference range 0.5–2.5 mIU/L or μIU/mL); FT$_4$ 4.2 ng/dL (54.1 pmol/L; reference range 0.7–1.9 ng/dL, or 9.0–24.5 pmol/L); + TSHR-SAbs

*What therapeutic options exist for this patient's Graves disease?*

*What pharmacotherapy would you recommend? What if she were pregnant?*

*How would you initiate and titrate therapy?*

*What would you tell the patient regarding the cause of her signs and symptoms, significance of her abnormal thyroid function tests, and therapeutic options?*

PTU (500–1000 mg load; then 250 mg every 4 hours) or MMI (60–80 mg/day). Supportive care with acetaminophen to suppress fever, fluid and electrolyte management, and antiarrhythmic agents are important components of therapy. IV hydrocortisone 300 mg initially and then 100 mg every 8 hours is used often because of the potential presence of adrenal insufficiency.

## NONTHYROIDAL ILLNESS (EUTHYROID SICK SYNDROME)

A number of changes in the hypothalamic–pituitary–thyroid axis occur during acute illness.[46] These changes are termed *nonthyroidal illness* or *euthyroid sick syndrome*. The type and degree of abnormalities depend on the severity of illness. Mild to moderate

## Patient Care Process: Hyperthyroidism

**Patient Assessment:**

- A low or undetectable TSH level identifies thyrotoxicosis. See Clinical Presentation and Diagnosis of Hyperthyroidism.
- Via a diagnostic assessment, identify the underlying cause. (eg, presence of eye and/or skin findings and presence of TSHR-SAbs may be used to identify Graves disease).

**Therapy Evaluation:**

- If patient has been or is currently receiving pharmacotherapy to treat hyperthyroidism, assess efficacy, safety, and patient adherence. Are there any significant drug interactions?
- If patient is not at desired TSH level, determine if pharmacotherapy is indicated.

**Care Plan Development:**

- Treat severe or troublesome autonomic signs and symptoms with a nonselective β-blocker such as propranolol 20 to 40 mg four times daily. Titrate β-blocker dose based on signs and symptoms.
- Consider reducing excess thyroid hormone production with an antithyroid drug and/or radioactive iodine. If radioactive iodine is given, make sure that antithyroid drugs are stopped 4 to 6 days before treatment.
- MMI is the antithyroid drug of choice in most patients.

- Refer patients with Graves disease to an ophthalmologist for assessment and monitoring.
- Treat pregnant hyperthyroid women with PTU.
- Address any patient concerns regarding therapy.

**Follow-up Evaluation:**

- Monitor patients on antithyroid drugs for signs and symptoms of adverse effects. For example,
  - After baseline CBC with differential and liver profile, repeat CBC when patient has a febrile illness and repeat liver panel if signs or symptoms of hepatotoxicity occur (some recommend routine monitoring during the first 6 months of therapy).
  - Assess any skin rash or development of arthralgias.
- Antithyroid drugs have a delayed effect. After 2 to 4 weeks of therapy, adjust the dose if TSH is not in target range (0.5–2.5 mIU/L or μIU/mL). When patient is euthyroid, consider reducing dose of antithyroid drug to avoid hypothyroidism.
- Consider stopping antithyroid therapy in patients with Graves disease after 12 to 18 months to see if remission has occurred.
- Several months after radioactive iodine, expect that the patient will require permanent LT$_4$ replacement; thus, evaluate for such.

medical illness, surgery, or starvation causes a decrease in serum $T_3$ levels owing to decreased peripheral conversion of $T_4$ to $T_3$. The reduced $T_3$ levels do not correlate with ultimate mortality and are thought to be an adaptive response to stress. Patients with more severe illness, especially those in the intensive care unit, frequently have reduced total $T_4$ levels, although $FT_4$ levels often are normal. In critically ill patients, there is a correlation between degree of serum $T_4$ reduction and mortality. In most acutely ill patients who are euthyroid, TSH level is normal. However, administration of dopamine, octreotide, or high doses of glucocorticoids can reduce TSH levels. During recovery from acute illness, the TSH level may become modestly elevated to renormalize serum $T_4$ levels. During this time, thyroid function tests may be misinterpreted to indicate hypothyroidism. Despite the sometimes very low $T_4$ levels, there is no evidence that $LT_4$ administration has any survival benefit.[47] Patients with possible thyroid abnormalities during acute illness should be evaluated by an endocrinologist.

## THYROID CANCER AND LT$_4$ SUPPRESSION

**KEY CONCEPT** *The growth and spread of thyroid carcinoma are stimulated by TSH. An important component of thyroid carcinoma management is the use of $LT_4$ to suppress TSH secretion. Early in therapy, patients receive the lowest $LT_4$ dose sufficient to fully suppress TSH to undetectable levels. Controlled trials show that suppressive $LT_4$ therapy reduces tumor growth and improves survival. These patients are purposefully "overtreated" with $LT_4$, sometimes to a fully suppressed TSH level, and rendered subclinically or mildly hyperthyroid. Postmenopausal women should receive aggressive osteoporosis therapy to prevent $LT_4$-induced bone loss. Other thyrotoxic complications, such as atrial fibrillation, should be monitored and managed appropriately.*

## DRUG-INDUCED THYROID ABNORMALITIES

Drugs can affect thyroid function in a number of ways.[3,11] The effects of drugs on thyroid hormone protein binding, $LT_4$ absorption, and metabolism have been discussed previously. Several commonly used medications can alter thyroid hormone secretion.

### Amiodarone

Amiodarone is a commonly prescribed antiarrhythmic drug that contains two iodide atoms, constituting 38% of its mass.[48] Each 200-mg dose of amiodarone provides 75 mg of iodide. Amiodarone deiodination releases about 6 mg of free iodine daily, 20 to 40 times more than the average daily intake of iodine in the United States. Amiodarone blocks conversion of $T_4$ to $T_3$, inhibits entry of $T_3$ into cells, and decreases $T_3$ receptor binding. Amiodarone causes rapid reduction in serum $T_3$ levels, increases free and total $T_4$ levels, and increases TSH level. After 3 months of therapy, TSH levels usually return to normal, although the serum $T_3$ and $T_4$ level changes may remain. Most of these patients are euthyroid because the $FT_3$ levels are in the low-normal range.

Amiodarone can frequently cause thyroid abnormalities in previously euthyroid patients. In a study of amiodarone treatment of persistent atrial fibrillation, 25.8% of patients developed subclinical hypothyroidism, and 5% developed overt hypothyroidism.[49] Hyperthyroidism occurred in 5.3%. Thyroid abnormalities, when they occurred, were seen within 6 months of initiation of amiodarone therapy in almost all patients. Amiodarone-induced hypothyroidism is more common in iodine-sufficient areas of the world. Patients with underlying autoimmune thyroiditis are much more likely to develop amiodarone-induced hypothyroidism. Amiodarone-induced hypothyroidism occurs most commonly within the first year of therapy. If amiodarone cannot be discontinued, $LT_4$ therapy will be effective in most patients. If amiodarone can be stopped, thyroid function will return to normal in 2 to 4 months.

Amiodarone is more likely to cause thyrotoxicosis in iodine-deficient areas. Type 1 amiodarone-induced thyrotoxicosis is caused by iodine excess and typically occurs in patients with pre-existing multinodular goiter or subclinical Graves disease. Type 2 amiodarone-induced thyrotoxicosis is a destructive thyroiditis that occurs in patients with no underlying thyroid disease. Amiodarone-induced thyrotoxicosis is more common in men. Because amiodarone has β-blocking activity, palpitations and tachycardia may be absent. In type 1 thyrotoxicosis, amiodarone should be discontinued. If amiodarone therapy cannot be stopped, larger doses of antithyroid drugs may be needed to control thyrotoxicosis. In type 2 thyroiditis, stopping amiodarone may not be necessary because spontaneous resolution may occur. Prednisone 40 to 60 mg/day will quickly improve thyrotoxic symptoms. Prednisone may be tapered after 1 to 2 months of therapy.

**KEY CONCEPT** *Patients receiving amiodarone must receive monitoring for thyroid abnormalities. Baseline measurements of serum TSH, $FT_4$, $FT_3$, anti-TPOAbs, and TSHR-SAbs should be performed. TSH, $FT_4$, and $FT_3$ should be checked 3 months after initiation of amiodarone and then a TSH at least every 3 to 6 months.*

### Lithium

Lithium is associated with hypothyroidism in up to 34% of patients, and hypothyroidism may occur after years of therapy.[50] Lithium appears to inhibit thyroid hormone synthesis and secretion. Patients with underlying autoimmune thyroiditis are more likely to develop lithium-induced hypothyroidism. Patients may require $LT_4$ replacement even if lithium is discontinued.

### Interferon-α

Interferon-α causes hypothyroidism in up to 39% of patients being treated for hepatitis C infection.[3,11] Patients may develop a transient thyroiditis with hyperthyroidism before becoming hypothyroid. The hypothyroidism may be transient as well. Asians and patients with preexisting anti-TPOAbs are more likely to develop interferon-induced hypothyroidism. The mechanism of interferon-induced hypothyroidism is not known. If $LT_4$ replacement is initiated, it should be stopped after 6 months to reevaluate the need for replacement therapy.

### Tyrosine Kinase Inhibitors

Tyrosine kinase inhibitors (TKIs) are targeted antineoplastic agents used in several types of malignancies, including thyroid cancer.[12] Several TKIs have significant effects on thyroid function, both in previously hypothyroid patients on $LT_4$ replacement and in previously euthyroid patients. Imatinib has been shown to cause a fourfold increase in TSH levels in patients being treated for thyroid cancer. Sunitinib and sorafenib have been associated with primary hypothyroidism in 20% to 40% of treated patients. Some sorafenib patients developed mild hyperthyroidism before becoming hypothyroid. Patients receiving TKI therapy should have baseline and periodic thyroid function monitoring.

## OUTCOME EVALUATION

- Desired outcomes include relieving signs and symptoms and achieving a euthyroid state.

- Success of therapy for thyroid disorders must be based not only on short-term improvement of the patient's clinical status and abnormal laboratory values but also on achievement of a long-term, stable euthyroid state. Maintaining TSH level in the normal range improves symptoms and reduces the risk of long-term complications.

- Because pharmacotherapy often is lifelong, especially in patients with hypothyroidism, patients must undergo periodic monitoring to avoid long-term complications. In hypothyroid patients, such monitoring may involve simply asking the patient about signs and symptoms and a yearly measurement of TSH level.

- Any change in the patient's clinical status, such as a new pregnancy or a major change in body weight, necessitates a reevaluation of therapy. Patients at high risk for complications, such as pregnant women, the elderly, and patients with underlying cardiac disease, must be monitored more closely.

- Patients should be educated and periodically reminded about the importance of adherence and long-term tight control, the need for periodic clinical and laboratory monitoring, and the importance of staying on one $LT_4$ product.

- In hyperthyroid patients, the method of achieving desired outcomes may change over time with the use of antithyroid drugs versus radioactive iodine.

- Patients who receive antithyroid drugs must be monitored for adverse drug events such as hepatotoxicity and agranulocytosis.

- Patients who receive radioactive iodine must be monitored for development of hypothyroidism.

- In patients with thyroid cancer, the desired outcomes with $LT_4$ therapy often are different from those in hypothyroid patients. $LT_4$ doses sufficient to suppress tumor growth may result in a suppressed TSH and mild hyperthyroidism. These patients must be monitored closely for complications of the mild hyperthyroid state, such as bone mineral loss and development of atrial fibrillation.

## Abbreviations Introduced in This Chapter

| | |
|---|---|
| ANCA | Antineutrophil cytoplasmic antibody |
| ANDA | Abbreviated New Drug Application |
| Anti-TGAb | Antithyroglobulin antibody |
| Anti-TPOAb | Antithyroid peroxidase antibody |
| AUC | Area under the (time-concentration) curve |
| β-hCG | β-Human chorionic gonadotropin |
| CBC | Complete blood count |
| CNS | Central nervous system |
| FDA | Food and Drug Administration |
| $FT_3$ | Free $T_3$ |
| $FT_4$ | Free $T_4$ |
| GI | Gastrointestinal |
| hCG | Human chorionic gonadotropin |
| IV | Intravenous |
| LDL | Low-density lipoprotein |
| $LT_4$ | Levothyroxine |
| MMI | Methimazole |
| NHANES | National Health and Nutrition Examination Survey |
| NTI | Narrow therapeutic index |
| PTU | Propylthiouracil |
| RAIU | Radioactive iodine uptake |
| SSKI | Saturated solution of potassium iodide |

| | |
|---|---|
| $T_3$ | Triiodothyronine |
| $T_4$ | Thyroxine |
| TBG | Thyroxine-binding globulin |
| TKI | Tyrosine kinase inhibitor |
| TRH | Thyrotropin-releasing hormone |
| TSH | Thyroid-stimulating hormone (thyrotropin) |
| TSHR-Sab | Thyroid-stimulating hormone receptor-stimulating antibodies |
| TSI | Thyroid-stimulating immunoglobulin |

# 45 Adrenal Gland Disorders

Devra K. Dang, Judy T. Chen, Frank Pucino, Jr, and Karim Anton Calis

## LEARNING OBJECTIVES

**Upon completion of the chapter, the reader will be able to:**

1. Explain the regulation and physiologic roles of hormones produced by the adrenal glands.
2. Recognize the clinical presentation of adrenal insufficiency.
3. Describe the pharmacologic management of acute and chronic adrenal insufficiency.
4. Recommend therapy monitoring parameters for adrenal insufficiency.
5. Recognize the clinical presentation of Cushing syndrome and the physiologic consequences of cortisol excess.
6. Describe the pharmacologic and nonpharmacologic management of Cushing syndrome.
7. Recommend strategies to prevent the development of hypercortisolism and hypocortisolism.
8. Recommend therapy monitoring parameters for Cushing syndrome.

## INTRODUCTION

The adrenal glands are important in the synthesis and regulation of key human hormones. They play a crucial role in water and electrolyte homeostasis, as well as regulation of blood pressure, carbohydrate and fat metabolism, physiologic response to stress, and sexual development and differentiation. This chapter focuses on pharmacologic and nonpharmacologic management of the two most common conditions associated with adrenal gland dysfunction: glucocorticoid insufficiency (eg, Addison disease) and glucocorticoid excess (Cushing syndrome). Other adrenal disorders such as congenital adrenal hyperplasia, pheochromocytoma, hypoaldosteronism, and hyperaldosteronism are beyond the scope of this chapter.

## PHYSIOLOGY, ANATOMY, AND BIOCHEMISTRY OF THE ADRENAL GLAND

The adrenal gland is located on the upper segment of the kidney. It consists of an outer cortex and an inner medulla. The adrenal medulla secretes the catecholamines epinephrine (also called adrenaline) and norepinephrine (also called noradrenaline), which are involved in the regulation of the sympathetic nervous system. The adrenal cortex consists of three histologically distinct zones: the outer zona glomerulosa, the zona fasciculata, and an innermost layer called the zona reticularis. Each zone is responsible for production of different hormones (Figure 45–1).[1]

The zona glomerulosa is responsible for the production of the mineralocorticoids aldosterone, 18-hydroxy-corticosterone, corticosterone, and deoxycorticosterone. Aldosterone promotes renal sodium retention and potassium excretion. Its synthesis and release are regulated by renin in response to decreased vascular volume and renal perfusion. Adrenal aldosterone production is regulated by the renin-angiotensin-aldosterone system.

The zona fasciculata is the middle layer and produces the glucocorticoid hormone cortisol. Cortisol is responsible for maintaining homeostasis of carbohydrate, protein, and fat metabolism. Its secretion follows a circadian rhythm, generally beginning to rise at approximately 3 to 4 AM and peaking around 6 to 8 AM. Thereafter, cortisol levels decrease throughout the day, approach 50% of the peak value by 4 PM, and reach their nadir around midnight.[2] The normal rate of cortisol production is approximately 8 to 15 mg/day.[3] Cortisol plays a key role in the body's response to stress. Its production increases markedly during physiologic stress, such as during acute illness, surgery, or trauma. In addition, certain conditions such as alcoholism, depression, anxiety disorder, obsessive-compulsive disorder, poorly controlled diabetes, morbid obesity, starvation, anorexia nervosa, and chronic renal failure are associated with increased cortisol levels. High total cortisol levels are also observed in the presence of increased cortisol binding globulin (the carrier protein for 80% of circulating cortisol molecules), which is seen in pregnancy or other high-estrogen states (eg, exogenous estrogen administration).[2] Cortisol is converted in the liver to an inactive metabolite known as cortisone.

The zona reticularis produces the androgens androstenedione, dehydroepiandrosterone (DHEA), and the sulfated form of dehydroepiandrosterone (DHEA-S). Only a small amount of testosterone and estrogen is produced in the adrenal glands. Androstenedione and DHEA are converted in the periphery, largely to testosterone and estrogen.

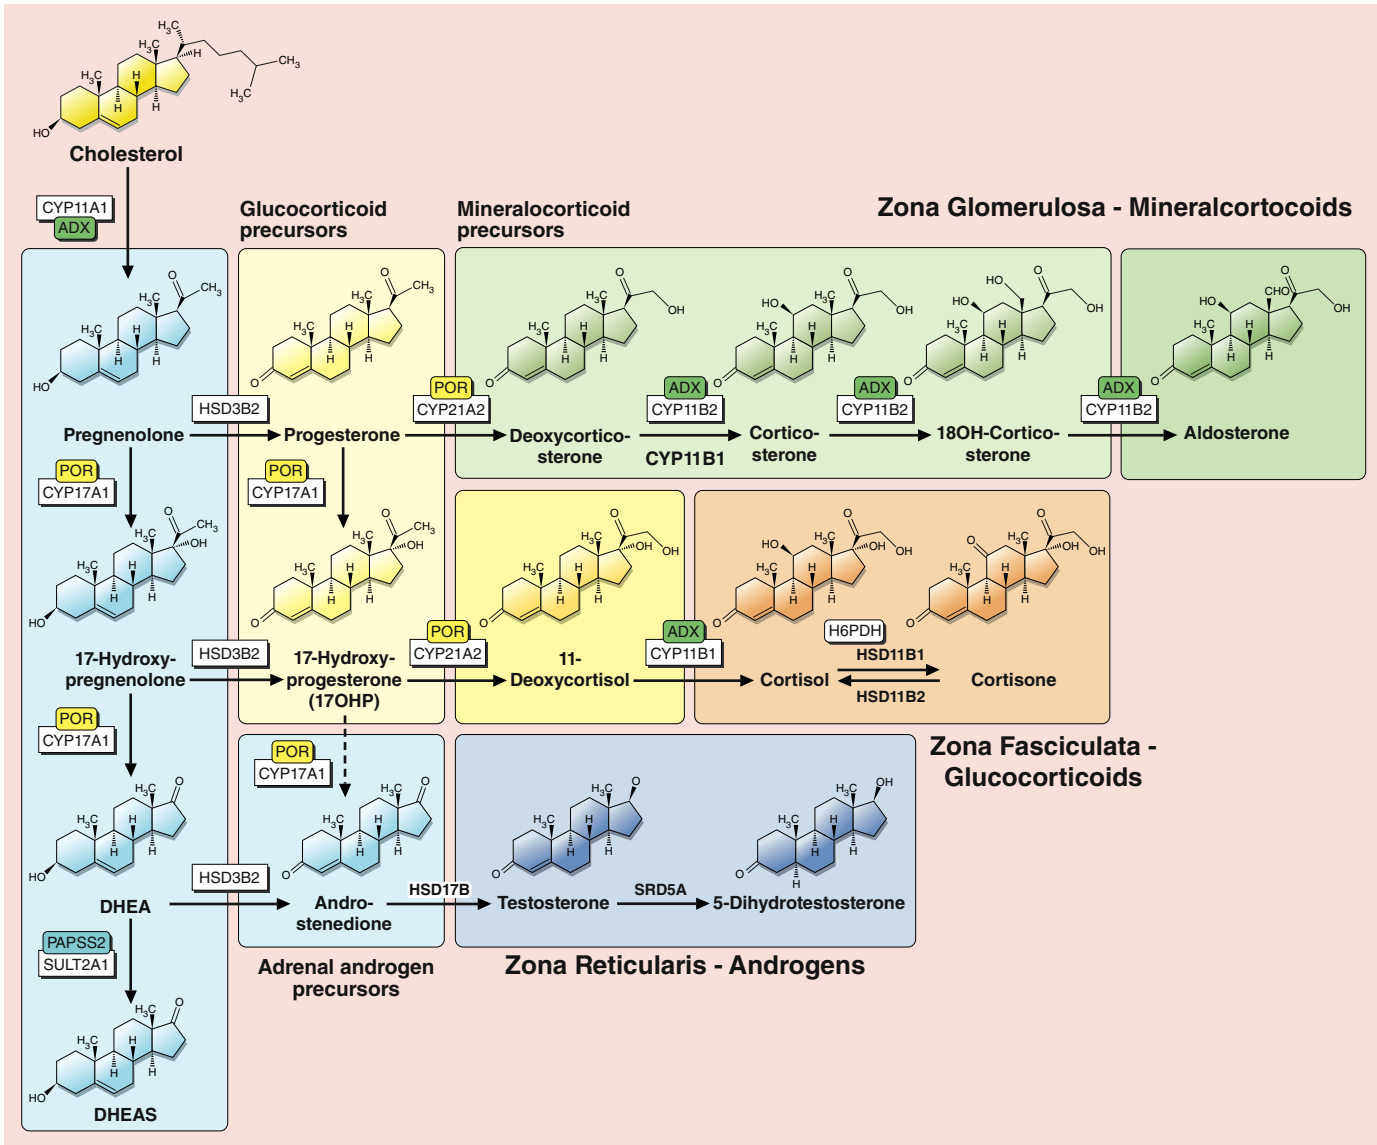
Adrenal hormone production is controlled by the hypothalamus and pituitary. Corticotropin-releasing hormone (CRH) is secreted by the hypothalamus and stimulates secretion of adrenocorticotropic hormone (ACTH; also known as corticotropin) from the anterior pituitary. ACTH in turn stimulates the adrenal cortex to produce cortisol. When sufficient or excessive cortisol


**FIGURE 45–1.** The adrenal cortex consists of three histologically distinct zones: the outer zona glomerulosa, the middle zona fasciculata, and an innermost layer called the zona reticularis. Each zone is responsible for production of different hormones. The zona glomerulosa is responsible for the production of mineralocorticoids such as aldosterone. The zona fasciculata produces cortisol and the zona reticularis produces androgens. levels are reached, a negative feedback is exerted on the secretion of CRH and ACTH, thereby decreasing overall cortisol production. The control of adrenal androgen synthesis also follows a similar negative feedback mechanism. Figure 46–1 depicts hormonal regulation with the hypothalamic-pituitary-adrenal (HPA) axis.

## ADRENAL INSUFFICIENCY
### Epidemiology and Etiology

Adrenal insufficiency generally refers to the inability of the adrenal glands to produce adequate amounts of cortisol for normal physiologic functioning or in times of stress. The condition is usually classified as primary, secondary, or tertiary, depending on the etiology (Table 45–1).[2,4–7] The estimated prevalence of primary adrenal insufficiency and secondary adrenal insufficiency is approximately 60 to 143 and 150 to 280 cases per 1 million persons, respectively. Whereas primary adrenal insufficiency is usually diagnosed in the third to fifth decade of life, secondary adrenal insufficiency is commonly detected during the sixth decade.[2,8] Adrenal insufficiency is more prevalent in women than in men, with a ratio of 2.6:1.[2] Chronic adrenal insufficiency is rare.

## Table 45–1

**Etiologies of Adrenal Insufficiency[2,4–7]**

**Primary Adrenal Insufficiency (Addison disease)**

- Autoimmune—accounts for 70%–90% of all cases of primary adrenal insufficiency
- Infectious or granulomatous diseases
  - Cytomegalovirus
  - Fungal (histoplasmosis, coccidioidomycosis, cryptococcosis, *Blastomyces dermatitidis* infection)
  - HIV (human immunodeficiency virus), AIDS (acquired immunodeficiency syndrome)
    - Mycobacterial, cytomegaloviral, *Pneumocystic jiroveci*, and *Toxoplasma gondii* infection
  - Sarcoidosis
  - Tuberculosis
- Bilateral adrenal hemorrhage or infarction—usually due to anticoagulant therapy, coagulopathy, thromboembolic disease, or meningococcal infection. Causes acute adrenal insufficiency
- Adrenalectomy
- Adrenoleukodystrophy (in men)
- Adrenomyeloneuropathy
- Infiltrative disorders: amyloidosis, hemochromatosis
- Genetic causes
  - Congenital adrenal hyperplasia
  - Familial glucocorticoid deficiency and hypoplasia
- Metastatic malignancy

**Secondary Adrenal Insufficiency**

- Cushing syndrome
- Panhypopituitarism
- Pituitary tumor
- Transsphenoidal pituitary microsurgery
- Pituitary irradiation
- Traumatic brain injury

**Tertiary Adrenal Insufficiency**

- Hypothalamic dysfunction

**Drug-induced (most common cause of secondary and tertiary adrenal insufficiency)**

- Chronic glucocorticoid administration at supraphysiologic doses
- Steroidogenesis inhibitors
- Megestrol acetate—has glucocorticoid-like activity
- Mifepristone (RU 486)—antagonizes glucocorticoid receptors
- Tyrosine kinase inhibitors
- Inducers of CYP450 enzymes that increase cortisol metabolism (2B1, 2B2, 3A4)

CYP450, cytochrome P-450

## Pathophysiology

Primary adrenal insufficiency, also known as Addison disease, occurs when the adrenal glands are unable to produce cortisol. It occurs from destruction of the adrenal cortex, usually from an autoimmune process. In general, the clinical manifestations are observed when destruction of the cortex exceeds 90%.[6] **KEY CONCEPT** Signs and symptoms of adrenal insufficiency reflect the disturbance of normal physiologic carbohydrate, fat, and protein homeostasis caused by inadequate cortisol production and inadequate cortisol action. Primary adrenal insufficiency usually develops gradually. Patients may remain asymptomatic in the early stages with signs and symptoms present only during times of physiologic stress. Persistent signs and symptoms of hypocortisolism typically occur with disease progression. Additionally,

## Clinical Presentation and Diagnosis of Chronic Adrenal Insufficiency[2,5,6,8]

**General**

- Symptoms develop gradually, especially in the early stages, may be vague, and mimic other medical conditions.
- Patients with autoimmune adrenal insufficiency may have other autoimmune disorders such as type 1 diabetes mellitus or autoimmune thyroiditis.

**Symptoms (Percent Prevalence)**

- Weakness and fatigue (99%)
- Anorexia, nausea, and diarrhea (56%–90%); may range from mild to severe with vomiting and abdominal pain
- Hypoglycemia may occur
- Amenorrhea may occur
- Salt craving occurs in approximately 22% with Addison disease due to aldosterone deficiency

**Signs**

- Weight loss (97%)
- Hypotension (less than 110/70 mm Hg) and orthostasis (87%)
- Dehydration, hypovolemia, and hyperkalemia (in primary adrenal insufficiency only) due to aldosterone deficiency.
- Hyponatremia and hypochloridemia levels due to aldosterone deficiency. Hyponatremia can also be present in secondary insufficiency due to cortisol deficiency and increased antidiuretic hormone secretion leading to subsequent water retention.
- Increased serum blood urea nitrogen and creatinine due to dehydration.
- Hyperpigmentation of skin and mucous membranes (92%). Usually observed around creases, pressure areas, areolas, genitalia, and new scars. Dark freckles and patches of vitiligo may be present. Hyperpigmentation, due to increased ACTH levels, occurs in most patients with primary but not secondary or tertiary insufficiency.
- Personality changes (irritability and restlessness) due to cortisol deficiency.
- Loss of axillary and pubic hair in women due to decreased androgen production.
- Blood count abnormalities (normocytic, normochromic anemia, relative lymphocytosis, neutrophilia, eosinophilia) due to cortisol and androgen deficiency.

**Laboratory Tests (see Table 45–2[1,5,9,10])**

- Decreased basal and stress-induced cortisol levels.
- Decreased aldosterone level (in primary insufficiency only).
- Lack of increase in cortisol and aldosterone level after ACTH stimulation.

**Other Diagnostic Tests**

- Computed tomography (CT) scan or magnetic resonance imaging (MRI) of the adrenal glands, pituitary, and/or hypothalamus can aid in determining etiology.
- Presence of antiadrenal antibodies is suggestive of an autoimmune etiology.

**Table 45–2**

**Tests for Diagnosing Adrenal Insufficiency[1,2,5,10]**

| Test | Procedure | Rationale | Finding in Adrenal Insufficiency | Comments |
|------|-----------|-----------|----------------------------------|----------|
| **Screening and Diagnostic Tests for Adrenal Insufficiency** | | | | |
| Unstimulated serum cortisol measurement | Measure serum cortisol at 6–8 AM | Serum cortisol level peaks in the early morning | Serum cortisol < 3 mcg/dL (83 nmol/L) | • Evaluate result in context of those from other test(s)<br>• Can be performed in conjunction with the rapid ACTH stimulation test (measure baseline serum cortisol before administering 250 mcg of cosyntropin) |
| Rapid ACTH stimulation test (also called cosyntropin stimulation test) | Measure serum cortisol 30–60 minutes after administering cosyntropin 250 mcg IM or IV | Increased cortisol secretion in normal individuals in response to ACTH stimulation but not in adrenal insufficiency | Serum cortisol concentration < 18–20 mcg/dL (497–552 nmol/L) | • Used as gold standard test for diagnosing primary adrenal insufficiency<br>• False negative results may occur if ACTH deficiency is of recent onset (< 1 month)<br>• If measured serum cortisol concentration is low, measure plasma ACTH, aldosterone, and renin concentrations to differentiate between primary and secondary or tertiary adrenal insufficiency (see below)<br>• A normal response does not exclude mild secondary adrenal insufficiency or recent onset ACTH deficiency. Additional testing (eg, insulin tolerance or metyrapone test) may be required |
| Insulin tolerance test (insulin-induced hypoglycemia test) | Administer insulin IV to induce hypoglycemia then measure serum cortisol during symptomatic hypoglycemia (confirm that blood glucose is < 40 mg/dL [2.2 mmol/L]) | Evaluates ability of entire HPA axis to respond to stress (hypoglycemia) | Serum cortisol concentration < 18 mcg/dL (497 nmol/L) is indicative of secondary adrenal insufficiency | • If the result of the rapid ACTH stimulation test is normal, either this or the overnight metyrapone test is still needed to evaluate for secondary adrenal insufficiency. The insulin tolerance test is considered the gold standard<br>• Contraindicated in patients with a seizure history, older than 60 years, or with cardiovascular or cerebrovascular disease<br>• Requires close medical supervision<br>• Contraindicated in adrenal crisis and primary adrenal insufficiency |
| Overnight metyrapone test | Administer metyrapone at midnight then measure serum cortisol at 8 AM the next day | Metyrapone inhibits cortisol synthesis. Its administration leads to rise in levels of ACTH and the precursor of cortisol, 11-deoxycortisol. Patients with adrenal insufficiency do not exhibit this | Normal response is a decrease in serum cortisol to < 5 mcg/dL (138 nmol/L) and an increase in 11-deoxycortisol to > 7 mcg/dL (202 nmol/L). Response not seen in secondary adrenal insufficiency | • Distinguishes between normal individuals and patients with secondary adrenal insufficiency<br>• Contraindicated in adrenal crisis and primary adrenal insufficiency |
| **Tests for Differential Diagnosis of Primary, Secondary, and Tertiary Adrenal Insufficiency** | | | | |
| Plasma ACTH concentration | Measure plasma ACTH | In primary adrenal insufficiency, hypocortisolism leads to elevated plasma ACTH concentration via positive HPA axis feedback | • Primary adrenal insufficiency: elevated plasma ACTH.<br>• Secondary or tertiary adrenal insufficiency: plasma ACTH low or inappropriately normal | • Evaluate result of test in combination with those from the plasma aldosterone and plasma renin tests |

*(Continued)*

**Table 45–2**

**Tests for Diagnosing Adrenal Insufficiency[1,2,5,10] (Continued)**

| Test | Procedure | Rationale | Finding in Adrenal Insufficiency | Comments |
|---|---|---|---|---|
| Plasma aldosterone concentration | Measure plasma aldosterone from same blood samples as those used in ACTH stimulation test | Patients with primary adrenal insufficiency may experience a reduction in aldosterone production | • Primary adrenal insufficiency: low plasma aldosterone<br>• Secondary or tertiary adrenal insufficiency: aldosterone concentration is usually normal (≥ 5 ng/dL [139 pmol/L]) | • Evaluate result of test in combination with those from plasma ACTH and plasma renin tests |
| Plasma renin concentration or activity | Measure plasma renin concentration or activity | Mineralocorticoid deficiency occurs in primary adrenal insufficiency but is usually not present in secondary or tertiary adrenal insufficiency | • Primary adrenal insufficiency: elevated plasma renin<br>• Secondary or tertiary adrenal insufficiency: plasma renin concentration or activity is usually normal | • Evaluate result of test in combination with those from plasma ACTH and plasma aldosterone concentration tests |

ACTH, adrenocorticotropic hormone or corticotropin; HPA, hypothalamic-pituitary-adrenal; IM, intramuscularly; IV, intravenously

primary adrenal insufficiency may be accompanied by a reduction in aldosterone and androgen production.

Secondary adrenal insufficiency occurs as a result of pituitary gland dysfunction, whereby decreased production and secretion of ACTH leads to a decrease in cortisol synthesis. Tertiary adrenal insufficiency is a disorder of the hypothalamus that results in decreased production and release of CRH, which in turn decreases pituitary ACTH production and release. In contrast to Addison disease, aldosterone production is unaffected in the secondary and tertiary forms of the disease. Chronic adrenal insufficiency often has a good prognosis if diagnosed early and treated appropriately.

Acute adrenal insufficiency (ie, adrenal crisis) results from the body's inability to sufficiently increase endogenous cortisol during periods of excessive physiologic stress. Adrenal crisis can occur when patients with chronic adrenal insufficiency do not receive adequate glucocorticoid replacement during stressful conditions such as those experienced during surgery, infection, fever, acute illness, invasive medical procedures, or trauma. Acute adrenal insufficiency can also result from bilateral adrenal infarction due to hemorrhage, embolus, sepsis, or adrenal vein thrombosis. Patients who are critically ill may also experience impaired HPA axis function, with an overall prevalence rate of 10% to 20%, and as high as 60% in those experiencing septic

**Clinical Presentation and Diagnosis of Acute Adrenal Insufficiency (Adrenal Crisis)[2,6,8]**

**General**

• Onset of symptoms is acute and precipitated by excessive physiologic stress or abrupt discontinuation of supraphysiologic doses of chronic glucocorticoid.

**Symptoms**

• Severe weakness and fatigue
• Abdominal or flank pain

**Signs**

• Severe dehydration leading to hypotension and shock (circulatory collapse). Hypovolemia may not be responsive to intravenous (IV) hydration and may require the use of vasopressors.
• Tachycardia
• Nausea, vomiting

• Fever
• Confusion
• Hypoglycemia
• Laboratory abnormalities are similar to those observed in chronic adrenal insufficiency.

**Laboratory Tests**

• The unstimulated serum cortisol and rapid ACTH stimulation tests are useful in diagnosis (see Table 45–2). The insulin tolerance test is contraindicated due to preexisting hypoglycemia. The metyrapone test is also contraindicated since metyrapone inhibits cortisol production.

*Note: Due to the life-threatening nature of this condition, empiric treatment should be started before laboratory confirmation in patients who present with the clinical picture of acute adrenal crisis.*

shock. These patients are also at risk for the life-threatening consequences of an adrenal crisis. To better recognize this condition, the term *critical illness–related corticosteroid insufficiency* was coined by the American College of Critical Care Medicine Task Force.[9] Additionally, abrupt discontinuation or rapid tapering of glucocorticoids, given chronically in supraphysiologic doses, may lead to adrenal crisis. This condition results from prolonged suppression of the HPA axis and subsequent adrenal gland atrophy and hypocortisolemia. Other drugs associated with adrenal insufficiency include those that inhibit production (eg, ketoconazole) or increase metabolism (eg, the cytochrome P-450 3A4 inducer rifampin) of cortisol.[6] Regardless of the etiology, patients experiencing an adrenal crisis require immediate glucocorticoid treatment since manifestations such as circulatory collapse can lead to life-threatening sequelae.

## Treatment and Outcome Evaluation

### ▶ Chronic Adrenal Insufficiency

The general goals of treatment are to manage symptoms and prevent development of adrenal crisis. **KEY CONCEPT** *Lifelong glucocorticoid replacement therapy may be necessary for patients with adrenal insufficiency, and mineralocorticoid replacement therapy is usually required for those with Addison disease.* Glucocorticoids with sufficient mineralocorticoid activity are generally required. However, the addition of a potent mineralocorticoid such as fludrocortisone, along with adequate salt intake, is sometimes needed to prevent sodium loss, hyperkalemia, and intravascular volume depletion. Mineralocorticoid supplementation typically is not indicated for the treatment of secondary or tertiary adrenal insufficiency because aldosterone production is often unaffected. Moreover, patients with secondary or tertiary adrenal insufficiency may only require replacement therapy until the HPA axis recovers. Hydrocortisone is often prescribed because it most closely resembles endogenous cortisol with its relatively high mineralocorticoid activity and short half-life, and allows the design of regimens that simulate the normal circadian cycle.[5] Other glucocorticoids, however, can be used.

Table 45–3 lists the pharmacologic characteristics of commonly used glucocorticoids.[11]

Because patients with primary adrenal insufficiency can experience DHEA deficiency, DHEA replacement has also been tried. Several small clinical studies, consisting mostly of women, suggest that treatment with DHEA can improve mood and fatigue and provide a general sense of well-being.[12–14] However, a recent meta-analysis of 10 studies found that DHEA use in women only slightly improved health-related quality of life and depression but did not affect anxiety or sexual well-being; it concluded that the totality of available data does not support routine supplementation with DHEA.[15] The use of DHEA remains controversial and requires further study. Management strategies for chronic adrenal insufficiency are outlined below:[2,4,5,8,16]

- For the treatment of primary adrenal insufficiency (Addison disease) in adults, 15–25 mg/day of oral hydrocortisone is typically administered in two divided doses, with two-thirds of the dose given in the morning upon awakening to mimic the early morning rise in endogenous cortisol, and the remaining one-third of the dose given in the late afternoon to avoid insomnia and allow for the lowest concentration in the blood at around midnight. Hydrocortisone may also be given in three doses but this may decrease adherence. The longer-acting glucocorticoids (eg, prednisone, dexamethasone) may provide a more prolonged clinical response thereby avoiding symptom recurrence that can occur at the end of the dosing interval with short-acting agents such as hydrocortisone. Longer-acting agents also may improve adherence in some patients. Monitor the patient's weight, blood pressure, and serum electrolytes along with symptom resolution and general well-being; adjust dosages accordingly as needed. Doses of hydrocortisone, dexamethasone, prednisone, and other glucocorticoids may need to be increased or decreased in patients taking cytochrome P-450 (CYP450) 3A4 inducers or inhibitors, respectively. Monitor for adverse drug reactions related to glucocorticoid administration. Glucocorticoid therapy at physiologic replacement doses should not lead to development of Cushing syndrome;

| Table 45–3 | | | | |

## Patient Encounter 1, Part 1: Presentation and Medical History

A 48-year-old woman presents to the primary care clinic with complaints of fatigue and asking for a prescription for "vitamin injections." She states that she has been feeling very tired for the past year. Upon further questioning, she also complains of dizziness, especially with positional changes, and intermittent nausea, abdominal pain, and diarrhea.

**PMH:** Tuberculosis—completed treatment course; history of candidal vulvovaginitis; depression

**FH:** Mother with type 1 diabetes

**SH:** Denies smoking, alcohol use or illicit drug use

**Current Meds:** Sertraline 100 mg once daily; loperamide 2 mg as needed for diarrhea (nonprescription)

**PE:**

**VS:** Sitting BP 106/68 mm Hg, P 74 beats/min, standing BP 96/68 mm Hg, RR 14 breaths/min, Wt 130 pounds (59 kg)—5 pound (2.3 kg) loss in last 6 months, Ht 5′2″(157 cm)

**Skin:** Hyperpigmentation in creases of palms

**CV:** RRR, normal $S_1$, $S_2$; no murmurs, rubs, or gallops

**Labs (fasting):** Serum electrolytes: sodium 133 mEq/L (133 mmol/L), potassium 5.2 mEq/L (5.2 mmol/L), chloride 98 mEq/L (98 mmol/L), bicarb 30 mEq/L (30 mmol/L), blood urea nitrogen (BUN) 25 mg/dL (8.9 mmol/L), serum creatinine 1.2 mg/dL (106 μmol/L), glucose 60 mg/dL (3.3 mmol/L).

*Which signs or symptoms of adrenal insufficiency does the patient exhibit?*

*Does her presentation offer any clues as to etiology or classification of adrenal insufficiency?*

*Which tests would be most useful for determining etiology and confirming diagnosis of adrenal insufficiency?*

---

however, careful monitoring should still be performed, and the smallest effective dose used. Educate patients regarding the need for increased glucocorticoid dosage during excessive physiologic stress. In addition, administer oral fludrocortisone at a daily dose of approximately 0.05 to 0.2 mg in the morning. Monitor for resolution of hypotension, dizziness, dehydration, hyponatremia, and hyperkalemia; and increase the dose if needed. Conversely, consider decreasing the dose if adverse reactions from mineralocorticoid administration such as hypertension, hypokalemia, fluid retention, and other significant adverse events occur. In patients receiving hydrocortisone, it should be noted that this drug also possesses mineralocorticoid activity. All patients with Addison disease should also maintain adequate sodium intake. Lastly, although controversial, consider giving DHEA 25–50 mg/day (in the morning) to female patients who do not experience an improvement in mood and well-being even with adequate glucocorticoid and mineralocorticoid replacement. In these patients, monitor serum DHEA-S (aim for the middle range of normal levels in healthy young people) and free testosterone level.

- Patients with secondary and tertiary adrenal insufficiency are treated with oral hydrocortisone or a longer-acting glucocorticoid as described for primary adrenal insufficiency.

## Patient Encounter 1, Part 2: Treatment

After appropriate laboratory and diagnostic tests are performed, the patient is diagnosed with Addison disease.

*How should her chronic primary adrenal insufficiency be treated?*

*What monitoring parameters (therapeutic and toxic) should be implemented?*

However, patients with secondary and tertiary adrenal insufficiency may require a lower dose. Some patients (eg, patients with drug-induced adrenal insufficiency or adrenal insufficiency following treatment for Cushing syndrome) will only require glucocorticoid replacement temporarily, which can be discontinued after recovery of the HPA axis. Monitor for progression of the underlying etiology of adrenal insufficiency. Fludrocortisone therapy is generally not needed.

### ▶ Acute Adrenal Insufficiency

**KEY CONCEPT** *During an acute adrenal crisis, the immediate treatment goals are to correct volume depletion, manage hypoglycemia, and provide glucocorticoid replacement.* Volume depletion and hypoglycemia can be corrected by giving large volumes (~ 2–3 L) of IV normal saline and 5% dextrose solution.[2] Glucocorticoid replacement can be accomplished by administering IV hydrocortisone, starting at a dose of 100 mg every 6 hours for 24 hours, decreasing to 50 mg every 6 hours on the second day after achieving hemodynamic stability, and thereafter be tapered to a lower maintenance dose by the fourth or fifth day and fludrocortisone can be added if needed. The dose can be increased to 200 to 400 mg/day if complications.[2] For the treatment of patients with critical illness-related corticosteroid insufficiency, see the 2008 consensus statements from the American College of Critical Care Medicine Task Force.[9]

**KEY CONCEPT** *Patients with known adrenal insufficiency should be educated about the need for additional glucocorticoid replacement and prompt medical attention during periods of physiologic stress.* Although the dosage of glucocorticoid is generally individualized, a common recommendation is to double the maintenance dose of hydrocortisone if the patient experiences fever or undergoes invasive dental or diagnostic procedures.[5] Patients who experience vomiting or diarrhea may not adequately absorb oral glucocorticoids and may benefit from parenteral therapy until symptoms resolve. Prior to surgery, additional glucocorticoid replacement (higher dose and parenteral route) must be given to prevent adrenal crisis. The dose and protocol varies depending

## Patient Care Process: Adrenal Insufficiency

**Patient Assessment:**

- Evaluate for typical clinical manifestations of chronic or acute adrenal insufficiency. Clinical presentation can differentiate between chronic primary and secondary/tertiary adrenal insufficiency.
- Review medical and medication history to determine if the patient has any etiologies of adrenal insufficiency.
- Perform the rapid ACTH stimulation test to assess for presence of adrenal insufficiency (see Table 45–2).
- After diagnosis is confirmed, perform further testing to differentiate between primary, secondary, and tertiary adrenal insufficiency (see Table 45–2).

**Therapy Evaluation:**

- Determine whether patient will require mineralocorticoid replacement therapy in addition to glucocorticoid supplementation.

**Care Plan Development:**

- In patients presenting with acute adrenal crisis not previously diagnosed with adrenal insufficiency, immediate treatment with injectable hydrocortisone and IV saline and dextrose solutions should be initiated prior to confirmation of diagnosis because of the life-threatening nature of this condition. Determine and correct the underlying cause of the acute adrenal crisis (eg, infection).
- In patients with chronic adrenal insufficiency, devise a strategy to give supplemental doses of glucocorticoid when varying degrees of physiologic stress are experienced (eg, minor infection, pending surgery). Monitor patient for signs of an acute adrenal crisis and develop a plan to treat this emergency condition.
- Educate both patient and family members/caregiver regarding:
  - Causes of adrenal insufficiency, including drug-induced etiologies.
  - How to recognize clinical manifestations.
  - How to prevent an acute adrenal crisis: adhere to therapy; do not abruptly stop glucocorticoid treatment; increase glucocorticoid dose during different severity levels of physiologic stress including childbirth.
  - When to self-administer parenteral glucocorticoid and seek emergency care.
  - Need to notify all health care providers of condition.
  - Wearing or carrying a medical alert (eg, bracelet, card).
  - Dietary and pharmacologic therapy, including duration of treatment and potential adverse consequences of glucocorticoid and mineralocorticoid replacement.

**Follow-Up Evaluation:**

- Monitor for adequacy of treatment and adverse reactions from glucocorticoid and/or mineralocorticoid therapy.
- Determine duration of treatment for patients with secondary and tertiary adrenal insufficiency.

on the type of surgery (eg, larger doses for major surgery compared to minor surgery).

## HYPERCORTISOLISM (CUSHING SYNDROME)

### Epidemiology and Etiology

Cushing syndrome refers to the pathophysiologic changes associated with exposure to supraphysiologic cortisol concentrations (endogenous hypercortisolism) or pharmacologic doses of glucocorticoids (exogenous hypercortisolism). Cushing syndrome from endogenous causes is a rare condition, with an estimated incidence of two to five cases per 1 million persons per year.[17] Patients receiving chronic supraphysiologic doses of glucocorticoids, such as those with rheumatologic disorders, are at high risk of developing Cushing syndrome.

### Pathophysiology

Cushing syndrome can be classified as ACTH-dependent or ACTH-independent (Table 45–4).[1,18–20] ACTH-dependent Cushing syndrome results from ACTH-secreting (or rarely CRH-secreting) adenomas. The term *Cushing disease* refers specifically to Cushing syndrome from an ACTH-secreting pituitary adenoma. ACTH-independent Cushing syndrome is due either to excessive cortisol secretion by the adrenal glands (independent of ACTH stimulation) or to exogenous glucocorticoid administration. The plasma ACTH concentration is elevated in ACTH-dependent conditions but not in ACTH-independent conditions because elevated cortisol concentrations suppress pituitary ACTH secretion via negative feedback. ACTH and cortisol concentrations are elevated episodically in ACTH-dependent

---

**Table 45–4**

### Etiologies of Cushing Syndrome[2,18–20]

**ACTH-Dependent**

- ACTH-secreting pituitary tumor (Cushing *disease*)—70% of endogenous cases
- ACTH-secreting nonpituitary tumors (ectopic ACTH syndrome)—15% of endogenous cases; usually from small cell lung carcinoma and bronchial carcinoids; also from pheochromocytoma, or from thymus, pancreatic, ovarian, or thyroid tumor. The tumor is usually disseminated (difficult to localize).
- CRH-secreting nonpituitary tumors (ectopic CRH syndrome)—rare

**ACTH-Independent**—15% of endogenous cases

- Unilateral adrenal adenoma
- Adrenal carcinoma
- Bilateral nodular adrenal hyperplasia—rare (< 1%)

**Drug-Induced Cushing Syndrome** (ACTH-independent)—most common cause of Cushing syndrome

- Prescription glucocorticoid preparations (most routes of administration)
- Nonprescription and herbal products with glucocorticoid activity (eg, nonprescription anti-itch products with hydrocortisone, herbal products with magnolia bark or those claiming to contain adrenal cortex extracts or other by-products)
- Other drugs with glucocorticoid activity (eg, megestrol acetate, medroxyprogesterone)

ACTH, adrenocorticotropic hormone or corticotropin; CRH, corticotropin-releasing hormone

## Clinical Presentation and Diagnosis of Cushing Syndrome[2,17,18,24]

### General

- Onset of signs and symptoms range from gradual to rapid, depending on etiology.
- Differential diagnoses include diabetes mellitus and the metabolic syndrome because these conditions share several similar characteristics with Cushing syndrome (eg, obesity, hypertension, hyperlipidemia, hyperglycemia, and insulin resistance). In women, the presentations of hirsutism, menstrual abnormalities, and insulin resistance are similar to those of polycystic ovary syndrome. Cushing syndrome can be differentiated from these conditions by identifying the classic signs and symptoms described below.
- True Cushing syndrome also must be distinguished from other conditions that share some clinical presentations (as well as elevated plasma cortisol concentrations) such as depression, anxiety disorder, obsessive-compulsive disorder, alcoholism, obesity, uncontrolled diabetes, eating disorders, and physiologic stress—the so-called pseudo-Cushing states.

### Signs and Symptoms (Percent Prevalence)

General appearance
- Weight gain and obesity, manifesting as truncal obesity (90%)
- Rounded and puffy face ("moon facies") (75%)
- Dorsocervical ("buffalo hump") and supraclavicular fat accumulation
- Hirsutism (75%)

Skin changes from atrophy of dermis and connective tissue
- Thin skin
- Facial plethora (70%)
- Skin striae ("stretch marks" that are usually red or purple in appearance and greater than 1 cm) (50%)—not common in patients older than 40 years of age
- Acne (35%)
- Easy bruising (40%)
- Hyperpigmentation—typically with ectopic ACTH syndrome

Metabolic
- Hyperglycemia that can range from impaired glucose tolerance (75%) to diabetes mellitus (20%–50%)
- Hyperlipidemia (70%)
- Polyuria (30%)

- Kidney stones (15%–50%)
- Hypokalemic alkalosis (from mineralocorticoid effect of cortisol)

Cardiovascular
- Hypertension (from mineralocorticoid effect of cortisol) (85%)
- Peripheral edema

Genitourinary
- Menstrual irregularities (typically amenorrhea) (70%)
- Erectile dysfunction (85%)

Other
- Psychiatric changes such as depression, emotional lability, psychosis, euphoria, anxiety, and decreased cognition (85%)
- Sleep disturbances
- Osteopenia (80%) and osteoporosis—usually affecting trabecular bone
- Linear growth impairment in children
- Proximal muscle weakness (65%)
- Avascular necrosis (more common in iatrogenic cases)
- Glaucoma, cataracts
- Impaired wound healing and susceptibility to opportunistic infections
- Hypothyroidism

### Laboratory tests

- Diagnosis is often complex and generally requires the involvement of endocrinologists and specialized testing centers.
- Initial screening tests are listed in Table 45–5.[2,24] Typically, a combination of two screening tests is used to establish the preliminary diagnosis.
- After the diagnosis is confirmed, additional tests (eg, midnight serum cortisol or combined dexamethasone suppression plus CRH test) can be performed to determine the etiology or rule out false positive/negative results.

### Other diagnostic tests

Imaging studies and inferior petrosal sinus sampling may be needed to distinguish between pituitary, ectopic, and adrenal tumors.

---

disease due to random hypersecretion of ACTH.[6] In general, patients with Cushing syndrome due to endogenous or exogenous glucocorticoid excess present with similar clinical manifestations. However, patients with ectopic ACTH syndrome may not exhibit the typical signs and symptoms of hypercortisolism due to the acute onset nature of the underlying disease process.[2]

Cushing disease and adrenal carcinomas cause adrenal androgen hypersecretion in high enough concentrations to result in signs of androgen excess such as acne, menstrual irregularities, and hirsutism, and cause virilization in women.[6] Drug-induced Cushing syndrome from glucocorticoid administration occurs most commonly in patients receiving oral therapy, but other

routes such as inhalation, dermal, nasal, and intraarticular have also been implicated.[18] Over-the-counter products, including dietary supplements, should also be evaluated since they may contain corticosteroids. Drug-induced Cushing syndrome has been reported with the use of Chinese herbal products adulterated with corticosteroids.[21,22] The risk of glucocorticoid-induced Cushing syndrome appears to increase with higher doses and/or longer treatment durations.[18]

Left untreated, patients with Cushing syndrome may experience severe complications of hypercortisolism, resulting in up to a nearly four-fold increase in mortality.[23] Mortality in patients with Cushing is mostly attributed to cardiovascular disease.

**Table 45–5**

**First-Line Screening Tests in Patients with Characteristics of Cushing Syndrome[2,24]**

| Test | Test Procedure and Measurement | Rationale | Typical Finding in Cushing Syndrome | Comments |
|---|---|---|---|---|
| 24-hour urinary free cortisol | Collect urine over 24 hours and measure unbound cortisol excreted by kidneys | Urinary cortisol is elevated in hypercortisolic states | Elevated urinary free cortisol (value depends on the assay used) | • Easy to perform but should not be used alone since sensitivity and specificity depend on assay used<br>• To exclude periodic hypercortisolism, two or more samples should be obtained (with urinary creatinine measurement to assess completeness of collection)<br>• Distinguishes the effects of Cushing syndrome (elevation) from obesity (no elevation). However, false positive in other pseudo-Cushing states, physiologic stress, if fluid intake ≥ 5 L/day, or taking carbamazepine or fenofibrate (if measured by HPLC)<br>• False negative if moderate to severe renal function, or subclinical hypercortisolism |
| Overnight dexa-methasone suppression test (DST) | Give 1 mg oral dexamethasone at 11 PM, then measure plasma cortisol at 8–9 AM the next morning | Dexamethasone administration suppresses morning plasma cortisol in normal individuals | Plasma cortisol < 1.8 µg/dL (50 nmol/L) is not suggestive of Cushing syndrome | • Simple to perform and inexpensive<br>• Can be used in conjunction with, or instead of, the urinary free cortisol test<br>• False positive if pseudo-Cushing states, physiologic stress, pregnancy, estrogen treatment (including contraceptives), uremia, taking inducers of dexamethasone metabolism (phenytoin, alcohol, etc), or decreased dexamethasone absorption<br>• False negative if subclinical hypercortisolism, slow metabolism of dexamethasone (eg, CYP3A4 inhibitors), or liver or renal impairment<br>• In pseudo-Cushing states, the 48-hour 2-mg DST (administer 0.5 mg dexamethasone every 6 hours for 48 hours then measure serum cortisol at 8 or 9 AM after the last dose) is preferred |
| Late-night salivary cortisol | Collect salivary cortisol concentration at 11 PM | Loss of circadian rhythm of cortisol secretion (no nadir at night) in Cushing syndrome but not in pseudo-Cushing states | Elevated late-night salivary cortisol | • Easiest screening test to perform (sample can be collected at home by patient)<br>• To exclude periodic hypercortisolism, two or more samples (on two separate evenings) should be obtained<br>• False positive possible with cigarette smoking, chewing tobacco, licorice ingestion, in pseudo-Cushing states<br>• Adjust collection time in shift workers and others with bedtime significantly after midnight |

CYP, cytochrome P-450; HPLC, high-performance liquid chromatography

Hypertension, hyperglycemia, and hyperlipidemia are common findings and can be associated with cardiac hypertrophy, athero-sclerosis, and hypercoagulability. Osteopenia, osteoporosis, and increased fractures also have been reported.[23] Prevention and management of these conditions are discussed elsewhere in this text. Children may experience linear growth retardation from reduced growth hormone secretion and inhibition of epiphyseal cartilage development in long bones.[17,23]

## Treatment

The goal of treatment in patients with Cushing syndrome is reversal of hypercortisolism and management of the associated comorbidities, including the potential for long-term sequelae such as cardiac hypertrophy. **KEY CONCEPT** *Surgical resection is considered the treatment of choice for Cushing syndrome from endogenous causes if the tumor can be localized and if there are*

*no contraindications.* The treatment of choice for Cushing syndrome from exogenous causes is gradual discontinuation of the offending agent.

#### ▶ *Nonpharmacologic Therapy*

**Transsphenoidal pituitary microsurgery** is the treatment of choice for Cushing disease. Removal of the pituitary tumor can bring about complete remission or cure in 78% to 97% of cases. HPA axis suppression associated with chronic hypercortisolism can result in prolonged adrenal insufficiency lasting for months after surgery and requiring exogenous glucocorticoid administration. Pituitary irradiation or bilateral adrenalectomy is usually reserved for patients who are not surgical candidates or for those who relapse or do not achieve complete remission following pituitary surgery. Because the response to pituitary irradiation can be delayed (several months to years), concomitant treatment with cortisol-lowering medication may be necessary. Bilateral adrenalectomy is also used for management of adrenal carcinoma and in patients with poorly controlled ectopic Cushing disease in whom the ACTH-producing lesion cannot be localized. Bilateral laparoscopic adrenalectomy achieves an immediate and total remission (nearly 100% cure rate), but these patients will require lifelong glucocorticoid and mineralocorticoid supplementation.[7,25] **Nelson syndrome** may develop in nearly 20% to 50% of patients who undergo bilateral adrenalectomy without pituitary irradiation. This condition presumably results from persistent hypersecretion of ACTH by the intact pituitary adenoma, which continues to grow because of the loss of feedback inhibition by cortisol. Treatment of Nelson syndrome may involve pituitary irradiation or surgery.[6]

The treatment of choice in patients with adrenal adenomas is unilateral laparoscopic adrenalectomy. These patients require glucocorticoid supplementation during and after surgery due to atrophy of the contralateral adrenal gland and suppression of the HPA axis. Glucocorticoid therapy is continued until recovery of the remaining adrenal gland is achieved. Patients with adrenal carcinomas have a poor prognosis, with a 5-year survival of 20% to 58%, because of the advanced nature of the condition (metastatic disease). Surgical resection to reduce tumor burden and size, pharmacologic therapy, or bilateral laparoscopic adrenalectomy are the treatment options commonly utilized to manage this condition.[2,7]

#### ▶ *Pharmacologic Therapy*

**KEY CONCEPT** *Pharmacotherapy is indicated when the ectopic ACTH-secreting tumor cannot be localized; to control hypercortisolism to prepare for surgery; and in patients who: (1) are not surgical candidates; (2) have failed surgery or had a relapse after surgery; or (3) have Cushing disease awaiting the onset of effect of pituitary radiation.*[26] The drugs used are classified according to their mechanism and site of action (**Table 45–6**[25–31]). The most widely used therapeutic class is the adrenal steroidogenesis inhibitors, which can improve hypercortisolism by inhibiting enzymes involved in the biosynthesis of cortisol.[26] Because of their potential to cause adrenal suppression, temporary glucocorticoid replacement, and in some cases mineralocorticoid supplementation, may be needed during and after treatment.

**KEY CONCEPT** *In drug-induced Cushing syndrome, discontinuation of the offending agent is the best management option. However, abrupt withdrawal of the glucocorticoid can result in adrenal insufficiency or exacerbation of the underlying disease.*[18] **KEY CONCEPT** *Glucocorticoid doses less than 7.5 mg/day of prednisone or its equivalent for less than 3 weeks generally would not be expected to lead to suppression of the HPA axis.*[3,7] However, in patients receiving pharmacologic doses of glucocorticoids for prolonged periods, gradual tapering to near physiologic levels (5–7.5 mg/day of prednisone or its equivalent) should precede drug discontinuation. Administration of a short-acting glucocorticoid in the morning and use of alternate-day dosing may reduce the risk of adrenal suppression. Testing of the HPA axis may be useful in assessing adrenal reserve. In some cases, supplemental glucocorticoid administration during excessive physiologic stress may be needed for up to 1 year after glucocorticoid discontinuation.[18]

**Table 45–7** lists strategies to prevent the development of hypercortisolism and hypocortisolism.

### Outcome Evaluation

- Monitor patients receiving surgical, medical, or radiation therapy for resolution of the clinical manifestations of hypercortisolism. Symptoms often improve immediately after surgery and soon after initiation of drug therapy. However, it may take months for symptoms to resolve following radiation therapy.
- Monitor for normalization of serum cortisol concentrations.
- Patient Care Process discusses additional evaluation strategies.

---

### Patient Encounter 2

A 61-year-old man presents to a clinical pharmacist for diabetes education. He was recently diagnosed with type 2 diabetes. He also has a diagnosis of hypertension, atrial fibrillation, dyslipidemia, chronic obstructive pulmonary disease (COPD), and depression. He complains of thirst, polyuria, and fatigue. Physical exam reveals an obese (BMI 37 kg/m$^2$) gentleman with truncal obesity, dorsocervical fat, several small bruises on abdomen and extremities, and facial plethora. His current medications include metformin, lisinopril, hydrochlorothiazide, warfarin, atorvastatin, fluticasone/salmeterol, tiotropium, albuterol, and fluoxetine. He has been treated several times

this year with high-dose prednisone therapy for frequent COPD exacerbations. The clinical pharmacist suggests evaluation for possible Cushing syndrome.

*Which findings are suggestive of Cushing syndrome?*

*Aside from Cushing syndrome, what are some major differential diagnoses for clinical presentation?*

*The patient is diagnosed with drug-induced Cushing syndrome after evaluation and diagnostic testing by the endocrinologist. What patient education points should be provided?*

**Table 45–6**

**Pharmacologic Treatments for Cushing Syndrome[25–31]**

| Drug | Mechanism of Action | Dosage[a]: Initial, Usual, Maximum, Dosing Adjustment for Renal and/or Hepatic Failure | Common and/or Major Adverse Reactions | Comment |
|---|---|---|---|---|
| **Inhibitors of Adrenal Steroidogenesis** | | | | |
| Ketoconazole[b] (oral administration) | Inhibits several CYP450 enzymes including 17,20-lyase, 17-hydroxylase, and 11β-hydroxylase. Also inhibits cholesterol synthesis | *Adults*: 200 mg twice daily; 400–800 mg/day in two divided doses; NTE 1,200 mg/day in two to three divided doses<br>Extensively metabolized by liver and dosing adjustment should be considered in severe liver disease. Dosing adjustment not needed in renal disease | Generally well tolerated. Symptoms of adrenal insufficiency (eg, nausea, vomiting, decreased appetite, fatigue) Gynecomastia, decreased libido, and impotence (due to inhibition of testosterone synthesis) Hepatotoxicity | • Effective in a majority of causes; rapid clinical improvement seen<br>• Monitor efficacy with urinary cortisol<br>• Monitor liver transaminases for hepatotoxicity<br>• Useful in women with hirsutism and patients with hyperlipidemia<br>• Requires gastric acidity for dissolution and absorption therefore not useful in patients with achlorhydria and those taking proton pump inhibitors or round-the-clock antacids or histamine-2 receptor blockers<br>• Is a CYP3A4 substrate and a strong CYP3A4 inhibitor. Also has other CYP450 interaction potential. Coadministration with certain medications can lead to QT prolongation and dysrhythmia |
| Metyrapone[b] (oral administration) | Inhibits 11β-hydroxylase. Also suppresses aldosterone synthesis | *Adults*: 750 mg/day; 500–4000 mg/day in four divided doses; NTE 6 g/day<br>Dosages in special populations (liver and kidney disease, elderly patients) have not been established | Generally well-tolerated Hirsutism, acne, adrenal insufficiency, GI intolerance, rash, hypokalemia, edema, hypertension | • Used in Cushing disease, ectopic ACTH syndrome, and adrenal carcinoma<br>• Also used as a test to diagnose adrenal insufficiency |
| Etomidate[b] (intravenous infusion administration) | Inhibits 17,20-lyase, 17-hydroxylase, and 11β-hydroxylase | *Adults*: Limited clinical experience, 0.2–0.4 mg/kg/hour<br>Extensively metabolized in the liver to inactive metabolites. Because of changes in protein binding, dosing adjustment may be needed in kidney and liver disease | Injection site pain, nausea, vomiting, myoclonus, hypotension | • Is a general anesthetic<br>• Generally reserved for patients with more severe symptoms and in emergency settings |
| **Adrenolytic Agent** | | | | |
| Mitotane (oral administration) | Inhibits steroidogenesis at lower doses and is adrenolytic at higher doses. Inhibits 11β-hydroxylase and cholesterol side-chain cleavage. Reduces aldosterone synthesis | *Adults*: for adrenal carcinoma: 2 to 6 g/day in three to four divided doses; 9–10 g/day in three to four divided doses; NTE 18–19 g/day in three to four divided doses; for other types of Cushing syndrome: 0.5 g at bedtime; 1–2 g/day; NTE 2–3 g/day, (usual/max)—give ½ the dose at bedtime to minimize nausea. Elderly patients may require a dose decrease<br>Primarily metabolized by the liver and dosing adjustment may be needed in liver disease | GI intolerance (high incidence), fatigue, dizziness, somnolence, gynecomastia Hyperlipidemia requiring lipid-lowering treatment Adrenal insufficiency requiring glucocorticoid replacement therapy | • FDA-approved for treatment of inoperable adrenal cortical carcinoma. Can be used in other types of Cushing syndrome<br>• Efficacy takes several weeks<br>• Lower rate of relapse when used with pituitary radiation. Also enables lower doses and therefore lower rate of adverse reactions<br>• Hypocortisolism (if occurs) may persist several weeks/months after discontinuation as drug is stored in fatty tissues<br>• Strong inducer of CYP3A4 |

| **Peripheral Glucocorticoid Antagonist** | | | | |
| --- | --- | --- | --- | --- |
| Mifepristone (RU 486) (oral administration) | Antagonizes glucocorticoid receptors | *Adults*: 300 mg once daily; NTE 1200 mg once daily (but only up to 20 mg/kg/day)<br>Maximum 300 mg/day with concomitant strong CYP450 inhibitors<br>Do not exceed 600 mg/day in renal impairment or mild-to-moderate hepatic impairment. Do not use in severe hepatic impairment | Nausea, fatigue, headache, hypokalemia, arthralgia, vomiting, peripheral edema, hypertension, dizziness, decreased appetite, endometrial hypertrophy, prolonged QT interval. Has abortifacient and embryotoxic properties | • FDA-approved for control of hyperglycemia secondary to hypercortisolism in adult patients with endogenous Cushing syndrome who have type 2 diabetes mellitus or glucose intolerance and have failed surgery or are not candidates for surgery<br>• Increases cortisol and ACTH levels via antagonism of negative feedback of ACTH secretion<br>• Requires cautious use since limited clinical experiences and cannot use cortisol or ACTH levels to monitor efficacy of treatment<br>• Quicker effectiveness compared to other drug treatment options<br>• Is a CYP3A4 substrate. Also inhibits CYP3A and has other CYP450 interaction potential |
| **Somatostatin Analog** | | | | |
| Pasireotide (subcutaneous injection) | Binds to somatostatin receptor subtype 5 overexpressed in corticotroph tumor cells resulting in inhibition of ACTH secretion | *Adults*: 0.6 mg or 0.9 mg twice daily; 0.3–0.9 mg twice daily; NTE 0.9 mg twice daily. Consider lower initial dose in the elderly<br>Moderate hepatic impairment (Child Pugh B): initial 0.3 mg twice a day, maximum 0.6 mg twice a day. Avoid in severe hepatic impairment (Child Pugh C). No dosage adjustment needed in renal impairment | Hyperglycemia, GI pain, nausea, diarrhea, headache, fatigue, bradycardia, QT prolongation, liver test elevations, cholelithiasis, pituitary hormone (other than ACTH) inhibition | • FDA-approved for treatment of adult patients with Cushing disease for whom pituitary surgery is not an option or has not been curative<br>• Measure response based on 24-hour urinary free cortisol level and/or improvement in signs and symptoms |

[a]Dosing guidelines (including age ranges) and safety for children have not been definitively established.

[b]These medications do not have FDA-approved indications for the treatment of Cushing syndrome in either adults or children.

ACTH, adrenocorticotropic hormone or corticotropin; CYP, cytochrome P-450; FDA, Food and Drug Administration; GI, gastrointestinal; NTE, not to exceed.

---

**Table 45–7**

**Principles of Glucocorticoid Administration to Avoid Hypercortisolism or Hypocortisolism**

**To Prevent Hypercortisolism and Development of Cushing Syndrome**

- Give the lowest glucocorticoid dose that will manage the disease being treated and for the shortest possible duration
- If feasible, give glucocorticoid via administration routes that minimize systemic absorption (such as inhalation or dermal)
- If feasible, administer glucocorticoid treatment every other day (calculate the total 48-hour dose and give as a single dose of intermediate-acting glucocorticoid in the morning)[6]
- Avoid concurrent administration of drugs that can inhibit glucocorticoid metabolism

**To Prevent Hypocortisolism and Development of Adrenal Insufficiency or Adrenal Crisis**

- If the patient requires discontinuation from chronic treatment with supraphysiologic doses of glucocorticoid, the following discontinuation protocol can be used:[6]
  - Gradually taper the dose to approximately 20 mg of prednisone or equivalent per day, given in the morning, and then
  - Change glucocorticoid to every other day administration, in the morning
  - Stop the glucocorticoid when the equivalent physiologic dose is reached (20 mg/day of hydrocortisone or 5–7.5 mg/day of prednisone or equivalent)
  - Understand that recovery of the HPA axis may take up to a year after glucocorticoid discontinuation during which the patient may require supplementation therapy during periods of physiologic stress
- Evaluate patients at risk for adrenal insufficiency as a result of treatment(s) of Cushing syndrome and initiate glucocorticoid and mineralocorticoid replacement therapy as appropriate
- Avoid concurrent administration of drugs that can induce glucocorticoid metabolism
- Educate patients about:
  - The need for replacement or supplemental glucocorticoid and mineralocorticoid therapy
  - How to administer parenteral glucocorticoid if unable to immediately access medical care during an emergency
  - Need to wear or carry medical identification regarding condition (eg, card, bracelet)

HPA, hypothalamic-pituitary-adrenal

---

## Patient Care Process: Cushing Syndrome

**Patient Assessment:**

- Perform a comprehensive examination, including a thorough medical history and history of all medications and herbal or dietary supplements.
- Determine if Cushing syndrome is drug induced.
- Establish diagnosis and etiology based on diagnostic testing.

**Therapy Evaluation:**

- Evaluate patient for appropriateness of surgery, radiation, and/or pharmacologic therapy depending on etiology.

**Care Plan Development:**

- Attempt to taper glucocorticoid if etiology is exogenous administration.
- If endogenous Cushing syndrome, determine if patient is an appropriate candidate for surgical resection of the tumor or has contraindications to surgical resection such as advanced disease (metastatic adrenal carcinoma).
- Assess response and complications associated with surgery including:[25]
  - Measuring plasma cortisol postsurgery to determine if the patient displays persistent hypercortisolism (surgical treatment failure) or hypocortisolism (adrenal insufficiency requiring steroid replacement therapy).
  - In patients demonstrating hypocortisolism:
    i.  Monitor for signs and symptoms of glucocorticoid withdrawal (headache, fatigue, malaise, myalgia).

    ii. Monitor for signs and symptoms of adrenal insufficiency and develop a treatment plan.

    iii. Monitor morning cortisol or response to ACTH stimulation every 3 to 6 months to assess for HPA axis recovery. Discontinue glucocorticoid replacement therapy when cortisol concentrations are greater than 19 mcg/dL (524 nmol/L) on either test.

    iv. Monitor cortisol, ACTH, low-dose dexamethasone suppression, or other tests to assess for risk of relapse of hypercortisolism.

- If surgical resection does not achieve satisfactory disease control or is not indicated, evaluate the patient for pituitary radiation or bilateral adrenalectomy with concomitant pituitary radiation.
- Monitor patients treated with surgery or pituitary radiation for development of pituitary hormone deficiency.
- Evaluate patients with adrenal adenomas for unilateral adrenalectomy.
  - Give glucocorticoid and mineralocorticoid replacement (permanently in the case of bilateral adrenalectomy).
- Provide patient education regarding:
  - Causes of Cushing syndrome, including drug-induced etiologies
  - How to recognize the clinical manifestations
  - Possible sequelae of Cushing syndrome

## Patient Care Process: Cushing Syndrome (*Continued*)

- How to reduce the modifiable cardiovascular and metabolic complications
- Advantages and disadvantages of potential treatment options including possible adverse consequences
- Need for glucocorticoid and mineralocorticoid replacement after treatment, if appropriate
- Importance of adherence to therapy

**Follow-Up Evaluation:**

- Monitor for response to therapy, need for dose adjustments, and presence of adverse drug reactions.
- Once disease control is achieved, continue to monitor biochemical markers and patient for development of complications of Cushing syndrome, as relapse may occur.

## Abbreviation Introduced in This Chapter

| | |
|---|---|
| ACTH | Adrenocorticotropic hormone or corticotropin |
| AIDS | Acquired immunodeficiency syndrome |
| BUN | Blood urea nitrogen |
| CRH | Corticotropin-releasing hormone |
| COPD | Chronic obstructive pulmonary disease |
| CT | Computed tomography |
| CYP450 | Cytochrome P-450 |
| DHEA | Dehydroepiandrosterone |
| DHEA-S | Sulfated form of dehydroepiandrosterone |
| DST | Dexamethasone suppression test |
| FDA | Food and Drug Administration |
| GI | Gastrointestinal |

# Pituitary Gland Disorders

Judy T. Chen, Devra K. Dang, Frank Pucino, Jr, and Karim Anton Calis

## LEARNING OBJECTIVES

- **Upon completion of the chapter, the reader will be able to:**

1. List the mediators and primary effects of pituitary hormones.
2. Identify clinical features of patients with acromegaly.
3. Discuss the role of surgery and radiation therapy for patients with acromegaly.
4. Select appropriate pharmacotherapy for patients with acromegaly based on patient-specific factors.
5. Identify clinical features of children and adults with growth hormone (GH) deficiency and select appropriate pharmacotherapy for these patients.
6. Recommend monitoring parameters necessary to assess therapeutic outcomes and adverse effects in patients receiving GH therapy.
7. List common etiologies of hyperprolactinemia.
8. Identify clinical features of patients with hyperprolactinemia.
9. Select appropriate pharmacologic and nonpharmacologic treatments for patients with hyperprolactinemia based on patient-specific factors.

## PHYSIOLOGY OF THE PITUITARY GLAND

The pituitary, referred to as the "master gland," is a small endocrine gland located at the base of the brain and is responsible for the regulation of many other endocrine glands and body systems. Growth, development, metabolism, reproduction, and stress homeostasis are among the functions influenced by the pituitary. Functionally, the gland consists of two distinct sections: the anterior pituitary lobe and the posterior pituitary lobe. The pituitary receives neural and hormonal input from the inferior hypothalamus via blood vessels and neurons.

The posterior pituitary is innervated by nervous stimulation from the hypothalamus, resulting in the release of specific hormones to exert direct tissue effects. The hypothalamus synthesizes two hormones, oxytocin and vasopressin. These hormones are stored and released from the posterior pituitary lobe. The anterior pituitary lobe is under the control of several releasing and inhibiting hormones secreted from the hypothalamus via a portal vein system. It synthesizes and secretes six major hormones. Figure 46–1 summarizes the physiologic mediators and effects of each of these hormones.

### Hormonal Feedback Regulatory Systems

The hypothalamus is responsible for the synthesis and release of hormones that regulate the pituitary gland. Stimulation or inhibition of the pituitary hormones elicits a specific cascade of responses in peripheral target glands. In response, these glands secrete hormones that exert a negative feedback on other hormones in the hypothalamic–pituitary axis (see Figure 46–1). This negative feedback serves to maintain body system homeostasis.

In general, high circulating hormone concentrations inhibit the release of hypothalamic and anterior pituitary hormones. Damage and destruction of the pituitary gland may result in secondary hypothyroidism, hypogonadism, adrenal insufficiency, growth hormone (GH) deficiency, hypoprolactinemia, or panhypopituitarism. A tumor (adenoma) located in the pituitary gland may result in excess secretion of a hormone or may physically compress the gland and suppress adequate hormone release. The type, location, and size of a pituitary tumor often determine a patient's clinical presentation. This chapter discusses the pathophysiology and role of pharmacotherapy in the treatment of acromegaly, GH deficiency, and hyperprolactinemia. The following hormones are discussed elsewhere in this textbook: adrenocorticotropic hormone (ACTH), thyroid-stimulating hormone (TSH), luteinizing hormone (LH), follicle-stimulating hormone (FSH), antidiuretic hormone (or vasopressin; ADH), and oxytocin.

## GROWTH HORMONE (SOMATOTROPIN)

Somatotropin or GH, the most abundant hormone produced by the anterior pituitary lobe, is regulated primarily by the hypothalamic–pituitary axis. The hypothalamus releases growth hormone–releasing hormone (GHRH) to stimulate GH synthesis and secretion, whereas somatostatin inhibits it.[1] Release of GH into the circulation stimulates the liver and other peripheral target tissues to produce insulin-like growth factors (IGFs). These IGFs are the peripheral GH targets. There are two types of IGFs, IGF-I and IGF-II. IGF-I is responsible for growth of bone and other tissues, whereas IGF-II is primarily responsible for regulating fetal growth. High concentrations of IGF-I inhibit
**FIGURE 46−1.** Hypothalamic–pituitary–target-organ axis. The hypothalamic hormones regulate the biosynthesis and release of eight pituitary hormones. Stimulation of each of these pituitary hormones produces and releases trophic hormones from their associated target organs to exert their principal effects. These trophic hormones regulate the activity of endocrine glands. Subsequently, increased serum concentration of the trophic hormones released from the target organs can inhibit both the hypothalamus and the anterior pituitary gland to maintain homeostasis (negative feedback). Inhibin is produced by the testes in men and the ovaries in women during pregnancy. Inhibin directly inhibits pituitary production of follicle-stimulating hormone (FSH) through a negative feedback mechanism. Melanocyte-stimulating hormone (MSH) produced by the anterior pituitary is not illustrated in the figure. (–), inhibit; (+), stimulate; ACTH, adrenocorticotropic hormone (corticotropin); ADH, antidiuretic hormone (vasopressin); CRH, corticotropin-releasing hormone; FSH, follicle-stimulating hormone; GABA, γ-aminobutyric acid; GH, growth hormone (somatotropin); GHIH, growth hormone–inhibiting hormone (somatostatin); GHRH, growth hormone–releasing hormone; GnRH, gonadotropin-releasing hormone; IGF-I, insulin-like growth factor-I; LH, luteinizing hormone; LHRH, luteinizing hormone–releasing hormone; PRH, prolactin-releasing hormone; $T_3$, triiodothyronine; $T_4$, thyroxine; TRH, thyrotropin-releasing hormone; TSH, thyroid-stimulating hormone (thyrotropin).

GH secretion through somatostatin, thereby inhibiting GHRH secretion at the hypothalamus.[1] The hypothalamus also may stimulate the release of somatostatin to inhibit GH secretion. The effects of IGF-I in peripheral tissues are both GH dependent and GH independent.[2] GH is an anabolic hormone with direct "anti-insulin" metabolic effects. By stimulating protein synthesis and shifting the body's energy source from carbohydrates to fats, GH promotes a diabetic state (Table 46–1).[2] GH controls somatic growth and has a critical role in the development of normal skeletal muscle, myocardial muscle, and bone.

In healthy individuals, GH is secreted in a pulsatile manner with several short bursts occurring mostly during the night. The amount of GH secretion fluctuates throughout a person's lifetime. Secretion of GH is lowest during infancy, increases during childhood, peaks during adolescence, and then declines gradually during the middle years.[1] These changes are parallel to an age-related decline in lean muscle mass and bone mineral density.

## Growth Hormone Excess

### ▶ *Epidemiology and Etiology*

Acromegaly affects both genders equally, and the average age of presentation is 44 years. Approximately 40 to 125 people per

1 million are affected, with an estimated annual incidence of three to four cases per 1 million people.[3] In more than 95% of cases, overproduction of GH is caused by a benign pituitary adenoma, whereas malignant adenomas are rare. Most pituitary adenomas occur spontaneously as a result of a sporadic genetic mutation acquired during life. Depending on tumor size, pituitary adenomas

**FIGURE 46–2.** Before and after photographs of a patient with acromegaly. Compare the photographs (**A**) before the onset of acromegaly and (**B**) after approximately 20 years when the diagnosis was well established. Notice the coarsening of facial features, with an enlarged nose, lips, and forehead.

are classified as: (a) microadenomas if they are 10 mm or less in diameter; or (b) macroadenomas if they are greater than 10 mm. Although these tumors can produce GH, they more commonly secrete GHRH, resulting in excessive GH and IGF-I production.

▶ *Pathophysiology*

Acromegaly is a rare disorder that manifests gradually over time and typically occurs after fusion of the epiphyses (growth plates) of the long bones.[3] The facial and hand features of an acromegalic patient are depicted in Figures 46–2 and 46–3. Gigantism refers to GH excess that occurs during childhood before epiphyseal closure and results in excessive linear growth. Because the signs and symptoms of acromegaly are insidious, diagnosis of this disorder is often delayed for up to 10 years after the initial presentation of symptoms.[3] Therefore, it is important for practitioners to be vigilant in identifying this disease in the early stages.

Diagnosis of acromegaly is based on both clinical and biochemical findings. Because GH fluctuates throughout the day, a single random measurement is never a reliable diagnostic tool to evaluate GH excess.[1] GH is suppressed after administration of a 75-g oral glucose challenge because postprandial hyperglycemia inhibits secretion of GH. Therefore, measurement of serum GH secretion in response to an oral glucose tolerance test (OGTT) is the primary biochemical test for diagnosing acromegaly. If the nadir GH concentration is greater than 0.4 ng/mL (0.4 mcg/L;
18 pmol/L) during the test or the random GH concentration is greater than 1 ng/mL (1 mcg/L; 45 pmol/L), the patient is diagnosed with acromegaly.[4] In addition to clinical presentation, an elevated IGF-I serum concentration helps to confirm the diagnosis. IGF-I concentrations are often represented as age- and sex-matched population values.[4] They are relatively stable and correlate positively with mean GH concentrations,[1] thus making elevations in IGF-I concentrations an ideal and reliable biochemical marker to monitor disease activity and response to therapy.[3,4]

▶ *Acromegaly Treatment*

**Desired Outcomes** Patients with untreated acromegaly experience a two- to three-fold increase in mortality rate primarily because of cardiovascular and pulmonary diseases.[6] **KEY CONCEPT** *Prolonged exposure to elevated GH and IGF-I can lead to serious complications in patients with acromegaly. Aggressively manage comorbid conditions such as hypertension, diabetes, dysrhythmias, coronary artery disease, and heart failure to prevent cardiovascular, pulmonary, metabolic, respiratory, and neuropathic complications.*[4] Normalization of GH and IGF-I concentrations lowers the mortality risk and may improve overall life expectancy. The goals of therapy are as follows[3,7]:

- Reduce fasting morning GH and IGF-I concentrations as close to normal as possible
- Reduce tumor size to relieve tumor mass effect
- Prevent tumor recurrence
- Preserve normal pituitary function
- Improve clinical signs and symptoms
- Alleviate significant morbidities
- Reduce mortality rates to those of the general population

● **Surgical Treatment** According to the American Association of Clinical Endocrinologists (AACE) treatment guidelines for acromegaly, **KEY CONCEPT** *surgical resection of the pituitary tumor through* transsphenoidal pituitary microsurgery *is the treatment of choice for most patients with GH-producing pituitary adenomas.*[3] When performed by experienced surgeons, approximately 80% of patients with microadenomas and fewer than 50% of patients with macroadenomas achieve biochemical control.[3] Complete

**FIGURE 46–3.** Photograph of hands from a patient with acromegaly. Soft tissue swelling and enlargement of the hand in a woman with acromegaly resulting in increased ring and glove size.

## Clinical Presentation and Diagnosis of Acromegaly[3–5]

### General

The patient will experience slow development of soft tissue overgrowth affecting many body systems. Signs and symptoms may progress gradually over 7 to 10 years.

### Symptoms

- Headache and compromised visual function (loss of peripheral vision and blurred vision) caused by the actual tumor mass and its close proximity to the optic structures
- Weakness, low blood sugar, or weight loss caused by disruption of adrenal function (ie, ACTH deficiency) by effect of tumor mass on the pituitary
- Fatigue and weight gain caused by disruption of thyroid function (ie, TSH deficiency) by effect of tumor mass on the pituitary
- Absence of regular menstrual periods (amenorrhea), impotence, and decreased libido caused by disruption of the gonadotropin secretion (ie, LH and FSH)
- Excessive sweating, joint pain, nerve pain, and abnormal neurologic sensations (paresthesias) related to elevated GH and IGF-I concentrations

### Signs

- Coarsening of facial features
- Increased hand volume
- Increased ring and shoe size
- Increased spacing between teeth
- Increased acne or oily skin
- Enlarged tongue
- Deepening of voice
- Thick, irregular, and patchy skin discoloration
- Enlarged nose, lips, and forehead (frontal bossing)
- Abnormal protrusion of the mandible (prognathia) and bite abnormalities
- Inappropriate secretion of breast milk (galactorrhea)
- Abnormal enlargement of various organs (organomegaly) such as liver, spleen, and heart
- Carpal tunnel syndrome caused by nerve compression from the swollen tissue

### Laboratory Tests

- Random GH concentration greater than 1 ng/mL (1 mcg/L; 45 pmol/L) or nadir GH concentration greater than 0.4 ng/mL (0.4 mcg/L; 18 pmol/L) after an OGTT and elevated IGF-I concentration compared with age-matched control values.
- Loss of other hormonal functions caused by tumor mass compression of the anterior pituitary.
- Measure prolactin concentration in all patients because prolactin cosecretion is common.
- Glucose intolerance may be present in up to 50% of patients.

### Additional Clinical Sequelae

- Cardiovascular diseases: hypertension, coronary heart disease, cardiomyopathy, left ventricular hypertrophy, and arrhythmia.
- Osteoarthritis and joint damage develop in up to 75% of patients.
- Respiratory disorders and sleep apnea occur in up to 70% of patients.
- Type 2 diabetes mellitus develops in 56% of patients.
- Increased risk for the development of esophageal, colon, and stomach cancer.

### Other Diagnostic Tests

- Perform magnetic resonance imaging (MRI) examination of the pituitary to locate the tumor and validate the diagnosis.
- Obtain serum prolactin concentrations to assess for hyperprolactinemia and hypopituitarism.
- Without obvious pituitary tumor but proven acromegaly, measurement of GHRH may be helpful to detect ectopic tumors.

_____

Adapted from Jordan JK, Sheehan AH, Yanovski JA, Calis KA. Pituitary gland disorders. In: Dipiro JT, Talbert RL, Yee GC, et al, eds. Pharmacotherapy. A Pathophysiologic Approach. 9th ed. New York: McGraw-Hill; 2014:1237–1252.

resection of a macroadenoma may be difficult if the tumor has already invaded the surrounding nerves and tissues. In such cases, debulking of the tumor along with adjunctive radiation and/or pharmacotherapy may improve treatment outcome. Infrequent surgical complications include meningitis, serious visual impairment, cerebrospinal fluid leakage, diabetes insipidus, and permanent hypopituitarism.[3] Relative contraindications to surgery include patient frailty, acromegaly-associated comorbidities, and medically unstable conditions such as airway difficulties, severe hypertension, or uncontrolled diabetes.

**Pharmacologic Therapy** Pharmacologic therapy is often necessary for patients in whom surgery is not an option (Figure 46–4).[7] Somatostatin analogs, GH receptor antagonists, and dopamine agonists are the primary pharmacologic therapies used for the management of acromegaly (Table 46–2).[3,7,8] Pharmacologic therapy avoids hypopituitarism and other surgical risks.

*Somatostatin Analog (GH-Inhibiting Hormone)* **KEY CONCEPT** *Somatostatin analogs are the mainstay of pharmacotherapy for the treatment of acromegaly when surgery is not appropriate, or as an adjuvant therapy until patients achieve a sustained response to radiation therapy.*[7] These agents mimic endogenous somatostatins and bind to somatostatin receptors in the pituitary to cause potent inhibition of GH, insulin, and glucagon secretion. Long-term treatment can sustain GH suppression, alleviate soft tissue manifestations, and reduce tumor size. Use of the first-generation somatostatin analog octreotide is limited by its extremely short duration of action, which necessitates frequent injections of

## Patient Encounter 1, Part 1: Acromegaly: Medical History and Clinical Presentation

A 61-year-old Caucasian woman has not seen her primary care provider for years prior due to financial issues and now complains of a sore on her abdomen, frequent headaches, and seeing "red and blue spots" in her vision. The patient has noticeably large facial features, and manly arms, hands, and legs. She states, "I used to have those beautiful piano fingers until I reached my teens!" She had always believed her masculine features were due to growing up with five brothers.

**PMH:** Uncontrolled hypertension for 4 years; recently diagnosed type 2 diabetes mellitus

**FH:** Positive for diabetes in patient's mother and five brothers

**Allergies:** NKDA

**SH:** Unemployed and uninsured, cleans 60+ hallways at her apartment to cover rent and utility; recently quit smoking

**Meds:** Lisinopril/hydrochlorothiazide 20/12.5 mg once daily; metformin 1000 mg twice daily; insulin glargine 20 units once daily; aspirin 81 mg once daily

*Based on the information available, what signs and symptoms are suggestive of acromegaly?*

*What comorbidities are present in the patient as result of untreated acromegaly?*

*What diagnostic tests should be performed to confirm the patient's diagnosis of acromegaly?*

at least three times per day. The long-acting preparations of octreotide and lanreotide are considered the cornerstone of therapy because of improved patient adherence and acceptability. Somatostatin analogs modestly reduce pituitary tumor size in more than half of the patients with acromegaly.[9] Their efficacy and safety have been demonstrated in long-term studies (up to 9 years with octreotide and 4 years with lanreotide).[10–12] Overall, the somatostatin analogs normalize GH and IGF-I

concentrations in 56% and 55% of patients, respectively.[10] The efficacy of lanreotide autogel is comparable to that of depot formulations of lanreotide and octreotide in achieving clinical and biochemical control.[3,10] Because somatostatin analogs can achieve substantial relief of clinical symptoms with significant reduction in tumor size,[13] it is important to monitor patients for tumor recurrence if treatment is discontinued.[3] It is not yet

**First-line treatment**
SRL (long-acting lanreotide or octreotide)
Dopamine agonist (cabergoline) can be considered if IGF-I < 2×ULN

Disease well controlled → Consider reducing SRL dose or increasing dose interval → Disease well controlled → Consider SRL withdrawal and closely monitor IGF-I levels

Partial response → Increase SRL dose or decrease dose interval → No response → SRL + pegvisomant Pegvisomant + dopamine agonist SRL + dopamine agonist

Partial response → SRL + pegvisomant → No response → Increase pegvisomant dose and/or pegvisomant + dopamine agonist therapy

No response → Switch to pegvisomant → Disease well controlled → Consider reducing pegvisomant dose and/or increasing dose interval

**FIGURE 46–4.** Medical management of patients with acromegaly.[7] A proposed algorithm for the medical management of acromegaly after surgery or as primary treatment strategy when surgery is inappropriate. Radiation therapy as rescue therapy has not been considered in this algorithm because its use is usually determined by a multidisciplinary management team. IGF-I, insulin-like growth factor I; SRL, somatostatin receptor ligan; ULN, upper limit of normal. Expert consensus document: A consensus on the medical treatment of acromegaly. Nat Rev Endocrinol. 2014;10:243–248.)

## Table 46-2

**Comparison of Various Drugs for Treatment of Acromegaly[3,7,8]**

| Drug Class | Dopamine Agonist | Somatostatin Analog | | | | GH Receptor Antagonist |
|---|---|---|---|---|---|---|
| Medication | Cabergoline | Octreotide (Sandostatin) | Octreotide LAR (Sandostatin LAR) | Lanreotide SR | Lanreotide Autogel (Somatuline Depot) | Pegvisomant (Somavert) |
| Starting dose | 1 mg/week orally | 50 mcg SC thrice daily | 20 mg IM every 4 weeks | 60 mg IM every 2 weeks | 90 mg deep SC every 4 weeks[a] | 10 mg SC daily after initial loading dose of 40 mg |
| Maximal dose | 4 mg/week orally | 200 mcg SC thrice daily | 40 mg IM every 4 weeks[b] | 120 mg IM every 7 days | 120 mg deep SC every 4 weeks | 40 mg SC daily[c] |
| Dosage in hepatic insufficiency | Dosage reduction may be recommended for patients with severe hepatic failure | — | Cirrhosis: 10 mg IM every 4 weeks | Dosage reduction may be necessary; no guidelines available | Moderate to severe impairment: starting dose 60 mg every 4 weeks | Discontinue therapy if liver function tests are elevated at least five times the upper limit of normal or transaminase at least three times upper limit of normal with any increase in serum total bilirubin |
| Dosage in renal failure | None | Dialysis dependent: adjustment may be necessary; no guidelines available | Dialysis-dependent renal impairment: 10 mg IM every 4 weeks | Dosage reduction may be necessary; no guidelines available | Moderate to severe impairment: starting dose, 60 mg every 4 weeks | None |
| Side effects | Nausea, GI cramps, headache, drowsiness, dizziness, fatigue | Nausea, GI cramps, diarrhea, flatulence, abdominal pain, constipation, gallstones | Nausea, GI cramps, diarrhea, flatulence, abdominal pain, constipation, gallstones | Nausea, GI cramps, diarrhea, flatulence, abdominal pain, constipation, gallstones | Nausea, GI cramps, diarrhea, flatulence, abdominal pain, constipation, gallstones | Headache, fatigue, GI cramps, abnormal liver enzymes, injection site reactions, sweating |
| Monitoring suggestions | GH, IGF-I, and prolactin concentration 4–6 weeks after each dose change | GH and IGF-I 3 months after dose change, thyroid function tests and blood glucose | GH and IGF-I 3 months after dose change, thyroid function tests and blood glucose | GH and IGF-I 3 months after dose change, thyroid function tests and blood glucose | GH and IGF-I 3 months after dose change, thyroid function tests and blood glucose | Liver function tests (serum transaminase, total bilirubin, alkaline phosphatase) monthly for 6 months, quarterly for next 6 months, then biannually for the next year; MRI every 6 months; IGF-I (not GH) after first year, then yearly |

GH, growth hormone; GI, gastrointestinal; IGF-I, insulin-like growth factor-I; IM, intramuscularly; LAR, long-acting release; MRI, magnetic resonance imaging; SC, subcutaneously; SR, slow-release.

[a]In the United States, initiate lanreotide at 90 mg every 28 days for 3 months and then titrate accordingly based on patient response. Different labeled dosing guidelines exist for the United Kingdom and Canada.

[b]Product labeling recommends a maximum of 30 mg IM every 4 weeks.

[c]Alternative dose administration protocol of twice a week or once a week has been used.[3]

Adapted from AACE Medical Guidelines for Clinical Practice for the diagnosis and treatment of acromegaly. Endocr Pract. 2004;10:213–225 by permission of publisher, American Association of Clinical Endocrinologists (AACE) Corp.

known whether use of somatostatin analogs before surgery has additional benefits over surgery alone.[3]

Somatostatin analogs are generally well tolerated. Transient gastrointestinal (GI) disturbances are common but usually subside within the first 3 months of therapy. Somatostatin analogs inhibit gallbladder contractility and decrease bile secretion; therefore, their major adverse effect is development of **biliary sludge** and asymptomatic **gallstones** (**cholelithiasis**). Cholelithiasis typically occurs in patients treated for 12 months or longer and is unrelated to age, gender, or dose. Somatostatin analog-induced gallstones are generally asymptomatic, and prophylactic therapy is usually not needed.[6] Additionally, somatostatin analogs may alter the balance of counterregulatory hormones (ie, glucagon, insulin, and GH), resulting in either hypoglycemia or hyperglycemia. Octreotide also may suppress pituitary release of TSH, leading to decreased thyroid hormone secretion and subsequent hypothyroidism in 12% of treated patients. Close monitoring of thyroid function and glucose metabolism is recommended. Sinus bradycardia, conduction abnormalities, and arrhythmias have been reported with octreotide and lanreotide. Because of the potential adverse effects of the somatostatin analogs, concomitant use with insulin, oral hypoglycemic agents, β-blockers, or calcium channel blockers may require careful dosage adjustment. Somatostatin analogs may also alter the bioavailability and elimination of cyclosporine, and monitoring of cyclosporine serum concentration is necessary.

*GH-Receptor Antagonist*  The advent of a GH-receptor antagonist represents a novel approach to the treatment of acromegaly. Pegvisomant is the only genetically engineered GH-receptor antagonist that blocks the action of GH. Pegvisomant is indicated for treatment of acromegaly in patients who have an inadequate response to surgery or radiation therapy. The effects of pegvisomant work independently of tumor characteristics, somatostatin, and dopamine receptors. Long-term safety and efficacy of pegvisomant (up to 5 years) from an ongoing postmarketing surveillance registry (ACROSTUDY) suggest a reasonable benefit/risk balance.[14] In patients who were relatively unresponsive to other medical or surgical therapies, normal IGF-I concentrations were achieved in 63% of the patients treated with pegvisomant (mean dose of 18 mg/day)[14] and in 69% to 100% of patients treated with pegvisomant and somatostatin analog therapy.[15–17] Pegvisomant therapy may have favorable effects on glucose tolerance (the body's ability to metabolize glucose) and insulin sensitivity (capacity of cells to respond to insulin). However, use of pegvisomant is associated with significant dose-dependent increases in GH despite declining IGF-I concentrations. The dose-dependent increase in GH is troubling because it has been suggested that persistent elevation of GH concentration may be indicative of tumor growth. Although the incidence of pituitary tumor enlargement is low (3.2%), careful monitoring with periodic imaging scans is nonetheless warranted, especially when administering pegvisomant to patients at risk for visual damage from large tumors that may impinge on the optic chiasm.[14] KEY CONCEPT *Pegvisomant is recommended in patients who have inadequate response to somatostatin analogs, or as an adjuvant for patients who have only a partial response to somatostatin analogs.*[3,7] The long-term use of pegvisomant appears to be well tolerated with a low incidence of adverse effects, including self-limiting injection-site reactions (2.2%) and elevated liver enzymes (2.5%).[14] Although elevations of liver enzymes often are self-limiting and not associated with symptoms,[3] hepatotoxicity has been reported in clinical trials, particularly in diabetic patients receiving combined pegvisomant and somatostatin analogs.[17,18] Therefore, serum transaminases,

total bilirubin, and alkaline phosphatase should be assessed before initiating therapy and periodically thereafter. Use caution when administering pegvisomant to patients with elevated liver function tests, and therapy should be discontinued in patients who present with clinical signs and symptoms of hepatic injury.

*Dopamine Agonists*  Dopamine is one of the neurotransmitters that can increase GH secretion in healthy adults. However, dopamine agonists administered to patients with acromegaly exert the opposite effect and suppress GH release from the tumor. The first dopamine agonist used for acromegaly, bromocriptine, achieved normal IGF-I concentrations in fewer than 10% of patients.[6] The large doses of bromocriptine required to achieve the desired response are often associated with dose-limiting toxicity such as GI discomfort and orthostatic hypotension. Cabergoline, a selective long-acting dopamine agonist with improved tolerability, can effectively reduce GH and IGF-I concentrations in approximately 40% of patients.[3] Acromegalic patients with coexisting hyperprolactinemia achieve a more favorable response to cabergoline.[3] Although orally administered dopamine agonists are the least expensive medical therapy for managing acromegaly, the major disadvantage is their relative lack of efficacy compared with existing therapeutic options. KEY CONCEPT *Cabergoline may be considered for patients with modest elevation of GH and IGF-I concentrations less than two times the upper limit of normal. It may also be used as adjunctive therapy in patients unresponsive to monotherapy with somatostatin analogs or pegvisomant.*[7] Although cardiac valvular abnormalities have been observed in patients using higher doses of cabergoline for Parkinson disease, similar findings have not been reported in patients with acromegaly.[3,19] Nonetheless, echocardiographic monitoring for potential cardiac abnormalities is warranted for patients who require prolonged, high-dose cabergoline therapy.

**Radiation Therapy**  Radiation therapy is an important adjunctive therapy in patients with residual GH excess after surgery or pharmacologic therapy. Treatment involves the use of radiation to destroy rapidly growing tumor cells, and often results in a reduction in tumor size. A major complication of radiation therapy is hypopituitarism, requiring lifelong hormone replacement.[3] There is also the potential for optic nerve damage if the pituitary tumor is near the optic tracts. Radiation therapy may take 10 to 20 years before its full effects become evident.[3] Owing to this delay in onset of effectiveness, pharmacologic therapy with a somatostatin analog often is indicated as bridge therapy.[3] Men and women who desire to have children should be warned that pituitary irradiation therapy may impair fertility because of subsequent gonadotropin deficiency.[3]

▶ *Outcome Evaluation*

- Lifelong biochemical assessment is critical for determining therapeutic outcomes. Although some patients may experience a rapid decline in GH concentrations after surgery, stabilization of IGF-I concentrations usually occurs 3 months after surgery but rarely may be delayed for up to 12 months. Fully assess pituitary function 2 to 3 months after surgery.[3] Monitor GH and IGF-I concentrations every 3 to 6 months postoperatively to assess treatment response.[3] Obtain IGF-I concentrations annually in all postsurgical patients to monitor for potential pituitary tumor recurrence.[3]

- Assess MRI 3 to 4 months after surgery and 3 to 6 months after starting medical therapy.[20] Because up to 10% of pituitary tumors may recur within 15 years after surgery,[21] continual postoperative monitoring is recommended.

- For patients treated with somatostatin analogs, assess baseline fasting blood glucose, thyroid function tests, and heart rate. Thereafter, periodically monitor patients for adverse reactions such as GI disturbances, glucose intolerance, signs and symptoms of thyroid abnormalities, bradycardia, and arrhythmias in patients receiving long-term somatostatin analogs. Reevaluate IGF-I and GH concentrations at 3-month intervals to determine therapeutic response and inquire about symptoms of gallbladder disease (eg, intermittent pain in the upper right abdomen) during follow-up appointments.[3] If normalization of GH and IGF-I concentrations are not fully achieved after 1 year, perform MRI 6 months later and annually thereafter to monitor tumor mass.[3]

- For patients treated with a GH receptor antagonist, GH concentrations are not measured because pegvisomant is a modified GH molecule that is detected in commercial GH assays, resulting in falsely elevated GH concentrations. Therefore, monitor IGF-I concentrations to assess response to pegvisomant therapy. After appropriate dose titration, monitor IGF-I concentrations every 6 months.[3] Concern for tumor growth requires careful monitoring of tumor size; therefore, perform MRI every 6 months during the first year of therapy and annually thereafter.[3] Because of the potential for hepatotoxicity with pegvisomant therapy, it is mandatory to monitor liver enzymes prior to initiation of therapy, monthly during the first 6 months, quarterly for the next 6 months, and then biannually thereafter.[3] More frequent monitoring of liver enzymes is warranted in patients with elevated liver enzymes at baseline.[3]

- For patients receiving dopamine agonists, the maximal suppression of GH and IGF-I concentrations may take up to 3 months to achieve. After stable control of biochemical markers is achieved with dopamine agonists or somatostatin analogs, monitor GH and IGF-I concentrations annually.[3]

- With conventional multidose radiation therapy, the most rapid decline in GH serum concentrations occurs within the first 2 years; monitor GH concentrations at the second year and annually thereafter.[3,21] Patients who receive single-dose radiation therapy should be evaluated at 6-month intervals because response is observed earlier. Repeatedly assess pituitary function over the years after radiation therapy.[3]

## Growth Hormone Deficiency

### ▶ *Epidemiology and Etiology*

In the United States, GH deficiency affects approximately 50,000 adults, with around 6000 new cases diagnosed annually.[22] Approximately 10,000 to 15,000 children have growth failure owing to GH deficiency. Children may present with GH deficiency at any time during their developmental stages. The evaluation for GH deficiency in a child of short stature should be deferred until appropriate exclusion of other identifiable causes of growth failure, such as hypothyroidism, chronic illness, malnutrition, genetic syndromes, and skeletal disorders, has occurred. Several medications, such as somatostatin analogs, gonadotropin-releasing hormone (GnRH) agonists, methoxamine, phentolamine, isoproterenol, glucocorticoids, cimetidine, methylphenidate, and amphetamine derivatives, may induce GH insufficiency.[23]

### ▶ *Pathophysiology*

GH deficiency exists when GH is absent or produced in inadequate amounts. GH deficiency may be congenital, acquired, or result from disruption of the hypothalamus–pituitary axis. GH deficiency may be an isolated condition or occasionally be accompanied by another endocrine disorder (eg, panhypopituitarism). Because GH is frequently undetectable with random sampling, a stimulation or provocative test usually is performed to confirm the diagnosis. The gold standard for diagnosis of

## Patient Encounter 1, Part 2: Acromegaly: Physical Examination and Diagnostic Tests

**PE:**

**VS:** BP 162/116 mm Hg, P 112 beats/min, RR 18 breaths/min, T 36.8°C (98.3°F), Ht 168 cm (5′6″), Wt 72 kg (159 lbs), BMI 25.8 kg/m²

**ROS:** (+) HA, (+) deepening of voice

**HEENT:** Visual field defects; head is elongated with bony prominence of the forehead, nose, and lower jaw; large fleshy nose

**CV:** RRR, normal $S_1$ and $S_2$; no murmurs, rubs, or gallops, (–) chest pain, palpitation, orthopnea, and leg swelling

**Pulm:** (–) SOB, (–) cough

**GI:** (–) Nausea, vomiting, and abdominal pain

**Abd:** Soft, nontender, nondistended; (+) bowel sounds, (–) hepatosplenomegaly

**Skin:** Skin lesion healing

**Neuro:** A & O x 3. Normal reflexes

**Psychiatric:** Normal mood and affect. Spacy, sweet, but needs extra help understanding instructions

**Available Labs:** Electrolytes and renal function are within normal limits. Fasting blood glucose concentration is 346 mg/dL (19.2 mmol/L), HgbA$_{1c}$ is 11.9% (0.119; 107 mmol/mol), (+) microalbuminuria. GH concentration 1 hour after an OGTT is 83.6 ng/mL (83.6 mcg/L; 3779 pmol/L). Elevated IGF-I concentration at 998 ng/mL (998 mcg/L; 131 nmol/L). TSH is slightly low at 0.33 μU/mL (0.33 mU/L) and FT$_4$ is within normal range at 1.1 ng/dL (14.2 pmol/L)

**MRI:** (+) 12 mm benign pituitary adenoma extending toward the optic chiasm; no invasion into the cavernous sinus

*If the patient is unwilling to undergo surgery, what pharmacologic treatment options are available for her?*

*Given that she is currently uninsured without a source of income, what factors need to be considered when choosing a pharmacologic treatment option?*

*Provide monitoring parameters to assess efficacy and safety to the patient starting on octreotide long-acting release.*

## Patient Care Process: Acromegaly

**Patient Assessment:**

- Assess the patient's clinical signs and symptoms to determine the severity of acromegaly.
- Review the biochemical disease markers to assess the severity of acromegaly.
- Review the available diagnostic data to determine pituitary tumor size and location.
- Determine if the patient has a coexisting prolactin secreting tumor and if the tumor extends toward the optic chiasm or if it is continuous on the optic tracts.

**Therapy Evaluation:**

- Assess presence of acromegaly complications. Identify any significant comorbidities associated with acromegaly that require immediate treatment or early diagnosis.
- Determine treatment options the patient has tried in the past.
- Evaluate patient for presence of surgical contraindications to transsphenoidal microsurgery. Determine if the patient is able or willing to undergo surgical intervention.
- If surgical intervention does not achieve satisfactory disease control, select subsequent appropriate pharmacologic therapy based on patient-specific factors (see Figure 46–4). Be sure to consider if the patient has any contraindications or allergies to therapies (see Table 46–2).

**Care Plan Development:**

- Assess patient's response and complications to surgical intervention. Measure both GH and IGF-I concentrations.

- Determine if selected drug doses are optimal (see Table 46–2). Consider if the patient's therapy requires any dose adjustments.
- Provide patient education regarding disease state, and nondrug and drug therapy:
  - Possible complications of acromegaly
  - How to reduce the modifiable cardiovascular and metabolic risk factors
  - Potential effectiveness and disadvantages of existing treatment options
  - Importance of adherence to therapy
  - Potential adverse effects
- Evaluate patient for presence of adverse drug reactions and drug interactions.

**Follow-up Evaluation:**

- Assess biochemical markers annually once disease control is achieved.
- Routinely assess acromegaly complications; include blood pressure, glucose tolerance, fasting lipid profile, cardiac evaluations (if clinically indicated), colonoscopy, dual-energy x-ray absorptiometry (DEXA) scan (hypogonadal only), evaluation of residual pituitary function, and sleep apnea.

adults with GH deficiency is the insulin tolerance test (ITT), with glucagon as an alternative if GHRH is unavailable.[24] Adults exhibiting a peak GH concentration of less than 5.1 ng/mL (5.1 mcg/L; 230 pmol/L) after two ITT simulation tests would warrant treatment.[24] In prepubertal children, measurement of IGF-I concentrations may be useful in evaluating GH deficiency.[25] The diagnosis of GH deficiency in children is further supported if height is more than two standard deviations below

## Clinical Presentation and Diagnosis of Growth Hormone Deficiency in Children[5,22]

**General**

The patient will have a physical height that is greater than two standard deviations below the population mean for a given age and gender.

**Signs**

- The patient will present with reduced growth velocity and delayed skeletal maturation.
- Children with GH-deficient or GH-insufficient short stature also may present with abdominal obesity, prominence of the forehead, and immaturity of the face.

**Laboratory Tests**

- Patients will exhibit a peak GH concentration of less than 10 ng/mL (10 mcg/L; 452 pmol/L) after a GH stimulation test.
- Reduced IGF-I concentration also may be present.

- Because GH deficiency may be accompanied by the loss of other pituitary hormones, hypoglycemia, and hypothyroidism also may be noted.

**Other Diagnostic Tests**

- Perform MRI or computed tomography (CT) scan of the hypothalamic–pituitary region to detect structural or developmental anomaly.
- Perform radiography of the left wrist and hand for children older than 1 year of age to estimate bone age (knee and ankle for children younger than 1 year of age).

Adapted from Jordan JK, Sheehan AH, Yanovski JA, Calis KA. Pituitary gland disorders. In: Dipiro JT, Talbert RL, Yee GC, et al, eds. Pharmacotherapy. A Pathophysiologic Approach. 9th ed. New York: McGraw-Hill; 2014:1237–1252.

## Clinical Presentation and Diagnosis of Growth Hormone Deficiency in Adults[24,26,27,31,34]

**General**

The patient likely will have a history of childhood-onset GH deficiency; hypothalamic or pituitary disorder; or the presence of three or four other pituitary hormone deficiencies caused by head trauma, tumor, infiltrative diseases, surgery, or radiation therapy.

**Symptoms**

- Reduced strength and exercise capacity
- Defective sweating
- Psychological problems
- Low self-esteem
- Depression
- Fatigue or listlessness
- Sleep disturbance
- Anxiety
- Social isolation
- Emotional lability and impaired self-control
- Poor marital and socioeconomic performance

**Signs**

- Increased fat mass (especially abdominal obesity)
- Reduced lean body mass

- Reduced muscle strength
- Reduced exercise performance
- Thin, dry skin; cool peripheries; poor venous access
- Depressed affect, labile emotions
- Impaired cardiac function as evidenced by abnormal echocardiography or stress test results

**Laboratory Tests**

- Patients will exhibit a peak GH concentration of less than 5.1 ng/mL (5.1 mcg/L; 231 pmol/L) after a GH stimulation test. Insulin tolerance test (ITT) is the gold standard stimulation test. Low or low-normal IGF-I concentration also may be present. Presence of three or more pituitary hormone deficiencies with a low IGF-I concentration do not require further stimulation test.
- Increased low-density lipoprotein cholesterol, total cholesterol, triglycerides; decreased high-density lipoprotein cholesterol.
- Reduced bone mineral density associated with an increased risk of fracture.
- Increased insulin resistance and prevalence of impaired glucose tolerance.
- GH deficiency may be accompanied by the loss of other pituitary hormones.

the population mean (age- and sex-matched).[22] Failure of linear growth is an almost universal presenting feature of childhood GH deficiency.

Childhood GH deficiency may or may not continue into adulthood. Most adults with GH deficiency have overt pituitary disease and present with nonspecific clinical disorders distinct from pediatric GH deficiency. Adult GH deficiency presumably is associated with an increased risk of death from cardiovascular diseases.[24]

▶ **Treatment**

**Desired Outcomes** The goal of treatment for GH deficiency is to correct associated clinical symptoms.[22] In children, prompt diagnosis and early initiation of treatment are important to maximize final adult height. In adults, the goal is to achieve normal physiologic GH concentrations in an attempt to reverse metabolic, functional, and psychological abnormalities.[24,26]

**Pharmacologic Therapy** KEY CONCEPT *Recombinant GH therapy is the main pharmacologic treatment for GH deficiency in both children and adults.* It promotes skeletal, visceral, and general body growth; stimulates protein anabolism; and affects bone, fat, and mineral metabolism (see Table 46–1).[2] GH therapy requires subcutaneous or intramuscular administrations. Because two-thirds of GH secretion normally occurs during sleep, it is recommended to administer GH injections in the evening.[27] Many preparations of synthetic GH (somatropin) are available with a variety of injection devices to make administration more appealing and easier. Tev-Tropin is only approved for use in

children, and other somatropin products such as Nutropin AQ, Humatrope, Norditropin, Genotropin, Omnitrope, and Saizen are approved in both children and adults.

KEY CONCEPT *Although comparative trials have not been conducted to date, recombinant GH products appear to have similar efficacy for treating GH deficiency as long as the regimen follows currently approved guidelines.* GH secretion decreases with age; therefore, older adults with GH deficiency often require substantially lower replacement doses than younger individuals. The optimal therapeutic approach is to initiate GH therapy at lower doses and titrate according to clinical response, adverse effects, and IGF-I concentrations.[28,29] Table 46–3 lists the recommended GH replacement doses for children and adults.[29,30] Conventional weight-based regimens are not recommended in adults due to lack of evidence supporting higher dosages in heavier individuals and greater potential for adverse effects.[24,26,31] Maintenance doses may be lower with chronic GH therapy.[32] For elderly patients, lower GH replacement doses often are adequate because of increased GH sensitivity.[26,28,29] Women with intact hypothalamic–pituitary–gonadal axis or on estrogen therapy (or oral contraceptives) generally require a higher GH dose than men due to decreased GH concentrations associated with estrogen.[28,29] Carefully monitor patients requiring replacement therapy with estrogens, thyroid hormones, or glucocorticoids because of potential interactions with GH therapy.[26] The potency of GH products is generally expressed as 3 international units (IU or mU) per 1 milligram of protein.[24] Selection of an injection device depends on patient preference due to lack of differences in clinical outcomes among the various injection systems.[29,30]

**Table 46–3**

**Dose Recommendation for Growth Hormone Deficiency in Children and Adults[29,30]**

| | Growth Hormone Replacement Dose | Dose Titration |
|---|---|---|
| **Children[30]** | **Dosing Range** | • Evaluate every 3–6 months based on height and height velocity. |
| Prepubertal children | 25–50 mcg/kg/day | • Monitor IGF-I and IGFBP-3 yearly. |
| Adolescents | 25–100 mcg/kg/day | • Monitor TSH and $T_4$ for hypothyroidism. |
| | | • Reduce dose if serum IGF-I concentration is substantially above normal after 2 years of therapy. |
| **Adults[29]** | **Starting Dose** | • Increase dose by 0.1–0.2 mg/day based on clinical response, serum IGF-I concentrations, and side effects at 1- to 2-month intervals. Longer time intervals and smaller dose titration may be necessary in older adults. |
| Age < 30 years | 0.4–0.5 mg/day[a] | |
| Age 30–60 years | 0.2–0.3 mg/day | |
| Age > 60 years | 0.1–0.2 mg/day | |
| Diabetes or glucose intolerance (overweight, obese, or history of gestational diabetes) | 0.1–0.2 mg/day | |
| Hepatic impairment | — | • Clearance may be reduced in patients with severe hepatic dysfunction; specific dosing suggestions are not available. |
| Renal impairment | — | • Patients with chronic renal failure tend to have decreased clearance; specific dosing suggestions are not available. |

[a]Might require a higher dose for patients transitioning from pediatric treatment.

IGFBP-3, insulin-like growth factor-bind protein 3; IGF-I, insulin-like growth factor-I; $T_4$, thyroxine; TSH, thyroid-stimulating hormone.

Evidence has suggested that GH treatment in GH-deficient children can increase short-term growth and improve final adult height.[22] Beneficial effects of GH therapy in adults with GH deficiency have been demonstrated to normalize body composition and metabolic process; improve cardiac risk profile, bone mineral density, quality of life, and psychological well-being; and increase muscle strength and exercise capacity.[24,33] The available data on cardiovascular and metabolic benefits of long-term GH replacement therapy in adults are inconsistent and additional research is needed to adequately assess the risks and benefits of long-term GH replacement.[33] Overall, reduction in mortality with GH therapy remains to be established.

Practitioners should begin GH therapy as soon as possible to optimize long-term growth, especially for young children in whom GH deficiency is complicated by fasting hypoglycemia.[22] Selection of the optimal GH replacement dose will need to be individualized depending on response, financial resources, and product availability. Although the appropriate time to discontinue therapy remains controversial in childhood GH deficiency, it is reasonable to continue GH replacement until the child has reached satisfactory adult height, achieved documented epiphyseal closure, or failed to respond to therapy.[22] Management of the transition between pediatric and adult GH replacement remains a challenge because limited data are available. The secretion of GH during adolescence is normally lower than during puberty but higher than during adulthood. Therefore, for patients in a transition phase who may be restarting GH therapy, the initial dose for an adolescent is approximately the average of the pediatric dose required for growth and the adult dose.[29] Starting GH therapy at a low dose and gradually titrating upward may decrease the potential for adverse effects. The optimal duration of treatment with GH therapy remains unclear, but lifelong therapy may be required. However, GH replacement should be discontinued if therapeutic benefit is not achieved after 2 years of therapy.[29]

In both children and adults, treatment with GH may mask underlying central hypothyroidism and adrenal insufficiency.[35]

Treatment with GH also may induce insulin resistance and lead to the development of glucose intolerance in patients with preexisting risk factors. Adults are more susceptible to dose-related adverse effects of GH-induced symptoms, such as edema, arthralgia, myalgia, and carpal tunnel syndrome, which may necessitate dose reductions in up to 40% of adults.

Children treated with GH replacement therapy rarely experience significant adverse effects. Benign increases in intracranial pressure related to GH therapy may manifest as headaches, visual changes, or altered concentrations of consciousness. This condition is generally reversible upon discontinuation of treatment. Often, GH therapy can be restarted with smaller doses without symptom recurrence. Presently, there is no compelling evidence that GH replacement therapy is associated with an increased risk of leukemia, solid tumor, or tumor recurrence.[22,26,29] GH replacement therapy is contraindicated in all patients with active malignancy.[29] However, in children with a history of malignancies, it would be prudent to wait for a 1-year tumor-free period (5 years for adults) before initiating GH therapy.[22] Any patients treated for a prior malignancy may be at risk for a second malignancy and should be monitored carefully for tumor recurrence.[22] Because deaths have been reported with use of GH in children with Prader-Willi syndrome who are severely obese or suffer from respiratory impairments, use of GH is contraindicated in these individuals. Evidence from the long-term surveillance study, Safety and Appropriateness of Growth hormone treatments in Europe (SAGhE), remains inconclusive regarding GH therapy and its risk of increased morbidity. Therefore, further surveillance monitoring is warranted.[36]

► *Outcome Evaluation*

• Children with GH deficiency should be evaluated by a pediatric endocrinologist every 3 to 6 months. Monitor for an increase in height and change in height velocity to assess response to GH therapy.[22,30] Every effort should be made

## Patient Care Process: GH Deficiency in Children

**Patient Assessment:**

- Assess the child's growth characteristics and compare the physical height with a population standard (eg, Centers for Disease Control and Prevention Growth Charts).
- Obtain a thorough history and physical examination that may indicate the possible presence of GH deficiency.
- Exclude other identifiable causes of growth failure.
- Perform imaging tests of the hypothalamic–pituitary region to detect structural or developmental anomalies.
- Perform radiography of the wrist and hand to estimate bone age.
- Perform a provocative test to measure GH and IGF-I concentrations.

**Therapy Evaluation:**

- Determine if GH therapy is indicated. Make sure the child does not have any contraindications to GH therapy.
- Determine whether patient has prescription coverage.

**Care Plan Development:**

- Initiate GH replacement therapy based on patient preference (see Table 46–3).

- Assess response (increase in height and change in height velocity) and adverse effects of GH replacement therapy. Make dosage adjustments when appropriate.
- Provide patient education regarding disease state and drug therapy. Discuss with child and parents:
  - GH deficiency
  - Potential effectiveness and disadvantages of existing GH replacement therapy
  - Importance of adherence to therapy
  - Potential for adverse effects or need for lifelong replacement.

**Follow-up Evaluation:**

- Continue GH replacement therapy until child reaches satisfactory adult height, achieves documented epiphyseal closure, or fails to respond to treatment.
- Review and retest the child using adult GH deficiency diagnostic criteria when the child reaches final adult height.

to maximize height before the onset of puberty. After final adult height is reached and GH is discontinued for at least 1 month, retest and reevaluate the patient using the adult GH-deficiency diagnostic criteria.[24,29,30]

- Although GH and IGF-I concentrations do not always correlate with growth response, measure IGF-I concentrations yearly to assess adherence to therapy and patient response. If the IGF-I concentrations are substantially

above the normal range 2 years after GH replacement therapy, the dose should be reduced.[30] IGF-I concentration may be used as a guide to gradually reduce replacement dose after epiphyseal closure.

- Routine monitoring of fasting lipid profile, bone mineral density, and body composition in children is not typically required during GH replacement but should be done before and after discontinuation of therapy.[22,30]

## Patient Care Process: GH Deficiency in Adults

**Patient Assessment:**

- Assess the patient's clinical signs and symptoms to determine the severity of GH deficiency.
- Perform a provocative test to measure GH concentrations.
- Evaluate the patient for the presence of metabolic abnormalities and cardiovascular and fracture risks.

**Therapy Evaluation:**

- Determine if GH therapy is indicated. Make sure the patient does not have any contraindications to GH therapy.
- Determine whether patient has prescription coverage.

**Care Plan Development:**

- Initiate GH replacement therapy based on patient preference and characteristics (see Table 46–3)
- Assess the efficacy and adverse effects of GH therapy and consider if the patient's therapy requires any dose

adjustments based on IGF-I concentration, patient response, and adverse effects

- Provide patient education regarding disease state and drug therapy:
  - Possible complications of GH deficiency
  - How to reduce the modifiable cardiovascular and metabolic risk factors
  - Potential disadvantages and effectiveness of existing GH replacement therapy
  - Importance of adherence to therapy
  - Potential for adverse effects or need for lifelong replacement

**Follow-up Evaluation:**

- Monitor for improvement of metabolic, cardiovascular, bone mineral density, and body composition parameters to assess response to GH therapy

- In adults, measurement of serum IGF-I, along with careful clinical evaluation, appears to be the most reliable way to assess the appropriateness of the GH dose. Measure IGF-I serum concentrations 1 to 2 months during dose titration and semiannually thereafter.[24]

- Continuously monitor for dose-related adverse effects such as edema, arthralgia, myalgia, and carpal tunnel syndrome.

- Evaluate psychological well-being.

- Assess patients' bone mineral density every 2 to 3 years.[29]

- When maintenance therapy is achieved, assess body composition (body mass index [BMI], waist circumference, waist-to-hip ratio), metabolic status (fasting glucose concentration, free thyroxine serum, hemoglobin $A_{1c}$), cardiac risk factors (eg, fasting lipid profile), hypothalamic–pituitary–adrenal axis function (eg, morning serum cortisol response to ACTH stimulation), and testosterone concentrations at 6- to 12- month intervals.[26,29]

## PROLACTIN

Prolactin is an essential hormone for normal production of breast milk after childbirth. It also plays a pivotal role in a variety of reproductive functions. Prolactin is regulated primarily by the hypothalamus–pituitary axis and secreted solely by the lactotroph cells of the anterior pituitary gland. Under normal conditions, secretion of prolactin is predominantly under inhibitory control by dopamine. Increases of hypothalamic thyrotropin-releasing hormone in primary hypothyroidism can stimulate the release of prolactin.

### Hyperprolactinemia

#### ▶ Epidemiology and Etiology

Hyperprolactinemia affects women of reproductive age more than men. Although this disorder occurs in less than 1% of the general population, the estimated prevalence in women with reproductive disorders is as high as 15% to 43%.[37] The etiologies of hyperprolactinemia are presented in **Table 46–4**.[5,23,37–40] Any medications that antagonize dopamine or stimulate prolactin release can induce hyperprolactinemia.[5,23,37,38] Therefore, it is important to exclude medication-induced hyperprolactinemia from other common causes such as pregnancy, primary hypothyroidism, benign prolactin-secreting pituitary adenoma (prolactinoma), and renal insufficiency. Prolactinomas are the most common pituitary tumors. They are classified as microprolactinomas if they are less than 10 mm in diameter and as macroprolactinomas if they are 10 mm or larger in diameter.[38] In general, microprolactinomas rarely increase in size, but macroprolactinomas have the potential to enlarge and invade the surrounding tissues.[41]

#### ▶ Pathophysiology

Hyperprolactinemia is a condition of elevated serum prolactin. It is the most common endocrine disorder of the hypothalamic–pituitary axis. High prolactin concentrations inhibit the release of gonadotropin-releasing hormone by the hypothalamus and subsequently suppress secretion of LH and FSH from the anterior pituitary (see Figure 46–1). High prolactin concentrations result in reduced gonadal hormone concentrations, often leading to reproductive dysfunction and galactorrhea (inappropriate breast milk production).

In combination with clinical symptoms, one or more serum prolactin concentrations greater than 25 ng/mL (25 mcg/L;

---

### Table 46–4

**Causes of Hyperprolactinemia**[5,23,37–40]

**Physiologic Causes**
Pregnancy
Stress (including exercise and hypoglycemia)
Breast stimulation
Breastfeeding
Coitus
Sleep
Meal
Increased prolactin production
Ovarian: Polycystic Ovarian Syndrome
Oophorectomy (removal of an ovary)
Pituitary tumors
    Adenomas
    Microprolactinoma (< 10 mm diameter)
    Macroprolactinoma (≥ 10 mm diameter)
    Hypothalamic stalk interruption (prevent dopamine from reaching the pituitary)
Hypophysitis (inflammation)
Ectopic tumors

**Hypothalamic Prolactin Stimulation**
Primary hypothyroidism
Adrenal insufficiency

**Reduced Prolactin Elimination**
Chronic renal failure
Hepatic cirrhosis

**Neurogenic Causes**
Chest wall injury (eg, surgery, herpes zoster)
Spinal cord lesions

**Abnormal Molecules**
Macroprolactinemia

**Medications**
Dopamine antagonists: antipsychotics[a], phenothiazines, metoclopramide, domperidone
Dopamine-depleting agents: reserpine, α-methyldopa
Prolactin stimulators: serotonin reuptake inhibitors, dexfenfluramine, estrogens, progestins, antiandrogens, gonadotropin-releasing hormone analogs, benzodiazepines, tricyclic antidepressants, monoamine oxidase inhibitors, protease inhibitors, histamine$_2$ receptor antagonists
Other: isoniazid, cocaine, opioids, verapamil

**Seizures**
**Idiopathic (Unknown)**

[a]Atypicals (olanzapine and clozapine) other than risperidone may cause an early but transient elevation in prolactin.[32]

Adapted in part, with permission, from Jordan JK, Sheehan AH, Yanovski JA, Calis KA. Pituitary gland disorders. In: Dipiro JT, Talbert RL, Yee GC, et al, eds. Pharmacotherapy. A Pathophysiologic Approach. 9th ed. New York: McGraw-Hill; 2014:1237–1252.

---

1087 pmol/L) will confirm the diagnosis of hyperprolactinemia in women.[39] A number of physiologic factors such as eating, exercise, and stress can transiently elevate prolactin concentrations.[5] Therefore, prolactin measurements should be obtained at rest, preferably in the morning under fasting conditions.[37] If an intravenous line is present or planned, it is prudent to wait at least 2 hours after line insertion before measuring serum prolactin to decrease detecting transient physiologic increases in prolactin concentration.[5,23,37–40] Although medication-induced hyperprolactinemia is typically associated with prolactin concentrations

## Clinical Presentation and Diagnosis of Hyperprolactinemia[5,38–40]

**General**

Hyperprolactinemia most commonly affects women of reproductive age and is very rare in men.

**Signs and Symptoms**

Premenopausal women

- Headache and compromised or loss of vision caused by the prolactin-secreting tumor and its close proximity to the optic structures.
- Clinical presentation is associated with the degree of prolactin elevation:
  - Prolactin greater than 100 ng/mL (100 mcg/L; 4348 pmol/L): hypogonadism, galactorrhea, and amenorrhea
  - Prolactin 51 to 75 ng/mL (51–75 mcg/L; 2217–3261 pmol/L): oligomenorrhea (infrequent menstruation)
  - Prolactin 31 to 50 ng/mL (31–50 mcg/L; 1348–2174 pmol/L): decreased libido and infertility
- Increased body weight may be associated with a prolactin-secreting pituitary tumor.
- The degree of hypogonadism generally is proportionate to the degree of prolactin elevation.
- Excessive hair growth (hirsutism) and acne also may be present owing to relative androgen excess compared with low estrogen concentrations.

Men

- Decreased libido, decreased energy, erectile dysfunction, impotence, decreased sperm production, infertility, gynecomastia, and rarely, galactorrhea.
- Impotence is unresponsive to treatment and is associated with reduced muscle mass, loss of pubic hair, and osteoporosis.

**Laboratory Tests**

- Prolactin serum concentrations at rest will be greater than 20 ng/mL (20 mcg/L; 870 pmol/L) in men or 25 ng/mL (25 mcg/L; 1087 pmol/L) in women with at least three measurements.
- Obtain β-human chorionic gonadotropin (β-hCG) concentration to exclude pregnancy.
- Obtain TSH concentration to exclude primary hypothyroidism.
- Obtain blood urea nitrogen and serum creatinine tests to exclude renal failure.

**Other Diagnostic Tests**

- Perform MRI to locate the tumor, exclude a pseudo-prolactinoma, and validate the diagnosis.
- Consider a bone mineral density test in patients with long-term hypogonadism.

**Additional Clinical Sequelae**

- The prolonged suppression of estrogen in premenopausal women with hyperprolactinemia leads to decreases in bone mineral density and significant risk for the development of osteoporosis.
- Risk for ischemic heart disease may be increased with untreated hyperprolactinemia.

---

of 25 to 100 ng/mL (25–100 mcg/L; 1087–4348 pmol/L), metoclopramide, risperidone, and phenothiazines have been associated with concentrations greater than 200 ng/mL (200 mcg/L; 8696 pmol/L). However, prolactin concentrations greater than 500 ng/mL (500 mcg/L; 21739 pmol/L) are almost always associated with the presence of a macroprolactinoma.[39]

▶ **Treatment**

**Desired Outcomes** Because hyperprolactinemia is often associated with hypogonadism, the goals for management of hyperprolactinemia are as follows[39,40]:

- Normalize prolactin concentration
- Restore normal gonadal function and fertility
- Prevent development of osteoporosis
- If a pituitary tumor is present:
  - Ablate or reduce tumor size to relieve tumor mass effect
  - Preserve normal pituitary function
  - Prevent progression of pituitary tumor or hypothalamic disease

**General Approaches to Treatment** Management of drug-induced hyperprolactinemia is to discontinue the offending agent, if clinically feasible, and replace it with an appropriate alternative that does not cause hyperprolactinemia.[39] When the offending agent cannot be discontinued, cautious use of hormone replacement, biphosphonate therapy, or dopamine agonists may be considered depending on the patient's clinical circumstances.[23] Treatment options for the management of hyperprolactinemia include: (a) clinical observation, (b) pharmacologic therapy with dopamine agonists, (c) transsphenoidal pituitary adenomectomy, and (d) radiation therapy. Clinical observation and close monitoring are justifiable in patients with asymptomatic elevation of prolactin.[39] **KEY CONCEPT**

*Dopamine agonists are the first-line treatment of choice for all patients with symptomatic hyperprolactinemia; transsphenoidal surgery and radiation therapy are reserved for patients who are resistant to or severely intolerant of pharmacologic therapy.*[39] However, in patients with underlying psychiatric symptoms, use of dopamine agonists in addition to an antipsychotic therapy may exacerbate the underlying psychosis and should be used with caution in consultation with a mental health clinician.[23]

**Pharmacologic Therapy** Dopamine is the principal neurotransmitter responsible for the inhibition of prolactin secretion from the anterior pituitary. Thus, dopamine agonists are the main pharmacologic therapy used for management of hyperprolactinemia. Treatment with dopamine agonists has proven to be extremely effective in normalizing serum prolactin concentration, restoring gonadal function, decreasing tumor size, and improving visual fields.[39,42] Patients with macroprolactinomas generally require a higher dose to normalize prolactin concentrations compared with patients with microprolactinomas.[43]

Two dopamine agonists—bromocriptine and cabergoline—are used for the management of hyperprolactinemia (Table 46–5).[37,44] Because these two dopamine agonists are ergot derivatives, they are contraindicated in combination with potent cytochrome P-450 subfamily IIIA polypeptide 4 (CYP3A4) inhibitors, including protease inhibitors, azole antifungals, and some macrolide antibiotics. Furthermore, ergot derivatives can cause constriction of peripheral and cranial blood vessels. These medications are also contraindicated in patients with uncontrolled hypertension, severe ischemic heart disease, or peripheral vascular disorders.

*Bromocriptine* Bromocriptine directly binds to the $D_2$ dopamine receptors. It normalizes prolactin concentration in 68% of patients and reduces tumor size in 62% of patients.[42] Treatment with bromocriptine may also restore menses and fertility in women and improve testosterone secretion, sperm count and erectile function in men. It may also improve visual field defects associated with macroadenomas.[42] Adverse effects such as nausea, dizziness, and orthostatic hypotension often limit 5% to 10% of patients from continuing treatment. To reduce risk of adverse effects and improve patient adherence, bromocriptine may be initiated at a low dose at bedtime.[41] Slowly titrate up to the optimal therapeutic dose because most adverse effects subside with continual treatment. In women, if the adverse GI effects are not tolerable, bromocriptine can be administered vaginally at a reduced dose (2.5 mg/day).[45] Owing to its short half-life of only 6 hours, bromocriptine must be administered in divided doses, which may compromise patient adherence.

*Cabergoline* Cabergoline has a higher affinity for $D_2$ dopamine receptors than bromocriptine and possesses a long half-life, allowing for once- or twice-weekly administration. Cabergoline appears to be better tolerated than bromocriptine, and may be more effective in normalizing prolactin concentrations and restoring menses.[46] It is also effective in treating hyperprolactinemia in patients who are resistant to or intolerant of bromocriptine and in men and women with microprolactinomas and macroprolactinomas.[39,46] Given its favorable safety and efficacy profile and ease of administration, cabergoline has replaced bromocriptine as first-line therapy for the management of hyperprolactinemia.[39] Withdrawal of pergolide from the US market due to increased risk for valvular heart disease raised concerns about the safety of cabergoline. However, to date, cabergoline use in patients with hyperprolactinemia[47] or prolactinoma[48] has not been associated with clinically significant valvular heart disease.

**Nonpharmacologic Therapy** In a small number of patients who have failed or are intolerant of dopamine agonists, transsphenoidal adenomectomy may be necessary.[39] Surgical treatment is also considered in patients with nonprolactin-secreting tumors or macroprolactinomas that jeopardize the optic chiasm.[43] Nonetheless, surgical intervention does not reliably lead to long-term cure and may cause permanent complications.[40,42] Radiation therapy is reserved for failures of both pharmacologic therapy and surgery.[39] However, normalization of prolactin concentration with radiation therapy may take 20 years to show full benefit, and radiation-induced hypopituitarism may require lifelong hormone replacement.

▶ *Management of Hyperprolactinemia in Pregnancy*

Most women with hyperprolactinemia require dopamine agonist therapy to achieve regular ovulatory cycles and pregnancy. Because restoration of the ovulatory cycle may occur immediately after initiation of therapy, it is necessary to caution patients regarding their potential to become pregnant and ensure adequate contraception when beginning therapy.[43]

Overall, there is reassuring evidence that bromocriptine use during pregnancy does not increase fetal malformations, spontaneous abortions, preterm deliveries, or multiple births.[39,49] Although experience during pregnancy is limited, cabergoline does not appear to be teratogenic.[49] Despite these data, continuation of dopamine agonists during pregnancy is generally not recommended. **KEY CONCEPT** *Women who become pregnant while taking a dopamine agonist should discontinue treatment to minimize fetal exposure.*[39] *Because cabergoline has a prolonged*

| **Table 46–5** | | |
|---|---|---|
| **Comparison of Dopamine Agonists for Treatment of Hyperprolactemia**[37,44] | | |
| | **Bromocriptine (Parlodel)** | **Cabergoline** |
| Starting dose | 0.625–1.25 mg/day at bedtime | 0.5 mg/week or 0.25 mg twice/week |
| Titrating dose | 1.25 mg increments at 1-week interval | 0.5 mg increment at 4-week intervals |
| Usually effective dose | 2.5–15 mg/day | 1–2 mg/week |
| Maximal dose | 40 mg/day | 4.5 mg/week |
| Dosing frequency | Two to three divided doses per day | Once or twice weekly |
| Dosage in hepatic insufficiency | May be required in acute hepatitis or cirrhosis; no guidelines are available | Dose reductions may be recommended for patients with severe hepatic failure (Child-Pugh scores of 10 or higher) |
| Dosage in renal failure | None | None |
| Adverse effects | Dizziness, headache, syncope, nausea, vomiting, GI cramps, orthostatic hypotension, nasal congestion | Similar but orthostatic hypotension less common |
| Cost | Moderately expensive | More expensive |

GI, gastrointestinal.

## Patient Encounter 2: Hyperprolactinemia: Medical History, Physical Examination, and Diagnostic Tests

A 30-year-old woman presented to primary care clinic 6 months ago with complaints of infrequent menstruation and infertility. Since she started treatment for hyperprolactinemia 5 months ago, she was excited to see return of her regular menses for several months until she realized her last menstrual period was 4 weeks ago.

**PMH:** None

**FM:** Mother has hypertension, father with high cholesterol

**SH:** Married, dental assistant; sexually active (occasional use of condoms)

**Meds:** Prenatal vitamin one tablet daily; cabergoline 1 mg tablet weekly; acetaminophen 325 mg one to two tablets as needed for menstrual cramps

**ROS:** Negative, other than in history of present illness

**PE:**

**HEENT:** Ophthalmic examination reveals normal visual acuity and fields. (–) goiter

**VS:** BP 120/65 mm Hg, P 80 beats/min, RR 19 breaths/min, T 37.1°C (98.8°F)

**CV:** RRR, normal S1, S2; no murmurs, rubs, or gallops

**Breasts:** (–) Galactorrhea with no abnormalities

**Abd:** Soft, nontender, nondistended; (+) bowel sounds; (–) hepatosplenomegaly

**Rectal:** Heme (–) stool

**Labs:** Electrolytes, renal and thyroid function, β-human chorionic gonadotropin (β-hCG) elevated at 6500 mIU/mL (6500 U/L)

**Prolactin:** Elevated prolactin at 89 ng/mL (89 mcg/L; 3870 pmol/L) 6 months ago; prolactin at 26 ng/ml (26 mcg/L; 1130 pmol/L) today

**Imaging:** MRI revealed a 5 mm pituitary tumor (6 months ago)

*What signs and symptoms were suggestive of hyperprolactinemia in the patient?*

*What nonpharmacologic and pharmacologic treatment options are available for her at this time?*

---

half-life, women who plan to become pregnant should discontinue the drug at least 1 month before planned conception.[44]

Microadenomas rarely cause complications during pregnancy. However, untreated macroprolactinomas carry about a 31% risk of tumor enlargement and potentially can jeopardize vision.[39] Therefore, monitor female patients with macroprolactinomas closely for the development of headache and visual impairments. Baseline and routine visual field examinations are essential. Evidence of abnormal visual fields may indicate tumor growth and should be followed by an MRI. If tumors enlarge, bromocriptine is the preferred choice over cabergoline because of greater experience with this drug during pregnancy.[39,49]

## Patient Care Process: Hyperprolactinemia

**Patient Assessment:**

- Assess the patient's clinical signs and symptoms of hyperprolactinemia.
- Review the available diagnostic data to determine severity and exclude other common causes of hyperprolactinemia (see Table 46–4).
- Obtain a thorough medication history to exclude medication-induced hyperprolactinemia (see Table 46–4).

**Therapy Evaluation:**

- Determine the patient's plan regarding pregnancy because this influences treatment selection.
- Determine if drug therapy is indicated. Make sure the patient does not have any contraindications or allergies to drug therapies.
- Determine whether patient has prescription coverage.

**Care Plan Development:**

- Initiate the appropriate dopamine agonist at the lowest effective dose for management of hyperprolactinemia (see Table 46–5)

- Provide patient education regarding disease state, and nondrug and drug therapy:
  - Risk factors associated with hyperprolactinemia
  - Potential disadvantages, safety and effectiveness of existing dopamine agonist therapy
  - Potential disadvantages, safety and effectiveness of surgery and radiation treatment
  - Importance of adherence to therapy
  - Potential for adverse effects or long-term complications

**Follow-up Evaluation:**

- Assess response and adverse effects of dopamine agonists. When appropriate, be sure to make dose adjustments (see Table 46–5).
- If the prolactin concentration remains normal for 2 years, reassess the need to continue treatment.

## ► *Outcome Evaluation*

- Assess patients for tolerability to dopamine agonists.

- Monitor clinical symptoms associated with hyperprolactinemia every month for the first 3 months to assess therapeutic efficacy and assist with dose titration.

- Evaluate the patient for symptoms, such as headache, visual disturbances, menstrual cycles in women, and sexual function in men, to assess clinical response to therapy.[39]

- When the prolactin concentration is normalized and clinical symptoms of hyperprolactinemia have resolved, monitor prolactin concentration every 6 to 12 months.[40]

- If the prolactin concentration is well controlled with dopamine agonist therapy for 2 years with significant tumor reduction, gradually taper therapy to the lowest effective dose or consider discontinuing therapy.[39] Check prolactin concentration after each dose reduction.

- If the prolactin concentrations remain unchanged for 1 year at the reduced dose, dopamine agonist therapy may be discontinued.

- It is essential to monitor prolactin concentration every 6 months or annually to detect the possibility of permanent remission of pituitary disease.[40]

- The need to continue dopamine agonists in postmenopausal women with microprolactinomas must be reassessed because these patients have a higher probability of maintaining normal prolactin concentrations after treatment is discontinued.[38]

- In patients with macroprolactinomas, monitor visual field at baseline and repeat the test 1 month after initiation of a dopamine agonist.

- Repeat the MRI in 1 year after initiating therapy or in 3 months in patient with macroprolactinoma or if an increase in symptoms or rise in prolactin concentration suggests the presence of tumor growth.[39]

- Discontinuation of therapy in patients with macroprolactinomas usually leads to tumor regrowth and recurrence of hyperprolactinemia. This decision warrants careful consideration.

## Abbreviations Introduced in This chapter

| | |
|---|---|
| AACE | American Association of Clinical Endocrinologists |
| ACTH | Adrenocorticotropic hormone or corticotropin |
| ADH | Antidiuretic hormone or vasopressin |
| β-hCG | β-Human chorionic gonadotropin |
| BMI | Body mass index |
| CRH | Corticotropin-releasing hormone |
| CT | Computed tomography |
| CYP3A4 | Cytochrome P-450 subfamily IIIA polypeptide 4 |
| DEXA | Dual-energy x-ray absorptiometry |
| FSH | Follicle-stimulating hormone |
| $FT_4$ | Free $T_4$ |
| GABA | γ-Aminobutyric acid |
| GH | Growth hormone or somatotropin |
| GHIH | Growth hormone–inhibiting hormone or somatostatin |
| GHRH | Growth hormone–releasing hormone |
| GI | Gastrointestinal |
| GnRH | Gonadotropin-releasing hormone |
| $HgbA_{1c}$ | Glycated hemoglobin $A_{1c}$ |
| IGF | Insulin-like growth factor |
| IGF-I | Insulin-like growth factor-I |
| IGF-II | Insulin-like growth factor-II |
| IGFBP-3 | Insulin-like growth factor-bind protein-3 |
| IM | Intramuscular |
| ITT | Insulin tolerance test |
| LAR | Long-acting release |
| LH | Luteinizing hormone |
| LHRH | Luteinizing hormone–releasing hormone |
| MRI | Magnetic resonance imaging |
| MSH | Melanocyte-stimulating hormone |
| OGTT | Oral glucose tolerance test |
| PRH | Prolactin-releasing hormone |
| SAGhE | Safety and Appropriateness of Growth hormone treatments in Europe |
| SC | Subcutaneous |
| SR | Slow release |
| SRL | Somatostatin receptor ligan |
| $T_3$ | Triiodothyronine |
| $T_4$ | Thyroxine |
| TRH | Thyrotropin-releasing hormone |
| TSH | Thyroid-stimulating hormone or thyrotropin |
| ULN | Upper limit of normal |

# Pregnancy and Lactation: Therapeutic Considerations

Ema Ferreira, Évelyne Rey, Caroline Morin, and Katherine Theriault

## LEARNING OBJECTIVES

**Upon completion of the chapter, the reader will be able to:**

1. Explain the principles of embryology and teratology.
2. Identify known teratogens and drugs of concern during lactation.
3. Compare the main sources of drug information relevant to pregnancy and lactation.
4. Evaluate the risks of a drug when taken during pregnancy or lactation.
5. Apply a systematic approach to counseling on the use of drugs during pregnancy and lactation.
6. Recommend the appropriate dose of folic acid to prevent congenital anomalies.
7. Describe physiologic changes during pregnancy and their impact on pharmacokinetics.
8. Choose an appropriate treatment for common conditions in a pregnant or lactating woman.

## EPIDEMIOLOGY AND ETIOLOGY

### Medication Use During Pregnancy

Most women take at least one medication during their pregnancy (average number of two to four, vitamins and minerals excluded).[1] The most common types of medications used include vitamins and minerals, allergy medication, analgesics, antacids, antibiotics, antiemetics, laxatives, asthma medication, cold and flu remedies, levothyroxine, and progesterone.[1,2]

The safety profile of some medications taken during pregnancy is difficult to assess making it difficult to balance risks and benefits of treatment.

▶ **Background Risks of Anomalies in Pregnancy**

Table 47–1 describes the baseline risks of congenital anomalies and some obstetrical complications observed in the general population—essential information to evaluate risks associated with medication use and to counsel pregnant women.

▶ **Causes of Congenital Anomalies**

**KEY CONCEPT** *Although the risk of drug-induced teratogenicity is of concern, the actual risk of birth defects from most drug exposures is small.* Medications are associated with less than 1% of all congenital anomalies, although they may play a more important role through interaction with genetic factors. **KEY CONCEPT** *Health professionals should know which medications have teratogenic risk.* It is important to evaluate and manage drug use in pregnant women and women planning a pregnancy.

Other causes of anomalies include genetic causes in 25 % of cases (inherited disease, gene mutation, chromosomal disorder), maternal infections (1%), maternal conditions (1%–3%; eg, pregestational diabetes), multifactorial heredity (23%–50%), and unknown causes (34%–43%).[5] Theoretical concerns regarding paternal exposure to genotoxic medication are reported, but currently no medication taken by a man has been proven teratogenic.[6]

## PATHOPHYSIOLOGY

### Age of Pregnancy

The age of pregnancy can be defined as gestational or postconceptional age (PCA).[6] *Gestational age* (GA) is the term used in clinical practice. It is calculated from the first day of the last menstruation or by ultrasound dating.

PCA, calculated from the day of conception, is 14 days shorter than GA if the menstrual cycle is 28 days. Some references in the field of teratology and embryology refer to PCA to describe stages of pregnancy.

### Principles of Embryology

Pregnancy can be divided into three development phases: implantation and predifferentiation, organogenesis (or embryogenesis), and fetogenesis. Table 47–2 describes these phases and possible drug effects if taken during these phases, and Figure 47–1 illustrates the critical periods of human in utero development. **KEY CONCEPT** *The risk of birth defects is usually higher during organogenesis.*

▶ **Teratogens**

A teratogen is an exogenous agent that can modify normal embryonic or fetal development.[5] Teratogenicity can manifest as structural anomalies, functional deficit, cancer, growth retardation, neurologic impairment, or death (spontaneous abortion, stillbirth).

In utero exposure to medication at the end of the pregnancy can also lead to transient neonatal complications, such as withdrawal or side effects (eg, opioids, selective serotonin reuptake inhibitors, antipsychotics, lithium).[6–8]

---

## Patient Encounter, Part 1

A 30-year-old woman comes to your office after a positive urine pregnancy test. You collect the following data:

**Estimated Gestational Age:** 5 weeks, regular menstrual cycles of 28 days

**PMH:** Bipolar disorder, hypothyroidism, one spontaneous abortion

**FH:** Diabetes, hypothyroidism, hypercholesterolemia

**SH:** Unemployed; cigarettes, one-half pack daily; no alcohol or illicit substances

**Meds:** Lithium 900 mg orally at bedtime; quetiapine 50 mg orally at bedtime; levothyroxine 50 mcg orally in the morning; all discontinued 1 week ago

**Allergy:** Dust mites

**ROS:** Morning nausea; tiredness

**VS:** Wt 198 lb (90 kg)/Ht 63 in (160 cm), BP 110/72 mm Hg, P 70 beats/min, RR 12 breaths/min; slight enlargement of thyroid

*How will you confirm gestational age?*

*What prenatal work up would you perform at this time?*

*What is the appropriate counseling at this time?*

*What are the risks of drugs taken in the first weeks of pregnancy? What resources will you use to find the appropriate information?*

*What do you recommend for her pharmacologic treatment?*

---

Although we use the term *teratogen* in this chapter, we agree with some authors who prefer to use instead *teratogenic exposure*. *Teratogenic exposure* considers level (dose) and timing of exposure during pregnancy to determine whether it could lead to a higher risk of a specific malformation.[9]

Criteria have been proposed to determine whether a causal relationship between congenital anomalies and a medication is plausible (teratogenic effect).[9] Exposure to the medication must have happened during the critical period of development of the organ for which a malformation is noticed (see Figure 47–1). Also, a pattern of anomaly or a specific syndrome must be present, and the observed effects must be reproducible in at least two studies conducted in different populations. A rare anomaly associated with a rare exposure is also indicative of a teratogenic effect (eg, ear anomalies and isotretinoin).

Other criteria, listed below, are considered (the probability of finding an association increases with the number of criteria):

- Strength of the association
- Same effects observed in animal studies
- Biological plausibility based on pharmacologic effect
- Higher incidence of the anomaly in the population with the period of use of the medication (eg, thalidomide and limb anomalies)
- Dose–response relationship

With these criteria, there are approximately 30 medications or classes of medications that are considered teratogens (Table 47–3). Drugs not on this list are not necessarily safe to use during pregnancy. We must be careful not to interpret a lack of data as an absence of risk. If a medication is on this list, it does not mean that it is contraindicated during pregnancy. Severity and occurrence of malformations vary from one agent to another; some are always contraindicated, but some others can be used when benefits outweigh potential risks.

Some medications associated with a higher risk of malformation are not included in Table 47–3 since they do not meet all the teratogenicity criteria. For example, benzodiazepines (oral cleft), lamotrigine and topiramate (oral clefts), paroxetine (cardiac septal anomalies), pseudoephedrine (gastroschisis).

## RISK EVALUATION

### Desired Outcomes

The goal of drug use during pregnancy and lactation is to treat maternal or fetal conditions effectively when necessary while minimizing risk to the developing embryo/fetus or the neonate.

### Medication and Pregnancy

▶ *Data Published on Medication Safety During Pregnancy*

Classical randomized controlled trials are usually not available to evaluate the safety of medications used during pregnancy and lactation. Most available data on drug safety during pregnancy come from postmarketing reports.

Animal studies, now mandatory before marketing a medication, can identify high-risk medications and prevent congenital anomalies. However, they must be interpreted with great caution because of many limitations; the major ones are that different species do not share the same pharmacodynamics and pharmacokinetics for the same medication, and usually much higher doses than those used in clinical settings are tested.[11]

Case reports and case series provide the first published data on the use of medications during pregnancy. A causal relationship between a single case report and an anomaly cannot usually be established unless a rare anomaly is repeatedly associated with the use of a specific medication.

Cohort studies and company registries seek to compare the risks observed after exposure to a medication with the risk observed in a control group or in the general population. When

### Table 47–1

**Occurrence of Some Obstetrical Complications and Risk of Congenital Anomalies in the General Population**

|  | Risk of Occurrence in Population (%) |
|---|---|
| Spontaneous abortion/miscarriage (pregnancy loss that occurs after the pregnancy is known and before 20 weeks of GA; risk increases with higher maternal age) | 10–15 |
| Congenital anomalies (percentage of live births): |  |
| • Minor malformations | 14 |
| • Major malformations at birth | 3 |
| • Major malformations at 2 years old | 6 |
| Preterm birth (< 37 completed weeks gestation)* | 11.5 |
| Low birth weight (< 2500 g)[a] | 8.0 |

[a]United States data from 2012

GA, gestational age.

Data from Refs. 3, 4, and 5.

| Table 47–2 | | | |
|---|---|---|---|
| **Phases of Embryonic and Fetal Development** | | | |
| **Phase of Development** | **Stage of Pregnancy[a]** | **Development Description** | **Potential Complications** |
| Implantation and predifferentiation (all-or-none period) | 0–14 days after conception (14–28 days after LMP) | Very little contact between the blastocyst and the mother's blood<br>Cells are pluripotent, capacity to repair a damage remains<br>Cells are fragile at this moment. If too many are destroyed, a miscarriage will occur before the pregnancy is detected | Spontaneous abortion; Even if stopped during this period, long half-life drugs could cause organogenesis problems |
| Organogenesis (embryogenesis) | From day 14 until the 9th week after conception (From day 28 until the 11th week after LMP) | Organs are formed; most critical period for structural anomalies<br>Organs are formed at different times; different period of sensitivity for each organ<br>Refer to Figure 47–1 for the time frame of organ formation | Major or minor structural anomalies;<br>Spontaneous abortion |
| Fetogenesis | After the organogenesis and until birth | The fetus grows<br>Organs begin to function (eg, glomerular filtration)<br>Active cell growth, proliferation, and migration (eg, CNS) | Fetal growth retardation; functional deficit (eg, renal insufficiency), neurologic impairment; spontaneous abortion, stillbirth;neonatal complications |

[a]Stage of pregnancy based on a menstrual cycle of 28 days

LMP, last menstrual period; CNS, central nervous system

Data from Refs. 5 and 6.

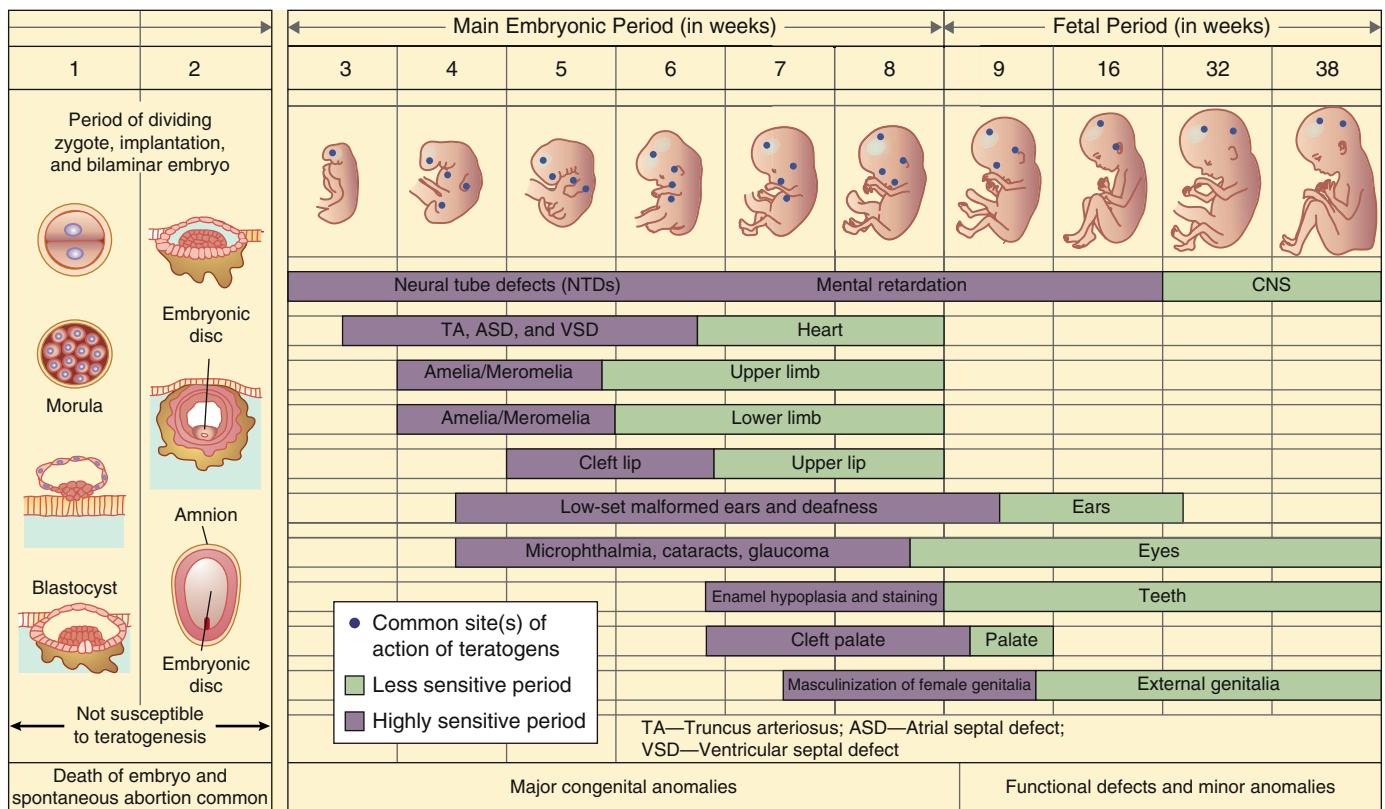

**FIGURE 47–1.** Embryonic and fetal development. The horizontal bars represent potential sensitivity to teratogens. The colored areas represent the more critical times. Embryonic period is in postconceptional weeks. (Reprinted with permission from Moore KL. The Developing Human. New York: Elsevier, p. 976: copyright 1974.)

| Table 47–3 | | |
|---|---|---|
| **Medications with Proven Teratogenic Effects in Humans** | | |
| **Drug or Drug Class** | **Teratogenic Effects** | **Critical Period[a]** |
| Alkylating agents | Malformations of many different organs | Organogenesis |
| Amiodarone | Transitory hypothyroidism (17%, goiter in some cases) or transitory hyperthyroidism | From 12th week after LMP |
| Androgens (danazol, testosterone) | Masculinization of genital organs in female fetus | From 9th week after LMP |
| Angiotensin converting enzyme inhibitors | Renal failure, anuria, oligohydramnios, pulmonary hypoplasia, intrauterine growth restriction, limbs contracture, skull hypoplasia | After the first trimester |
| Angiotensin II receptor antagonists | Contraindicated after first trimester | |
| Anticonvulsants (first generation) | NTDs (carbamazepine and valproic acid); oral cleft, skeletal, urogenital, craniofacial, digital, and cardiac malformations; microcephalia | Organogenesis for structural anomalies |
| • Carbamazepine | Major malformations: 5%–10% depending on the agent used (10%–15% for valproic acid). | Valproic acid : whole pregnancy for neurologic impairment |
| • Phenytoin | | |
| • Phenobarbital | Valproic acid: abnormal neurologic development | |
| • Valproic acid, divalproex | | |
| Corticosteroids (systemic) | Oral cleft (risk of 3–4/1000 vs 1/1000 in general population) | Organogenesis (most critical period for palate formation between 8 and 11 weeks after LMP) |
| Diethylstilbestrol | Girls: Cervical or vaginal adenocarcinoma, incidence about 1/1000 exposures. Structural genital anomalies (eg, of cervix, vagina) | First and second trimesters |
| | Boys: Genital anomalies, spermatogenesis anomalies | |
| Fluconazole high doses | Skeletal and craniofacial malformations, cleft palate, cardiac anomaly (with chronic dose > 400 mg/day; not reported with 150-mg single dose) | Not defined, but cases are reported where exposure was for most parts of pregnancy |
| Iodine (supraphysiologic dosage) | Hypothyroidism, goiter | From 12th week after LMP |
| Isotretinoin, acitretin, and high dose of vitamin A (> 10,000 IU/day) | Spontaneous abortion, CNS, skull, eyes and ears malformations, micrognathia, oral cleft, cardiac malformations, thymus anomalies, mental retardation: estimated at 25%–30% (may be higher for neurologic development impairment) | Organogenesis (risk of teratogenic effect after organogenesis not excluded) |
| | Contraindicated throughout pregnancy | |
| | Isotretinoin: discontinue 1 month before pregnancy, prescribed under a special program called iPLEDGE | |
| | Acitretin: discontinue 3 years before pregnancy | |
| Lithium | Cardiac malformations: risk of 0.9%–6.8% (higher risks from small studies) (compare to a baseline risk of ~1%) | Cardiac organogenesis (5–10 weeks after LMP) |
| | Includes Ebstein's anomaly: risk estimated at 0.05%–0.1% | |
| Methimazole/ propylthiouracil | Methimazole: aplasia cutis, choanal atresia, esophageal atresia, minor facial anomalies, growth delay; risk probably low | Organogenesis |
| | Methimazole/propylthiouracil: fetal hypothyroidism in 1%–5% of newborns, goiter | Second and third trimesters |
| Methotrexate, aminopterine | Spontaneous abortion, CNS and cranial malformations (large fontanelles, hydrocephalia, incomplete cranial ossification, craniosynostosis), oral cleft, ear, skeletal and limb malformations, mental retardation | Organogenesis (between 6 and 8 weeks after LMP for structural anomalies but some exceptions reported) |
| | Do not use in pregnancy; stop 1 to 3 months before pregnancy | |
| Misoprostol | Moebius syndrome ± limb anomalies ± CNS anomalies | Organogenesis |
| | Abortion, preterm birth | Throughout pregnancy for abortion/preterm birth |
| Mycophenolate mofetil, mycophenolic acid | Anomalies including ear anomalies (with or without ear canal), oral cleft, micrognathia; ophtalmic, cardiac and digital anomalies (risk of structural anomalies estimated from 20%–25%); spontaneous abortion (30%–50%) | Uncertain, probably organogenesis |
| Nonsteroidal anti-inflammatory drugs | In utero closure of ductus arteriosus (constriction is rare before 27 weeks, 50%–70% at 32 weeks (GA) and neonatal pulmonary hypertension | Third trimester |
| | Renal toxicity possible after prolonged use from second half of second trimester | |
| Penicillamine | Cutis laxa | Not defined |
| | Joints and CNS anomalies | |
| | Risk probably low | |
| Tetracyclines | Teeth discoloration | From 16 weeks after LMP |

*(Continued)*

**Table 47–3**

**Medications with Proven Teratogenic Effects in Humans (*Continued*)**

| Drug or Drug Class | Teratogenic Effects | Critical Period[a] |
|---|---|---|
| Thalidomide | Limb anomalies (amelia, phocomelia)<br>Cardiac, urogenital, gastrointestinal, and ear malformations<br>Risk of 20%–50 %<br>Prescribed under a special program called STEPS (System for Thalidomide Education and Prescribing Safety) | 34–50 days after LMP |
| Trimethoprim | Cardiac and urogenital malformations, neural tube defects, oral cleft; overall risk probably < 6% | Organogenesis |
| Warfarin/acenocoumarol | Before 6 weeks: no higher risk of anomaly<br>Taken between 6 and 12 weeks: nasal hypoplasia, epiphysis dysplasia, vertebral malformations, rarely ophtalmic anomalies, scoliosis, hearing loss; overall risk estimated between 6% and 10%.<br>After 12 weeks after LMP: more rarely, heterogeneous CNS anomalies | Between weeks 6 and 12 after LMP |

[a]Stages of pregnancy in this table are calculated after last menstrual period (gestational age) and not after conception to be more clinically useful.

CNS, central nervous system; LMP, last menstrual period; NTD, neural tube defect.

Data from Refs. 6, 7, 9, and 10.

studying structural anomalies, it is important to select women exposed to medication during organogenesis. Cohort studies usually are not powerful enough to assess the risk associated with rare anomalies. When a signal of association between an anomaly and a drug exposure is observed, a case-control study, which has more power to detect rare anomalies, can be conducted to clarify the relationship. When several studies have been published using very similar methodologies, meta-analyses can be conducted to yield higher statistical power.[11]

▶ *Sources of Information on the Use of Drugs During Pregnancy and Lactation*

Some specialized information sources provide data on the use of medications during pregnancy and lactation (Table 47–4).

The 1979 Food and Drug Administration (FDA) regulations establishing pregnancy categories for drugs (A, B, C, D, and X) are well known to health care providers. This categorization has long been criticized by experts who recommend instead relying on other information sources.[12] They assert that the categories are too simplistic, can lead to a risk misperception, and do not take into account important information such as expected incidence, severity of anomalies, degree of risk, gestational timing of exposure, and route of administration.[12] In May 2008, the FDA proposed that the categories be removed and replaced by a short statement including description and risk of fetal defects, sources of data (animal or human), comparison with population baseline risk of birth defects, and the relationship with the dosage. An equivalent section for drug use during lactation will be inserted.[12] This new regulation is in the process of being implemented. Meanwhile, clinicians should rely on other information sources to evaluate the risk of a medication during pregnancy.

▶ *Communication of Information*

Communication of data on medication use during pregnancy can be challenging[13]:

- Data may be limited or contradictory.
- Taking medications during pregnancy is a source of anxiety.
- Pregnant women tend to overestimate their risk of an anomaly associated with medication use and to

underestimate their risk associated with undertreating their condition.
- Most people do not properly understand numbers and probability.

The objective is to give precise data that will help the patient make an informed decision for her health and the health of her

baby. Unconfirmed hypotheses should not be communicated. Information should include a well-grounded assessment of risks, including baseline risks in the general population, risks associated with the medication, and risks of not treating the disease during pregnancy.[11]

When discussing numbers (eg, percentages, probabilities), some tips to facilitate effective risk communication are[13]:

- Use absolute risks instead of relative risks.
- Use negatively and positively framed information at the same time (eg, 3% chance of having a malformed child; 97% chance of having a normal child).
- Use the same denominator when discussing probabilities.

Finally, to determine a woman's risk of birth defects, obtain good medical, obstetrical, and pharmacotherapeutic histories (including over-the-counter medications and natural health products) and take into account exposures to alcohol, tobacco, and other recreational drugs.[13]

### ▶ Preconception Care

Adverse pregnancy outcomes, including prematurity, low birth weight, and birth defects, are major health concerns. One contributing factor to adverse outcomes is the late start in prenatal care, which can delay the identification and modification of risk factors that can affect pregnancy outcomes. Strategies to improve pregnancy outcomes include identifying and treating nutritional deficiencies and disorders, taking folic acid, avoiding alcohol and substance abuse, smoking cessation, optimizing the management of chronic illnesses and genetic disorders (eg, diabetes, epilepsy, hypertension, maternal phenylketonuria), screening for infections (eg, human immunodeficiency virus, sexually transmitted infections), appropriate vaccination, pregnancy planning, and reaching a healthy weight.[14]

### ▶ Folic Acid

Approximately 1 in every 1000 pregnancies is affected by a neural tube defect (NTD).[15] Data indicate that multivitamins containing folic acid reduce NTD and other congenital anomalies including oral clefts and cardiovascular, limb, and urinary malformations.[16] **KEY CONCEPT** *All women of childbearing age should be counseled on the appropriate dose of folic acid to prevent congenital anomalies.* The American College of Obstetricians and Gynecologists (ACOG) and the US Preventive Services Task Force recommend that all women of childbearing age take 0.4 to 0.8 mg of folic acid daily, beginning 1 month before pregnancy and through the first 2 to 3 months.[15] Women at higher risk of NTD (eg, previous child or a first-, second-, or third-degree relative with a NTD, those with prepregnancy diabetes, those with epilepsy taking carbamazepine or valproic acid) should take 4 mg of folic acid per day.[15]

### ▶ Iron Supplements

Anemia during pregnancy is defined as a hemoglobin level less than 11 g/dL (110 g/L; 6.83 mmol/L) during the first and third trimesters and less than 10.5 g/dL (105 g/L; 6.52 mmol/L) during the second trimester.[17] Maternal symptoms of anemia include fatigue, palpitations, and decreased resistance to exercise and infections. Fetal risks are prematurity, low birth weight, and perinatal death. All pregnant women should be screened for anemia, and those with iron deficiency should be treated with oral iron preparations in addition to prenatal vitamins.[17] Iron supplementation decreases the prevalence of maternal anemia at delivery. It is unclear whether supplementing nonanemic pregnant women will improve perinatal outcomes.[17]

### ▶ Impact of Physiologic Changes During Pregnancy on Pharmacokinetics

**Absorption** Drug absorption is affected in several ways during pregnancy. Decreased gastrointestinal transit can delay drug peak effect, prolonging the time of contact of drugs with the intestinal mucosa, and possibly enhancing absorption of certain drugs. Higher gastric pH may affect absorption of weak bases or acids. Skin, tissue, and lung absorption might also be increased by physiologic changes during pregnancy.[18]

**Distribution** Volume of distribution increases for most drugs during pregnancy due to plasma volume expansion and the presence of amniotic fluid, the placenta, and the fetus. This results in a decrease in maximal concentrations of drugs. In addition, hypoalbuminemia and decreased protein binding increases free fraction of some medications.[18]

**Metabolism** During pregnancy, the activity of some isoenzymes is increased (eg, CYP3A4, CYP2A6, CYP2D6, CYP2C9), while activity of others is decreased (eg, CYP1A2, CYP2C19). Net impact on drug effect is unpredictable since there is a wide interindividual variability, and some drugs are metabolized by several isoenzymes.[18]

**Renal Elimination** Renal blood flow and glomerular filtration increase significantly during pregnancy. The impact of this is more important for drugs that are eliminated in the urine which results in a decrease in their half-lives.

Table 47–5 shows clinical recommendations based on pharmacokinetic changes during pregnancy for several drugs.[6,18]

## Medication and Lactation

According to the 2012 policy statement from the American Academy of Pediatrics (AAP), mothers should breast-feed exclusively for 6 months and continue for 1 year if possible. Approximately 75% of mothers initiate breast-feeding at birth. However, exclusive breast-feeding drops to 17% at 6 months, as many new mothers supplement breast-feeding with other foods or quit entirely by this point.[19]

### ▶ Drug Transfer into Breast Milk

To study drug effects, breast-fed infant's serum drug levels could be measured to evaluate safety; however, these data are often unavailable. In most instances, the approximate quantity of drug ingested by the breast-fed infant is estimated using published measured drug concentrations in breast milk. With these data, the percentage of pediatric dose or the relative infant dose (percentage of weight-adjusted maternal dose) can be calculated, assuming an average of 150 mL/kg/day of milk ingested by a breast-fed infant.

Percentage of pediatric dosage =

$$\left(\frac{\text{Quantity of medication taken from milk by the baby (mg/kg/day)}}{\text{Usual initial daily pediatric dose (mg/kg/day)}}\right)\times100$$

Weight adjusted maternal dose or relative infant dose =

$$\left(\frac{\text{Quantity of medication taken from milk by the baby (mg/kg/day)}}{\text{Maternal dose adjusted by weight (mg/kg/day)}}\right)\times100$$

In the latter equation, maternal dose refers to the dose used by patients in the published study or case report, not to the dose of your actual patient.

| Table 47–5 | | |
|---|---|---|
| **Altered Pharmacokinetics During Pregnancy: Clinical Implications and Management** | | |
| **Drugs** | **Pharmacokinetic Changes** | **Recommendations and Monitoring** |
| Aminoglycosides | $\uparrow V_d, \uparrow Cl, \downarrow t_{1/2}$ | Monitor peaks and troughs; increase doses if necessary |
| Antiretrovirals | Variable Cl and $C_{max}$ | Monitor clinical response; drug levels can be useful to adjust some drug dosages |
| Caffeine | $\uparrow t_{1/2}$ $\downarrow Cl\ (T_1, T_2, T_3)$ | Risk of more frequent and prolonged side effects; decrease caffeine consumption |
| Carbamazepine | $\uparrow Cl$ $\downarrow t_{1/2}$ | Measure free fraction (preferably); increase dose according to clinical response and levels |
| Digoxin | $\uparrow Cl$ $\downarrow C_{max}$ | Follow plasma levels; adjust according to clinical response and plasma levels; increase doses if necessary; to treat fetal disease, higher doses might be required; digoxin-like immunoreactive substance might alter levels |
| Fluoxetine and other SSRIs | $\uparrow Cl\ (T_3)$ | Increase dose according to clinical response; consider decreasing dose after delivery |
| Heparin | $\uparrow Cl\ (T_1, T_2, T_3)$ | Consider increasing frequency of administration |
| LMWH | | If necessary, follow anti-Xa levels |
| Lamotrigine | $\uparrow Cl\ (T_1, T_2, T_3)$ | For epilepsy: Measure drug levels at least every trimester; increase dose according to clinical response and levels; return to prepregnancy dose after delivery |
| Levothyroxine (T4) | $\downarrow ff$ | Increase dose at the beginning of pregnancy; follow TSH levels at least every trimester; return to prepregnancy dose after delivery |
| Lithium | $\uparrow Cl\ (T_1, T_2, T_3)$ $\downarrow t_{1/2}$ | Measure drug levels at least every trimester and monthly in T3; increase dose according to levels if necessary; return to prepregnancy dose after delivery |
| Nicotine | $\downarrow t_{1/2}$ $\uparrow Cl\ (T_2, T_3)$ | Higher doses might be required (smoking cessation) at T2 and T3; however, increased transdermal absorption might lead to higher nicotine plasma levels |
| Nifedipine | $\uparrow Cl\ (T_3)$ | Monitor clinical effect; increase doses/frequency of administration if necessary |
| Phenytoin | $\downarrow C_{total}, ff$ $\uparrow Cl\ (T_3)$ $\downarrow t_{1/2}$ | Measure free fraction; increase dose according to clinical response and levels |
| Valproic acid | $\downarrow C_{total}$ $\uparrow ff$ | Measure free fraction if prepregnancy reference level is available; dose will remain the same in most cases. Increase dose according to clinical response and levels |

$\uparrow$, increase; $\downarrow$, decrease; $\leftrightarrow$, unchanged; $C_{max}$, maximum serum concentration; Cl, clearance; ff, free fraction; T, trimester; $t_{1/2}$, elimination half-life; LMWH, low-molecular-weight heparin; $C_{total}$, total concentration; SSRI: selective serotonin reuptake inhibitor.

Data from Refs. 6 and 18.

Usually, a percentage of less than 10% of the pediatric dose or, when a pediatric dose is not available, a percentage of less than 10% of weight adjusted maternal dose, is acceptable in full-term healthy infants unless a drug has a toxic side effect profile.[20]

▶ *Drug Pharmacokinetics*

If clinical data are unavailable on drug transfer into breast milk, choose drugs that are highly protein bound, have a high molecular weight, have a short half-life, have no active metabolites, and are well tolerated by children.[20]

▶ *Drugs of Concern During Breast-Feeding*

**KEY CONCEPT** *Most drugs are safe during breast-feeding*. However, some drugs are of concern and require a more thorough assessment by the clinician (Table 47–6). One should also consider additive side effects of medication for the baby when the mother is taking several medications.

## CONDITIONS PREVALENT IN PREGNANCY AND LACTATION

**KEY CONCEPT** *When possible, treat conditions occurring during pregnancy with nonpharmacologic treatments instead of drug therapy.*
**KEY CONCEPT** *Evaluate the need for treatment, including benefits and risks. Avoid treatments that do not show evidence of benefit or that can be delayed until after pregnancy or breast-feeding.*

For chronic diseases, please refer to the relevant chapter where you will find considerations during pregnancy under "Special populations".

### Nausea and Vomiting of Pregnancy (NVP)

As many as 85% of pregnant women suffer from nausea or vomiting.[23] Nonpharmacologic measures, such as lifestyle (rest, avoidance of nausea triggers) and dietary changes (small and frequent meals, fluid restriction during meals, avoiding spicy or fatty foods, consuming crackers upon rising) should be used as first-line management. Acupuncture and acupressure also can be helpful.[23]

The combination of pyridoxine and doxylamine is the first-line pharmacologic treatment of NVP. When this combination is insufficient, other drugs such as metoclopramide, diphenhydramine, or ondansetron can be prescribed (Table 47–7).[24]

### Pain

Pregnant or lactating women experience pain from preexisting conditions or from temporary pathologies (eg, vaso-occlusive crisis in sickle cell disease, fibromas, migraine, etc)

The general principles of treatment are[6,7,25]:

- Maximize nonpharmacological measures
- Acetaminophen is the safest analgesic during pregnancy
- If medications are required, avoid nonsteroidal anti-inflammatory drugs (NSAIDs) during the third trimester, and use them with caution otherwise

| Table 47–6 | |
|---|---|
| **Drugs of Concern During Breast-Feeding** | |
| **Drug or Class** | **Comments** |
| *Drugs that can decrease the breast milk production* | |
| Clomiphene | Has been used to suppress lactation |
| Ergot derivatives (bromocriptine, cabergoline, ergotamine) | Have been used to suppress lactation |
| Estrogens | Hormonal contraceptives with ethinylestradiol should be delayed for 4–6 weeks following delivery |
| Pseudoephedrine | Do not use in women with low milk production; a few doses will probably not have significant effect |
| *Drugs for which use during breast-feeding may expose the neonate to a significant quantity and may necessitate a strict follow-up* | |
| β-blocking agents (acebutolol, atenolol, sotalol) | Neonatal β-blockade reported |
| | Concern for acebutolol, atenolol and sotalol, but other β-blocking agents such as metoprolol, propranolol and labetalol are safe |
| Amiodarone | May accumulate because of long half-life; possible neonatal thyroid and cardiovascular toxicity |
| Antineoplastics | Neonatal myelosuppression possible |
| Chloramphenicol | Severe side effects reported when used to treat babies (blood dyscrasia, grey baby syndrome) |
| Ergotamine | Symptoms of ergotism (vomiting and diarrhea) reported |
| Illicit drugs | Unknown contents and effects |
| Lamotrigine | A breast-fed infant could have blood concentrations between 10% and 50% of maternal blood concentrations (can be in therapeutic range for babies). More than 100 breast-fed babies followed with rare side effects reported including apnea attributed to excessive sedation ($n = 1$), hepatotoxicity ($n = 1$) and a few cases of nonsevere or unrelated rashes. Monitor for CNS side effects (sedation, hypotonia, weight gain, and poor sucking) and rash. |
| Lithium | Up to 50% of maternal serum levels have been measured in infants; cases of infant toxicity (lethargy, cyanosis, electrocardiogram anomalies, dysthyroidia, tremors) have been reported. Monitor infant serum lithium, creatinine, urea, and TSH levels every 4 to 12 weeks and other side effects (jittery, feeding problems, signs of dehydration). |
| Phenobarbital/ primidone | Drowsiness and reduced weight gain reported. Up to 25% of a pediatric dose can be ingested via breast milk. Monitor for CNS side effects (sedation, hypotonia, weight gain, and poor sucking). |
| Radioactive iodine-131 | No breast-feeding for days to weeks to achieve nonsignificant radiation levels (long radioactive half-life). Monitor radioactive levels in milk before allowing breast-feeding. |
| Tetracyclines | Chronic use may lead to dental staining or decreased epiphyseal bone growth. |

Data from Refs. 6, 7, and 20.

- Opiates are not associated with a higher risk of malformations. However, close neonatal monitoring is necessary due to possible withdrawal if opiates are taken regularly near delivery. Limited data exist for some opiates during the first trimester, eg, for fentanyl and tramadol
- There is a lack of information for some medications (eg, pregabalin)
- For migraine, triptan use remains controversial. Sumatriptan has not been associated with a higher risk of birth defects. It can be used but not routinely.

## Urinary Tract Infections

Urinary tract infections during pregnancy, including asymptomatic disease, increase the risk of hypertension, low birth weight, and preterm delivery.[5]

Asymptomatic bacteriuria and cystitis cause acute pyelonephritis more often in pregnancy than in nonpregnant women.[26] Acute pyelonephritis may lead to septic shock and adult respiratory distress syndrome and should be treated aggressively with intravenous antibiotics. Outpatient treatment with intramuscular therapy alone or followed by oral treatment is feasible for some women (eg, stable and pregnancy less than 24 weeks).[26] Treatment reduces pregnancy complications.[26–28]

Antimicrobial therapy should target *Escherichia coli* infection and should vary according to local bacterial resistance (see Table 47–7).[26] Avoid trimethoprim-sulfamethoxazole during organogenesis (congenital malformations) and near term (theoretical risk of neonatal jaundice).[7] Quinolones should be reserved for resistant infections due to theoretical concerns of arthropathy.[7]

Repeat urine culture 10 to 14 days after completion of acute pyelonephritis therapy and monthly thereafter. After completion of the acute episode of pyelonephritis, recommend suppressive therapy prophylaxis for the remainder of the pregnancy and for 4 to 6 weeks after delivery (See Table 47-7).[26]

## Preterm Labor

Preterm birth, especially before 32 weeks of pregnancy, is the major cause of short- and long-term neonatal mortality and morbidity. The underlying pathophysiologic conditions are diverse, and most are unknown. There is wide variation in management, diagnosis, and treatment of preterm labor across the world.

### ▶ Antenatal Corticosteroids

The most beneficial intervention in preterm labor is administration of antepartum corticosteroids. Provide a single course of antenatal corticosteroids to women at risk of preterm delivery within 7 days between 24 and 34 weeks' gestation (see Table 47–7).[29] This approach decreases the incidence and severity of neonatal respiratory distress syndrome, intraventricular hemorrhage, **necrotizing enterocolitis**, and death.[29] Current data do not support the use of repeated courses of corticosteroids (see Table 47–7).[30]

### ▶ Tocolytic Agents

**Tocolytic** therapy is used when preterm labor occurs before 33.6 weeks to delay delivery in order to complete a course of corticosteroids and allow transfer of the mother to a center with neonatal intensive care facilities. Tocolytics include magnesium sulfate, β-mimetics (terbutaline), prostaglandin inhibitors (indomethacin), oxytocin receptors blockers (atosiban), and calcium channel blockers (nifedipine) (see Table 47–7).[30] All these agents are effective in delaying delivery by 48 hours. Data indicate that

## Clinical Confirmation and Associated Problems of Pregnancy and Lactation

### Confirmation of Pregnancy

Positive urine or blood human chorionic gonadotropin followed by positive ultrasound, fetal heart sounds, and/or fetal movement.

### Pregnancy Dating and Gestational Age

Calculated from the first day of the last menstrual period.

An ultrasound between 10+0 and 13+6 weeks determines gestational age based on crown-rump length and identifies multiple pregnancies.

Due dates typically are estimated at 40 weeks of gestation; however, infants delivered between 37 and 42 weeks are considered full term.

### Pregnancy Symptoms

First trimester : Menstrual spotting, missed menses, fatigue, breast tenderness, increased urination, mood swings, nausea/vomiting, headache, heartburn, constipation

Second trimester : Frequent urination, heartburn, constipation, dry skin, edema, linea nigra, melasma

Third trimester : Backache, edema, shortness of breath, insomnia

### Routine Pregnancy Visits

In a normal, uncomplicated pregnancy, visits should occur monthly until 28 weeks of gestation, every 2 to 3 weeks from 28 to 36 weeks of gestation, and then weekly until delivery.

Assess for each of the following at each visit:

- Blood pressure
- Weight
- Urine protein (dipstick)
- Uterine size
- Fetal heart rate
- Fetal movement

### Routine Lab Testing for Normal Pregnancies (First Trimester Unless Otherwise Indicated)

- Hemoglobin and hematocrit for anemia (repeated at 26–32 weeks)
- Blood type, Rh, red blood cell antibody screening
- Human immunodeficiency virus
- Venereal Disease Research Laboratory (VDRL) slide test for syphilis
- Rubella immunity
- Varicella immunity
- Hepatitis B surface antigen
- Urinalysis with culture for bacteriuria
- Gonorrhea and chlamydia
- Cervical cytology
- Screens for Down syndrome and neural tube defects (between 11 and 20 weeks)

*Refs. 21 and 22.*

- Gestational diabetes screening (at 24–28 weeks)
- Group B Streptococcus screening (at 35–37 weeks)
- Women at high risk for these conditions should be tested at the first visit:
  - Hypothyroidism
  - Type 2 diabetes
  - Sickle cell disease or thalassemia
  - Hepatitis C
  - Tuberculosis
  - Bacterial vaginosis

### Selected Problems Experienced During Pregnancy or Lactation

*Hyperemesis gravidarum.* Severe, persistent nausea and vomiting during pregnancy accompanied by dehydration, electrolyte disturbance, ketonuria, and weight loss.

*Urinary tract infection.* Bacteriuria often asymptomatic in pregnancy. Diagnosed by positive urine culture.

*Bacterial vaginosis.* Clinically diagnosed by presence of three of the following (Amsel criteria):

- White, homogenous, noninflammatory discharge
- Clue cells on microscopic examination
- Vaginal pH greater than 4.5
- A fishy odor before or after addition of 10% potassium hydroxide (ie, "whiff" test)

*Vulvovaginal candidiasis.* Typical symptoms include vaginal itching and whitish discharge.

*Sexually transmitted infections:* Refer to Table 47–8.

*Preterm labor.* Onset of uterine contractions and cervical modification which may lead to delivery prior to 37 weeks of gestation.

*Preterm premature rupture of the membranes.* Rupture of the amniotic membranes before 37 weeks and before active labor.

*Abruptio placentae. Sudden detachment of the placenta presenting with* uterine bleeding, abdominal pain with or without maternal and fetal hemodynamic compromise.

*Group B streptococcus colonization.* Diagnosed by positive culture on vaginal and rectal swab.

*Gestational diabetes.* See Chapter 43.

*Gestational hypertension.* Asymptomatic or presence of neurologic, hepatic, or cardiovascular symptoms. Check for proteinuria.

*Mastitis.* Characterized by localized redness, tenderness, and warmth on one breast accompanied by fever and flulike symptoms. Although uncommon, symptoms also may be bilateral.

*Breast candidiasis.* Typical symptoms include nipple pain, itching, burning, and/or breast pain that persist after feeding.

| Table 47–7 |
| --- |

**Medication Dosing Recommendations During Pregnancy and Lactation**

| Drug | Dosage | Comments |
| --- | --- | --- |
| **Micronutrients and Vitamins** | | |
| Folic acid | 0.4–0.8 mg po daily | Dosage necessary to reach RDA: 0.6 mg (pregnancy), 0.5 mg (breast-feeding) |
| | 4 mg po daily | For women at higher risk of having a child with NTD |
| Iron | 60–200 mg (elemental iron) po per day (divided doses if > 60 mg) | Doses to treat iron-deficiency anemia |
| **Nausea and Vomiting** | | |
| Diphenhydramine or dimenhydrinate | 25–50 mg po four times daily as needed | |
| Doxylamine | 12.5 mg po three to four times daily as needed | |
| Pyridoxine | 25 mg po three times daily as needed | |
| Doxylamine + pyridoxine (Diclegis) | Two pills at bedtime, one pill in the morning and one pill in the afternoon (one to eight pills daily) | Delayed-release combination of doxylamine and pyridoxine |
| Metoclopramide | 5–15 mg po three to four times daily as needed | |
| Ondansetron | 4–8 mg po three times daily as needed | |
| **Urinary Tract Infections** | | |
| ***Asymptomatic bacteriuria and uncomplicated acute cystitis*** | | |
| Nitrofurantoin | 100 mg po four times daily for 3 to 7 days<br>100 mg po twice daily (macrocrystalline) for 3 to 7 days | |
| Cephalexin | 250–500 mg po four times daily for 3 to 7 days | |
| Amoxicillin | 500 mg po three times daily for 3 to 7 days | Check for local resistance before prescribing |
| ***Acute pyelonephritis*** | | |
| Ampicillin + gentamicin | 1–2 g IV every 6 hours +<br>1.5 mg/kg/dose IV every 8 hours | Switch to oral antibiotic after 48 hours afebrile and treat for a total of 10 to 14 days, for example:<br>• Cephalexin 500 mg po four times daily<br>• Cefprozil 500 mg po twice daily<br>• Amoxicillin clavulanate 875/125 mg po twice daily |
| Cefazolin | 1–2 g IV every 8 hours | |
| Cefuroxime | 0.75–1.5 g IV every 8 hours | |
| Ceftriaxone | 1–2 g IV or IM every 24 hours | |
| ***Prophylaxis*** | | |
| Nitrofurantoin | 50–100 mg po at bedtime | Start after the end of the treatment for pyelonephritis and continue until 4 to 6 weeks after delivery |
| Cephalexin | 250 mg po at bedtime | Nitrofurantoin should be preferred to prevent resistance to cephalosporins. |
| **Fetal Lung Maturation** | | |
| Betamethasone | 12 mg IM every 24 hours for two doses | A single rescue course may be considered after at least 2 weeks of treatment if gestational age is < 32 6/7 weeks and the woman is likely to give birth within the next week. |
| Dexamethasone | 6 mg IM or IV every 12 hours for four doses | |
| **Tocolytic agents** | | |
| Nifedipine (short acting) | 30 mg oral load (divided over at least 1 hour), then 10–20 mg every 4–6 hours for 48 hours | Maternal adverse reactions include headache, flushing, dizziness, transient hypotension, and maternal pulmonary edema. |
| Magnesium sulfate | 4–6 g IV bolus over 20 minutes,<br>Then 2–3 g/hour IV drip | Contraindicated in women with myasthenia gravis. Maternal pulmonary edema and cardiac arrest have been reported. Benign side effects include flushing, headache, and nausea. |
| Indomethacin | 50–100 mg oral load, then 25–50 mg po every 6 hours for 48 hours | Avoid in women with a history of renal or hepatic impairment, aspirin or nonsteroidal anti-inflammatory drug (NSAID) allergy, peptic ulcer disease, other bleeding disorders, or after 32 weeks of pregnancy. Reports of increased risk of maternal postpartum hemorrhage, and neonatal complications (eg, premature closure of the ductus arteriosus, renal insufficiency and, if delivery close to NSAID administration, pharmacologic treatment ineffectiveness for patent ductus arteriosus, necrotizing enterocolitis, bronchopulmonary dysplasia, and intraventricular hemorrhage) are worrisome. |

*(Continued)*

**Table 47–7**

**Medication Dosing Recommendations During Pregnancy and Lactation (*Continued*)**

| Drug | Dosage | Comments |
|---|---|---|
| **Magnesium sulfate**<br>For neuroprotection or prevention of eclampsia. | 4 g IV bolus over 20 minutes, then 1 g/hour IV drip | Contraindicated in women with myasthenia gravis. Maternal pulmonary edema and cardiac arrest have been reported. Benign side effects include flushing, headache, and nausea. Treatment limited to 24 hours for neuroprotection. |
| **Premature Rupture of Membranes** | | |
| Ampicillin | 2 g IV every 6 hours for 48 hours followed by amoxicillin | Ampicillin/amoxicillin are used with erythromycin |
| Amoxicillin | 250 mg po three times daily for 5 days | Ampicillin/amoxicillin are used with erythromycin |
| Erythromycin base | 250 mg IV every 6 hours for 48 hours followed by 333 mg three times daily for 5 days | Ampicillin/amoxicillin are used with erythromycin |
| **Preterm Labor Prevention** | | |
| 17-α-hydroxyprogesterone | 250 mg IM each week | |
| Progesterone (micronized) | 100 mg intravaginally daily<br>or 90 mg (8% gel) (previous preterm delivery)<br>200 mg intravaginally daily (short cervix) | Start at 16–20 weeks' gestation if previous preterm delivery and at 22 to 26 weeks if short cervix |
| **Group B Streptococcus** | | |
| Penicillin G | 5 million units IV initially, then 2.5–3 million units IV every 4 hours until delivery | First choice |
| Ampicillin | 2 g IV initially, then 1 g IV every 4 hours until delivery | |
| Cefazolin | 2 g IV initially, then 1 g IV every 8 hours until delivery | |
| Clindamycin | 900 mg IV every 8 hours until delivery | Only if isolate proven sensitive to clindamycin and erythromycin, or sensitive to clindamycin and testing for inducible clindamycin resistance is negative |
| Vancomycin | 1 g IV every 12 hours until delivery | If other options are inappropriate |
| **Cervical ripening** | | |
| Misoprostol | 25 mcg (1/4 of 100 mcg tablet) vaginally every 3–6 hours | Check for uterine tachysystole with or without fetal heart rate changes |
| Dinoprostone | 0.5 mg gel in cervical canal every 6 hours up to 1.5 mg/24 hours | Do not used if previous uterine surgery including cesarean section |
| | 10 mg extended-release vaginal insert in posterior fornix | Check for uterine tachysystole with or without fetal heart rate changes |
| **Induction of labor** | | |
| Misoprostol | 25 mcg (one-fourth of 100-mcg tablet) vaginally every 3–6 hours | Check for uterine tachysystole with or without fetal heart rate changes |
| Oxytocin | 0.5–6 mU/min with 1–6 mU/min increases every 15–40 minutes according to contractions | Check for uterine tachysystole and water intoxication |
| **Postpartum hemorrhage treatment** | | |
| Oxytocin | 10 units IM or 5 units push or 20–40 units in 1 L if IV fluid | Use normal saline or lactated Ringer. Cautious with bolus in women with cardiac disease |
| Carbetocin | 100 mcg IM or IV over 1 minute | |
| Methylergonovine | 0.2 mg IM or IV every 2–4 hours up to five doses | Do not use in hypertensive women |
| Carboprost tromethamine | 0.25 mg IM every 15–90 min up to eight doses | Use with caution in asthmatic women |
| Dinoprostone | 20 mg vaginal suppository every 2 hours | |
| Misoprostol | 400–800 mcg po or 800–1000 mcg rectally once | |
| Tranexamic acid | 10–15 mg/kg IV over 20 minutes | |
| **Hyperthyroidism** | | |
| Methimazole | 5–10 mg po once or twice daily | Second and third trimesters |
| Propylthiouracil | 50–100 mg po one to three times daily | First trimester. Risk of hepatotoxicity. |
| **Severe Hypertension** | | |
| Labetalol | Start with 10–20 mg IV over 2 minutes; repeated 20–80 mg every 15–30 minutes (300 mg total dose)<br>Or 1–2 mg/min IV drip | Not for asthmatic women.<br>May cause fetal bradycardia |
| Nifedipine (short acting) | 5–10 mg po; could be repeated after 30 minutes | Maternal adverse reactions include headache, flushing, dizziness, hypotension, tachycardia, and maternal pulmonary edema. |
| Hydralazine | 5 mg IV or IM; repeated 5–10 mg IV every 30 minutes (20 mg IV and 30 mg total dose)<br>Or<br>0.5–10 mg/hour IV drip | May cause tachycardia, headaches, hypotension |

*(Continued)*

**Table 47–7**

**Medication Dosing Recommendations During Pregnancy and Lactation** (*Continued*)

| Drug | Dosage | Comments |
|---|---|---|
| **Nonsevere Hypertension** | | |
| ***First choices*** | | |
| Methyldopa | 250–500 mg po two to four times daily | May cause orthostatic hypotension, drowsiness, depression, hemolytic anemia, positive antibodies antinuclear |
| Labetalol | 100–400 mg po two to four times daily | Not for asthmatic women. May cause hypotension, tiredness, headaches, hepatotoxicity |
| Nifedipine extended release | 20–60 mg po one to two times daily | May cause tachycardia, headaches, edema, hypotension |
| ***Second choices*** | | |
| Hydralazine | 10–50 mg po two to four times daily with methyldopa or labetalol | May cause tachycardia, headaches, hypotension, lupus-like syndrome |
| Metoprolol | 25–100 mg po two times daily | Not for asthmatic women; may cause fetal bradycardia, hypotension |
| Clonidine | 0.05–0.2 mg po (maximum: 0.8 mg daily) | May cause hypotension, drowsiness |
| Hydrochlorothiazide | 12.5–50 mg po once daily | May cause hypokalemia, dehydration |
| **Bacterial Vaginosis** | | |
| Metronidazole | 250 mg po three times daily for 7 days or 500 mg orally twice a day for 7 days<br>0.75% vaginal gel, once or twice daily for 5 days | Safe in all trimesters |
| Clindamycin | 300 mg po twice daily for 7 days<br>2 % cream, 5 g intravaginally at bedtime for 7 days<br>100-mg ovules intravaginally at bedtime for 3 days<br>bedtime for 7 days (breast-feeding) | For metronidazole and clindamycin, use oral formulation during pregnancy and intravaginal formulation during breast-feeding |
| **Vulvovaginal Candidiasis: refer to chapter 83** | | |
| 6–7 days treatments for intravaginal antifungal azoles are recommended during pregnancy to prevent recurrent episodes; shorter courses are appropriate during breast-feeding | | |
| **Mastitis** | | |
| ***Outpatient Treatment*** | | |
| Dicloxacillin | 500 mg po four times daily | Treat for 10–14 days |
| Cephalexin | 500 mg po four times daily | |
| Amoxicillin 875 mg + 125-mg clavulanate | One tablet po twice daily | |
| ***Inpatient Treatment for More Severe Cases*** | | |
| Oxacillin | 2 g IV every 4 hours | Treat IV for 24–48 hours until afebrile then continue with outpatient treatment |
| Nafcillin | 2 g IV every 4 hours | |
| Clindamycin | 600–900 mg IV every 8 hours | |
| Vancomycin | 1 g IV every 8–12 hours | If MRSA suspected or proven |
| **Breast Candidiasis** | | |
| **Mother** | | |
| Clotrimazole, miconazole, or nystatin | Topical cream | After each feeding and for 1 week after symptoms have resolved. Also treat infant even if asymptomatic |
| Fluconazole | 200–400 mg po for one dose followed by 100–200 mg po daily | If topical treatment not efficacious, add fluconazole; use until 1 week after symptoms have resolved (minimum of 2 weeks of treatment). Also treat infant even if asymptomatic. |
| ***Infant*** | | |
| Nystatin oral solution | 100,000–200,000 units (1–2 mL) to be swabbed into infant's mouth four times daily, after feedings | |
| Clotrimazole or miconazole topical cream | Apply in a thin layer in infant's mouth four times daily, after feedings | |
| ***Other Treatments for Candidiasis*** | | |
| Gentian violet 0.5%–1% solution | To be swabbed into infant's mouth once daily for 5 days before a feeding | To be used if other options fail. Can stain clothes and skin<br>If nipples or mouth are not violet after application and the feeding, reapply the treatment |

MRSA, methicillin-resistant *Staphylococcus aureus*; NTD, neural tube defect; po, orally; RDA, recommended daily allowance.

Data from Refs. 6, 10, 15, 17, 21, 25–31, and 33–49.

indomethacin and nifedipine have the highest probability of delaying delivery and improving neonatal and maternal outcomes.[32] Combined tocolytics or prolonged or repeated tocolytic therapy may increase fetal risk without evidence of efficacy.[31]

The FDA has advised against the use of terbutaline for tocolysis due to the risk of serious side effects including increased heart rate, transient hyperglycemia, hypokalemia, cardiac arrhythmias, pulmonary edema, and myocardial ischemia.[31]

#### ▶ *Neuroprotection*

Magnesium sulfate given to women at imminent risk of preterm delivery up to 33.6 weeks gestation decreases the incidence of death, cerebral palsy, and gross motor dysfunction. (see Table 47–7).[33]

#### ▶ *Antibiotics*

In the presence of preterm premature rupture of membranes (PPROM), 2 days of parenteral ampicillin/erythromycin followed by 5 days of oral amoxicillin and erythromycin are associated with a delay of delivery and reduction in maternal and neonatal morbidity (see Table 47–7).[34]

#### ▶ *Progesterone*

Progesterone is used to prevent preterm birth in women with previous preterm delivery and may also be used in women with a sonographic short cervix.[35,36]

### Group B *Streptococcus* Infection

Ten percent to 30% of pregnant women are colonized by group B streptococcus (GBS) at term. Maternal transmission of GBS during delivery can cause neonatal sepsis and death. Antibiotic therapy is effective in reducing the incidence of early-onset neonatal GBS infection when administered to high-risk groups including women with GBS vaginal/rectal colonization, GBS bacteriuria in the current pregnancy, and those who previously delivered a neonate with GBS disease.[37]

All women should be screened for GBS colonization using a vaginal-rectal swab between 35 and 37 weeks of gestation unless they had a proven GBS bacteriuria during the current pregnancy or a previous neonate with GBS disease. If treatment is indicated, it should be started at the time of membrane rupture or onset of labor, whichever comes first and continued until delivery (see Table 47–7). All women with unknown GBS status should be treated if labor or PPROM occur before 37 weeks. Intravenous penicillin G or ampicillin, or if penicillin-allergic, cefazolin (nonanaphylactic allergy) or clindamycin (anaphylaxis to penicillin) can be used. To use clindamycin, sensitivity to both clindamycin and erythromycin should be proven, or if resistant to erythromycin, testing for clindamycin inducible resistance must be negative. If resistance to either of these is present, vancomycin should be administered.[37]

Neonates should be monitored for signs and symptoms of sepsis for 48 hours after birth. If present, a full diagnostic workup should be initiated and empirical antibiotic therapy started.[38]

### Induction of Labor

Several mechanical and pharmacological methods of cervical ripening can be used. Mechanical methods include hygroscopic dilator, Foley catheter, and extraamniotic saline infusion.[39,40]

Pharmacological methods include the administration of prostaglandin E1 (eg, misoprostol) and E2 (eg, dinoprostone). Misoprostol is less expensive, more stable at room temperature,

has a higher 24-hour delivery rate, and requires less oxytocin than dinoprostone, but it is associated with more uterine tachysystole.[39] Prostaglandins should not be used in women with a previous caesarean section due to the increased risk of uterine rupture.[40]

When the cervix is deemed favorable, nonpharmacological options for producing contractions are membranes sweeping, nipple stimulation, and amniotomy. Membrane sweeping and breast stimulation are effective in inducing labour within 48 to 72 hours.[39] Amniotomy is more effective when oxytocin is added early after the intervention.[39]

Oxytocin is the most frequently used pharmacological method of labor induction.[39] Active management of labor with oxytocin is associated with more deliveries within 24 hours; however, it increases the use of epidural and the rate of caesarean sections.[39,40] A rare but serious complication of high cumulative dose of oxytocin is water intoxication due to its antidiuretic action.[40] Oral misoprostol is also effective for labor induction but not licensed in the United States for this use.

### Postpartum Hemorrhage

Postpartum hemorrhage is generally defined as blood loss greater than 500 mL after vaginal delivery or 1000 mL following a caesarean section.[41] Uterine atony accounts for up to 80% of primary postpartum hemorrhage, but vaginal or cervical trauma, retained placenta, and coagulopathies are also implicated. Supportive measures should be implemented, and the most likely cause of bleeding should be identified and corrected.

Oxytocin and carbetocin (long-acting analog of oxytocin) can prevent excessive blood loss associated with delivery and caesarian section. If this fails, use uterotonics, eg, methylergonovine, carboprost tromethamine, dinoprostone, and misoprostol, which are effective in the treatment of postpartum hemorrhage secondary to uterine atony, used separately or in combination.[42] Methylergonovine should not be administered to hypertensive women. Carboprost tromethamine should be used with caution in asthmatic women.[41] As a last resort, tranexamic acid, an antifibrinolytic agent can be used.[42] Surgical management ranging from uterine tamponade to hysterectomy is used in unresponsive postpartum hemorrhages.[41]

### Thyroid Disorders

Notice that the thyroxine-stimulating hormone (TSH) reference range is lower in pregnancy, 0.1 to 2.5 μIU/mL (0.1–2.5 mIU/L) in the first trimester and 0.3 to 3.0 μIU/mL (0.3–3.0 mIU/L) thereafter. Transient gestational hypothyroidism or hyperthyroidism can occur and have adverse effects on the pregnancy and the fetus/neonate, even if subclinical.[43]

Universal screening of thyroid disorders (TSH or thyroid peroxidase antibody) in pregnancy is debated.[43] Subclinical hypothyroidism should be treated, although there are no solid data on the impact of thyroid replacement therapy on maternal and neonatal morbidity, especially in women without thyroid peroxidase antibodies.[43]

Gestational hyperthyroidism associated with hyperemesis gravidarum is self-remitting and does not require antithyroid treatment. In maternal hyperthyroidism, propylthiouracil is used in the first trimester (methimazole is associated with fetal malformations) and methimazole is used thereafter (propylthiouracil is associated with an increased risk of hepatotoxicity) (see Table 47–7).[43] Close fetal and neonatal monitoring is necessary to detect signs of hypothyroidism (induced by antithyroid drugs)

or hyperthyroidism (induced by maternal thyroid-stimulating antibodies).

TSH level should be evaluated 6 to 12 weeks after delivery in all women with thyroid disorders during pregnancy. Thyroid replacement drugs and antithyroid drugs can be used during lactation.[20]

## Hypertension

Both preexisting (chronic) and gestational hypertension increase the risk of maternal and perinatal morbidity and mortality. Women with preeclampsia, a syndrome generated by endothelial dysfunction, may present with seizures (eclampsia), neurologic, hepatic, and renal or coagulation complications, as well as fetal death and intrauterine growth restriction. Delivery is the only treatment for preeclampsia. Intravenous magnesium sulfate is used to prevent eclampsia (see Table 47–7).[33–44]

During pregnancy, severe hypertension (systolic blood pressure greater than or equal to 160 mm Hg or a diastolic blood pressure greater than or equal to 110 mm Hg) is an emergency and should be treated aggressively, but a limited number of drugs can be used (see Table 47–7). Methyldopa, labetalol, and nifedipine are accepted as first-line treatments for nonsevere hypertension, however, the blood pressure level at which they should be used is debated. Caution is advised with atenolol (intrauterine growth restriction). Angiotensin-converting enzyme inhibitors, angiotensin II receptor antagonists, or renin inhibitors (fetopathy) are contraindicated.[44]

In high-risk women, to prevent preeclampsia, initiate early in pregnancy, low-dose aspirin (75–160 mg daily). Also, if low dietary intake, start calcium supplements (1–2 g/day).[44]

See all women with hypertensive disorders 6 to 12 weeks after delivery to measure blood pressure and proteinuria, assess cardiovascular risk markers, and counsel them on healthy diet, lifestyle modification, future pregnancy, and risk of cardiovascular diseases.

## Anticoagulation

The risk of thromboembolic events is increased during pregnancy and even more during the postpartum. Anticoagulation is required in some women, even if they were not anticoagulated before pregnancy.[7,10]

Low-molecular-weight heparins are preferred over unfractionated heparin due to a favorable pharmacokinetic profile. Both are safe during pregnancy and lactation. Doses should be specific to the underlying condition.

Warfarin is associated with fetal malformations when used between 6 and 12 weeks of pregnancy and with fetal and maternal bleeding when used during the third trimester and delivery (see

---

**Patient Encounter, Part 2**

At 28 weeks of pregnancy, the patient is admitted for acute pyelonephritis and back pain. Blood glucose levels are between 100 and 160 mg/dL (5.6 and 8.9 mmol/L). Urine culture reports the presence of *E. coli* and group B Streptococcus.

**Meds:** Lithium 600 mg orally in the morning and at bedtime; quetiapine 100 mg orally at bedtime; levothyroxine 75 mcg orally daily; insulin NPH 10 units subcutaneously at bedtime; insulin aspart 10 units subcutaneously before breakfast

*What treatment do you recommend at this time?*

---

**Patient Encounter, Part 3**

At 35 weeks' gestation, the patient is admitted for preterm labor.

**Meds:** Lithium 600 mg orally in the morning and at bedtime; quetiapine 100 mg orally at bedtime; levothyroxine 75 mcg orally in the morning; insulin NPH 16 units subcutaneously at bedtime; Insulin aspart 20 units subcutaneously before breakfast

*Will you recommend a tocolytic agent?*

*If labor progresses, what special care should be provided?*

---

Table 47–3).[7,10] However, it could be used by some women with prosthetic heart valves in the second trimester and early third trimester, as valve thrombosis has been reported with heparin therapy.[10] Warfarin and heparins are safe for use during lactation.[20]

## Bacterial Vaginosis

Bacterial vaginosis is associated with PPROM, chorioamnionitis, preterm birth, and postpartum endometritis.[45] Treatment is recommended in all symptomatic women and in asymptomatic women at high risk for preterm delivery, although the treatment has not been shown to reduce the risk of delivery before 37 weeks. The Centers for Disease Control and Prevention (CDC) recommends oral metronidazole or oral clindamycin for the treatment of bacterial vaginosis in pregnant women (see Table 47–7).[45]

Culture should be performed 1 month after completion of therapy since the cure rate is approximately 70%.[45]

## Vulvovaginal Candidiasis

Only symptomatic vulvovaginal candidiasis should be treated in pregnant or lactating women (see Table 47–7).[45]

## Sexually Transmitted Infections

Table 47–8 presents the management of sexually transmitted infections during pregnancy and lactation, associated risks, and recommended follow-up.[45,46] Treatment of all recent sexual partners is mandatory.

## Enhancement of Lactation

Optimization of breast-feeding techniques is the first-line strategy for decreased lactation. No drug is currently approved by the FDA for lactation enhancement, but dopamine antagonists, metoclopramide, and domperidone (not available in the United States), which increase prolactin levels are used for this purpose.[47] Metoclopramide's maternal side effects include fatigue, irritability, headache, and extrapyramidal symptoms. Very few side effects in the infant have been reported. Domperidone has been associated with abnormal heart rhythm and sudden cardiac

---

**Patient Encounter, Part 4**

After 10 hours of labor, the patient delivers vaginally a 5.6 lb (2.55 kg) baby. She plans to breast-feed.

*What treatment plan do you recommend after delivery?*

*What surveillance do you suggest for the newborn/baby?*

*Can she breast-feed while taking her medications?*

| **Management of Sexually Transmitted Infections During Pregnancy and Lactation** | | | | |
| | **Indications for Treatment** | **Associated Risks During Pregnancy** | **When to Repeat Testing During Pregnancy** | **Other** |
| Chlamydia trachomatis | All women with a positive test, even if asymptomatic | Preterm labor; neonatal infection | Third trimester: < 25 years of age, those at increased risk of infection or if first screening positive | Repeat testing 3–4 weeks after therapy |
| *Treatment* | Azithromycin 1 g po once<br>Amoxicillin 500 mg po three times daily for 7 days<br>Erythromycin base 500 mg po four times daily for 7 days or 250 mg po four times daily for 14 days<br>Doxycycline 100 mg po twice daily for 7 days only during lactation (discoloration of teeth if used after 16 weeks of gestational age). | | | |
| Gonorrhea | All women with a positive test, even if asymptomatic | Preterm labor; neonatal infection | Third trimester: (or 3–6 months after first trimester) if first screening positive or if at risk of reinfection | Repeat testing 1 week after treatment if cefixime or azithromycin used. Repeat 3 weeks after therapy otherwise |
| *Treatment (uncomplicated infection,(pharynx, cervix, urethra, rectum)* | First choice : ceftriaxone 250 mg IM once + azithromycin 1 g po once<br>Second choice during breast-feeding : ceftriaxone 250 mg intramuscularly once + doxycycline 100 mg po twice daily for 7 days. Do not use doxycycline during pregnancy<br>Azithromycin 2 g po once for cephalosporin-allergic patients. | | | |
| Genital Herpes Simplex | Active lesions; disseminated; Starting at 36 weeks: prevention of recurrence at term | Neonatal infection, especially if acquired near time of delivery (30%–50%) | | Cesarean section if active genital lesions at delivery; evaluate newborn for herpes infection |
| *Treatment* | **First episode:**<br>*Acyclovir:* 400 mg po three times daily for 7–10 days, or 200 mg five times daily for 7–10 days<br>*Valacyclovir:* 1000 mg po twice daily for 10 days<br><br>**Recurrent episodes:**<br>*Acyclovir:* 400 mg po three times daily for 5 days, or 800 mg twice daily for 5 days, or 800 mg three times daily for 2 days<br>*Valacyclovir:* 500 mg po twice daily for 3 days<br><br>**Suppressive therapy:** start at 36 weeks of gestation (or earlier if at risk of preterm delivery) until delivery<br>*Acyclovir:* 400 mg po three times daily<br>*Valacyclovir:* 500 mg po twice daily | | | |
| Syphilis | All women with confirmed positive serology | In utero fetal and neonatal infection; congenital malformations | At 28–32 weeks and at delivery if at risk of reinfection, if untested before, if positive serology in the first trimester, or if was previous stillborn at more than 20 weeks | Therapy is efficacious to treat the fetus and to prevent transmission; be aware of Jarisch-Herxheimer reaction; fetal evaluation should include ultrasounds. |
| *Treatment* | Desensitize penicillin-allergic patients<br>Primary, secondary, or early latent: Benzathine penicillin G 2.4 million units IM once<br>Late latent or of unknown duration or tertiary: Benzathine penicillin G 2.4 million units IM three times at 1-week interval<br>Neurosyphilis: Aqueous crystalline penicillin G 3–4 million units IV six times daily for 10–14 days or<br>Procaine penicillin 2.4 million units IV daily + probenecid 500 mg four times daily | | | |
| Trichomoniasis | Symptomatic women | PPROM, preterm birth, low birth weight; neonatal infection | | Therapy does not decrease perinatal mortality |
| *Treatment* | Metronidazole 2 g po for one dose.<br>Lactation: consider holding breast-feeding for 12 hours (most important for premature or very young infants). | | | |

po, orally; PPROM, preterm premature rupture of membranes.

Data from Refs. 45 and 46.

## Patient Care Process

**Patient Assessment:**

- Complete medical history including obstetrical history.
- Inquire about changes in disorders evolution and last follow-up with the treating physician.
- Conduct medication history (past/current treatments, compliance, efficacy, and safety).
- Verify immunization status.
- Assess for pregnancy signs and symptoms.
- Perform physical examination.
- Evaluate nutritional status and socioeconomic environment.
- Perform first trimester routine lab testing.
- Order serum drug levels.

**Therapy Evaluation:**

- Evaluate the need for continuing medication (benefits and risks for mother and fetus).
- Assess efficacy, safety, and patient adherence, and screen for drug interactions.
- Evaluate whether safer and more effective alternative medications are available.

**Care Plan Development:**

- Avoid treatments without evidence of benefit or that can be delayed until after pregnancy and breast-feeding.

- Address patient concerns (risks of medication, risks of relapse if condition is untreated, prescription coverage and access to care).
- Treat pregnancy symptoms (eg, nausea) if they are bothersome or interfering with other pathologies (eg, diabetes).
- When possible, treat pregnancy conditions with nonpharmacologic treatments instead of drug therapy.
- Recommend appropriate folic acid and multivitamins.
- Provide prenatal counseling regarding lifestyle modifications (healthy diet, exercise, avoidance of tobacco, alcohol, and illicit or unnecessary drugs).
- Encourage breast-feeding. If maternal drug therapy is required during breast-feeding, choose drugs with the best safety profile. Communicate information to all other health care professionals to ensure continuing of care.

**Follow-Up Evaluation:**

- Follow up at each prenatal visit or more frequently to assess compliance, effectiveness, and safety of treatment.
- Review and repeat assessments as necessary.
- Monitor infants for birth defects, developmental delays, or unusual reactions, and report suspected drug-related reactions to the FDA or pharmaceutical companies.

---

death; caution is advised when prescribing it with other drugs that prolong the QT interval or that inhibit its metabolism or for women with underlying cardiac conditions.[48]

### Mastitis

Bacterial mastitis, seen typically within the first 6 weeks of breast-feeding, is characterized by localized signs of inflammation and engorgement. Fever, shivering, and malaise can also occur. The most commonly encountered bacteria are *Staphylococcus aureus* (including methicillin-resistant), followed by *Streptococcus, Staphylococcus epidermidis*, and *E. coli*.[49]

Cold or warm compresses and more frequent breast-feeding or breast pumping, should be encouraged. Antibiotics (see Table 47–7) and analgesics (eg, acetaminophen, NSAIDs) can be used to relieve pain.[20,49] If a breast abscess is suspected, ultrasound should be performed before surgical drainage.

### Breast Candidiasis

Candidiasis presents with severe and persistent nipple pain, which may throb and radiate to the breasts and back. Pain is usually more intense during and immediately after breast-feeding. The breast-fed infant can be symptomatic or asymptomatic. *Candida albicans* is the most commonly found species. It is recommended to breast-feed more frequently than usual for a shorter period of time. Milk does not have to be discarded; however, clothes and towels in contact with breasts and the baby's mouth should be washed in hot water. Antifungal treatment must be given to the mother and the baby simultaneously (see Table 47–7). If no improvement is seen within 24 to 48 hours, treatment should be reevaluated. Analgesics (eg, acetaminophen, NSAIDs) can be used.[49]

# Contraception

Julia M. Koehler and Kathleen B. Haynes

## LEARNING OBJECTIVES

● **Upon completion of the chapter, the reader will be able to:**

1. Discuss the physiology of the female reproductive system.

2. Compare the efficacy of oral contraceptives with that of other methods of contraception.

3. State the mechanism of action of hormonal contraceptives.

4. Discuss risks associated with the use of contraceptives, and state absolute and relative contraindications to their use.

5. List side effects associated with the use of various contraceptives, and recommend strategies for minimizing or eliminating such side effects.

6. Describe advantages and disadvantages of various contraceptives, including oral and nonoral formulations.

7. Cite important drug interactions that may occur with oral contraceptives.

8. Provide appropriate patient education regarding the important differences between various barrier methods of contraception.

9. Discuss how emergency contraception may be employed to prevent unintended pregnancy.

10. Provide appropriate patient education regarding the use of oral contraceptives, and recommend and discuss the use of nonoral contraceptives when appropriate.

## INTRODUCTION

Historically, the 1950s was an important time in the control of human fertility. It was during that decade that the first combination oral contraceptives (COCs) were developed. Shortly after the discovery that the exogenous administration of hormones such as progesterone successfully blocked ovulation, the use of hormonal steroids quickly became the most popular method of contraception worldwide. COCs are the most commonly used reversible form of contraception in the United States today, with an estimated 10.6 million women users.[1] Studies of women of childbearing age in the United States estimate that 62% are currently using a contraceptive method.[1] Since the introduction of oral contraceptives, many additional contraceptive forms have been developed and are available for use in the United States, including transdermal systems, transvaginal systems, and intrauterine devices (IUDs). These additional forms of contraception offer women effective and potentially more convenient alternatives to oral contraceptives.

## EPIDEMIOLOGY

According to the National Survey of Family Growth, approximately 6.58 million pregnancies occur annually in the United States.[2] It is estimated that nearly half of all pregnancies that occur each year in the United States are unintended.[2,3] Contributing to the risk of unintended pregnancy is the fact that approximately 11% of all women who are at risk of becoming pregnant

do not use any form of contraception.[1] In addition, many women who do use contraceptives use their chosen method of contraception imperfectly, and this also increases the risk of unintended pregnancy. For patients with certain medical conditions, such as epilepsy, hypertension, ischemic heart disease, sickle cell disease, lupus, or thromboembolic mutations, unintended pregnancy can further increase the risk for adverse health events.[4] The provision of appropriate and adequate instruction to patients regarding how to use contraceptive methods effectively is essential in order to reduce the risk of unintended pregnancy and, for some women, the associated increase in risk for adverse health-related events.

Exposure to sexually transmitted infections (STIs) is also a concern for women who are sexually active. It is estimated that 20 million people in the United States become newly infected annually with an STI.[5] Given that not all methods of contraception protect the user against STIs, the provision of proper patient education by health care professionals regarding this risk is absolutely essential.

## PHYSIOLOGY

● The female menstrual cycle is divided into four functional phases: follicular, ovulatory, luteal, and menstrual.[3] The follicular phase begins the cycle, and ovulation generally occurs around day 14. The luteal phase then begins and continues until menstruation occurs.[3] The menstrual cycle is regulated by a negative-feedback
**FIGURE 48–1.** Menstrual cycle events. [a]Estradiol: 40 pg/mL = 147 pmol/L; 250 to 400 pg/mL = 918 to 1468 pmol/L; 125 to 250 pg/mL = 459 to 918 pmol/L. [b]Progesterone: 1 ng/mL = 3 nmol/L; 10 to 15 ng/mL = 32 to 48 nmol/L. (Adapted with permission from Shulman LP. The menstrual cycle. In: Hatcher RA, Trussel J, Nelson AL, Cates W Jr, Kowal D, Policar M. Contraceptive Technology, 20th rev. ed. New York: Ardent Media, 2011:29–44.)

hormone loop between the hypothalamus, anterior pituitary gland, and ovaries[3] (**Figure 48–1**).

Initially, the hypothalamus releases gonadotropin-releasing hormone (GnRH), which stimulates the anterior pituitary to produce follicle-stimulating hormone (FSH) and luteinizing hormone (LH). The levels of FSH and LH released vary depending on the phase of the menstrual cycle. Just prior to ovulation, FSH and LH both are at their peak levels. The FSH helps to promote growth of the follicle in preparation for ovulation by causing granulosa cells lining the follicle to grow and produce estrogen. LH promotes androgen production by theca cells in the follicle, promotes ovulation and oocyte maturation, and converts granulosa cells to cells that secrete progesterone after ovulation.

Conception is most likely to occur when viable sperm are present in the upper region of the reproductive tract at the time of ovulation. Fertilization occurs when a spermatozoan penetrates an ovum. Approximately 6 to 8 days after ovulation, attachment of the early embryo to the lining of the uterine cavity—implantation—occurs.

## PREVENTION OF PREGNANCY: CONTRACEPTIVES AND DEVICES
### Goals of Contraception/Desired Outcome

The most common goal of contraception is the prevention of pregnancy. However, some patients use contraceptive methods for other benefits, such as menstrual cycle regulation, reduction of premenstrual symptoms, or treatment of acne.

### Choice of Contraceptives: Important Considerations

When helping a patient with contraceptive selection, the most important goal is finding an option the patient is comfortable with and the clinician feels is beneficial for the patient. It is imperative to explain the side effects, safety concerns, and noncontraceptive benefits of each alternative to the patient so that she may make an informed decision. Fertility goals vary for each patient. It must be determined whether the goal is to postpone conception, space out the next pregnancy, or avoid

further pregnancy altogether. Also, a clinician must understand the patient's desire to have or not have a regular bleeding pattern, because many contraceptives will affect menses.

As discussed later in this chapter, contraindications exist for various forms of contraception. Patients must be evaluated by a health care professional to rule out medical contraindications to certain contraceptives. The physical examination also allows health care professionals to identify other medical concerns, such as hypertension or liver disease, that need to be considered when selecting an appropriate contraceptive agent. Clinicians also should review family history for potential risks with certain forms of birth control.

Sexual behavior of the female must be determined to understand the risk for STIs. Women not in a monogamous relationship must consider their risk of STIs as a factor in their contraceptive decision. Some barrier methods protect against STIs, but hormonal contraceptives do not prevent STIs if used alone.

Personal preference plays a large role when determining the best contraceptive option. For instance, if a woman is not interested in using a method that interrupts sexual activity, then a diaphragm would be an inappropriate choice. Preference of the sexual partner may also be important. Certain agents such as male condoms require the male partner to play an active role in contraception.

Cost may also be an issue for patients. Insurance may not cover all forms of contraception, and patients may have to bear the entire cost for certain options.

## Efficacy of Contraceptives

The unintended pregnancy rate for women who do not use any form of contraception is unknown. Therefore, it is difficult to determine the true efficacy of contraceptives in preventing unwanted pregnancy. Table 48–1 shows the percentage of women who experience unintended pregnancy within 1 year of contraceptive use with ongoing sexual activity.[3]

## Oral Contraceptives (Combination)

COCs contain a synthetic estrogen and one of several steroids with progestational activity. Most oral contraceptives contain one of three types of estrogen: ethinyl estradiol (EE), which is pharmacologically active; mestranol, which is converted by the liver to EE; or estradiol valerate, which is metabolized to estradiol and valeric acid. Many different progestins are found in the various oral contraceptives. These include norethindrone, norethindrone acetate, ethynodiol diacetate, norgestrel, levonorgestrel, desogestrel, norgestimate, drospirenone, and dienogest.

The primary mechanism by which COCs prevent pregnancy is through inhibition of ovulation. FSH and LH regulate the production of estrogen and progesterone by the ovaries. Secretion of estrogen and progesterone by the ovaries occurs in a cyclic manner, which determines the regular hormonal changes that occur in the uterus, vagina, and cervix associated with the menstrual cycle. Cyclic changes in the levels of estrogen and progesterone in the blood, together with FSH and LH, modulate the development of ova and the occurrence of ovulation. The estrogen component of COCs is most active in inhibiting FSH release.[3] However, at sufficiently high doses, estrogens also may cause inhibition of LH release. In low-dose COCs, the progestin component causes suppression of LH.[3] Ovulation is prevented by this suppression of the midcycle surge of both FSH and LH[3] and mimics the physiologic changes that occur during pregnancy.

[a]Among typical couples who initiate use of a method (not necessarily for the first time), the percentage who experience an accidental pregnancy during the first year if they do not stop use for any other reason. Estimates of the probability of pregnancy during the first year of typical use for spermicides, withdrawal, periodic abstinence, the diaphragm, the male condom, the pill, and Depo-Provera are taken from the 1995 National Survey of Family Growth corrected for underreporting of abortion.

[b]Among couples who initiate use of a method (not necessarily for the first time) and who use it *perfectly* (both consistently and correctly), the percentage who experience an accidental pregnancy during the first year if they do not stop use for any other reason.

[c]Among couples attempting to avoid pregnancy, the percentage who continue to use a method for 1 year.

Adapted from Trussel J, Guthrie KA. Choosing a contraceptive: Efficacy, safety, and personal considerations. In: Hatcher RA, Trussel J, Nelson AL, Cates W Jr, Kowal D, Policar M. Contraceptive Technology, 20th rev. ed. New York: Ardent Media, 2011:45–74, with permission.

Although suppression of FSH and LH is the primary mechanism by which COCs prevent ovulation, there are other mechanisms by which these hormones work to prevent pregnancy. Other mechanisms include reduced penetration of the egg by sperm, reduced implantation of fertilized eggs, thickening of

cervical mucus to prevent sperm penetration into the upper genital tract, and slowed tubal motility, which may delay transport of sperm.[3] Thus, in addition to inhibiting ovulation, COCs induce changes in the cervical mucus and endometrium that make sperm transport and implantation of the embryo unlikely.[3]

Table 48–2 contains a partial listing of the many oral contraceptives available in the United States.[6] Since the mid-1960s, EE has been the primary estrogen used in most COCs. However, the amount of EE used in COCs has decreased progressively since that time, and most now contain 35 mcg or less of EE. In

EE, ethinyl estradiol

[a]Each tablet also contains 451 mcg of levomefolate calcium

[b]Some references may classify as monophasic since the variation in hormone content does not occur during the first three weeks of the pill pack.

Data compiled in part from Anonymous. Choice of contraceptives: Treatment Guidelines from The Medical Letter. Med Lett. 2010;8:89–96.

addition, to reduce side effects and improve tolerability associated with oral contraceptive use, new progestins and different routes of administration have been explored. In an attempt to minimize the undesirable androgenic side effects associated with the progestins of COCs, the original synthetic progestins were modified to create "third generation" progestins (eg, desogestrel and norgestimate), and newer progestins with antiandrogenic properties (eg, drospirenone) have been discovered. Overall, the synthetic progestins found in today's COCs are extremely potent in their ability to inhibit ovulation and prevent pregnancy.

COCs are available in monophasic, biphasic, triphasic, and quadriphasic preparations. Monophasic preparations contain fixed doses of estrogen and progestin in each active pill. Although all four preparations contain both estrogens and progestins, biphasic, triphasic, and quadriphasic preparations contain varying proportions of one or both hormones during the pill cycle. These preparations were introduced to reduce a patient's cumulative exposure to progestins, as well as to mimic more closely the hormonal changes of the menstrual cycle. However, there is no evidence to suggest that the multiphasic preparations offer any significant clinical advantage over monophasic pills.[6]

Most traditional COCs are packaged as 21/7 cycles (ie, 21 days of active pills and 7 days of placebo). However, newer regimens offer either fewer hormone-free days per traditional, 28-day pill cycle or extended (or in some cases continuous) cycles, which may allow for fewer withdrawal bleeds per year and fewer menstrual-related side effects (eg, menstrual pain, bloating, headaches) for some women.

### ▶ Noncontraceptive Benefits of Combination Oral Contraceptives

In addition to preventing pregnancy, there are several noncontraceptive benefits associated with the use of COCs.

**Reduction in the Risk of Endometrial Cancer** The risk of endometrial cancer among women who have used oral contraceptives for at least 1 year is approximately 40% less and for at least 10 years is approximately 80% less than the risk in women who have never used oral contraceptives.[3,7] There is additional evidence to suggest this benefit is detectable within 1 year of use, and the reduced risk may persist for up to 20 years following discontinuation of oral contraceptives.[3,8]

**Reduction in the Risk of Ovarian Cancer** When compared with women who have never used oral contraceptives, women who have used oral contraceptives for up to 4 years are 30% less likely to develop ovarian cancer. There is also additional evidence to suggest that the longer the duration of oral contraceptive use, the greater the reduction in the risk of ovarian cancer. Women who have taken oral contraceptives for 5 to 11 years are 60% less likely to develop ovarian cancer, and women who have taken oral contraceptives for more than 12 years are 80% less likely to develop ovarian cancer than those who have never used oral contraceptives. As with the reduced risk of endometrial cancer, there is evidence to suggest the reduced risk of ovarian cancer may persist for years following discontinuation of oral contraceptives.[9,10]

**Improved Regulation of Menstruation and Reduction in the Risk of Anemia** Women who take oral contraceptives typically experience more regular menstrual cycles. In general, oral contraceptive use is associated with less cramping and dysmenorrhea.[3,6] Also, women who take oral contraceptives have a smaller volume of menstruum and experience fewer days of menstruation each month and consequently experience less blood loss with each menstrual period.[3,11] Some studies suggest that oral contraceptive

use decreases overall monthly menstrual flow by 60% or more and conserves hemoglobin and ferritin levels, which may be particularly beneficial in women who are anemic or at risk for anemia.[3] In addition, some COC formulations contain iron, which may also minimize the risk for anemia (See **Unique Oral Contraceptives** section.)

**Reduction in the Risk of Fetal Neural Tube Defects** While COCs are not 100% effective at preventing pregnancy, it is possible that a woman may conceive while taking a COC. In addition, many women may become pregnant very soon after discontinuing a COC. In order to decrease the risk of neural tube defects in the fetuses associated with such pregnancies, COC formulations that contain a source of folate in every pill are also available.[3]

**Relief from Symptoms Associated with Premenstrual Dysphoric Disorder** COCs have been widely used for the treatment of premenstrual dysphoric disorder (PMDD). Current evidence suggests that these agents are most effective at targeting the physical symptoms associated with the disorder and less effective in treating mood-related symptoms.[12] Although multiphasic COCs have been used effectively in the treatment of PMDD, monophasic preparations may yield fewer mood swings and are generally easier to manage. Yaz, which contains the progestin, drospirenone, carries an FDA-approved indication for PMDD.[6]

**Relief of Benign Breast Disease** Women who use oral contraceptives are less likely to develop benign breast cysts or fibroadenomas and are less likely to experience progression of such conditions.[3,6]

**Prevention of Ovarian Cysts** Because oral contraceptives suppress ovarian stimulation, women who take them are less likely to develop ovarian cysts.[6]

**Decrease in Symptoms Related to Endometriosis** COC use has been linked to a decreased incidence of symptomatic endometriosis. In women who suffer from endometriosis, the extended-cycle COCs may provide the most effective relief from menstrual pain by reducing the total number of painful episodes per year.[3]

**Improvement in Acne Control** All COCs can improve acne by increasing the quantity of sex hormone–binding globulin and thereby decreasing free testosterone concentrations.[6] Third-generation progestins, such as desogestrel and norgestimate, are believed to have less androgenic activity compared with older progestins, and drospirenone is considered to be antiandrogenic.[6] However, it is not clear that COCs containing any of these progestins confer any advantage over other COCs with respect to their ability to improve acne control. Ortho Tri-Cyclen (EE and norgestimate), Estrostep Fe (EE and norethindrone acetate), Yaz, and Beyaz (EE and drospirenone) each carry an FDA-approved indication for the treatment of acne.[3,6]

### ▶ Potential Risks of Combination Oral Contraceptives

Although there are many noncontraceptive benefits associated with the use of COCs, their use is not without risk or potential for adverse effects.

**Sexually Transmitted Infections** Because the use of COCs may decrease the use of selected barrier contraceptive methods (eg, latex condoms) that do protect against STIs, one of the most common potential risks associated with the use of oral contraceptives is the increased risk of acquiring an STI.[4]

**Cardiovascular Events and Hypertension** A World Health Organization (WHO) collaborative study found that high-dose

(50 mcg or more of EE) oral contraceptive users with uncontrolled hypertension have an increased risk of experiencing a myocardial infarction or stroke.[6,13] In this study, women who had the lowest risk for experiencing a myocardial infarction or stroke were those who did not smoke, took low-dose oral contraceptives, and had their blood pressure checked prior to beginning oral contraceptives.[14–16] Hypertension secondary to oral contraceptive use is thought to occur in up to 3% of women and is believed to be attributed to the effect that estrogens and progestins can have on aldosterone activity.[3] Given this and the risk for cardiovascular events, women should have their blood pressure checked prior to initiating oral contraceptives, as well as periodically throughout oral contraceptive use. If significant elevations in blood pressure are noted, oral contraceptives should be discontinued. Estrogen-containing contraceptives are not recommended for smokers who are 35 years of age or older, for women with hypertension (especially if untreated), or for women who experience migraine headaches (especially those with focal neurologic symptoms).[4,6]

**Venous Thromboembolism** It is believed that the estrogen component of COCs stimulates enhanced hepatic production of clotting factors. COCs have been associated with a two- to three-fold increase in the risk of venous thromboembolism compared with women who do not use oral contraceptives.[6] Contraceptive users at greatest risk for the development of venous thromboembolism include those who are obese, smoke, have hypertension, have diabetes complicated by end-organ damage, are immobile, have experienced recent trauma or surgery, or have a history of prior thromboembolism. It is important to note, however, that the increase in risk of venous thromboembolism in oral contraceptive users is lower than that associated with pregnancy and the postpartum period.[6,17] Newer, less androgenic progestins, such as desogestrel and drospirenone, have been reported to be associated with a higher risk of venous thromboembolism.[18–21] Currently available studies validating this risk have produced conflicting results. Two studies published in 2011 reported a two- to three-fold greater risk of venous thromboembolic events in women using oral contraceptives containing drospirenone when compared with women using levonorgestrel-containing contraceptives.[22,23] However, the results of the International Active Surveillance Study of Women Taking Oral Contraceptives, published in 2014, demonstrated similar rates of venous and arterial thromboembolism in women taking COCs containing drosperinone, levonorgesterol, or other progestins.[24] In general, progestin-only contraceptives are preferred for women who are at increased risk of cardiovascular or thromboembolic complications, including women with a prior history of thromboembolic disease.[4,6]

**Gallbladder Disease** In women with preexisting gallstones, low-dose estrogen-containing oral contraceptives may enhance the potential for the development of symptomatic gallbladder disease and may worsen existing gallbladder disease.[3,4] Although this risk has not been demonstrated with the use of higher-dose oral contraceptives, COCs containing estrogen should be used with caution in patients with a history of gallbladder disease.

**Hepatic Tumors** Although the use of oral contraceptives is not associated with an increased risk for the development of hepatocellular carcinoma, long-term use of high-dose oral contraceptives has been associated with the development of benign liver tumors.[3] Because even benign liver tumors may pose significant risk to the patient, oral contraceptives should be discontinued if liver enlargement is noted on physical examination. In cases of hepatoma (malignancy), the use of COCs is contraindicated.[4]

**Patient Encounter, Part 1**

A 22-year-old nulliparous woman, presents to your clinic requesting information on contraception. She specifically inquires about options that allow for fewer or no menstrual periods. You begin to take a history and determine that the patient is currently sexually active and is not using any method of birth control. She weighs 135 lb(61.4 kg), is 64 in (163 cm) tall, and has a blood pressure of 108/70 mm Hg. She has no history of smoking. She has migraines without aura, for which she takes propranolol. On further questioning, you discover that she has a positive family history of breast cancer (both her mother and maternal aunt), but no personal history. As you discuss various contraceptive options with the patient, it is clear that she has a preference for an oral contraceptive agent.

*What additional information do you need to know before recommending a contraceptive for this patient?*

*Based on the information provided by the patient, what oral contraceptive agent would you recommend for the patient and why?*

*What education would you provide to this patient regarding risks associated with oral contraceptive use?*

**Cervical Cancer** There appears to be an increased risk for the development of cervical cancer among long-term users of oral contraceptives.[3] It is uncertain whether this increase in risk is directly attributed to the use of oral contraceptives. Data suggest that oral contraceptive users tend to have more sexual partners and use condoms less frequently, and as a result, this may increase their susceptibility to infection with human papilloma virus (HPV), a known risk factor for cervical cancer.

**KEY CONCEPT** *Absolute and relative contraindications to the use of oral contraceptives are listed in* Table 48–3.[3,4,25]

▶ *Adverse Effects of Oral Contraceptives and Their Management*

As with all medications, there are potential adverse effects with COCs. **KEY CONCEPT** *Many side effects can be minimized or avoided by adjusting the estrogen and/or progestin content of the oral contraceptive.* It is also important to individualize the selection of oral contraceptives, because some women are at increased risk for potentially serious side effects.

Common complaints with COCs include headaches, nausea, vomiting, mastalgia, and weight gain; although studies have shown a similar percentage of patients taking placebo experience these side effects.[26] Given that oral contraceptives often are discontinued owing to side effects, proper counseling before initiation of COCs is necessary.

Between 30% and 50% of women complain of breakthrough bleeding or spotting when oral contraceptives are initiated. These side effects tend to resolve by the third or fourth cycle.[3] Before changing formulations, other more serious causes of bleeding or spotting, such as pregnancy, infection, and poor absorption of the oral contraceptive owing to drug interaction or GI problems, should be ruled out. Once these causes have been ruled out, the timing of the spotting must be determined in order to adjust the formulation appropriately.

## Table 48–3

**Contraindications to the Use of Combined Oral Contraceptives (COCs)**

**Absolute Contraindications**

History of thromboembolic disease
History of stroke (or current cerebrovascular disease)
History of (or current) coronary artery disease, ischemic heart disease, or peripheral vascular disease
History of carcinoma of the breast (known or suspected)
History of any estrogen-dependent neoplasm (known or suspected)
Undiagnosed abnormal uterine or vaginal bleeding
Pregnancy (known or suspected)
Heavy smoking (defined as 15 cigarettes or more per day) by women who are 35 years of age or older
History of hepatic tumors (benign or malignant)
Active liver disease
Migraine headaches with focal neurologic symptoms
Postpartum (during the first 21 days, as well as during days 21 through 42 in women with additional risk factors for thromboembolism, including age ≥ 35 years, history of previous venous thromboembolism, preeclampsia, recent cesarean delivery, obesity, and smoking)

**Relative Contraindications**

Smoking (< 15 cigarettes per day) at any age
Migraine headache disorder without focal neurologic symptoms
Hypertension (NOTE: WHO considers health risk posed by COC use to be "unacceptable" when either systolic blood pressure 160 mm Hg or more, or diastolic blood pressure 90 mm Hg or more)
Fibroid tumors of the uterus
Breast-feeding
Diabetes mellitus
Family history of dyslipidemia
Sickle cell disease
Active gallbladder disease
Age > 50 years
Elective major surgery requiring immobilization (planned in the next 4 weeks)

Data from Refs. 3, 4, and 25.

The most common side effects and ways to adjust therapy to minimize these side effects are listed in Table 48–4.[1,3,6,27,28]

As highlighted in Table 48–4, many of the side effects of COCs may be minimized by adjusting the estrogen or progestin content of the preparation. However, although low-dose COCs may cause fewer side effects, it is important to note that in the event that doses are missed, such COCs may be more likely to result in contraceptive failure.

### Progestin-Only Pills

For women unable to take estrogen-containing oral contraceptives, there is an alternative: oral contraceptives containing only the progestin, norethindrone. These agents are slightly less effective than COCs but have other advantages over COCs. Progestin-only products have not shown the same thromboembolic risk as estrogen-containing products. Therefore, women at increased risk for or with a history of thromboembolism may be good candidates for progestin-only oral contraceptives. Also, these products can minimize menses, and many women have amenorrhea after six to nine cycles. These products have also been found safe to use in women who are nursing, so they are a viable option for women who breast-feed and desire hormonal

contraception. In such patients, it should not be initiated until 6 weeks postpartum. Spotting does not subside in some women, and this is a common cause for discontinuation. These products should be taken at the same time every day, and there is no pill-free or hormone-free period.

### Unique Oral Contraceptives

Along with varying doses of estrogen and different progestins, there are also formulation modifications that may benefit various patient situations. In the United States, these formulations include products such as Lo-Loestrin Fe; Amethia, Camrese, Daysee, Introvale, and Seasonale; Amethia Lo and Camrese Lo; Seasonique and Lo Seasonique; Yasmin, Yaz, and Beyaz; Ortho Tri-Cyclen and Estrostep Fe; Kariva, Mircette, Pimtrea, and Viorele; Ovcon 35; Lybrel; Natazia; and Quartette. Each of these products may show benefit in certain women owing to their unique characteristics.

Lo-Loestrin Fe (norethindrone/EE) contains a low-dose estrogen, a high amount of progestin, and medium androgenic activity. Similar to other low-dose estrogen COCs, Lo-Loestrin Fe may offer a smaller margin of error when pills are missed but provide the potential advantage of fewer estrogen-related side effects (eg, nausea and breast tenderness). Unlike the typical 28-pill packs that contain 21 active tablets and seven placebo tablets, Lo-Loestrin Fe contains 24 combination hormone tablets, two estrogen-only tablets, and two placebo (iron-only) tablets. This product provides a shorter hormone-free interval and may allow for shorter menstrual periods and fewer menstrual-related symptoms, such as menstrual-related headaches, menorrhagia, and anemia.

Amethia, Camrese, Daysee, Introvale, Jolessa, and Seasonale, (levonorgestrel/EE) are each monophasic combinations that are packaged as a 91-day treatment cycles with 84 active tablets that are taken consecutively followed by seven placebo tablets. The extended cycle length of these products allows for one menstrual cycle per "season," or four per year. This type of formulation may be appealing to women with perimenstrual side effects or those at higher risk for anemia with menstrual bleeding. These products may improve anxiety, headache, fluid retention, dysmenorrhea, breast tenderness, bloating, and menstrual migraines. However, in the SEA 301 clinical trial comparing the efficacy of Seasonale with that of an equivalent-dosage 28-day cycle regimen, 7.7% versus 1.8% of women discontinued prematurely for unacceptable bleeding.[30] The risk of intermenstrual bleeding and/or spotting may be higher for patients taking these extended-cycle combinations than for patients taking typical 28-day-regimen COCs.

Seasonique and Lo Seasonique (levonorgestrel/EE) are also extended cycle preparations that are similar to those mentioned earlier, but instead these preparations contain seven tablets with low-dose estrogen rather than placebo. Menstruation-related problems that may improve with Seasonique or Lo Seasonique include menstrual-related headaches, menorrhagia, and anemia. In addition, endometriosis-related menstrual pain may be relieved by providing a continuous regimen without a pill-free interval.[31]

Yasmin and Yaz (drospirenone/EE) are unique oral contraceptives that contain the progestin drospirenone. This hormone not only has antiandrogenic properties, but also showed anti-mineralocorticoid activity in preclinical trials. It has a unique application in young women who experience problems associated with producing too much androgen. Drospirenone is a spironolactone analog, and the 3-mg dose available in COC preparations has antimineralocorticoid activity equal to 25 mg of spironolactone. It can affect the sodium and water balance in the body, although it has not shown superior efficacy for side

| Table 48–4 | | | |
|---|---|---|---|
| **Management of Adverse Effects of Oral Contraceptives** | | | |
| **Adverse Effect** | **Cause** | **Adjustment** | **Notes** |
| Spotting/bleeding before finishing active pills | Insufficient progestin | Monophasic with increased progestin or triphasic with increasing progestin[3] | |
| Continued bleeding after menses | Insufficient estrogen | Increase estrogen or triphasic with lower early progestin[3] | |
| Midcycle bleeding | Difficult to determine | Increase estrogen and progestin[1] | |
| Increased breakthrough bleeding in general | Insufficient estrogen | Increase estrogen or triphasic formulation | Will increase amount of withdrawal bleeding during menses |
| Acne, PMDD, **hirsutism** | Progestin with higher androgenicity (eg, norgestrel, levonorgestrel) | Switch to progestin with lower androgenicity such as norgestimate, norethindrone or drospirenone[6] | |
| Nausea, vomiting | Related to estrogen | Take at bedtime or with food; decrease estrogen or switch to a progestin-only product | Symptoms often resolve in 1–3 months |
| Constipation, bloating, distention | Related to progestin | Decrease progestin[1] | Symptoms often resolve in 1–3 months |
| Headache | Must be evaluated because of warning sign for stroke – monitor blood pressure | If determined to not be serious, but still troublesome consider:[3] a. Discontinue oral contraceptive b. Decrease estrogen c. Decrease progestin d. Eliminate pill-free interval for 2–3 cycles (when headaches occur during pill-free interval) | Discontinue oral contraceptive immediately if any neurologic symptoms or blurred vision |
| Decrease in libido, decreased vaginal lubrication[27] | Insufficient estrogen | Increase estrogen or consider vaginal hormonal ring (NuvaRing)[3] | Feelings of depression may coincide |
| Dyslipidemia in general | Progestin with higher androgenicity (eg, norgestrel, levonorgestrel) | Switch to progestin with lower androgenicity such as norgestimate, norethindrone or drospirenone[6] | Obtain a baseline lipid panel in women with risk factors for dyslipidemia – smoking, hypertension, family history of heart disease |
| Triglycerides > 350 mg/dL (3.96 mmol/L) | Related to estrogen | Decrease estrogen to 20–25 mcg or a progestin-only formulation[3] | |
| Mastalgia | Related to estrogen | Decrease estrogen[28] or switch to an extended cycle formulation (see Unique Oral Contraceptives, later) if it occurs prior to menses | |
| Weight gain, fluid retention | Excess estrogen[29] and progestin with higher androgenicity (eg, norgestrel, levonorgestrel) | Decrease estrogen and switch to progestin with lower androgenicity such as norgestimate, norethindrone or drospirenone[3] | |
| Visual changes or disturbances with contact lenses | Related to estrogen | Use saline eye drops | Referral to ophthalmology if eye drops do not help |
| **Melasma, chloasma** | Related to estrogen stimulation of melanocyte production | Consider progestin-only product and use of sunscreen[3] | Women with darker pigmentation are more susceptible; melasma may not be completely reversible on discontinuation |

Data from Refs. 1, 3, 6, and 27–29.

effects such as bloating compared with other oral contraceptives. Caution should be used in women with chronic conditions or in women taking other medications that may affect serum potassium. Yaz (drospirenone/EE) is an extended-cycle preparation that contains a low-dose estrogen and antimineralocorticoid and antiandrogenic activity. Yaz also contains 24 rather than 21 active tablets and four rather than seven placebo tablets, allowing for shorter menstrual periods and fewer menstrual-related symptoms, such as menstrual-related headaches, menorrhagia, and anemia.

In 2003, the FDA Advisory Committee for Reproductive Health Drugs recommended the development of a COC tablet containing folic acid in order to minimize the risk of neural tube defects in cases of contraceptive failure. Beyaz and Safyral, which

were FDA approved in 2010, are combination tablets containing drospirenone and EE (like Yaz and Yasmin) and 451 mcg of levomefolate calcium, the primary metabolite of folic acid. Similar to Yaz, Beyaz is an extended-cycle preparation, which may allow for shorter menstrual periods and fewer menstrual-related symptoms.

In addition to the prevention of pregnancy, Yaz, Beyaz, Ortho Tri-Cyclen (norgestimate/EE), and Estrostep Fe (norethindrone acetate/EE) each carry an approved indication for treatment of moderate acne vulgaris in females 15 years of age or older desiring contraception who have not responded adequately to conventional antiacne medication. This can help clinicians to streamline medications by serving dual purposes.

Mircette, Kariva, Pimtrea, and Viorele (desogestrel/EE) have a unique dosing schedule. After the usual 21 active tablets, there are only two tablets with inert ingredients. The last five tablets in the package have 10 mcg of EE. In theory, this may minimize bleeding during the menstrual cycle, although the clinical significance of this dosing schedule has not been established. With each of these products, it is important to counsel patients to complete the entire pack and not to discard the last 7 days of medication.

Another unique formulation is a chewable tablet available to women who have difficulty swallowing medications. Ovcon 35 (norethindrone/EE) has all 28 tablets in chewable form and has added spearmint flavoring.

Lybrel (levonorgestrel/EE) was the first continuous-cycle COC approved by the FDA. Active pills are taken every day throughout the year with no pill-free interval. The major advantage of this product is elimination of menstrual periods, resulting in improvement in or elimination of menstrual-related symptoms. The most bothersome side effect associated with Lybrel is a high incidence of spotting and breakthrough bleeding during the initial months of use. It appears as though the incidence of breakthrough bleeding with Lybrel decreases with continued use.

Natazia was approved by the FDA in 2010 and is a quadriphasic COC containing estradiol valerate and the progestin, dienogest. Estradiol valerate is metabolized endogenously to estradiol, and dienogest is a strong progestin with antiandrogenic activity. Natazia provides a unique estrogen step-down/progestin step-up regimen, and like Mircette, Kariva, Pimtrea, and Viorele, this COC offers the advantage of a shorter hormone-free interval. This results in fewer days of withdrawal bleeding and may help with menstrual-related headaches.

Finally, Quartette (levonorgestrel/EE), an extended-cycle, quadriphasic preparation approved by the FDA in 2013, contains

increasing doses of EE throughout the 91-day pill period. The increasing dose of EE is intended to reduce the rate of breakthrough bleeding or spotting.

## Drug Interactions with Oral Contraceptives

EE is metabolized in the liver primarily via cytochrome P-450 (CYP450) 3A4. When reviewing drug interactions of oral contraceptives, **KEY CONCEPT** *clinicians should be aware of the many drugs that may potentially interact with contraceptives—especially those that may reduce the effectiveness of contraceptives.* Refer to Table 48–5 for a list of some of the most common drug interactions seen with oral contraceptives.[3,32,33]

## Nonoral Hormonal Contraceptives

**KEY CONCEPT** *As an alternative to oral contraceptive pills, which must be taken daily in order to reliably prevent pregnancy, non-oral contraceptives in the form of transdermal, transvaginal, and injectable preparations are available and offer patients safe and effective alternatives to the pills for prevention of pregnancy. These formulations also do not require daily administration, making them more convenient than the pill formulations.*

Ortho-Evra is a transdermal patch that contains both an estrogen (20 mcg of EE) and a progestin (150 mcg of norelgestromin). A new patch is applied to the abdomen, buttocks, upper torso, or upper (outer) arm once weekly for 3 weeks, followed by seven patch-free days.[6] Although some women have noted irregular bleeding during the first two cycles of patch use, the patch has been demonstrated to provide similar menstrual cycle control and contraceptive efficacy to that of COCs.[34] It is important to note, however, that higher contraceptive failure rates are seen when the patch is used in women weighing more than 90 kg (about 200 lb).[6,34] Further, manufacturer prescriber information indicates that women who take Ortho-Evra are exposed to approximately 60% more estrogen than women who take COCs with 35 mcg of estrogen.[35] Although the clinical significance of this is not well defined, studies have suggested a link between the use of the patch and an increased risk for venous thromboembolism. A slightly higher reported incidence of breast discomfort and local skin irritation has also been reported with the patch.[6,36]

NuvaRing is a unique transvaginal delivery system that provides 15 mcg of EE and 120 mcg of etonogestrel for the prevention of ovulation. NuvaRing is inserted into the vagina on or before day 5 of the menstrual cycle and is removed from the vagina 3 weeks later.[6] Seven days after the ring is removed, a new ring should be inserted. In clinical trials, NuvaRing demonstrated comparable efficacy and cycle control to COCs as well as a similar side-effect profile.[6,37] NuvaRing should not be removed during intercourse.

Depo-Provera is a progestin-only, injectable contraceptive that contains depot medroxyprogesterone acetate. Depo-Provera is administered intramuscularly as a 150-mg injection once every 3 months. An advantage of Depo-Provera is that it provides an estrogen-free method of contraception either for women in whom estrogens are contraindicated or for women who cannot tolerate estrogen-containing preparations. Depo-Provera is extremely effective in preventing pregnancy. However, the incidence of menstrual irregularities (including amenorrhea) and weight gain appears to be much greater than that seen with COCs. The use of Depo-Provera also has been demonstrated to result in significant loss of bone mineral density (BMD).[38] Although the effect is known to be reversible following product discontinuation, a black-box warning within the product labeling cautions against the risk of potentially irreversible BMD loss

---

## Patient Encounter, Part 2: Adverse Effects

After 3 months of taking LoSeasonique, she returns to your clinic complaining of breakthrough bleeding during her sixth week of active pills. She reports no change or increase in frequency of her migraine headaches, and her blood pressure is 110/72 mm Hg. She is frustrated with the breakthrough bleeding and wants to explore other contraceptive options.

*What are some potential causes of the breakthrough bleeding that the patient has been experiencing?*

*What strategy would you recommend to eliminate or minimize the potential adverse effects experienced by the patient?*

| Table 48–5 | | |
|---|---|---|
| **Commonly Seen Drug Interactions With COCs** | | |
| **Medication** | **Mechanism** | **Clinical Effect** |
| Anticonvulsants (carbamazepine, oxcarbazepine, phenytoin, phenobarbital, primidone, topiramate, and felbamate) | Increase metabolism of COCs via induction of various cytochrome P-450 enzymes | Decrease efficacy of COCs (EE doses < 35 mcg are not recommended in women on these medications) |
| Benzodiazepines (alprazolam) | COCs may inhibit oxidative metabolism | Increase side effects of benzodiazepines |
| Bosentan | Increase metabolism of COCs via induction of cytochrome P-450 3A4 enzyme | Decrease efficacy of COCs |
| Colesevelam | Reduce absorption of COCs by nonspecific binding with colesevelam | Decrease efficacy of COCs |
| Corticosteroids (hydrocortisone, methylprednisolone, prednisone) | COCs may inhibit metabolism of corticosteroids | Increase side effects of corticosteroids |
| Griseofulvin | Increase metabolism of COCs | Decrease efficacy of COCs; backup method of contraception is recommended |
| Lamotrigine | COCs increase metabolism of lamotrigine via induction of glucuronidation | Decrease efficacy of lamotrigine; dose adjustment may be necessary |
| Modafinil | Increase metabolism of COCs | Decrease efficacy of COCs; alternative method of contraception is recommended |
| Penicillins (amoxicillin, ampicillin); tetracyclines (doxycycline, minocycline, tetracycline) | Broad-spectrum antibiotics may alter intestinal flora, reducing enterohepatic circulation of estrogen metabolites; although the drop in estrogen levels has been shown to be only statistically significant, rather than clinically significant; | Decrease efficacy of COCs; backup barrier method of contraception is controversial[a] |
| Non-nucleoside reverse transcriptase inhibitors (delavirdine, efavirenz, nevirapine, rilpivirine) | Increase metabolism of COCs | Decrease efficacy of COCs; alternative method of contraception is recommended with efavirenz and nevirapine |
| Protease inhibitors (amprenavir, atazanavir, boceprevir, darunavir, fosamprenavir, indinavir, nelfinavir, ritonavir, saquinavir, simeprevir, telaprevir, tipranavir) | Increase or decrease in metabolism of COCs | Decrease efficacy of COCs or increase side effects of COCs; alternative method of contraception is recommended with nelfinavir and ritonavir |
| Rifampin, rifabutin | Increase metabolism of COCs | Decrease efficacy of COCs; backup method of contraception is recommended |
| Selegiline | COCs decrease metabolism of selegiline | Increase side effects of selegiline; may adjust dose of selegiline if needed |
| St. John's wort | Increase metabolism of COCs via induction of various cytochrome P-450 enzymes | Decrease efficacy of COCs; avoid use with COCs |
| Theophylline | COCs decrease theophylline clearance by 34% and increase half-life by 33% | Increase side effects of theophylline |

[a]Although package inserts warn of this potential interaction, no scientific literature exists to support that concomitant antibiotics and COCs is associated with contraceptive failure.[33]

Data from Refs. 1, 32, and 33.

associated with long-term use (eg, greater than 2 years) of the injectable product. Although the extended duration of activity of this product may offer women the advantage of less frequent administration, it is important to note that on discontinuation of Depo-Provera, the return of fertility can be delayed by approximately 10 to 12 months (range 4–31 months).[6]

Depo-SubQ Provera 104 is also an injectable contraceptive product that contains only progestin (depot medroxyprogesterone acetate). This product differs from Depo-Provera in that it is given subcutaneously rather than intramuscularly, and it contains only 104 mg of medroxyprogesterone acetate (~30% less hormone) administered every 3 months for the prevention of pregnancy. Clinical trials have demonstrated that the subcutaneous formulation of depot medroxyprogesterone acetate is as effective as the intramuscular formulation in the prevention of pregnancy.[39] This product carries the same warning in its package labeling regarding possible effects on BMD as Depo-Provera.

## Long-Acting Reversible Contraception

The currently available products for long-term reversible contraception (LARC) are listed in Table 48–6. Surveys have shown that LARC has the highest satisfaction rate among patients using reversible contraceptives, and use within the United States is on the rise.[1]

Although the mechanism of action for IUDs is not completely understood, several theories have been suggested. The original theory is that the presence of a foreign body in the uterus causes an inflammatory response that interferes with implantation. It is believed that copper-containing IUDs may interfere with sperm transport and fertilization and prevent implantation. Progestin-containing implantable contraceptives can have direct effects on the uterus, such as thickening of cervical mucus and alterations to the endometrial lining.[52] Paragard T 380A does not prevent ovulation, although the other LARCs can because they are progestin-containing products.

| Table 48–6 | | | |
| --- | --- | --- | --- |
| **Long-Acting Reversible Contraception** | | | |
| **Product** | **Ingredient** | **Dosage Form** | **Duration** |
| Mirena | Levonorgestrel | Intrauterine device | Up to 5 years |
| Skyla | Levonorgestrel | Intrauterine device | Up to 3 years |
| ParaGard T 380A | Copper | Intrauterine device | Up to 10 years |
| Implanon | Etonorgestrel | Implantable device | Up to 3 years |
| Nexplanon | Etonorgestrel | Implantable device | Up to 3 years |

Data from Refs. 52–55.

It is important to evaluate a patient to determine whether she is an appropriate candidate for an implantable contraceptive. IUDs are recommended for women who are in a monogamous relationship, are at low risk for acquiring STIs, have no history of pelvic inflammatory disease (PID), and no history or risk of ectopic pregnancy. Contraindications to the use of progestin-containing LARC products include (a) known or suspected pregnancy, (b) hepatic tumors or active liver disease, (c) undiagnosed abnormal genital bleeding, (d) known or suspected carcinoma of the breast or personal history of breast cancer, (e) history of thrombosis or thromboembolic disorders, and (f) hypersensitivity to any components of the products. There are also multiple additional contraindications to IUD use. Evaluation of the patient is essential because IUDs cannot be used in the following situations: (a) anatomically abnormal or distorted uterine cavity, (b) acute PID or history of PID unless there has been a subsequent intrauterine pregnancy (c) postpartum endometritis or infected abortion in the past 3 months, (d) known or suspected uterine or cervical malignancy, (e) untreated acute cervicitis, (f) previously inserted IUD still in place, (g) increased susceptibility to pelvic infections, and (h) Wilson disease (Paragard T 380A only).

The most common adverse effects are abdominal/pelvic cramping, abnormal uterine bleeding, and expulsion of the device. Other side effects seen are ectopic pregnancy, sepsis, PID, embedment of the device, uterine or cervical perforation, and ovarian cysts.

## Nonpharmacologic Contraceptive Methods

### ▶ Barrier Contraceptives

As an alternative to hormonal contraceptives, several barrier contraceptive options are available for the prevention of pregnancy. Although barrier contraceptives are associated with far fewer adverse effects compared with hormonal contraceptives, their efficacy is highly user-dependent. Overall, compared with both hormonal contraceptives and IUDs, barrier contraceptives are associated with much higher unintended pregnancy rates[6] (see Table 48–1).

**Diaphragms and Cervical Caps**  Diaphragms and cervical caps are dome-shaped rubber caps that are placed over the cervix to provide barrier protection during intercourse. Both diaphragms and cervical caps require fitting by a health care professional, and they must be refitted in the event of weight gain or weight loss. Diaphragms or cervical caps typically can be placed over the cervix as much as 6 hours prior to intercourse. They must be left in place for at least 6 hours after intercourse before they can be removed. Diaphragms should not be left in place longer than 24 hours, and smaller cervical caps should not be left in place longer than 48 hours owing to the risk of toxic shock syndrome (TSS). Diaphragms and cervical caps are used along with spermicides to prevent pregnancy. When sexual intercourse is repeated with the diaphragm, reapplication of the spermicide is necessary. However, when sexual intercourse is repeated with a cervical cap, reapplication of the spermicide typically is not necessary.[6] Whether or not diaphragms or cervical caps provide adequate protection against STIs remains unclear.[40]

**Spermicides**  Nonoxynol-9, a surfactant that destroys the cell membranes of sperm, is the most commonly used spermicide in the United States.[3,6] Nonoxynol-9 is available in a variety of forms, including a cream, foam, film, gel, suppository, and tablet. Spermicides may be used alone, with a barrier method, or adjunctively with other forms of contraceptives to provide additional protection against unwanted pregnancy.[3] To be used most effectively, spermicides must be placed in the vagina not more than 1 hour prior to sexual intercourse, and they must come in contact with the cervix.[6] Although the efficacy of spermicides depends largely on how consistently and correctly they are used, their efficacy is enhanced when they are used in combination with a barrier contraceptive device.[40] Clinical trials assessing the ability of spermicides to protect against STIs have failed to produce positive results.[3] Further, there exists some evidence to suggest that frequent use of spermicides actually may increase risk for acquisition of human immunodeficiency virus (HIV) secondary to vaginal mucosal tissue breakdown, which may allow a portal of entry for the virus.[6] In December 2007, the FDA issued a statement requiring manufacturers of nonoxynol-9 products to include a warning on the product label indicating that the spermicide does not provide protection against infection from HIV or other STIs.

**Condoms**  Condoms, which are available for both male and female use, act as physical barriers to prevent sperm from coming into contact with ova.[3] Condoms are easy to use, available without a prescription, and inexpensive. Most condoms are made of latex. When used correctly, condoms can be very effective in prevention of unwanted pregnancy.[41] Condoms should be stored in a cool, dry place, away from exposure to direct sunlight. When stored improperly or when used with oil-based lubricants, however, latex condoms can break during intercourse, increasing the risk of pregnancy.[6] For latex-sensitive individuals, condoms made from lamb intestine ("natural membrane" condoms) and synthetic polyurethane condoms are available. Unlike latex condoms, condoms made from lamb intestine contain small pores that may permit the passage of viruses and therefore do not provide adequate protection against STIs.[3] **KEY CONCEPT** *Both latex and synthetic condoms can provide some protection against many STIs. Data from one meta-analysis suggested that HIV transmission can be reduced by as much as 90% when condoms are consistently used.[42] This is in contrast to hormonal contraceptives (oral, transdermal, or vaginal), IUDs, and most other barrier contraceptives, which do not protect against STIs.* Relative to male condoms,

## Patient Encounter, Part 3: Missed Doses

The patient calls your clinic in a panic today because she forgot to take her oral contraceptive for the past 3 days, beginning the third week of active pills. Three days have elapsed since she took her last active pill, and she reports having had unprotected sexual intercourse last night. The patient is very concerned about her risk of pregnancy and is interested to learn more about emergency contraception and what her options are.

*Given this patient's reported imperfect use of her oral contraceptive, what information can you provide to the patient regarding her risk of pregnancy?*

*What additional education should be provided to the patient regarding her risk of STIs related to unprotected intercourse?*

*Provide appropriate patient education regarding the use of various forms of emergency contraception, in the event she decides to use EC.*

female condoms may offer even better protection against STIs because they provide more extensive barrier coverage of external genitalia, including the labia and the base of the penis.[3] It is important to note that the male and female condoms are not recommended to be used together because they may adhere to one another, causing displacement of one or both condoms.[3]

**Sponge**  The Today sponge is a small, pillow-shaped polyurethane sponge impregnated with nonoxynol-9.[40] It is an over-the-counter barrier contraceptive that has been shown to be generally less effective at preventing pregnancy than diaphragms.[42] The sponge is moistened with water and then is inserted and placed over the cervix for up to 6 hours prior to sexual intercourse. The sponge then is left in place for at least 6 hours following intercourse.[3] Although the sponge maintains efficacy for 24 hours (even if intercourse is repeated), as with diaphragms, the sponge should be removed after 24 hours owing to the risk of TSS.[6]

▶ *Fertility Awareness–Based Methods*

Fertility awareness–based methods (natural methods) represent another nonpharmacologic means of pregnancy prevention. Although failure rates of such methods can be high, some couples still prefer these types of approaches. Fertility awareness–based methods depend on the ability of the couple to identify the woman's "fertile window," or the period of time in which pregnancy is most likely to occur as a result of sexual intercourse.[3] During the fertile window, the couple practices abstinence, or avoidance of intercourse, in order to prevent pregnancy. In some cases, rather than practicing abstinence during the fertile period, some couples may prefer to employ barrier methods or spermicides as a means of preventing pregnancy rather than to avoid intercourse altogether.[6] In order to identify the fertile window, a number of different fertility awareness–based methods may be tried. The calendar (rhythm) method involves counting the days in the menstrual cycle and then using a mathematical equation to determine the fertile window.[3] The temperature method involves monitoring changes in the woman's basal body temperature using a basal thermometer.[3] The cervical mucus (or Billings ovulation) method involves observing changes in the characteristics of cervical secretions throughout the cycle.[3] Around ovulation, the mucus becomes watery. The symptothermal method, which is considered to be the most difficult to learn but potentially the most effective, is a combination of both the temperature method and the cervical mucus method.[6] In general, fertility awareness–based methods are not recommended for women who have irregular menstrual cycles or who have difficulty interpreting their fertility signs correctly.[3]

### Emergency Contraception

Emergency contraception (EC) is used to prevent pregnancy after known or suspected unprotected sexual intercourse. There are five FDA-approved oral agents available for use as EC, with availability from over the counter to prescription only access. The product known as ella (ulipristal acetate), a progesterone-receptor agonist/antagonist, can delay follicular rupture if taken just before ovulation and may cause endometrial changes to interfere with implantation. The available products are listed in the Table 48–7 along with information on availability and correct dosage. It is important to note that EC is more effective the earlier it is used after unprotected intercourse. Common side effects include headache, nausea, abdominal pain, dysmenorrhea, fatigue, and dizziness. If severe abdominal pain occurs, patients should be referred to their health care provider for evaluation of risk of an ectopic pregnancy. Patients should also contact their health care provider if their menstrual cycle is more than 1 week late after taking EC.

### Table 48–7

**Emergency Contraception**

| Product | Where stocked | Availability | Ingredient | Dose | When taken |
|---|---|---|---|---|---|
| Plan B One-Step | Over the counter | All ages with no identification required | Levonorgestrel | 1.5 mg | Within 72 hours of unprotected sex |
| Next Choice One Dose | Behind the counter | Over the counter for 17 years and older; prescription required for 16 years and younger | Levonorgestrel | 1.5 mg | Within 72 hours of unprotected sex |
| My Way | Behind the counter | Over the counter for 17 years and older; prescription required for 16 years and younger | Levonorgestrel | 1.5 mg | Within 72 hours of unprotected sex |
| Levonorgestrel | Behind the counter | Over the counter for 17 years and older; prescription required for 16 years and younger | Levonorgestrel | 0.75 mg (two tablets for a total of 1.5 mg) | Both tablets within 72 hours of unprotected sex |
| ella | Behind the counter | Only as a prescription | Ulipristal acetate | 30 mg | Within 120 hours of unprotected sex |

## Patient Care Process

### Patient Assessment:

- Determine goals related to contraceptive use (pregnancy prevention, menstrual regulation, control of acne?).
- Based on physical exam findings, as well as medical, social (ie, smoking) and family history, determine if patient qualifies for hormonal contraceptives. Rule out pregnancy, and evaluate patient's risk for STIs.
- Conduct thorough medication history to identify potential for drug interactions.

### Therapy Evaluation:

- At follow-up visits, assess blood pressure, weight, and menstrual patterns for changes from baseline.
- Assess tolerability of and adherence to the prescribed contraceptive method.
- Assess safety by using the pneumonics, "ACHES" for hormonal contraceptives, and "PAINS" for IUDs:

### ACHES -

- A = Abdominal pain
- C = Chest pain
- H = Headaches (especially if associated with focal neurologic symptoms)
- E = Eye problems (blurred vision, ocular pain, visual changes)
- S = Severe leg pain
- Also monitor for missed periods, signs of pregnancy, appearance of jaundice, and/or severe mood changes.

### PAINS -

- P = Period late
- A = Abdominal pain, pain with intercourse
- I = Infection, abnormal/odorous vaginal discharge
- N = Not feeling well, fever, chills
- S = String (missing, shorter, longer)

### Care Plan Development:

- Select a contraceptive option that the patient is comfortable with, that is likely to achieve the patient's desired goal(s), and is not contraindicated.
- Educate regarding the potential for side effects, safety risks, drug interactions, and any noncontraceptive benefits that may result for the chosen method.
- Determine the patient's sexual behavior and evaluate whether the contraceptive method will impact the risk for STIs.
- Evaluate insurance coverage/cost factors.

### Follow-up Evaluation:

- Instruct the patient to consult a health care professional upon noticing or experiencing any warning signs.
- Stress the importance of adherence (especially if prevention of pregnancy is desired).
- Educate on what to do in the event of missed doses.

## OUTCOME EVALUATION

Side effects of contraceptives tend to occur in the first few months of therapy. Thus schedule a follow-up visit 3 to 6 months after initiating a new contraceptive. Yearly checkups usually are sufficient for patients who are doing well on a particular product.[3] At each follow-up visit, assess blood pressure, headache frequency, and menstrual bleeding patterns, as well as compliance with the prescribed regimen. Strict adherence to the prescribed hormonal contraceptive regimen is essential for effective prevention of unintended pregnancy. **KEY CONCEPT** *When a contraceptive dose is missed, the risk of accidental pregnancy may be increased. Depending on how many doses were missed, the contraceptive formulation being used, and the phase of the cycle during which doses were missed, counseling regarding the use of additional methods of contraception may be warranted.*

## Abbreviations Introduced in This Chapter

| | |
|---|---|
| BMD | Bone mineral density |
| COC | Combined oral contraceptive |
| CYP450 | Cytochrome P-450 |
| EC | Emergency contraception |
| EE | Ethinyl estradiol |
| FSH | Follicle-stimulating hormone |
| GnRH | Gonadotropin-releasing hormone |
| HIV | Human immunodeficiency virus |
| HPV | Human papilloma virus |
| IUD | Intrauterine device |
| LARC | Long-acting reversible contraception |
| LH | Luteinizing hormone |
| PID | Pelvic inflammatory disease |
| PMDD | Premenstrual dysphoric disorder |
| STI | Sexually transmitted infection |
| TSS | Toxic shock syndrome |
| WHO | World Health Organization |

# Menstruation-Related Disorders

Jacqueline M. Klootwyk and Elena M. Umland

## LEARNING OBJECTIVES

**Upon completion of the chapter, the reader will be able to:**

1. Describe the underlying etiology and pathophysiology of dysmenorrhea, amenorrhea, anovulatory bleeding, and menorrhagia and how they relate to selecting effective treatment modalities.

2. Describe the clinical presentation of dysmenorrhea, amenorrhea, anovulatory bleeding, and menorrhagia.

3. Recommend appropriate nonpharmacologic and pharmacologic interventions for patients with dysmenorrhea, amenorrhea, anovulatory bleeding, and menorrhagia.

4. Identify the desired therapeutic outcomes for patients with dysmenorrhea, amenorrhea, anovulatory bleeding, and menorrhagia.

5. Design a monitoring plan to assess the effectiveness and adverse effects of pharmacotherapy for dysmenorrhea, amenorrhea, anovulatory bleeding, and menorrhagia.

## INTRODUCTION

The most common menstruation-related disorders include dysmenorrhea, amenorrhea, anovulatory bleeding, and menorrhagia. These disorders negatively affect quality of life, reproductive health, work productivity, and may lead to adverse long-term health consequences, such as osteoporosis or polycystic ovarian syndrome.

## DYSMENORRHEA

Dysmenorrhea is pelvic pain, generally described as cramping, that occurs during or just prior to menstruation. Primary dysmenorrhea is pain in the setting of normal pelvic anatomy and physiology, whereas secondary dysmenorrhea is associated with underlying pelvic pathology.[1]

### Epidemiology and Etiology

Rates of dysmenorrhea range from 16% to 90%.[2] Around 8% to 15% percent of women with dysmenorrhea report limited daily activities or missed days in work or school.[1,3] Risk factors for dysmenorrhea include irregular or heavy menses, age less than 30, menarche prior to age 12, body mass index (BMI) less than 20 kg/m$^2$, history of sterilization or sexual abuse, and smoking.[1,2] Causes of secondary dysmenorrhea may include endometriosis, pelvic inflammatory disease, uterine or cervical polyps, and uterine fibroids.[1,4,5]

### Pathophysiology

**KEY CONCEPT** *In primary dysmenorrhea, elevated arachidonic acid levels in the menstrual fluid lead to increased concentrations of prostaglandins and leukotrienes in the uterus.* This induces uterine contractions, stimulating pain fibers, reducing uterine blood flow, and causing uterine hypoxia.[1,3,4]

### Treatment

#### ▶ Desired Outcomes

Desired treatment outcomes (**Figure 49–1**) are relief of pelvic pain, improved quality of life, and fewer lost days at school and work.

#### ▶ Nonpharmacologic Therapy

Nonpharmacologic interventions which diminish dysmenorrhea symptoms include topical heat therapy, regular exercise, transcutaneous electric nerve stimulation (TENS), and acupuncture.[1,3,5] In addition, a low-fat vegetarian diet has been shown to lessen the intensity and duration of dysmenorrhea.[5]

#### ▶ Pharmacologic Therapy

Medication management options are summarized in **Table 49–1**.

**Nonsteroidal Anti-inflammatory Drugs (NSAIDs)** **KEY CONCEPT** *NSAIDs are the treatment of choice for dysmenorrhea. By inhibiting prostaglandin production, they exert analgesic properties, decrease uterine contractions, and reduce menstrual blood flow.* Choice of one agent over another is based on cost, convenience, and patient preference.[1–4] Most commonly used agents are naproxen and ibuprofen.

Treatment with an NSAID should begin 1 to 2 days prior to the start of menses or at the onset of dysmenorrhea and continued for 2 to 3 days or until pain resolves.[1] A loading dose (twice the usual single dose) is recommended, followed by the usually recommended dose.[1,2,5] For patients in whom NSAIDs are contraindicated, combination hormonal contraceptives should be considered.[1,4]

**Combination Hormonal Contraceptives (CHCs)** CHCs improve mild to severe dysmenorrhea by inhibiting the

---

## Clinical Presentation and Diagnosis of Dysmenorrhea

### General
- Acute distress may be present depending on the severity of menstrual pain.

### Symptoms
- Crampy pelvic pain (lasting 1–3 days) beginning shortly before or at menses onset. Associated symptoms may include nausea, vomiting, diarrhea, hypertension, and/or tachycardia.

### Laboratory Tests
- Sexually active females should receive a pelvic examination to screen for sexually transmitted diseases.
- Gonorrhea, chlamydia cultures or PCR, wet mount.

### Other Diagnostic Tests
- Pelvic ultrasound may be used to identify anatomic abnormalities (eg, masses/lesions), ovarian cysts, or endometriomas.

---

**Patient Encounter 1, Part 1**

A 22-year-old white woman presents to her physician reporting severe pelvic pain and cramping during menses that results in 1 to 2 missed work days each menstrual cycle. Her last menstrual cycle was 9 days ago, and she had her first menstrual cycle at age 11. She is sexually active with one partner and has had 5 sexual partners in the past. Of note, she has a history or Chlamydia in the past. She has been using acetaminophen or ibuprofen as needed for pain and is a current smoker. She does not follow a diet or exercise regimen.

*What risk factors does this patient have for primary dysmenorrhea?*

*What risk factors does the patient have for secondary dysmenorrhea?*

---

proliferation of endometrial tissue and ovulation, thereby reducing prostaglandin secretion and menstrual blood volume.[1,3–5] Two to three months of therapy are required to achieve the full effect.[1] Both standard (28-day) and extended cycle (91-day) therapies are effective for primary dysmenorrhea.[1,2] Extended cycle regimens are considered first line for dysmenorrhea due to endometriosis.[2] Additional benefits include contraception and improving acne.[5] Although monophasic formulations are purported to be more efficacious for this indication, evidence supporting this is limited.[16] If no response occurs after 3 months of therapy, the patient should be evaluated for secondary causes.[1,5]

**Progestin-only Hormonal Contraceptives** These agents diminish dysmenorrhea by reducing or eliminating menses over time, thus eliminating prostaglandin release.[5] Three agents are available: depot medroxyprogesterone acetate, etonogestrel implant, and levonorgestrel-releasing intrauterine system.

Observational data show a reduction in dysmenorrhea from 60% to 29% with levonorgestrel-releasing intrauterine device (IUD) therapy for 3 years.[5] Although data are limited, this is an option for dysmenorrhea management.[16]

### Dysmenorrhea in Adolescents

Dysmenorrhea is reported in 60% to 90% of adolescent females.[1] It is the most common reason for adolescents to miss school or work. One study showed that most young females are treating pelvic pain with nonpharmacologic therapies, while other studies showed that many either do not know to use NSAIDs or use subtherapeutic doses.[5] Treatment in adolescents includes any of the therapies previously discussed. Although NSAIDs and oral CHCs are most common, levonorgestrel IUD use is also an option.[16] **KEY CONCEPT** *The American College of Obstetricians and Gynecologists (ACOG) states that any woman, including adolescents (regardless of parity) at low risk of sexually transmitted diseases and thus pelvic inflammatory disease, is a good candidate for IUD use.*[17,18]

### AMENORRHEA

Amenorrhea is the absence of menses. **Primary amenorrhea** occurs prior to age 15 in the presence of normal secondary sexual development or within 5 years of **thelarche** (if occurring before age 10).[19,20] **Secondary amenorrhea** is the absence of menses for three cycles or 6 months in a previously menstruating woman.[6]

**Table 49–1**

**Therapeutic Agents for Selected Menstrual Disorders**

| Specific Menstrual Disorders(s) | Agent(s) | Dose Recommended | Common Adverse Effects |
|---|---|---|---|
| Amenorrhea (primary or secondary) | CEE[a] | 0.625–1.25 mg by mouth daily on cycle days 1–26[6] | Thromboembolism, breast enlargement, breast tenderness, bloating, nausea, GI upset, headache, peripheral edema |
| | Ethinyl estradiol patch[a] | 50–100 mcg/24 hours[6] | |
| | Oral CHC[a] | 30–40 mcg formulations | |
| Amenorrhea (secondary) | Oral medroxyprogesterone acetate[a] | 10 mg by mouth on cycle days 14–26[6] | Edema, anorexia, depression, insomnia, weight gain or loss, elevated total and LDL cholesterol, may reduce HDL cholesterol |
| Amenorrhea (hyperprolactinemia) | Bromocriptine | 2.5 mg by mouth two to three times daily[7] | Hypotension, nausea, constipation, anorexia, Raynaud phenomenon |
| Anovulatory bleeding | Oral CHC[a] | Optimal dose unknown[8] | As noted above for CEE, ethinyl estradiol, and oral CHC (progesterone side effects with the CHC depend on agent chosen) |
| | | For acute bleeding, product containing 35 mcg ethinyl estradiol; take one tablet by mouth three times daily × 1 week; then one tablet by mouth daily × 3 weeks.[8] | |
| | Oral medroxyprogesterone acetate[a] | For acute bleeding, 20 mg by mouth three times daily × 1 week; then 20 mg by mouth once daily × 3 weeks.[8] | As noted above for oral medroxyprogesterone acetate |
| Dysmenorrhea | Oral CHC[9,a] | < 35 mcg formulations + norgestrel or levonorgestrel[11]; use of extended-cycle formulations are beneficial for this indication | As noted above for CEE, ethinyl estradiol, and oral CHC (progesterone side effects with the CHC depend on agent chosen) |
| | Depot medroxyprogesterone acetate[a] | 150 mg intramuscularly every 12 weeks | Irregular menses, amenorrhea |
| | Levonorgestrel IUD[12,a] | 20 mcg released daily | Irregular menses, amenorrhea |
| | NSAIDs—any are acceptable; the most commonly studied/ cited are included in this table[1–4,9] | Diclofenac 50 mg by mouth three times daily[b] | GI upset, stomach ulcer, nausea, vomiting, heartburn, indigestion, rash, dizziness |
| | | Ibuprofen 800 mg by mouth three times daily[a] | |
| | | Mefenamic acid 500 mg by mouth as a loading dose, then 250 mg by mouth up to four times daily as needed[b] | |
| | | Naproxen 550-mg loading dose by mouth started 1–2 days prior to menses, followed by 275 mg by mouth every 6–12 hours as needed[c] | |
| | | Treatment should begin 1–2 days prior to the expected onset of menses | |
| Menorrhagia | Oral CHC[a] | Optimal dose unknown | As noted above |
| | Levonorgestrel IUD[a] | 20 mcg released daily | As noted above |
| | Medroxyprogesterone acetate (oral)[a] | 5–10 mg by mouth on days 5–26 of the cycle *or* during the luteal phase[10] | As noted above |
| | NSAIDs | Doses as recommended for above; therapy should be initiated with the onset of menses[10] | As noted above |
| | Tranexamic acid | 1300 mg (650 mg × 2) by mouth three times days × 5 days[8,11,44,45] | Fatigue, abdominal, back, or muscle pain |
| PCOS-related amenorrhea and/or anovulatory bleeding | Clomiphene[5] | 50 mg by mouth daily × 5 days starting 3–5 days after the start of menses; doses up to 100 mg by mouth daily have been used in significantly obese patients. | Hot flashes, ovarian enlargement, thromboembolism, blurred vision, breast discomfort |
| | Depot medroxyprogesterone acetate[a] | 150 mg intramuscularly every 12 weeks | As noted above |
| | Letrozole | 2.5–7.5 mg by mouth cycle days 3–7[12] | Hot flashes, fatigue, dizziness, edema |

| **Therapeutic Agents for Selected Menstrual Disorders** (*Continued*) | | | |
| **Specific Menstrual Disorders(s)** | **Agent(s)** | **Dose Recommended** | **Common Adverse Effects** |
| | Medroxyprogesterone acetate (oral)[a] | 10 mg by mouth × 10 days[13] | As noted above |
| | Metformin[a] | 1500–2000 mg by mouth daily in 2–3 divided dose[a,d] | Anorexia, nausea, vomiting, diarrhea, flatulence, lactic acidosis |

CEE, conjugated equine estrogen; CHC, combination hormonal contraceptive; HDL, high-density lipoprotein; IUD, intrauterine device; LDL, low-density lipoprotein.

[a]Use is contraindicated in patients with severe hepatic impairment.

[b]Not recommended in patients with severe renal impairment.

[c]Use is contraindicated with creatinine clearance less than 30 mL/min (0.5 mL/s).

[d]Contraindicated in males with serum creatinine more than 1.5 mg/dL (133 μmol/L); females with serum creatinine more than 1.4 mg/dL (124 μmol/L); caution with creatinine clearance less than 60 mL/min (1 mL/s).

[e]Contraindicated in patients with active liver disease or if transaminases more than 2.5 times upper limit of normal at baseline, discontinue therapy if ALT is more than three times upper limit of normal.

Data from Refs. 1, 2, 5–15, 44, 45.

## Epidemiology and Etiology

**KEY CONCEPT** *Unrecognized pregnancy is the most common cause of amenorrhea, therefore, a urine pregnancy test should be one of the first steps in evaluating amenorrhea.* Amenorrhea not related to pregnancy, lactation, or menopause occurs in 3% to 4% of women.[20] Additional causes of secondary amenorrhea include polycystic ovarian syndrome (PCOS), hypothalamic suppression, hyperprolactinemia, or primary ovarian insufficiency.[6]

## Pathophysiology

In the diagnosis and management of amenorrhea, the uterus, ovaries, anterior pituitary, and hypothalamus should be considered (**Figure 49–2**). Normal menstrual cycle physiology depends on hormonal interactions involving the hypothalamus, anterior pituitary gland, ovary, and endometrium (**Figure 49–3**).[5,6,21] **Table 49–2** shows causative condition(s) and the organ system(s) involved in the pathophysiology of amenorrhea. Amenorrhea is a potential side effect from using low-dose or extended oral CHCs and depot medroxyprogesterone acetate.[6,26] Many women experience delayed return of menses after CHC discontinuation. If spontaneous resolution of amenorrhea does not occur within 3 to 6 months following CHC discontinuation, evaluation for other conditions should be considered (eg, PCOS).

## Patient Encounter 1, Part 2

Additional workup reveals:

**PMH:** asthma

**PSH:** none

**FH:** Mother and father are alive and well. She has two younger siblings (ages 17 and 12) who are alive and well.

**SH:** (+) smoking; (–) drug use; (+) alcohol use (2–4 drinks per week)

**Meds:** Fluticasone 110 mcg 2 puffs twice daily and albuterol 90 mcg 2 puffs prn SOB

**Past Gynecologic Hx:** Menarche at age 11; never pregnant; (+) sexual activity; 6 sexual partners; (+) history of Chlamydia; (+) history of painful menses beginning at age 12; (+) heavy menstrual flow; menstrual cycle 26 to 28 days.

**ROS:** (–) fatigue; (–) headaches; (+) mild acne on face and chest; (+) moderate to severe pelvic pain with menses

**PE:**

**General:** Thin-appearing white woman, in no acute distress

**VS:** BP 116/64, P 74, RR 14, Wt 128 lbs (58.2 kg), Ht 5'4" (163 cm), BMI: 22 kg/m$^2$

**HEENT:** (–) hirsutism

**Breasts:** (–) galactorrhea

**Pelvic examination:** normal appearance of external genitalia and vagina, cervix without lesions, uterus midposition without masses, adnexa without masses

**Labs:** (–)hCG

*Given this information, what is your assessment of this patient's condition?*

## Clinical Presentation and Diagnosis of Amenorrhea

### General
- Concerns about cessation of menses and fertility implications
- Not generally in acute distress

### Symptoms
- Cessation of menses
- Possible reports of infertility, vaginal dryness, decreased libido

### Signs
- Absence of menses by age 15 in the presence of normal secondary sexual development or within 5 years of thelarche (if occurs before age 10).
- Recent significant weight loss or gain
- Presence of acne, hirsutism, hair loss, or acanthosis nigricans may suggest androgen excess.

### Laboratory Tests
- Pregnancy test
- TSH
- Prolactin
- If PCOS is suspected, consider free or total testosterone, 17-hydroxyprogesterone, fasting glucose, and fasting lipid panel.
- If premature ovarian failure is suspected, consider follicle-stimulating hormone (FSH) and luteinizing hormone (LH) measurements.

### Other Diagnostic Tests
- Progesterone challenge
- Pelvic ultrasound to evaluate for polycystic ovaries

**FIGURE 49–2.** Summary of normal menstrual cycle. (FSH, follicle-stimulating hormone; GnRH, gonadotropin-releasing hormone; LH, luteinizing hormone.)

## Treatment

### ▶ Desired Outcomes

Treatment goals include restoring the normal menstrual cycle, preserving bone density, preventing bone loss, improving quality of life, and restoring ovulation, thus improving fertility. Amenorrhea attributable to hypoestrogenism (eg, premature ovarian insufficiency) can cause hot flashes and dyspareunia. In prepubertal females, the absence of secondary sexual characteristics and menarche may occur.[6]

### ▶ Nonpharmacologic Therapy

Nonpharmacologic therapy for amenorrhea depends on the underlying cause. Amenorrhea secondary to undernutrition or anorexia may respond to weight gain and psychotherapy.[20] If excessive exercise is the culprit, exercise reduction is recommended.[6]

### ▶ Pharmacologic Therapy

**Estrogen/Progestin Replacement Therapy** KEY CONCEPT *For most conditions associated with primary or secondary amenorrhea,* *estrogen treatment is recommended. To minimize risk of endometrial hyperplasia and cancer, progestin should also be given to women with an intact uterus.* Estrogen's role is to reduce osteoporosis risk, stimulate and maintain secondary sexual characteristics, and improve quality of life.[14,20] Table 49–1 lists the types and doses of estrogen and progestin therapy for amenorrhea.

**Dopamine Agonists** In women with hyperprolactinemia who desire conception, dopamine agonists are an option. Dopamine agonists reduce prolactin levels and resolve amenorrhea. Additionally, they restore ovulation in 80% to 90% of women.[27] The most commonly studied agents are bromocriptine and cabergoline.[7,27]

**Progestins** Progestins have long been used to induce withdrawal bleeding in women with secondary amenorrhea. Efficacy varies depending on the formulation used. Withdrawal bleeding occurs with intramuscularly injected progesterone and oral medroxyprogesterone acetate in 70% and 95% of patients, respectively.[28] The usual dose of medroxyprogesterone acetate is 10 mg orally once daily for 7 to 10 days.[6]

**Insulin-Sensitizing Agents** Amenorrhea related to anovulation and PCOS may respond to insulin sensitizing agents.[13] Using metformin for this purpose is discussed in the anovulatory bleeding section.

All patients experiencing amenorrhea should follow a diet rich in calcium and vitamin D to support bone health. Supplemental calcium and vitamin D (1200 mg/800 International Units per day) should be recommended for patients with inadequate dietary consumption.[6] Figure 49–4 illustrates treatment recommendations for amenorrhea.[6]

## Amenorrhea in Adolescents

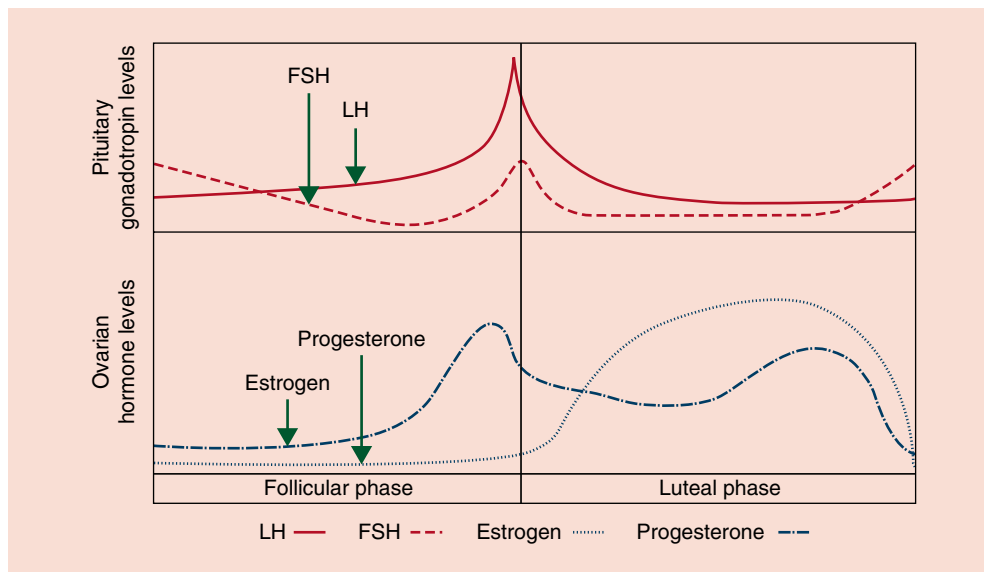
Adolescence is when peak bone mass is achieved. The cause of amenorrhea and appropriate treatment must be identified promptly in this population because hypoestrogenism contributes negatively to bone development.[20] Estrogen replacement, typically via a CHC, is important. Although recent data suggest that CHCs and depot medroxyprogesterone acetate may reduce bone mineral density (BMD) for short term, their long-term effects on fractures are unknown. These negative BMD effects


**FIGURE 49–3.** Hormonal fluctuations with the normal menstrual cycle. (FSH, follicle-stimulating hormone; LH, luteinizing hormone.) (Data from Umland EM, Weinstein LC, Buchanan E. Menstruation- related disorders (Chapter 89). In: Pharmacotherapy: A Pathophysiologic Approach, 8th ed. New York, NY: McGraw-Hill, 2011, with permission.)

appear to be reversible; therefore, CHCs are recommended in the adolescent population.[29] Ensuring adequate dietary or supplemental calcium and vitamin D intake in this population is imperative.

## ANOVULATORY BLEEDING

Anovulatory uterine bleeding (AUB) is irregular menstrual bleeding from the endometrium ranging from light spotting to heavy blood flow.[30]  **KEY CONCEPT** *It includes noncyclic menstrual bleeding due to ovulatory dysfunction (AUB-O), including anovulation or oligo-ovulation.[24] AUB-O is secondary to the effects of unopposed estrogen and does not include bleeding owing to an anatomic lesion of the uterus.* AUB is a diagnosis of exclusion and includes PCOS, which typically presents with irregular menstrual bleeding, hirsutism, obesity, and/or infertility.[13]

### Epidemiology and Etiology

Anovulatory uterine bleeding is the most common form of noncyclic uterine bleeding.[30] Medical care is often pursued to regulate menstrual cycles or improve fertility. All women of reproductive age should have a pregnancy test when presenting with irregular menstrual bleeding. Anovulation results from dysfunction at any level of the hypothalamic-pituitary-ovarian (HPO) axis which can be due to physiologic life stages such as adolescence, perimenopause, pregnancy, and lactation or pathologic causes (see Table 49–2).[19,24]

During adolescence, ovulatory menstrual cycles may not be regular for 12 to 18 months after menarche.[24,30] Ovulation frequency is related to the age at and time since menarche.[19] In the year following menarche, the feedback mechanism in the HPO axis may be immature, and the luteinizing hormone (LH) surge needed for ovulation fails to occur.[30] During perimenopause, anovulatory cycles occur due to declining quality and quantity of ovarian follicles. As ovarian function declines, estrogen secretion continues, and progesterone secretion decreases. Chronic

anovulatory cycles and unopposed estrogen secretion lead to endometrial proliferation and increased risk of polyps, endometrial hyperplasia, and endometrial carcinoma.[24]

Anovulation also occurs at any time during the reproductive years due to a pathologic cause. The most common causes of nonphysiologic ovulatory dysfunction are PCOS, hypothalamic amenorrhea, hyperprolactinemia, and premature ovarian failure. PCOS, responsible for 55% to 91% of ovulatory dysfunction cases, occurs in approximately 7% of women.[13,24]

### Pathophysiology

A normal ovulatory cycle includes follicular development, ovulation, corpus luteum development, and luteolysis. During the cycle, the endometrium proliferates and undergoes secretory changes and desquamation. This is influenced by estrogen alone, then by estrogen and progesterone, and culminates with estrogen and progesterone withdrawal. Progesterone stops endometrial growth and stimulates endometrial differentiation. In anovulatory women, a corpus luteum is not formed, and the ovary does not secrete progesterone. Without progesterone, there is no endometrial desquamation or differentiation. Chronic unopposed estrogen causes endometrial proliferation. The endometrium becomes vascular and fragile, resulting in noncyclic menstrual bleeding. The endometrium may also become hyperplastic and progress to a precancerous state, increasing the woman's risk of endometrial cancer (see Table 49–2).[1]

The most common pathologic cause of anovulation is PCOS. Two sets of closely related criteria have been developed. The Rotterdam criteria identify PCOS as a syndrome of ovarian dysfunction diagnosed when two of the following characteristics exist: (a) oligoanovulation or anovulation; (b) clinical signs (hirsutism, acne) or laboratory evidence of hyperandrogenism (total testosterone and sex hormone-binding globulin); and (c) polycystic ovary morphology on ultrasound.[13,31] The Androgen Excess and PCOS Society (AE-PCOS) defines PCOS as hyperandrogenism (clinical or biochemical), ovarian dysfunction

## Table 49–2

**Pathophysiology of Selected Menstrual Bleeding Disorders[1,6,13,19,22–25]**

| Organ System | Condition | Pathophysiology/Laboratory Findings |
|---|---|---|
| **Amenorrhea[1,6,22]** | | |
| Uterus | Asherman syndrome | Postcurettage/postsurgical uterine adhesions |
| | Congenital uterine abnormalities | Abnormal uterine development |
| Ovaries | Turner syndrome | Lack of ovarian follicles |
| | Gonadal dysgenesis | Other genetic anomalies |
| | Premature ovarian failure | Early loss of follicles |
| | Chemotherapy/radiation | Gonadal toxins |
| Anterior pituitary | Pituitary prolactin-secreting adenoma | ↑ Prolactin suppresses HPO axis |
| | Hypothyroidism | TRH causing ↑ prolactin, other abnormalities |
| | Medications—antipsychotics, verapamil | ↑ Prolactin suppresses HPO axis |
| Hypothalamus | "Functional" hypothalamic amenorrhea | ↓ Pulsatile GnRH secretion in the absence of other abnormalities |
| | Disordered eating | ↓ Pulsatile GnRH secretion, ↓ FSH and LH secondary to weight loss |
| | Exercise | ↓ Pulsatile GnRH secretion, ↓ FSH and LH secondary to low body fat |
| | Anovulation/PCOS | Asynchronous gonadotropin and estrogen production, abnormal endometrial growth |
| **Anovulatory Bleeding[1,13,23,24]** | | |
| Physiologic causes | Adolescence | Immature hypothalamic-pituitary-ovarian axis: no LH surge |
| | Perimenopause | Declining ovarian function |
| Pathologic causes | Hyperandrogenic anovulation (PCOS, congenital adrenal hyperplasia, androgen-producing tumors) | Hyperandrogenism: high testosterone, high LH, hyperinsulinemia, and insulin resistance |
| | Hypothalamic dysfunction (physical or emotional stress, exercise, weight loss, anorexia nervosa) | Suppression of pulsatile GnRH secretion and estrogen deficiency: low LH, low FSH |
| | Hyperprolactinemia (pituitary gland tumor, psychiatric medications) | High prolactin |
| | Hypothyroidism | High TSH |
| | Premature ovarian failure | High FSH |
| **Menorrhagia[25]** | | |
| Hematologic | von Willebrand disease | Factor VII defect causing impaired platelet adhesion and increased bleeding time |
| | Idiopathic thrombocytopenic purpura | Decrease in circulating platelets—can be acute or chronic |
| Hepatic | Cirrhosis | Decreased estrogen metabolism, underlying coagulopathy |
| Endocrine | Hypothyroidism | Alterations in HPO axis |
| Uterine | Fibroids | Alteration of endometrium, changes in uterine contractility |
| | Adenomyosis | Alteration of endometrium, changes in uterine contractility |
| | Endometrial polyps | Alteration of endometrium |
| | Gynecologic cancers | Various dysplastic alterations of endometrium, uterus, cervix |

↑, high; ↓, low; FSH, follicle-stimulating hormone; GnRH, gonadotropin-releasing hormone; HPO, hypothalamic-pituitary-ovarian axis; LH, luteinizing hormone; PCOS, polycystic ovary syndrome; TRH, thyrotropin-releasing hormone; TSH, thyroid-stimulating hormone.

(oligoanovulation or polycystic ovaries) and the exclusion of other causes of androgen excess.[32] No gene or environmental substance appears to cause PCOS.[13] However, familial clustering of PCOS cases suggests that genetics play a role. Insulin resistance, hyperandrogenism, and changes in gonadotropins also influence PCOS development. The underlying cause for increased androgens is unknown.[32,33]

Recently, discussion regarding the link to cardiovascular disease has been emphasized. PCOS is associated with two to five times increased risk of developing type 2 diabetes.[13] In women with PCOS, approximately 60% to 80% have impaired glucose tolerance (IGT).[34] Additionally, in obese women with PCOS, IGT prevalence increases to 95%, and 70% have dyslipidemia.[13,34] Women with PCOS should be screened for IGT, diabetes, hypertension, and dyslipidemia.[13] If any present, there is an increased risk of cardiovascular events.[34,35]

## Treatment

### ▶ Desired Outcomes

● The desired outcomes of therapy are to stop acute bleeding, prevent future episodes of noncyclic bleeding, decrease long-term complications of anovulation (eg, osteopenia and infertility), and improve overall quality of life.[24]

### ▶ Nonpharmacologic Therapy

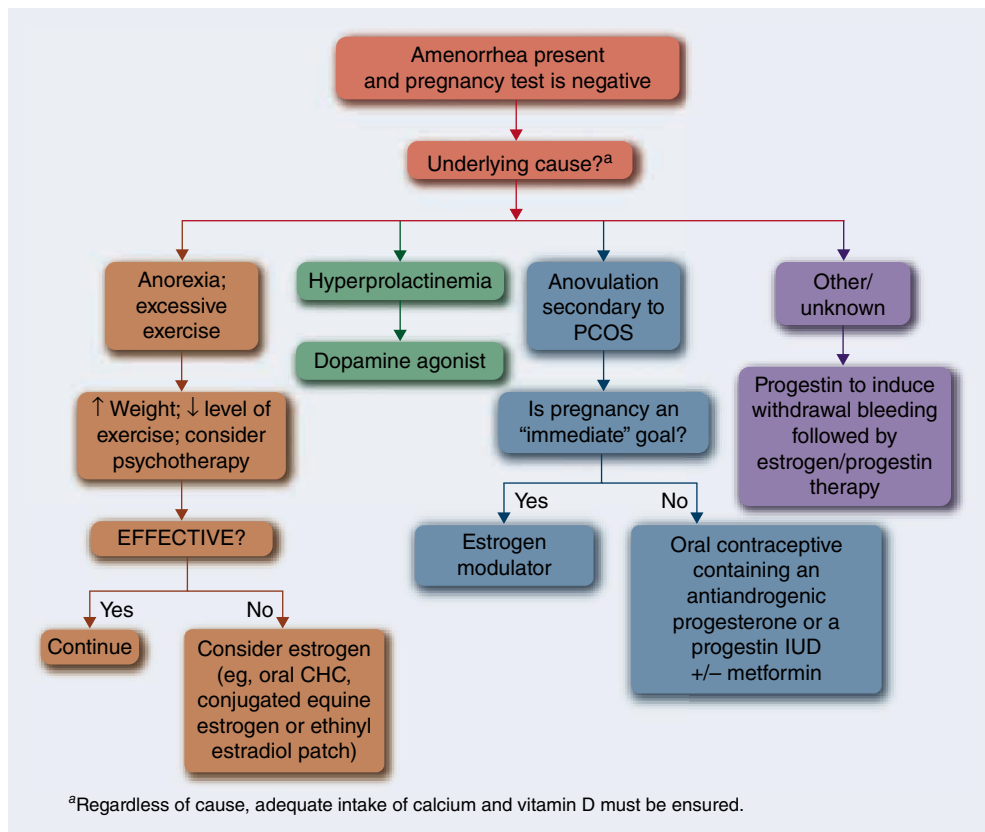
Nonpharmacologic treatment options depend on the underlying cause. For all women with PCOS, weight loss may be beneficial. In overweight or obese women, a 5% reduction in weight has been associated with resumption of menses, improved pregnancy rates, and decreased hirsutism, glucose, and lipid levels.[13] In women who have completed childbearing or who have failed medical management, endometrial ablation or resection, and


**FIGURE 49–4.** Treatment algorithm for amenorrhea. (CHC, combination hormonal contraceptive; IUD, intrauterine device; PCOS, polycystic ovarian syndrome.)

hysterectomy are surgical options. The preferred procedure is unclear. For short term, it appears that ablation or resection results in less morbidity and shorter recovery periods.[36] However, a significant number of these women eventually undergo hysterectomy within 5 years.[24]

## Clinical Presentation and Diagnosis of Anovulatory Bleeding

**General**
- Acute distress may or may not be present

**Symptoms**
- Irregular, heavy, or prolonged vaginal bleeding, perimenopausal symptoms (hot flashes, etc)

**Signs**
- Acne, hirsutism, obesity

**Laboratory Tests**
- If suspect PCOS, consider free or total testosterone, fasting glucose, fasting lipid panel.
- If suspect perimenopause, FSH.

**Other Diagnostic Tests**
- Pelvic ultrasound to evaluate for polycystic ovaries

### ▶ Pharmacologic Therapy

Table 49–1 summarizes therapeutic agents and doses.

**Estrogen**  Estrogen is the recommended treatment for managing acute bleeding episodes. It promotes endometrial growth and stabilization.[24] Given as a CHC, it has averted emergency surgery in 95% of patients.[8] It should then be continued to prevent recurrent anovulatory bleeding. Long-term therapy with a CHC reduces the risk of endometrial cancer compared to unopposed estrogen therapy.[6] CHCs suppress ovarian hormones and adrenal androgen production and indirectly increase sex hormone–binding globulin (SHBG). This, in turn, binds and reduces circulating androgen.[13,24,37] For women with high androgen levels and related signs (eg, hirsutism, acne), low-dose CHCs (35 mcg or less ethinyl estradiol) are the treatment of choice.[24] A CHC containing drospirenone, which has a greater impact on increasing SHBG and antiandrogenic effects, could be considered.[33] However, to date there is no consensus regarding the best CHC choice for treating PCOS.[13]

**Medroxyprogesterone Acetate**  Depot and intermittent oral medroxyprogesterone acetate suppresses pituitary gonadotropins and circulating androgens in women with PCOS.[13] Furthermore, cyclic progesterone may benefit women older than 40 years with anovulatory bleeding.[24] Similar to the use of CHCs, oral medroxyprogesterone acetate has averted emergency surgeries in 100% of patients with acute uterine bleeding justifying immediate medical attention.[8]

**Estrogen Modulators**  If the goal is to induce ovulation, the treatment of choice is clomiphene citrate. It is approximately

## Patient Encounter 2

A 40-year-old woman presents to your office for a routine gynecologic examination. She entered menarche at the age of 12. Her last menstrual period was 3 months ago. Her periods are often irregular and occur about every 2 to 3 months. All previous Pap smears have been normal, and there is no history of sexually transmitted infections. She has had one sexual partner whom she is married to. She had one successful pregnancy that took "several years" and three courses of clomiphene due to "follicles" on her ovaries. Her PMH is significant for diabetes and hypertension for which she takes metformin 1000 mg by mouth twice daily and lisinopril 10 mg by mouth once daily. She is married and is not using any form of contraception. She notes that they have decided not to continue to try to have children. On examination, she is an overweight female with mild hirutism.

**Labs:** Urine HCG negative, free testosterone 100 ng/dL (3.47 nmol/L) (elevated), TSH 2.1 μIU/mL (2.1 mIU/L) (within normal limits), prolactin 9 ng/mL (9 mcg/L [391 pmol/L]) (within normal limits), fasting glucose 120 mg/dL (6.7 mmol/L). Fasting lipid panel: total cholesterol 181 mg/dL (4.68 mmol/L), HDL cholesterol 58 mg/dL (1.50 mmol/L), triglycerides 65 mg/dL (0.73 mmol/L), LDL cholesterol 110 mg/dL (2.84 mmol/L)

**Pelvic ultrasound**: 17 follicles in right ovary, 13 follicles in left ovary, increased ovarian volume of 12 mL

*What anovulatory disorder is most likely present?*

*What signs/symptoms support this conclusion?*

*What pharmacologic therapies are recommended for this patient?*

three times more effective than metformin at achieving live births.[13] Limited data have shown that adding metformin to clomiphene citrate may be more effective in increasing pregnancy rates, especially in obese women with PCOS who are resistant to clomiphene citrate monotherapy.[13,33,38] Treatment with clomiphene citrate is commonly recommended following withdrawal bleeding induction with oral medroxyprogesterone acetate, 10 mg/day for 10 days.

Recent data have shown beneficial effects with the use of letrozole to improve fertility. In a large trial, when compared to clomiphene citrate, letrozole had a statistically higher live birth rate with a similar adverse effect profile. Additional trials are needed to support this finding.[12,33]

**Insulin-sensitizing Agents** Metformin improves insulin sensitivity and is recommended in women who cannot tolerate CHC and have IGT or type-2 diabetes mellitus.[33] KEY CONCEPT *In patients with PCOS, it is associated with reduced circulating androgen concentrations, increased ovulation rates, and improved glucose tolerance. Additionally, metformin may decrease cardiovascular risk and promote weight loss.*[13] These improvements are attributed to the SHBG increase that occurs via increased insulin sensitivity. Notably, metformin, a pregnancy category B agent, is not recommended as monotherapy to improve ovulation and fertility. Thiazolidinediones are no longer recommended due to a poor risk-benefit ratio.[33]

## Anovulatory Bleeding in Adolescents

Anovulatory cycles are common in the perimenarchal years. Ovulation typically is established a year or more following menarche. When anovulatory bleeding occurs in this population, it may be excessive. Thus, the patient should be evaluated for blood dyscrasias, including von Willebrand disease, prothrombin deficiency, and idiopathic thrombocytopenia purpura.[24,25]

In adolescents, blood dyscrasias should be treated. Acute, severe bleeding is managed with high-dose estrogen. Low-dose CHCs (35 mcg or less ethinyl estradiol) are the treatment of choice in adolescents with chronic anovulation.[24] If obesity is present, lifestyle changes are also recommended first line, and if IGT or metabolic syndrome is present, metformin can be recommended.[33]

## MENORRHAGIA

Menorrhagia describes prolonged menstrual bleeding (lasting greater than 7 days) or cyclic, heavy menstrual bleeding (HMB; greater than 80 mL per cycle).[23,30,39] It is difficult to quantify menstrual blood loss in clinical practice. Many women with less than 80 mL of blood loss seek medical attention with concerns of containment flow problems, unpredictable heavy flow, reduced quality of life, and other dysmenorrhea symptoms.[39]

### Epidemiology and Etiology

Menorrhagia rates in healthy women range from 9% to 14%, but can be as high as 30%.[23,39] KEY CONCEPT *Causes of menorrhagia can be*

## Clinical Presentation and Diagnosis of Menorrhagia

**General**
- Acute distress may or may not be present

**Symptoms**
- Reports of heavy/prolonged menstrual flow.
- Fatigue and light-headedness in the case of severe blood loss.
- Dysmenorrhea may be an accompanying symptom

**Signs**
- Orthostasis, tachycardia, and pallor may be noted, especially with significant acute blood loss.

**Laboratory Tests**
- Complete blood count (CBC) and ferritin levels; hemoglobin and hematocrit results may be low.
- If the history dictates, testing may be done to identify coagulation disorder(s) as a cause.

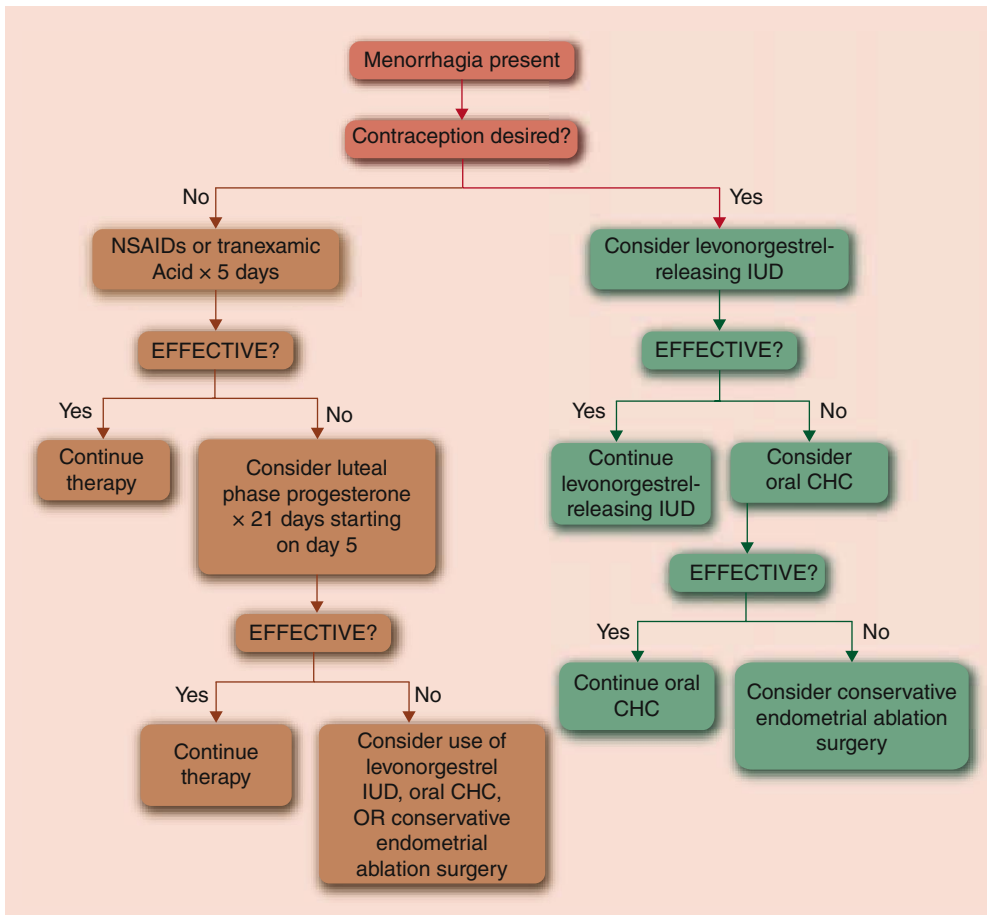
**Other Diagnostic Tests**
- Pelvic ultrasound
- Pelvic magnetic resonance imaging (MRI)
- Pap smear
- Endometrial biopsy
- Hysteroscopy
- Sonohysterogram


**FIGURE 49–5.** Treatment algorithm for menorrhagia. (CHC, combination hormonal contraceptive; IUD, intrauterine device; NSAID, nonsteroidal anti-inflammatory drug.)

*divided into systemic disorders and reproductive tract abnormalities.* **KEY CONCEPT** *Intrauterine pregnancy, ectopic pregnancy, and miscarriage are at the top of the differential diagnosis list for any woman presenting with heavy menses.* Additionally, genital tract malignancies and infections may present with abnormal bleeding.[23] Systemic disorders include coagulation dysfunction such as von Willebrand disease and platelet function disorders.[23,25,30] Hypothyroidism is also associated with heavy menses. Specific reproductive tract causes of menorrhagia are more common in older childbearing women, and they include fibroids, adenomyosis, endometrial polyps, and gynecologic malignancies.[30]

## Pathophysiology

Table 49–2 describes the pathophysiology of menorrhagia and specific conditions resulting in menorrhagia.

## Treatment

### ▶ Desired Outcomes

Goals of therapy are to reduce menstrual blood flow, reduce risk of anemia, improve quality of life, and defer the need for surgical intervention. Treatment recommendations are outlined in Table 49–1 and **Figure 49–5**.

### ▶ Nonpharmacologic Therapy

Surgical interventions are reserved for patients nonresponsive to pharmacologic treatment and include endometrial ablation and hysterectomy.[36]

### ▶ Pharmacologic Therapy

**Nonsteroidal Anti-inflammatory Drugs (NSAIDs)** NSAIDs are first-line treatments for menorrhagia associated with ovulatory cycles.[37] They are taken only during menses, and a 20% to 35% reduction in blood loss is reported in 75% of treated women.[10,37] **KEY CONCEPT** *This reduction is directly proportional to*

---

### Patient Encounter 3

A 14-year-old girl presents to her physician reporting moderate pelvic pain and cramping during menses. She also notes that her menses are "heavy" and require a change in tampon every 3–4 hours. Her last menstrual cycle was 12 days ago, and she had her first menstrual cycle at age 12. She is not sexually active. She does not take any routine medications. She is on the high school volleyball team.

*Identify the treatment goals for this patient's menorrhagia.*

*What diagnostic tests should be considered?*

*What pharmacologic therapies are recommended for this patient?*

*What monitoring parameters are recommended to assess efficacy and safety of the therapeutic options?*

### Table 49–3

**Expected Outcome Measures for Selected Menstrual Bleeding Disorders[19,23–26,39]**

| Menstrual Disorder | Expected Outcome Measures |
|---|---|
| Amenorrhea | *Efficacy:* Normal breast development (especially primary amenorrhea in adolescents); BMD preservation/ improvement; return of menses.<br>*Time to relief/effect:* Menses should occur within 1–2 months of therapy. |
| Anovulatory bleeding | *Efficacy:* Alleviation of acute bleeding when present; ovulation and subsequent pregnancy in women desiring this; reduced risk of developing the long-term complications of PCOS (eg, diabetes and cardiovascular disease); improved quality of life.<br>*Time to relief/effect:* The acute treatment of heavy bleeding should reduce bleeding within 10 days of therapy onset; return of ovulation may require several months of therapy; when oral CHCs are used, abnormal bleeding control can be expected within 1–2 treatment cycles. |
| Dysmenorrhea | *Efficacy:* Reduction in menses-related pelvic pain; reduction in time lost from work/school; improved quality of life.<br>*Time to relief/effect:* Improvement in pain may be observed within hours of NSAID therapy; improvement with other options such as oral CHCs may be observed after a full 1–3 cycles of use. |
| Menorrhagia | *Efficacy:* Decline in amount of blood loss with menses (monitor a decline in the number of times feminine hygiene products such as pads and tampons require changing during menses); increase in hemoglobin/ hematocrit if anemia was present as because of menorrhagia.<br>*Time to relief/effect:* A decline in menstrual blood loss should be realized within 1–2 cycles of therapy initiation. |

BMD, bone mineral density; CHCs, combination hormonal contraceptives; NSAID, nonsteroidal anti-inflammatory drug; PCOS, polycystic ovary syndrome.

the amount of pretreatment blood loss.[10] They may also improve dysmennorhea.

**Combination Hormonal Contraceptives** CHCs are beneficial to women with menorrhagia who do not desire pregnancy. A 40% to 50% reduction in menstrual blood loss is reported in 68% of menorrhagia patients treated with oral CHCs containing greater than or equal to 35 mcg estradiol.[10,16] Continuous and extended cycle options may also reduce the number of menstrual cycles.[16] As with NSAIDs, **KEY CONCEPT** *the reduction in blood loss is proportional to pretreatment blood loss.*

**Progestins** Menorrhagia may also be treated with the levonorgestrel-releasing IUD, which consistently reduces menstrual flow by 75% to 95%, and after 12 months, 20% to 80% of women experience amenorrhea.[10,16,17,37,40] When compared with endometrial ablation, the levonorgestrel IUD causes similar reductions in menstrual blood loss after 6, 12, and 24 months.[41]

## Patient Care Process

**Patient Assessment:**

- Based on physical examination, history, and review of systems, additional work-up may be necessary (eg, amenorrhea, menorrhagia, AUB, or PMDD).
- Document symptoms.
- Conduct a medication history. Have any treatments helped in the past?
- Review the medical history and laboratory data. Does the patient have any complications, such as symptoms of anemia in patients presenting with menorrhagia or difficulty conceiving in women with amenorrhea or anovulatory bleeding?
- Review available diagnostic data to determine hormonal, reproductive, and pregnancy status. Does the patient need a pregnancy test?

**Therapy Evaluation:**

- Is current pharmacotherapy safe and effective; is dosing appropriate?
- Is the patient adherent to current therapy?
- Does the patient have prescription insurance coverage?

**Care Plan Development:**

- Educate the patient on lifestyle modifications that will improve symptoms and prevent complications.
- Select pharmacotherapy, if indicated, that is safe and effective.
- Determine whether long-term maintenance treatment is necessary.
- Address any patient concerns on quality of life (physical, psychological, and social functioning) and infertility.
- Discuss the importance of adherence to medication management and lifestyle modifications.

**Follow-up Evaluation:**

- Develop a plan to assess effectiveness and safety of pharmacotherapy.
- Assess improvement in quality-of-life and well-being.
- Review medical history, physical examination findings, laboratory and diagnostic tests.
- Evaluate for adverse drug reactions, drug allergies, and drug interactions.

Compared with hysterectomy, it leads to similar rates of satisfaction and improved quality of life.[10,42]

Cyclic progestin therapy, either during the luteal phase or for 21 days of the menstrual cycle, reduces menstrual blood loss.[10] The levonorgestrel IUD is more effective than oral norethindrone administered cyclically.[16] In a small open-label study, the levonorgestrel IUD resulted in a greater menstrual blood loss reduction and number of lost days at work or school compared with oral CHCs.[43] Oral progestin therapy is considered a third-line option.[10]

**Tranexamic Acid** Tranexamic acid reduces plasmin activity and tissue plasminogen activator.[10,44] While an immediate-release product has been available for a long time, a modified-release product has recently become available. It has better gastrointestinal tolerability and gives women another non-hormonal option to manage menorrhagia.[44,45] Additionally, it can be recommended for women with von Willebrand disease.

## Menorrhagia in Adolescents

Up to 50% of adolescents with menorrhagia have been shown to have a bleeding disorder, most commonly von Willebrand disease or platelet dysfunction.[25] Although von Willebrand disease has a 1% to 2% incidence in the general population, it is estimated that 5% to 36% of adolescents presenting with heavy menses have this disorder.[25,26] Platelet function disorders exist in 2% to 44% of adolescents with menorrhagia.[25]

## OUTCOME EVALUATION

Treatment success for menstruation-related disorders is measured by the degree to which treatment (a) relieves or reverses symptoms, (b) prevents or reverses complications (eg, osteoporosis, anemia, and infertility), and (c) causes minimal adverse effects. Resumption of regular menstrual cycles with minimal premenstrual or dysmenorrhea symptoms should occur. Depending on the desire for conception and related therapy, these cycles may be ovulatory or anovulatory.

Assess treatment effectiveness in reinstating normal menstrual cycles with minimal adverse effects after an appropriate treatment interval (1–2 months). Assess improvement in well-being and quality-of-life (eg, physical, psychological, and social functioning). Evaluate the patient for adverse drug reactions (see Table 49–1), drug allergies, and drug interactions. Table 49–3 lists the expected outcome measures for each discussed menstruation-related disorder.

## Abbreviations Introduced in This chapter

| ACOG | American College of Obstetricians and Gynecologists |
| AUB | Anovulatory uterine bleeding |
| BMD | Bone mineral density |
| BMI | Body mass index |
| CBC | Complete blood count |
| CEE | Conjugated equine estrogen |
| CHC | Combination hormonal contraceptive |
| FSH | Follicle-stimulating hormone |
| GI | Gastrointestinal |
| GnRH | Gonadotropin-releasing hormone |
| HCG | Human chorionic gonadotropin |
| HMB | Heavy menstrual bleeding |
| HPO | Hypothalamic-pituitary-ovarian |
| IGT | Impaired glucose tolerance |
| IUD | Intrauterine device |
| LH | Luteinizing hormone |
| MPA | Medroxyprogesterone acetate |
| MRI | Magnetic resonance imaging |
| NSAID | Nonsteroidal anti-inflammatory drug |
| OC | Oral contraceptive |
| PCOS | Polycystic ovarian syndrome |
| PID | Pelvic inflammatory disease |
| SHBG | Sex hormone–binding globulin |
| TENS | Transcutaneous electrical nerve stimulation |

# 50 Hormone Therapy in Menopause

Nicole S. Culhane and Kelly R. Ragucci

## LEARNING OBJECTIVES

**Upon completion of the chapter, the reader will be able to:**

1. Explain the physiologic changes associated with menopause.
2. Identify the signs and symptoms associated with menopause.
3. Determine the desired therapeutic outcomes for a patient taking hormone therapy (HT).
4. Explain how to evaluate a patient for the appropriate use of HT.
5. Recommend nonpharmacologic therapy for menopausal symptoms.
6. List the adverse effects of and contraindications to HT.
7. Differentiate between topical and systemic forms of HT.
8. Explain the risks and benefits associated with HT.
9. Educate a patient regarding the proper use and potential adverse effects of HT.
10. Describe the monitoring parameters for a patient taking HT.
11. Describe the circumstances under which nonhormonal therapies for menopausal symptoms should be considered.

## INTRODUCTION

**M**enopause is the permanent cessation of menses following the loss of ovarian follicular activity. The diagnosis of menopause is primarily a clinical one and is made after a woman experiences amenorrhea for 12 consecutive months. The loss of ovarian follicular activity leads to an increase in follicle-stimulating hormone (FSH), which, on laboratory examination, may help to confirm the diagnosis.

The role of hormone therapy (HT) has changed dramatically over the years. HT has long been prescribed for relief of menopausal symptoms and, until recent years, has been purported to protect women from coronary heart disease (CHD). The reason behind recommending HT in postmenopausal women revolved around a simple theory: If the hormones lost during menopause were replaced through drug therapy, women would be protected from both menopausal symptoms and chronic diseases that often follow after a woman experiences menopause. Recent studies have disproved this theory.

In 1996, the United States Preventive Services Task Force first published its recommendations that not all postmenopausal women should be prescribed HT, but that therapy should be individualized based on risk factors. This recommendation was further supported with publication of the Heart and Estrogen/Progestin Replacement Study (HERS) in 1998, which demonstrated that women who had established CHD were at an increased risk of experiencing a myocardial infarction within the first year of HT use compared with a similar group of women without CHD risk factors. As a result, the authors concluded that HT should not be recommended for the secondary prevention of CHD.[1] Then, in 2002, the Women's Health Initiative (WHI) study was published. This trial demonstrated that HT was not protective against CHD but rather could increase the risk in women with underlying CHD risk factors. The risk of breast cancer was also increased after a woman was on combination estrogen and progestogen for approximately 3 years. It should be noted that this was not the case with estrogen alone. As a result of this study, the US Food and Drug Administration (FDA) issued a statement that HT, in general, should not be initiated or continued for the primary prevention of CHD.[2]

This series of trials led to dramatic changes in how HT is prescribed and greater understanding of the associated risks. HT, once thought of as a cure-all for menopausal symptoms, is now a therapy that should be used primarily to reduce the frequency and severity of moderate to severe **vasomotor symptoms** associated with menopause in women without risk factors for CHD or breast cancer. The changes that have occurred over the years in the use of HT further support the importance of evidence-based practice and judicious medication use.

## EPIDEMIOLOGY AND ETIOLOGY

Menopause is a period of time marked by loss of ovarian follicular activity, inadequate estradiol production, and the subsequent cessation of menses. The median age for a woman to experience menopause is 52 years. However, women who have undergone a total abdominal hysterectomy with bilateral salpingo-oophorectomy (surgical menopause) generally experience menopause earlier

compared with women who experience natural menopause. Some other factors that may be associated with early menopause include low body weight, increased menstrual cycle length, **nulliparity**, and smoking. Smokers generally experience menopause approximately 2 years earlier than nonsmokers.[3]

The usual transitional period prior to menopause, known as **perimenopause** or the *climacteric*, is a period when hormonal and biologic changes begin to occur. These changes may begin 2 to 8 years prior to menopause and eventually lead to irregular menstrual cycles, an increase in cycle interval, and a decrease in cycle length. During this time, women also may experience physical symptoms similar to menopausal symptoms, which may require treatment depending on symptom severity.[3]

Because the perimenopausal and postmenopausal periods are marked by many biologic and endocrinologic changes, women should inform their health care provider when they experience any signs and symptoms in order to discuss the most appropriate therapeutic approach.

## PHYSIOLOGY

Reproductive physiology is regulated primarily by the hypothalamic–pituitary–ovarian axis. The hypothalamus secretes gonadotropin-releasing hormone (GnRH), which stimulates the anterior pituitary to secrete FSH and luteinizing hormone (LH). FSH and LH regulate ovarian function and stimulate the ovary to produce sex steroids. All these hormones are influenced by a negative-feedback system and will increase or decrease based on the levels of estradiol and progesterone.

The physiologic changes that occur during the perimenopausal and menopausal periods are caused by the decrease and

eventual loss of ovarian follicular activity. As women age, the number of ovarian follicles decreases, and the remaining follicles require higher levels of FSH for maturation and ovulation. During perimenopause, anovulatory cycles are more likely, and the lack of progesterone production leads to irregular and unpredictable menses. During menopause, FSH concentrations increase 10- to 15-fold, LH concentrations increase fivefold, and levels of circulating estradiol decrease by more than 90%.[4]

**KEY CONCEPT** *Common symptoms of menopause include vasomotor symptoms (hot flashes, night sweats), vulvovaginal atrophy, vaginal dryness, and dyspareunia. Women less commonly may experience mood swings, depression, insomnia, arthralgia, myalgia, urinary frequency, and decreased libido.* Menopausal symptoms tend to be more severe in women who undergo surgical menopause compared with natural menopause because of the more rapid decline in estrogen concentrations.[3] Women who seek medical treatment should undergo laboratory evaluation to rule out other conditions that may present with similar symptoms, such as abnormal thyroid function or pituitary adenoma. Once symptoms have been evaluated and other conditions have been excluded, HT may be considered.

## TREATMENT
### Desired Outcomes

**KEY CONCEPT** *HT remains the most effective treatment for vasomotor symptoms and vulvovaginal atrophy and can be considered, especially for women experiencing moderate to severe symptoms.* The goals of treatment are to alleviate or reduce menopausal symptoms and to improve the patient's quality of life (QOL) while minimizing adverse effects of therapy. The appropriate route of administration should be chosen based on individual patient symptoms, and therapy should be continued at the lowest dose for the shortest duration consistent with treatment goals for each patient.

### General Approach to Treatment

There are a number of national and international guidelines and consensus statements available on the management of menopause.[5–9] The most current guidelines should always be consulted before making pharmacotherapeutic recommendations for women. Women suffering from vasomotor symptoms

should attempt lifestyle or behavioral modifications before seeking medical treatment. Women who seek medical treatment usually suffer from symptoms that diminish their QOL, such as multiple **hot flashes** per day or week, sleep disturbances, vaginal dryness, or mood swings. HT should be considered for these women but is not the most appropriate choice for all women. **KEY CONCEPT** . *Women should receive a thorough history and physical examination, including assessing for CHD and breast cancer risk factors and contraindications, before HT is considered. They should be informed of the risks and the benefits of HT and encouraged to be involved in the decision-making process. If a woman does not have any contraindications to HT, including CHD or significant CHD risk factors, and also does not have a personal history of breast cancer, HT could be an appropriate therapy option* (**Figure 50–1**). Women who have undergone a hysterectomy need only be prescribed estrogen. A progestogen should be added to the estrogen only for women with an intact uterus. Alternative and nonhormonal treatment options are available for women who are not candidates for HT, but they have limited effectiveness and may also have adverse effects.

## Nonpharmacologic Therapy

Nonpharmacologic therapies for menopause-related symptoms have not been studied in large randomized trials, and evidence of benefit is not well documented. Due to the minimal adverse effects of these interventions, patients should try lifestyle or behavioral modifications before and in addition to pharmacologic therapy. The most common nonpharmacologic interventions for vasomotor symptoms include the following[3,12,13]:

- Smoking cessation
- Limit alcohol and caffeine
- Limit hot beverages (eg, coffee/tea, soups)
- Limit spicy foods
- Keep cool, and dress in layers
- Stress reduction (eg, meditation, relaxation exercises)
- Increase exercise
- Paced respiration

Exercise demonstrated an improvement in QOL but did not improve vasomotor symptoms. Paced respiration, a form of deep, slow breathing, improved vasomotor symptoms in a small group of patients.

Dyspareunia may result from vaginal dryness. Water-based lubricants may provide relief for several hours after application. Moisturizers may provide relief for a longer period of time and potentially can prevent infections by maintaining the acidic environment in the vagina. Both these treatments require frequent application.

A decline in estrogen concentrations also may be associated with urinary stress incontinence. **Kegel exercises** are recommended as a first-line intervention for stress incontinence, although pharmacologic therapy also may be necessary. Kegel exercises strengthen the pelvic floor muscles and help to keep the urethral sphincter from relaxing at inappropriate times, such as when lifting heavy objects, coughing, or sneezing. These exercises have no adverse effects, take little time, may be done inconspicuously, and when done correctly, may help to restore normal urine flow.

---

## Patient Encounter, Part 2: Medical History, Physical Examination, and Diagnostic Tests

The workup reveals the following additional information:

**PMH:** Hypertension since age 45, currently controlled; hyperlipidemia, currently controlled; hypothyroidism since age 25, but symptoms indicative of worsening control; hysterectomy in 2010.

**FH:** Father: Alive with HTN and CHD (MI at age 60). Mother: Alive with hypothyroidism, HTN, and GERD. Siblings: Two sisters alive and well, menopausal with hx of hot flashes.

**SH:** Occupation: Nurse; nonsmoker; drinks one to two glasses of red wine with dinner on the weekends; denies illicit drug use.

**Meds:** Lisinopril/HCTZ 20/12.5 mg once daily; simvastatin 40 mg at bedtime; Synthroid 0.075 mg by mouth once daily; multivitamin by mouth once daily.

**ROS:** (+) hot flashes, night sweats, vaginal dryness and itching; (+) insomnia, bowel changes, 5-lb weight loss since last visit 6 months ago.

**PE:**

**VS:** BP 128/78, P 92, RR 16, T 37.0°C (98.6°F), Wt 74.5 kg (164 lb)

**HEENT:** WNL

**Neck:** Supple; no bruits, no adenopathy, no thyromegaly.

**Breasts:** Supple; no masses

**CV:** RRR, normal $S_1$ and $S_2$; no murmurs, rubs, or gallops

**Abd:** Soft, nontender, nondistended; (+) BS, no masses

**Genitourinary:** Pelvic examination normal except (+) mucosal atrophy; (+) hysterectomy

**Labs:**

**FSH:** 76 mIU/mL (76 IU/L)

**TSH:** 0.3 µIU/mL (0.3 mIU/L)

**Chem-7:** Na 135 mEq/L (135 mmol/L), K 4.5 mEq/L (4.5 mmol/L), Cl 109 mEq/L (109 mmol/L), $CO_2$ 25 mEq/L (25 mmol/L), BUN 9 mg/dL (3.2 mmol/L), SCr 0.9 mg/dL (80 µmol/L), Glucose 98 mg/dL (5.4 mmol/L)

**CBC:** Hgb 13 g/dL (130 g/L or 8.06 mmol/L), Hct 39% (0.39 volume fraction), WBC $5.5 \times 10^3/mm^3$ ($5.5 \times 10^9$/L), platelets $234 \times 10^3/mm^3$ ($234 \times 10^9$/L)

**Fasting lipid levels:** TC 200 mg/dL (5.17 mmol/L), low-density lipoprotein (LDL) 126 mg/dL (3.26 mmol/L), high-density lipoprotein (HDL) 50 mg/dL (1.30 mmol/L), Triglycerides (TG) 115 mg/dL (1.30 mmol/L)

*Assess the patient's condition based on this additional information.*

*What are the goals of treatment for this patient?*

*Assess the patient's risk factors for heart disease and breast cancer.*

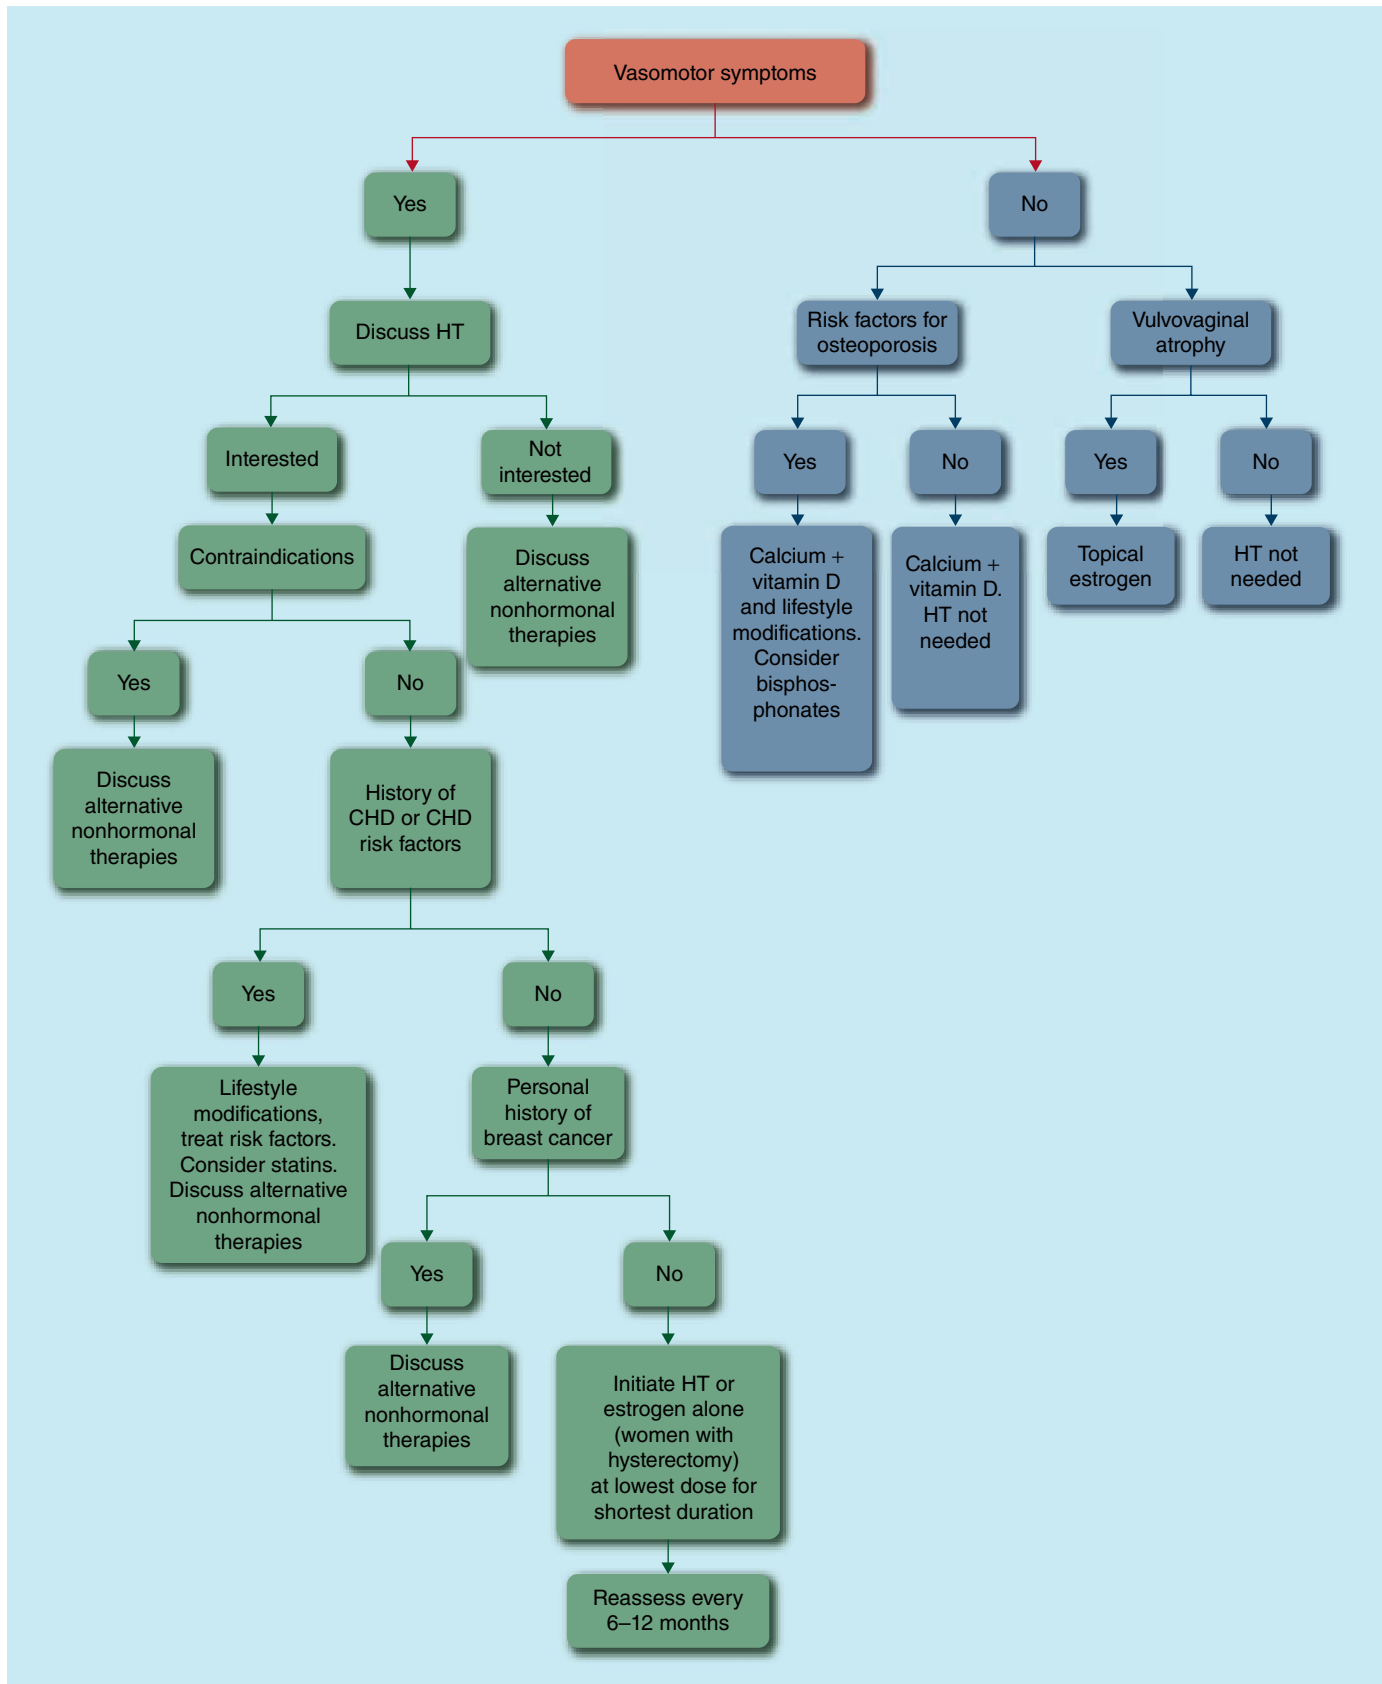
*Recommend nonpharmacologic and pharmacologic treatment for this patient. Justify your recommendations.*


**FIGURE 50–1.** Treatment algorithm for postmenopausal women.[2,10,11] (CHD, coronary heart disease; HT, hormone therapy.)

## Pharmacologic Therapy

### ▶ Estrogens

Estrogen is indicated for the treatment of moderate to severe vasomotor symptoms and vulvovaginal atrophy associated with menopause. In addition, it is indicated for the prevention of postmenopausal osteoporosis in women with significant risk; however, it is recommended that nonestrogen medications be used long-term. **KEY CONCEPT** *Oral or transdermal estrogen products should be prescribed at the lowest effective dose and for the shortest duration possible to provide relief of vasomotor symptoms. Topical vaginal products in the form of creams, tablets, or rings should be prescribed for women exclusively experiencing vulvovaginal atrophy.*

Many systemically administered estrogen products are available in the United States. Transdermal estrogen preparations are also available and usually are prescribed for patients who experience adverse effects, elevated triglycerides (TG), or liver function abnormalities while taking an oral product. Although there have been no randomized controlled trials (RCTs) published, one case control study suggests that transdermal preparations have a lower incidence of venous thromboembolism (VTE) than oral preparations.[5,14]

### ▶ Progestogens

**KEY CONCEPT** *Women who have an intact uterus should be prescribed a progestogen in addition to estrogen in order to decrease the risk of endometrial hyperplasia and endometrial cancer.*[5] Progestogens should be prescribed for at least 12 to 14 days of the month and often are prescribed continuously. Even low doses of oral estrogen therapy, as well as high dose vaginal preparations, require daily or intermittent administration of a progestogen in order to provide endometrial protection. Table 50–1 lists estrogen and progestogen preparations and dosages.

### ▶ Adverse Effects

Therapy with estrogen with or without a progestogen should be initiated at the lowest dose in order to minimize adverse effects. Because the adverse effects of these preparations can be similar, it may be difficult to assess whether the estrogen or the progestogen is the cause. Changing preparations, particularly the progestogen, or changing the method of administration may help to alleviate adverse effects. Table 50–2 lists the adverse effects that may be associated with estrogen and progestogen preparations.

### ▶ Contraindications

HT should not be prescribed to women with a history of or active thromboembolic disease, breast cancer or estrogen-dependent neoplasm, pregnancy, liver disease, or undiagnosed vaginal bleeding. It also should not be used for the prevention or treatment of cardiovascular disease, cerebrovascular disease, or dementia.[3]

### ▶ Methods of Administration

**Cyclic Estrogen and Progestogen** Estrogen is administered daily, and progestogen is administered for 12 to 14 days of the month. The disadvantage of this method of administration is the return of monthly menses in approximately 90% of women 1 to 2 days following the last progestogen dose. Women may view this scheduled bleeding as an advantage to this method of administration as it limits spotting or soiling of undergarments.

**Continuous Combined Estrogen and Progestogen** Estrogen and progestogen are administered daily and result in endometrial atrophy. Therefore, women do not experience a withdrawal bleed but may experience unanticipated breakthrough bleeding or spotting during the month. Although this may sound more appealing than a withdrawal bleed, women may view the unpredictable bleeding or spotting as a disadvantage to this type of administration. If bleeding persists beyond 6 to 12 months, women should seek medical attention to rule out endometrial hypertrophy or carcinoma.

### ▶ Low-Dose HT

There is an increasing body of evidence proving the effectiveness of low-dose HT regimens in the management of menopausal symptoms. Several trials demonstrated that lower doses of conjugated equine estrogen (CEE) ± medroxyprogesterone acetate (MPA) (CEE 0.45 mg or 0.3 mg ± MPA 2.5 mg or 1.5 mg) decreased hot flashes comparable with standard HT, improved vulvovaginal atrophy, increased bone mineral density (BMD) at the spine and hip, and provided sufficient endometrial protection.[17–20] Currently, no data are available on the effects of low-dose HT on the incidence of VTE, breast cancer, or CHD. Although many women have switched to low-dose HT, time will tell if lower doses translate into lower risks.

### ▶ Bioidentical HT

Bioidentical hormones are exogenous hormones that are identical to those produced in a woman's body (eg, estradiol, estrone, estriol, and progesterone). They are either commercially manufactured or chemically compounded in pharmacies into formulations such as topical creams, gels, and suppositories. The commercially manufactured prescription products are subject to regulation by the FDA and have been tested for potency, purity, efficacy, and safety (see Table 50–1). Conversely, pharmacist-compounded formulations are not subject to the same regulations and therefore, the efficacy and safety may be questionable. Often women view bioidentical hormones, particularly the pharmacist-compounded formulations, as "natural" and assume these formulations are safer than currently marketed prescription hormone products. Women may feel more comfortable using compounded products that are formulated based on individual hormone levels; however, due to a lack of regulation, these products may potentially cause more harm than benefit. In addition, pharmacist-compounded formulations can result in higher costs, because they are generally not covered by third-party payers. There is little evidence comparing the safety and efficacy of conventional HT to prescription bioidentical HT, and thus the same risks and benefits should be assumed.[5,21]

### ▶ Benefits of HT

**Vasomotor Symptoms** HT remains the most effective treatment for vasomotor symptoms, and systemic HT should be considered only in women experiencing these symptoms. Benefits must outweigh risks, and decisions should be made only after careful consideration by the woman and her health care provider. If it is decided to use HT, it should be prescribed at the lowest dose that relieves or reduces menopausal symptoms and should be recommended only for short-term use (generally less than 5 years). Women should be reassessed every 6 to 12 months, and discontinuation of therapy should be considered.

**Vulvovaginal Atrophy** Approximately 50% of postmenopausal women experience vulvovaginal atrophy and seek medical attention. Vulvovaginal atrophy is associated with vaginal dryness and dyspareunia and also may be associated with recurrent urinary tract infections, urethritis, and urinary urgency and frequency.

**Table 50–1**

**Estrogen and Progestogen Formulations and Dosages[10,15,16]**

| Product | Available Strengths | Common Dosages |
|---|---|---|
| **Oral estrogens** | | |
| CEE (Premarin) | 0.3-1.25 mg | 0.3-0.625 mg/day |
| Synthetic conjugated estrogens (Cenestin; Enjuvia) | 0.3-1.25 mg | 0.3-0.625 mg/day |
| Esterified estrogens (Menest) | 0.3-2.5 mg | 0.3-0.625 mg/day |
| Estradiol (Estrace[a]) | 0.5-2 mg | 0.5-1 mg/day |
| Estropipate (Ogen[a]) | 0.625-2.5 mg | 0.625 mg/day |
| **Transdermal estrogens** | | |
| Estradiol patch (Alora, Climara, Vivelle Dot) | 0.025-0.1 mg/24 hour | 0.025-0.05 mg, changed weekly (Climara) or changed twice weekly |
| (Minivelle) | 0.0375-0.1 mg/24 hour | Twice weekly |
| (Menostar[b]) | 14 mcg/24 hour | 14 mcg once weekly |
| Estradiol gel | | |
| (Elestrin, Estrogel Divigel) | 0.06% 0.1% | 0.87 g/day; 1.25 g/day 0.25, 0.5, 1 mg packets/day |
| Estradiol spray (Evamist) | 1.53 mg/actuation | Once daily |
| **Topical estrogens** | | |
| *Vaginal creams* | | |
| CEE (Premarin) | 0.625 mg/g | 0.5-2 g/day |
| Estradiol (Estrace) | 0.01% estradiol | 1 g one to three times/week |
| *Vaginal rings* | | |
| Estradiol (Estring; Femring) | 0.0075 mg/24 hour; 0.05-0.1 mg/24 hour | 1 ring every 3 months |
| *Vaginal tablet* | | |
| Estradiol (Vagifem) | 10 mcg estradiol | One tablet twice weekly |
| *Emulsions* | | |
| Estradiol (Estrasorb) | 0.25% | 3.84 g applied daily |
| **Progestogens[c,d]** | | |
| MPA (Provera) | 2.5-10 mg | |
| Micronized progesterone (Prometrium) Norethindrone acetate (Aygestin) | 100-200 mg 0.25-1 mg | |
| **Combination products** | | |
| *Oral* | | |
| CEE + MPA (Prempro; Premphase) | 0.3/1.5 mg-0.625/5 mg; | 0.3-0.625/2.5-5 mg/day |
| Conjugated estrogens + bazedoxifene (Duavee) | 0.625/5 mg 0.45 mg/20 mg | One tablet daily |
| Estradiol + norethindrone (Activella) | 0.5/0.1 mg-1/0.5 mg | One tablet daily |
| Estradiol + drospirenone (Angeliq) | 0.5/0.25 mg-1/0.5 mg | One tablet daily |
| Ethynyl estradiol + norethindrone (FemHRT) | 2.5 mcg/0.5 mg | One tablet daily |
| Estradiol + norgestimate (Prefest) | 1/0.09 mg | One tablet daily |
| Esterified estrogens + Methyltestosterone (Covaryx, Covaryx HS) | 1.25/2.5 mg; 0.625/1.25 mg | One tablet daily |
| *Transdermal* | | |
| Estradiol + norethindrone (Combipatch) | 0.05/0.14-0.05/0.25 mg/24 hour | Apply one patch twice weekly |
| Estradiol + levonorgestrel (Climara Pro) | 0.045/0.015 mg/24 hour | Apply one patch once weekly |

CEE, conjugated equine estrogens; MPA, medroxyprogesterone acetate.

[a]FDA-approved commercially available bioidentical product.

[b]Indicated for the prevention of postmenopausal osteoporosis only.

[c]May be administered cyclically or continuously.

[d]Dose varies based on daily or weekly administration.

Topical vaginal preparations generally should be prescribed as first-line therapy unless the patient is also experiencing vasomotor symptoms. Local vaginal estrogen has demonstrated increased efficacy over systemic estrogen and generally does not require supplementation with a progestogen in women with an intact uterus using low or ultralow doses.[5] Women using regular or high doses of topical estrogen products may require intermittent treatment with a progestogen. Although few data are available on the appropriate progestogen dose, some data indicate that 10 days every 12 weeks may be sufficient to prevent endometrial hyperplasia.[22] Estradiol in the form of a vaginal tablet or a ring is not significantly absorbed systemically and may be used safely in a woman with contraindications to estrogen therapy and symptoms of vulvovaginal atrophy.[5]

**Osteoporosis Prevention** Postmenopausal osteoporosis is a condition that affects millions of women. Fractures, particularly hip fractures, are associated with a high incidence of morbidity and mortality and decreased QOL. Before the WHI study, only observational data were available regarding the association of HT and the reduction of fractures. The WHI was the first RCT that

    Depression
*Serious adverse effects*
    Venous thromboembolism
    Decreased bone mineral density

---

demonstrated a reduction in total fractures, including the hip, spine, and wrist.[2,23]

**KEY CONCEPT** *Because HT should be maintained only for the short term, traditional therapies such as bisphosphonates should be considered as first-line therapy for the prevention of postmenopausal osteoporosis, in addition to appropriate doses of calcium and vitamin D.* Because of the associated risks, HT should not be prescribed solely for the prevention of osteoporosis.

### ► Risks of HT

**Cardiovascular Disease** CHD is the leading cause of death among women in the United States. Retrospective data indicated that HT was associated with a decrease in risk of CHD by 30% to 50%.[24] However, the results of RCTs demonstrate that HT does not prevent or treat CHD in women and that it actually may cause an increase in CHD events. The HERS was the first RCT conducted in women with established CHD. This trial demonstrated an increased incidence of CHD events within the first year of treatment with HT and an increased risk of VTE and gallbladder disease. There was a trend of decreasing incidence of CHD death in years 3 to 5 that prompted a discontinuation of the study.[1] A follow-up HERS II trial also showed no difference in CHD events after 2.7 years.[25] The WHI was the first RCT conducted in women without established CHD. Women aged 50 to 79 years with an intact uterus were assigned to receive HT (CEE 0.625 mg + MPA 2.5 mg) daily for 8.5 years. The trial was stopped after only 5.2 years owing to an increased incidence of invasive breast cancer in women taking HT compared with those taking placebo. The WHI demonstrated an increased risk of CHD with HT compared with placebo (approximately six more cases of CHD per 10,000 women years). There also was an increased risk of stroke with HT compared with placebo (approximately seven more cases of stroke per 10,000 women years).[26,27]

The estrogen-alone arm of the WHI, which included women aged 50 to 79 years with a history of hysterectomy, continued for

another 1.6 years (average follow-up 6.8 years). This arm of the study did not demonstrate an increased risk of CHD compared with placebo. However, there was an increased risk of stroke with estrogen-alone compared with placebo (approximately 12 more strokes for every 10,000 women treated per year with estrogen therapy).[24] Women who initiated HT 10 or more years after menopause tended to have an increased cardiovascular risk compared with women who initiated therapy within 10 years of menopause.[28,29]

These trials demonstrate that HT should not be prescribed for the prevention of CHD or in patients with preexisting CHD. It is important to note that the average age of women included in the HERS and the WHI trials was 67 and 63 years, respectively, and they started HT a mean of 10 years after menopause. Therefore, these trials were unable to assess the true risk in younger, potentially healthier women with fewer cardiovascular risk factors.[24]

**Breast Cancer** Breast cancer is the most common cancer in women in the United States. Observational data indicated an association between HT and breast cancer risk. The WHI was the first RCT to demonstrate an increased risk of invasive breast cancer among women taking HT. There were eight more cases of invasive breast cancer for every 10,000 women treated per year with HT.[2,30] The increase in risk did correlate with increased age of the women, and the risk appears to be greater in those who initiate therapy within 5 years of the start of menopause. These results are overall supported by results from a follow-up study of the WHI. During approximately 11 years of follow-up, there was a significant increase in invasive breast cancer cases with combination HT compared with placebo. There were also more deaths from breast cancer and deaths overall with combination therapy than with placebo.[31] It should be noted that any increase in risk for breast cancer appears to dissipate over 2 to 3 years after HT is discontinued.[5,32] Whether HT is associated with an increased risk for breast cancer recurrence is still questionable.

Breast cancer was not increased in the estrogen-alone arm of the WHI.[24] These data point to a possible link of progestogen with breast cancer risk. Whether or not the risk differs between continuous and sequential use of progestogens is questionable. Some evidence suggests that sequential use may be safer than taking progestogen each day.[5,33]

The Million Women Study, a prospective cohort study evaluating over one million women in the United Kingdom, demonstrated an increased risk of breast cancer and breast cancer mortality in women aged 50 to 64. Breast cancer risk increased in current users in both the estrogen and progestogen arm and the estrogen only arm of the study, and the risks increased with longer duration of use.[34]

Women with a personal history of breast cancer and possibly even a strong family history of breast cancer should avoid the use of HT and could consider alternative or nonhormonal therapies for the treatment of vasomotor symptoms.

**Venous Thromboembolism** The WHI demonstrated an increased risk for VTE with HT compared with placebo (approximately 18 more cases of venous thromboembolic events for every 10,000 women treated per year with HT).[2] The risk for deep vein thrombosis was also increased in the estrogen-alone arm of the WHI, but pulmonary embolism was not increased significantly.[24] The risk of thromboembolism may be dose related, and the oral route of administration is associated with a higher risk compared with the transdermal route.[14]

**KEY CONCEPT** *In summary, combined estrogen plus progestogen should not be used for the prevention of chronic diseases because it increases*

the risk of CHD, stroke, breast cancer, and VTE. However, rates of fracture were reduced with combined hormonal treatment.

▶ *Other Effects of HT*

**QOL and Cognition**  Although women generally consider QOL measures when deciding whether to use HT, the effects of HT on overall QOL have been inconsistent. HT did not demonstrate a clinically meaningful effect on QOL; however, women taking HT did have a small improvement in sleep disturbances, physical functioning, and bodily pain after 1 year of therapy.[35] Results from the HERS demonstrated that HT did improve emotional measures such as depressive symptoms, but only if women suffered from flushing at trial entry.[36]

Observational studies suggested a potential benefit of HT on cognitive functioning and dementia. However, the Women's Health Initiative Memory Study (WHIMS), conducted in postmenopausal women aged 65 years or older, failed to demonstrate an improvement in cognitive function and demonstrated a dementia rate, including Alzheimer disease, two times greater compared with placebo.[37,38] The estrogen-alone arm of the WHIMS also demonstrated similar results.[39,40]

KEY CONCEPT *HT improves overall well-being and mood in women with vasomotor symptoms, but it has not demonstrated an improvement in QOL in women without vasomotor symptoms.*

▶ *Discontinuation of HT*

KEY CONCEPT *When treating moderate to severe postmenopausal symptoms, the benefit-to-risk ratio appears to be best when HT is started close to the time of menopause. Therapy should be tapered before discontinuation in order to limit the recurrence of hot flashes.* Although vasomotor symptoms in most women will subside within 4 years, approximately 10% of women continue to experience symptoms that interfere with their QOL. Literature suggests that one of every four women needs to be reinitiated on HT due to persistent and bothersome symptoms.[41]

Limited evidence is available to guide health care providers regarding the least disruptive way to taper HT. Slowly discontinuing HT over 3 to 6 months may be associated with less risk of symptom return. Tapering HT may be done by a dose taper or day taper. The dose taper involves decreasing the dose of estrogen over several weeks to months and monitoring closely for symptom return. If symptoms recur, the next reduction in

---

**Patient Encounter, Part 4**

The patient has been in good health for the past 7 years. She reports adherence with her medications, a healthy diet and exercise routine, and her medical conditions are controlled. However, 1 month ago she was diagnosed with stage 2 breast cancer following a routine mammogram. She is concerned that her hormone therapy may have caused the breast cancer.

*Educate the patient regarding the risk of breast cancer and hormone therapy.*

---

dose should not occur until symptoms resolve or stabilize on the current dose. The day taper involves decreasing the number of days of the week that a woman takes the HT dose, for example, decreasing a daily dose of 0.3 mg estrogen to 0.3 mg estrogen 5 days a week. Again, if symptoms recur, continue on the current dose until symptoms resolve or stabilize before trying a subsequent decrease. These tapering regimens have not been studied in clinical trials and may not prove to be beneficial in individual women.[41]

▶ *Nonhormonal and Alternative Treatments*

KEY CONCEPT *Since publication of the WHI study, there has been an increase in the use of alternative and nonhormonal therapies for the management of menopausal symptoms, particularly for women with CHD and/or breast cancer risk factors. A wide range of therapies, both prescription and herbal, have been studied with limited success.*

A variety of nonhormonal and alternative therapies (**Table 50–3**) have been studied for symptomatic management of vasomotor symptoms.[42,43] The limited and often conflicting evidence demonstrates that these agents are only modestly effective and also have associated adverse effects. It should be noted that randomized, placebo-controlled trials of these alternative therapies have not established safety and efficacy for prevention or treatment of menopausal symptoms.

SSRIs and venlafaxine are theorized to reduce the frequency of hot flashes by increasing serotonin in the central nervous system and by decreasing LH. Of the SSRIs, paroxetine has the most published data demonstrating a reduction in hot flashes while treating other symptomatic complaints such as depression and anxiety.[45] Other SSRIs such as fluoxetine, citalopram, and sertraline may also be effective. These antidepressant medications offer a reasonable option for women who are unwilling to or cannot take hormonal therapies, particularly those who suffer from depression or anxiety.

Phytoestrogens are plant sterols that are structurally similar to human and animal estrogen. Soy protein is a common source of phytoestrogens.[42,43] There are differences among classes of phytoestrogens and biologic potencies vary, making it difficult to recommend specific dosing. The most commonly studied phytoestrogen is the isoflavone class. Because the effect of phytoestrogens on breast cancer and other female-related cancers is unknown, these products should not be considered in women with a history of estrogen-dependent cancers. After reviewing hundreds of studies, the North American Menopause Society (NAMS) determined that soy-based isoflavones are modestly effective in relieving menopausal symptoms.[46] The efficacy of

---

**Patient Encounter, Part 3: Creating a Care Plan**

*Based on the information presented, create a care plan for this patient's hot flashes and vaginal dryness. The plan should include:*

(a)  *A statement identifying the problem and its severity*

(b)  *Goals of therapy*

(c)  *A therapeutic plan based on individual patient-specific factors*

(d)  *Subjective and objective monitoring parameters*

(e)  *A follow-up evaluation to assess for adverse effects and adherence and to determine whether the goals of therapy have been achieved*

| Table 50–3 | | | | |
|---|---|---|---|---|
| **Nonhormonal Therapies for Menopause[42–48]** | | | | |
| **Drug** | **Brand Name** | **Initial Dose** | **Usual Dose Range** | **Comments** |
| Venlafaxine[a,b] | Effexor, Effexor XR | 37.5 mg | 37.5–150 mg/day | Potential adverse effects include nausea, HA, somnolence, dizziness, insomnia, hypertension, xerostomia constipation, diaphoresis, weakness |
| Paroxetine, Paroxetine CR | Brisdelle, Paxil, Paxil CR, Pexeva | 7.5–10 mg (12.5 mg CR) | 7.5–20 mg/day | Potential adverse effects include nausea, somnolence, insomnia, HA, dizziness, xerostomia, constipation, diarrhea, weakness, diaphoresis |
| Clonidine | Catapres, Catapres IIS, Kapvay | 0.1 mg/day | 0.1–0.4 mg/day | Potential adverse effects include drowsiness, dizziness, hypotension, dry mouth |
| Gabapentin[a] | Gralise, Neurontin | 300 mg at bedtime | 900 mg/day, divided in three daily doses (up to 2400 mg/day) | Potential adverse effects include somnolence and dizziness (can decrease with gradual increase in dosing) |
| Phytoestrogens (isoflavones) | | Products and dosages vary | 60–90 mg isoflavone | Best data of complementary treatments. Limited adverse effects |
| Black cohosh | | | | Long-term effects are unknown (concern of liver toxicity in long term). Should not be generally recommended for vasomotor symptoms |
| Dong quai, red clover leaf, kava | | | | Have not been shown to be effective and should generally not be recommended for vasomotor symptoms |

[a]Dosage adjustments recommended in patients with renal impairment.

[b]Dosage adjustment recommended in patients with hepatic impairment.

isoflavones on bone, cognitive improvement, and cardiovascular health has not been proven.

Black cohosh has been one of the most studied alternative therapies for vasomotor symptoms, but it has not demonstrated a substantial benefit over placebo. The mechanism of action, safety profile, drug–drug interactions, and adverse effects of black cohosh remain unknown. However, there have been case reports of hepatotoxicity with its use.[43,47] In non–placebo-controlled trials conducted for 6 months or less, black cohosh demonstrated small reductions in vasomotor symptoms.[42,43,45] Caution should be exercised when considering the use of this product, and it is not recommended for more than a 6-month period of time. Other alternative treatments that have been utilized include dong quai, red clover leaf, and kava. These have not been shown to be effective in the treatment of menopausal symptoms and may have significant adverse effects.[48]

Gabapentin and clonidine have also been studied for the management of menopausal symptoms. In RCTs, gabapentin at doses of 900 mg/day demonstrated significant reductions in severity and frequency of hot flashes compared with placebo. Clonidine has been studied in several small RCTs at doses of 0.1 to 0.4 mg/day and has demonstrated statistically significant reductions in hot flashes.[45] Overall, alternative and nonhormonal therapies are less effective in treating vasomotor symptoms than HT but do offer another option for women experiencing menopausal symptoms who cannot or are unwilling to take HT. SSRIs and phytoestrogens have the best evidence for efficacy. However, women should weigh the benefits and risks of all therapies, and discuss these options with their health care providers.

## OUTCOME EVALUATION

Evaluating the outcomes of any therapy for menopausal symptoms focuses primarily on the woman's report of symptom resolution.

Ask women to report the resolution or reduction of hot flashes, night sweats, and vaginal dryness and any improvement or change in sleep patterns. Also ask women taking hormonal therapies to report any breakthrough bleeding or spotting. If abnormal or heavy bleeding occurs, refer the woman to her primary care provider. Monitor subjective parameters such as adverse effects and adherence to the therapy regimen. In addition, monitor objective parameters, including blood pressure, at every outpatient visit; encourage yearly clinical breast examinations, mammograms, lipid panel, and thyroid-stimulating hormone (TSH) determination, particularly for women with hypothyroidism on thyroid therapy, and conduct a BMD test every 2 to 5 years as indicated. Also perform endometrial studies, as necessary, in women with undiagnosed vaginal bleeding. Lastly, evaluate the patient's overall QOL. Because the management of menopause is largely symptomatic, it is important to document symptoms at the beginning of therapy and monitor symptom improvement and potential adverse effects at each visit. Frequent follow-up, proper monitoring, and education will help to ensure that the woman achieves optimal results from any therapy chosen to treat menopausal symptoms.

## Patient Encounter, Part 5

It has been 6 months since this patient completed chemotherapy and radiation for breast cancer. She presents to her PCP for follow-up with a chief complaint of recurrent hot flashes. She also complains of recurrent vaginal dryness but denies insomnia.

*Recommend the most appropriate therapy for her recurrent hot flashes and vaginal dryness.*

## Patient Care Process

**Patient Assessment:**

- Obtain a thorough medication history, including the use of over-the-counter and herbal products.
- Rule out other medical conditions that could be contributing to symptoms and manage those conditions prior to initiating therapy for symptoms.
- Evaluate for the presence of vasomotor symptoms and document findings.

**Therapy Evaluation:**

- If the patient is experiencing bothersome vasomotor symptoms, consider the use of HT only after assessing for risk factors for heart disease and breast cancer.
- If vasomotor symptoms are tolerable and/or the patient has risk factors for heart disease and/or breast cancer, consider alternative, nonhormonal treatments for vasomotor symptoms.

**Care Plan Development:**

- Discuss lifestyle or behavioral interventions that may help to alleviate vasomotor symptoms.
- Discuss methods of HT administration, and decide in conjunction with the health care provider which one will work best for her.

- Recommend the appropriate dose of HT, and use the lowest effective dose for the shortest duration of time.
- Discuss proper administration, potential adverse effects, and expectations of HT.
- Discuss the importance of adhering to the medication regimen.

**Follow-Up Evaluation:**

- Monitor for a reduction in vasomotor symptoms, vaginal dryness, and improvement in sleep. Also monitor for breakthrough bleeding and spotting, adverse effects of HT, and improvement in QOL.
- Monitor the following objective parameters: blood pressure at every outpatient visit, yearly lipoprotein panels, yearly breast examinations and mammograms, yearly TSH determinations, and endometrial studies in women with undiagnosed vaginal bleeding.
- Assess symptoms every 6 to 12 months, and consider tapering the HT dose and discontinuing treatment after 5 years. If vasomotor symptoms return, determine whether a longer tapering schedule is warranted or if long-term treatment is necessary. If treatment beyond 5 years is necessary, consider switching to a nonhormonal product.

## Abbreviations Introduced in This Chapter

| | |
|---|---|
| BMD | Bone mineral density |
| CEE | Conjugated equine estrogen |
| CHD | Coronary heart disease |
| FDA | US Food and Drug Administration |
| FSH | Follicle-stimulating hormone |
| GnRH | Gonadotropin-releasing hormone |
| HDL | High-density lipoprotein |
| HERS | Heart and Estrogen/Progestin Replacement Study |
| HOPE | Women's Health, Osteoporosis, Progestin/Estrogen trial |
| HT | Hormone therapy |
| LDL | Low-density lipoprotein |
| LH | Luteinizing hormone |
| MPA | Medroxyprogesterone acetate |
| NAMS | North American Menopause Society |
| NNTH | Number needed to treat to harm |
| QOL | Quality of life |
| PCP | Primary care provider |
| RCT | Randomized controlled trial |
| SSRI | Selective serotonin reuptake inhibitor |
| TG | Triglycerides |
| TSH | Thyroid-stimulating hormone |
| VTE | Venous thromboembolism |
| WHI | Women's Health Initiative |
| WHIMS | Women's Health Initiative Memory Study |

# 51   Erectile Dysfunction

Cara Liday

## INTRODUCTION

**E**rectile dysfunction (ED) is defined as the persistent inability to achieve or maintain an erection sufficient for sexual intercourse. ED is the most prominent sexual problem in men, and it can lead to lower quality of life and self-esteem.[1] Patients may also develop **libido** or ejaculatory disorders, but these are not considered ED.

## EPIDEMIOLOGY AND ETIOLOGY

ED increases with age. Few men report erection problems before age 50, but ED increases to 20% to 40% in men aged 60 to 69 years and 50% to 100% in men older than 70 years.[2] The increase in incidence could be due to physiologic changes that occur with aging, the onset of chronic disease states associated with ED, increased medication use, lifestyle factors, or a combination of the above.

## PATHOPHYSIOLOGY

The penis consists of three components, two dorsolateral corpora cavernosa and a ventral corpus spongiosum that surrounds the penile urethra and distally forms the glans penis.

Sympathetic and parasympathetic nerves innervate the penis. In the flaccid state, arterial and corporal smooth muscles are tonically contracted, and a balance exists between blood flow into and out of the corpora. With sexual stimulation, nerve impulses from the brain travel down the spinal cord triggering a reduction in sympathetic tone and an increase in parasympathetic activity. This leads to an increased production of nitric oxide (NO). NO enhances the activity of guanylate cyclase, which results in increased production of cyclic guanosine monophosphate (cGMP). Vasoactive peptide and prostaglandins $E_1$ and $E_2$ stimulate increased production of cyclic adenosine monophosphate (cAMP). Both cAMP and cGMP reduce calcium concentrations within smooth muscle cells of the penile arteries and the sinusoidal spaces, leading to smooth muscle relaxation and increased blood flow. As the spaces become engorged, intracavernosal pressure increases, subtunical venules are compressed by the tunica albuginea, and the penis becomes rigid and elongated (**Figure 51–1**).

**Detumescence** occurs with sympathetic discharge after ejaculation. Sympathetic activity induces smooth muscle contraction of arterioles and vascular spaces leading to a reduction in blood inflow, decompression of the sinusoidal spaces, and enhanced outflow.

Testosterone also plays a significant albeit complex role in erectile function. In addition to stabilization of intracavernosal levels of NO synthase, the enzyme responsible for triggering the NO cascade, testosterone is responsible for much of a man's libido. Interestingly, some patients with low or borderline-low serum concentrations will have normal erectile function, whereas those with adequate levels may have dysfunction.

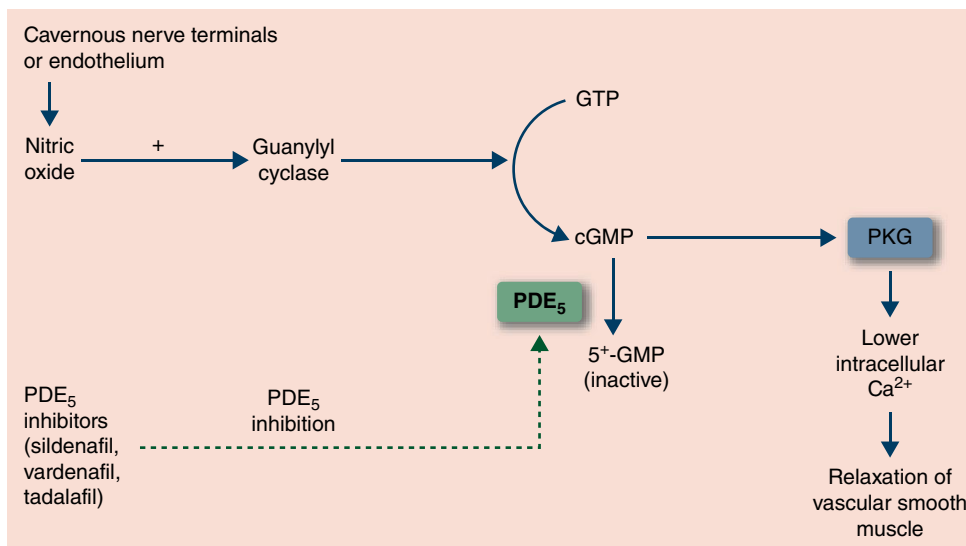
Normal penile erections are complex events that require the full function of the vascular, neurologic, hormonal and psychogenic systems. Anything that affects the function of these systems may lead to ED. **KEY CONCEPT** *ED can be classified as organic, psychogenic, or a mixture of these.* Organic dysfunction includes abnormalities in the vascular, hormonal, or neurologic systems or may be medication-induced (**Tables 51–1** and **51–2**). It is estimated that 25% of ED cases are due to medications.[5] Note that many of the risk factors for ED are the same as those for cardiovascular (CV) disease, including hypertension, diabetes, dyslipidemia, smoking, obesity, metabolic syndrome, and sedentary behavior.[4] In many patients, ED is the first indication of the endothelial dysfunction associated with CV disease, with two-thirds of patients with coronary artery disease having symptoms of ED before the onset of coronary symptoms.[5] The presence of ED risk factors


**FIGURE 51–1.** Mechanism of erection and sites of action of various treatment modalities for erectile dysfunction (ED). Penile erection is achieved through relaxation of smooth muscle cells lining arterial vessels and sinusoidal spaces in the corpora cavernosa, which leads to increased arterial inflow and pressure, decreased venous outflow, and increased intracavernosal pressure. Smooth muscle relaxation is mediated by intracellular generation of cyclic guanosine monophosphate (cGMP) from guanosine triphosphate (GTP) via activation of guanylate cyclase by nitric oxide. Treatment modalities for ED include oral phosphodiesterase type 5 (PDE-5) inhibitors, which inhibit the breakdown of cGMP, and local vasoactive agents. Nitric oxide–cGMP signaling in cavernous smooth muscle. (cGMP, cycle guanosine monophosphate; GTP, guanosine triphosphate; PDE$_5$, phosphodiesterase 5; PKG, protein kinase G.) (Reproduced, with permission, from Setter SM, Iltz JL, Fincham JE, Campbell RK, Baker DE. Phosphodiesterase 5 inhibitors for erectile dysfunction. Ann Pharmacother. 2005;39(7-8):1286–1295.)

leads to the assumption that the patient has organic dysfunction. Most commonly, medical conditions that impair arterial flow into or out of the erectile tissue or affect the innervation will be strongly associated with ED. Patients with diabetes mellitus have exceptionally high rates of ED as a result of vascular disease and neuropathy. Additionally, a relationship has been found between

---

**Table 51–1**

**Factors Associated with ED[1,4,11]**

**Chronic Medical Conditions**
Hypertension
Diabetes mellitus
BPH
Coronary and peripheral vascular disease
Neurologic disorders (eg, Parkinson disease and multiple sclerosis)
Endocrine disorders (hypogonadism, pituitary, adrenal, and thyroid disorders)
Psychiatric disorders
Dyslipidemia
Renal failure
Liver disease
Penile disease (Peyronie disease or anatomic abnormalities)

**Surgical Procedures**
Perineal or vascular surgeries
Radical prostatectomy

**Lifestyle**
Smoking
Excessive alcohol consumption
Obesity
Poor overall health and reduced physical activity

**Trauma**
Pelvic fractures or surgeries
Spinal cord or brain injuries

---

**Table 51–2**

**Medication Classes Associated with ED[3,4,5]**

**Antihypertensives**
β-Blockers (excluding nebivolol)
Thiazide diuretics
Centrally acting agents (clonidine, methyldopa, and reserpine)
Spironolactone
α-Blockers

**CNS Depressants**
Opioid analgesics
Benzodiazepines
Hypnotics

**Lipid Medications**
Gemfibrozil
HMG-CoA reductase inhibitors

**Antidepressants/Antipsychotics**
Tricyclic antidepressants
Monoamine oxidase inhibitors
Selective serotonin reuptake inhibitors/serotonin-norepinephrine reuptake inhibitors

**Anticonvulsants**
Carbamazepine
Phenytoin

**Gastrointestinal Agents**
Histamine 2-receptor antagonists
Proton pump inhibitors

**Antiandrogens and Hormones**
5α-Reductase inhibitors
Progesterone and estrogen
Corticosteroids

**Recreational Drugs**
Ethanol
Cocaine
Marijuana
Opiates

## Clinical Presentation and Diagnosis

**Possible Signs and Symptoms**

- Embarrassment
- Anxiousness
- Anger
- Marital difficulties
- Low self-confidence or morale; depression
- Full inability to achieve erections
- Ability to achieve partial erections, but not suitable for intercourse
- Erections sufficient for intercourse, but early detumescence
- The problem may have a slow or acute onset, or may wax and wane

**Diagnosis**

ED may be the presenting symptom of other chronic disease states.

The following should be performed to determine areas that can cause or exacerbate ED and to assess the patient's ability to safely perform intercourse.

- Medical history with emphasis on cardiovascular and psychiatric disorders, diabetes, trauma, and surgical procedures
- Social history including nutrition and history of smoking, recreational drug use, exercise, and alcohol consumption
- Medication history including prescription, nonprescription, and dietary supplements

**Physical Examination**

- Review for hypogonadism (gynecomastia, testicular atrophy, reduced body hair, increase in body fat)

- Digital rectal examination to determine whether prostate is enlarged
- Vital signs
- Abnormalities of the penis or impaired vasculature and nerve function to the penis

**Labs**

- Fasting glucose or $HbA_{1c}$
- Serum testosterone if signs of hypogonadism
- Fasting lipid panel
- Further cardiac testing if warranted

**Determine Severity**

- Use an abridged, five-item version of the International Index of Erectile Dysfunction (IIEF-5) as a diagnostic tool.[20]
- How do you rate your confidence that you could get and keep an erection?
- When you had erections with sexual stimulation, how often were your erections hard enough for penetration?
- During sexual intercourse, how often were you able to maintain your erection after you had penetrated (entered) your partner?
- During sexual intercourse, how difficult was it to maintain your erection to completion of intercourse?
- When you attempted sexual intercourse, how often was it satisfactory for you?
- Questions scored 1 to 5, very low to very high, respectively. Score of 21 or less indicates ED likely.

---

low testosterone levels and an increased incidence of metabolic syndrome and type 2 diabetes.[6]

Psychogenic dysfunction occurs if a patient does not respond to psychological arousal. Common causes include performance anxiety, strained relationships, lack of sexual arousability, and overt psychiatric disorders such as depression and schizophrenia.[7] **KEY CONCEPT** *Many patients may initially have organic dysfunction, but develop a psychogenic component as they try to cope with their inability to achieve an erection.*[1]

## CLINICAL PRESENTATION AND DIAGNOSIS OF ED

The introduction of oral medications and direct-to-consumer advertising has made patients feel more comfortable approaching practitioners for treatment advice. Despite this, some patients may only discuss their dysfunction when questioned directly by their provider or if their partner initiates the interaction.

## TREATMENT
### Desired Outcomes

ED is not a life-threatening condition, but if left untreated, it can be associated with depression, loss of self-esteem, poor self-image, and marital discord.[8] The primary goal of therapy is achievement of erections suitable for intercourse and improvement in patient and partner quality of life. Additionally, the ideal therapy should have minimal side effects, be convenient to administer, have a quick onset of action, and have few or no drug interactions.[9]

### General Approach to Treatment

**KEY CONCEPT** *Before initiating treatment for ED, a physical examination and thorough medical, social, and medication histories with emphasis on cardiac disease must be taken to assess for ability to safely perform sexual activity and to assess for possible drug interactions.* In patients with intermediate or high cardiovascular risk, additional testing should occur to determine whether sexual activity is safe.

**KEY CONCEPT** *Treatment options for ED include medical devices, pharmacologic treatments, lifestyle modifications, surgery, and psychotherapy. Reversible causes of ED should be identified first and treated appropriately.*

**KEY CONCEPT** *When determining the best treatment for an individual, the role of the clinician is to inform the patient and his partner of all available options while understanding his medical history, desires, and goals.* **KEY CONCEPT** *The choice of treatment is primarily left up to the couple, but most often treatment is initiated with the least invasive options such as oral phosphodiesterase (PDE) inhibitors and vacuum erection devices (VEDs).* Ultimately, the choice of therapy should be individualized, taking into account patient

and partner preferences, concomitant disease states, response, administration route, cost, tolerability, and safety. Common drug treatment regimens for ED are listed in Table 51–3.

▶ *Nonpharmacologic Therapy*

**Lifestyle Modifications** Lifestyle modifications should always be addressed in the management of ED. A healthy diet, increase in regular physical activity, and weight loss are associated with higher International Index of Erectile Function (IIEF) scores and an improvement in erectile function.[10] The clinician should also recommend smoking cessation, reduction in excessive alcohol intake, and discontinuation of illicit drug use.

**Psychotherapy** Psychotherapy is an appropriate treatment approach for patients with psychogenic or mixed dysfunction. Counseling may include simple sex education and improved partner communication in addition to cognitive and behavioral therapy.[1] Psychotherapy may help relieve anxiety and eliminate unrealistic expectations.[11] Effectiveness is not well documented for organic dysfunction unless combined with pharmacotherapy.

---

**Patient Encounter 1, Part 1**

A 68-year-old man with type 2 diabetes, hypertension, chronic kidney disease, and dyslipidemia returns to your clinic for follow-up on his chronic disease states. When reviewing his history, he describes problems with his erections as well as an increase in nocturnal urination and dribbling when voiding. After further questioning, you determine that his erectile dysfunction has progressively gotten worse over the last year. He is quite emotional and states that the problem is distressing and has caused significant marital discord. He wonders about "those ads on television" suggesting a pill.

*Based on the available information, how would you classify his erectile dysfunction (ED)?*

*What additional information do you need before establishing an appropriate treatment regimen and determining his ability to safely perform intercourse?*

---

**Table 51–3**

**Common Drug Treatment Regimens for ED**

| Route of Administration | Generic Name | Brand Name | Typical Dosing Range[a] | Maximum Dosing Frequency |
|---|---|---|---|---|
| Oral | Sildenafil | Viagra | 25–100 mg 1 hour prior to intercourse | Once daily |
| | Tadalafil | Cialis | 5–20 mg 30 minutes prior to intercourse or daily dose of 2.5–5 mg | Once daily |
| | Vardenafil | Levitra, Staxyn | 5–20 mg 1 hour prior to intercourse | Once daily |
| | Avanafil | Stendra | 100–200 mg 30 minutes prior to intercourse | Once daily |
| Intracavernosal | Alprostadil | Caverject, Caverject Impulse, Edex | 1.25–60 mcg 5–20 minutes prior to intercourse[b] | 3 times weekly, 24 hours between injections |
| Intraurethral | Alprostadil | MUSE | 125–1000 mcg 5–10 minutes prior to intercourse[b] | 2 times daily |
| **Testosterone Supplementation** | | | | |
| Intramuscular | Testosterone cypionate | Depo-Testosterone | 50–400 mg every 2–4 weeks | Once weekly |
| | Testosterone enanthate | Delatestryl | 50–400 mg every 2–4 weeks | Once weekly |
| Topical | Testosterone patch | Androderm | 2–4 mg/day applied to back, abdomen, upper arms, or thighs | Once daily |
| | Testosterone gel | AndroGel 1%, Testim, Vogelxo | 5–10 g gel per day (50–100 mg testosterone) to shoulders, upper arms, abdomen (AndroGel 1% only) | Once daily |
| | | AndroGel 1.62% | 40.5–81 mg/day to shoulders or upper arms | Once daily |
| | | Natesto | 11 mg every 8 hours (2 pump actuations, 1 per nostril) | 3 times daily |
| | | Fortesta | 10–70 mg/day to thigh | Once daily |
| | Testosterone solution | Axiron | 30–120 mg/day to axilla | Once daily |
| Buccal | Testosterone | Striant | 30 mg every 12 hours to gum region above incisor; rotate to alternate sides with each dose | 2 times daily |
| Subcutaneous implantable pellet | Testosterone | Testopel | 150–450 mg (150 mg for every 25 mg testosterone propionate required weekly) | Every 3–6 months |

MUSE, medicated urethral system for erection.

[a]Use the lowest effective dose to limit adverse effects.

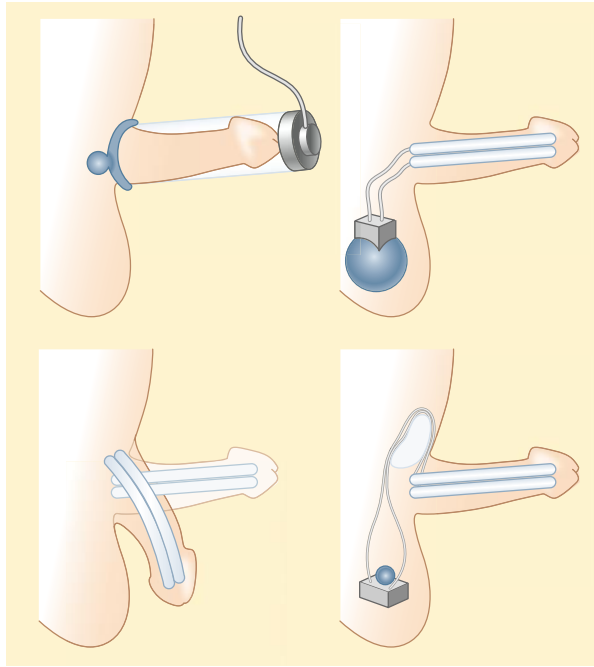
[b]Initial dose must be titrated in physician's office.


**FIGURE 51–2.** Available devices and prostheses used to treat ED. (From Wagner G, Saenz de Tejada I. Update on male erectile dysfunction. BMJ 1998;316:678–682.)

**Vacuum Erection Devices** Vacuum erection devices (VEDs) induce erections by creating a vacuum around the penis; the negative pressure draws blood into the penis by passively dilating arteries and engorging the corpora. The erection is maintained with a constriction band placed at the base of the penis to reduce venous outflow (**Figure 51–2**). VEDs may be used as often as desired, but it is recommended that the constriction band not be left in place longer than 30 minutes at a time.

Onset of action is slow, which limits spontaneity. In addition, patients and partners may complain of a cold, lifeless, discolored penis that has a hinge-like feel. Painful ejaculation or inability to ejaculate are additional adverse effects. VEDs are relatively contraindicated in persons with sickle cell disease and should be used with caution in those on oral anticoagulants or who have bleeding disorders due to the increased possibility of **priapism**.

VEDs are highly effective treatment modalities for ED and are considered a first- or second-line therapy. Efficacy rates are as high as 90% in obtaining an erection sufficient for **coitus**. Although satisfaction rates are as high as 94%, the discontinuation rate after 2 years is close to 50%.[12,13] A double pumping technique in which the vacuum is applied for a 1 to 2 minutes, removed, then reapplied for another 3 to 4 minutes may improve comfort levels and rigidity. Higher efficacy rates can also be achieved by combining VEDs with other therapies. VEDs are generally more acceptable to older patients in stable relationships and with infrequent sexual encounters.[13]

**Prostheses** Penile prostheses are semirigid malleable or inflatable rods, which are inserted surgically into the corpus cavernosa (see Figure 51–2). The malleable rods are rigid at all times, but may be bent into position by the patient when desired. The inflatable prostheses remain flaccid until the pump within the scrotum moves fluid from a reservoir to the cylinders within the penis. Detumescence is achieved when the fluid is then transferred back to the reservoir by activating a release button.

Patient satisfaction rates can be as high as 100%, with partner satisfaction rates slightly lower, but prostheses are the most invasive treatment available so are considered last-line therapy.[12] Infection occurs in 1% to 3% of first-time prostheses.[12] Semirigid malleable rods may interfere with urination, are difficult to conceal, and have a higher likelihood of erosion.[14]

▶ *Pharmacologic Therapy*

**Phosphodiesterase Type 5 Inhibitors** Avanafil, sildenafil, tadalafil, and vardenafil act by selectively inhibiting phosphodiesterase (PDE) type 5, which is responsible for degradation of cGMP. With prolonged cGMP activity, smooth muscle relaxation is induced, leading to an erection (see Figure 51–1). However, the PDE inhibitors are only effective in the presence of sexual stimulation to drive the NO/cGMP system, making them facilitators of an erection, not initiators.

**KEY CONCEPT** *Effectiveness of the four available PDE inhibitors is essentially comparable, but differences exist in onset, duration of action, absorption with a fatty meal and, to a small degree, incidence of side effects and drug interactions* (**Table 51–4**). Review of available data for each individual agent shows a 60% to 75% response rate depending on the dose of agent used and the etiology of dysfunction.[1,4,11] Response rates tend to be lower in patients with radical prostatectomy as well as those with diabetes, severe nerve damage, or severe vascular disease.[15] Although efficacy rates appear to be similar between agents, there are some data to suggest that continuation rates are higher and patient preference greater with tadalafil.[16] The PDE inhibitors are considered first-line therapies due to high efficacy rates, convenience of dosing, and minimal severe adverse effects.

The most dramatic difference among the four agents is tadalafil's extended duration of action (18 hours), earning it the nickname "the weekender drug." All are approved for as-needed dosing. Tadalafil has also been approved for use as a daily medication at a lower dose (2.5–5 mg) than the as-needed dose with similar efficacy.

The most common side effects experienced with PDE inhibitors include headache, facial flushing, nasal congestion, dyspepsia, myalgia, back pain, and, rarely, priapism. Vardenafil and sildenafil may also cause blurred vision, difficulty in discriminating blue from green, bluish tones in vision, or difficulty seeing in dim light due to cross-reactivity with PDE 6 in the retina. Labeling for all PDE inhibitors includes a warning about rare nonarteritic ischemic optic neuropathy (NAION) in which blood flow is blocked to the optic nerve. If patients experience sudden or decreased vision loss, they should call a health care provider immediately. PDE inhibitors have also been associated with acute hearing impairment although a causal relationship has not been established.[1]

Due to the coexistence of ED and coronary artery disease, a management approach was developed to give recommendations for the use of PDE inhibitors as well as to determine the safety of intercourse in patients with CV disease[17] (**Table 51–5**). In addition to the inherent risk of renewing sexual activity, PDE inhibitors can lead to significant hypotension. Patients taking organic nitrates are at highest risk, as these drugs potentiate the drop in blood pressure. All four PDE inhibitors are absolutely contraindicated in patients taking any form of nitrate, whether scheduled or sublingual for acute situations. Additionally, caution should be used when combining a PDE inhibitor with α-blockers. Vardenafil contains a precautionary statement about the possibility of QT prolongation. Drug interactions and cautions vary slightly between agents and are described in Table 51–4.

### Table 51–4

**Comparison of PDE Inhibitors**

| | Sildenafil (Viagra) | Tadalafil (Cialis) | Vardenafil (Levitra, Staxyn) | Avanafil (Stendra) |
|---|---|---|---|---|
| Available strengths | 25-, 50-, 100-mg tabs | 2.5-, 5-, 10-, 20-mg tabs | 2.5-, 5-, 10-, 20-mg tabs | 50, 100, 200 mg |
| Initial dosage in healthy adults | 50 mg up to once daily taken 1 hour prior to sexual activity | 10 mg up to once daily taken 30 minutes prior to sexual activity or 2.5 mg daily at the same time each day | 10 mg up to once daily taken 1 hour prior to sexual activity | 100 mg up to once daily taken 30 minutes prior to sexual activity |
| Dosing range for healthy adults | 25–100 mg | 5–20 mg | 5–20 mg | 50–200 mg |
| Dosage in the elderly | 25 mg | 5–10 mg | 5 mg | 50–100 mg |
| Dosage in renal impairment | 50 mg (moderate[a]) | 10 mg (moderate[a]) | 5–20 mg[c] | 50–200 mg[c] |
| | 25 mg (severe[b]) | 5 mg (severe[b]) | | |
| Dosage in hepatic impairment | 25 mg | 10 mg[c] | 5 mg[c] | 50–200 mg[c] |
| Time to onset | 30 minutes | 15 minutes | < 1 hour | 15 minutes |
| Onset delayed by high-fat meal? | Yes | No | Yes | No |
| Duration of effect | Up to 4 hours | Up to 36 hours | Up to 4 hours | Up to 4 hours |
| Half-life | 3–4 hours | 18 hours | 4–5 hours | 5 hours |
| Metabolism | CYP3A4 (major) | CYP3A4 | CYP3A4 (major) | CYP3A4 (major) |
| | CYP2C9 (minor) | | CYP3A5 (minor) | CYP2C9 (minor) |
| | | | CYP2C (minor) | |
| Clinically relevant drug interactions | Nitrates, protease inhibitors, azole antifungals, erythromycin | Nitrates, α₁-blockers[d], azole antifungals, erythromycin | Nitrates, antiarrhythmic agents[e], α₁-blockers[d], erythromycin | Nitrates, azole antifungals, erythromycin, α₁-blockers[d] grapefruit, protease inhibitors |

CYP, cytochrome P-450 isoenzyme.

[a]Moderate renal impairment = creatinine clearance (CrCl) 31 to 50 mL/min (0.51–0.83 mL/s).

[b]Severe renal impairment = CrCl less than 30 mL/min (0.50 mL/s).

[c]Mild to moderate only—contraindicated in severe disease.

[d]Selective α₁-blockers (such as alfuzosin, silodosin, and tamsulosin) are appropriate in combination. If nonselective, initiate with lowest dose possible.

[e]Vardenafil can cause QT-interval prolongation; this effect in combination with certain antiarrhythmic agents can lead to life-threatening arrhythmias.

Up to a third of patients will not respond to therapy with PDE inhibitors. To achieve the greatest effect, patients must be fully informed of onset and duration of effect, impact of high-fat meals, the need for sexual stimulation, and explanation that a single trial is not adequate are all necessary counseling points. It is estimated that six to eight attempts with a medication and specific dose may be needed before successful intercourse results.[4]

**Alprostadil** Alprostadil is a prostaglandin E₁ analog that induces an erection by stimulating adenyl cyclase, leading to increased cAMP, smooth muscle relaxation, rapid arterial inflow, and increased penile rigidity. Alprostadil is available as an intracavernosal injection (Caverject or Edex) or a transurethral suppository (MUSE, medicated urethral system for erection), with the injectable dose showing greater efficacy (**Figure 51–3**).[4,5] Both forms of alprostadil are considered more invasive than oral medications or VEDs and are therefore second-line therapies.

MUSE consists of a urethral pellet of alprostadil with an applicator. Onset of action is within 5 to 10 minutes and it is effective for 30 to 60 minutes. Initial dose titration should occur in a physician's office to ensure correct dose and prevent adverse events. Success rates in clinical trials are between 43% and 69%, but typical use has resulted in less successful results in postmarketing studies.[12,18] Aching in the penis, testicles, legs, and perineum; warmth or burning sensation in the urethra, minor urethral bleeding or spotting, priapism, and light-headedness are all possible adverse effects. In addition, partners may experience burning or itching, and use is contraindicated with a pregnant partner unless using a condom.

Intraurethral alprostadil injection is the more effective route and is the only FDA-approved injection for ED. The onset of action is similar to transurethral alprostadil, but duration varies with dose and must be titrated in a physician's office to achieve an erection lasting no more than 1 hour. Injections should be performed into one side directly into the corpus cavernosum, and then the penis should be massaged to distribute the drug to both corpora. Education is extremely important with intracavernosal injections. Patients must be adequately informed of technique, expectations, side effects, and when to seek help. Intracavernosal injections are effective in up to 80% of patients, but side effects, lack of spontaneity, and fear of needles limit their

**Table 51–5**

**Recommendations of the Second Princeton Consensus Conference for Cardiovascular Risk Stratification of Patients Being Considered for PDE Inhibitor Therapy**

| Risk Category | Description of Patients' Conditions | Management Approach |
|---|---|---|
| Low risk | Has asymptomatic CV disease with less than three risk factors for CV disease | Patient can be started on PDE inhibitor |
| | Has well-controlled hypertension | |
| | Has mild, stable angina | |
| | Has mild congestive heart failure (NYHA Class I) | |
| | Has mild valvular heart disease | |
| | Had a myocardial infarction more than 8 weeks ago | |
| Intermediate risk | Has three or more risk factors for CV disease | Patient should undergo complete CV workup and treadmill stress test to determine tolerance to increased myocardial energy consumption associated with increased sexual activity. Reclassify in low or high risk category |
| | Has mild or moderate, stable angina | |
| | Had a recent myocardial infarction or stroke within the past 2–8 weeks | |
| | Has moderate congestive heart failure (NYHA Class III) | |
| | History of stroke, transient ischemic attack, or peripheral artery disease | |
| High risk | Has unstable or refractory angina, despite treatment | PDE inhibitor is contraindicated; sexual intercourse should be deferred |
| | Has uncontrolled hypertension | |
| | Has severe congestive heart failure (NYHA Class IV) | |
| | Had a recent myocardial infarction or stroke within the past 2 weeks | |
| | Has moderate or severe valvular heart disease | |
| | Has high-risk cardiac arrhythmias | |
| | Has obstructive hypertrophic cardiomyopathy | |

## Patient Encounter 1, Part 2

**PMH:** Type 2 diabetes for 15 years; not controlled due to his stressful profession; he often works late, eats on the run, and has no time for exercise. Chronic kidney disease stage 3. Hypertension for 8 years, currently controlled. Dyslipidemia for 8 years, currently controlled

**SH:** Works long hours as a business executive; drinks alcohol only occasionally; has a 20-pack per year smoking history

**Meds:** Metformin 1000 mg orally twice daily; metoprolol XL 50 mg orally once daily; hydrochlorothiazide 25 mg once daily; simvastatin 40 mg orally once daily

**ROS:** (−) Morning, nocturnal, or spontaneous erections suitable for intercourse; (+) nocturia, urgency, incomplete bladder emptying, dribbling; (−) symptoms of prostatitis; (−) chest pain or anginal symptoms; (+) significant life stressors; (+) mild pain in feet

**PE:**

**VS:** BP 135/78, P 85, RR 18, Wt 249 lb (113 kg), Ht 70 in (178 cm)

**CV:** Normal examination

Genital/Rectal: Normal scrotum and testicles w/o masses; penis without discharge or curvature; DRE reveals enlarged prostate

**Labs:** lipid panel: total cholesterol, LDL, HDL, triglycerides at goal; HbA$_{1c}$ 8% (0.08; 64 mmol/mol Hgb), total testosterone 700 ng/dL (24 nmol/L), PSA 1.2 ng/ml (1.2 mcg/L), BUN 25 mg/dL (8.9 mmol/L); SCr 1.7 mg/dL (150 μmol/L)

*Given this additional information, what are his risk factors for ED?*

*Identify treatment goals for this patient.*

*Perform a cardiovascular risk assessment to determine risk.*

*What pharmacologic and nonpharmacologic alternatives are available for this patient?*

*Which of the available options will be your treatments of choice based on concomitant disease states and medications, degree of invasiveness, side effects, ease of use, and side-effect profile?*

*What are the safety and efficacy monitoring parameters for the chosen treatment?*
**FIGURE 51–3.** Intraurethral and intracavernosal administration of alprostadil. (From Wagner G, Saenz de Tejada I. Update on male erectile dysfunction. BMJ 1998;316:678–682.)

widespread use as first-line therapy, and therefore this therapy is most appropriate for patients in long-term stable relationships.[1,4] Adverse effects include pain with injection, bleeding or bruising at the injection site, fibrosis, or priapism. Use with caution in patients with sickle cell disease, those on anticoagulants, or those who have bleeding disorders, due to an increased risk of priapism and bleeding.

**Testosterone Supplementation** `KEY CONCEPT` *Androgens are important for general sexual function and libido, but testosterone supplementation is only indicated in patients with documented low serum testosterone levels.* In patients with **hypogonadism**, testosterone replacement is the initial treatment of choice, as it corrects decreased libido, fatigue, muscle loss, sleep disturbances, and depressed mood. However, testosterone is contraindicated in patients with prostate cancer, erythrocytosis, uncontrolled heart failure or sleep apnea.

Testosterone supplementation may improve ED symptoms, but is not universally effective. Initial supplementation should occur for 3 months with reevaluation and the addition of an another ED therapy if needed at that time. Dosage forms include intramuscular, an implanted pellet, topical patches or gel, and a buccal tablet.

Injectable testosterone cypionate and enanthate offer the most inexpensive replacement option. There are several drawbacks

associated with parenteral testosterone, including the need to administer deep intramuscular injections every 2 to 4 weeks. Concentrations of hormone are well above physiologic values within the first few days, and then decline and eventually dip below physiologic levels prior to the next dose. These changes in concentration may lead to mood swings and a reduced sense of well-being.[19] Implantable subcutaneous testosterone pellets are a longer-acting and convenient alternative which are placed every 3 to 6 months.

Treatment with topical products is attractive to patients due to convenience, but they tend to be more expensive than the injections. Testosterone patches and gels are administered daily and result in serum levels within the physiologic range during the 24-hour dosing period.[19] Care must be taken with the use of the gel to prevent transfer of testosterone to children and females by washing hands thoroughly, allowing the site to dry, and covering immediately. Newer formulations for the axilla and thigh may reduce this risk. The most common side effects of topical testosterone are dermatologic reactions.

Oral testosterone products are also available for supplementation. Unfortunately, testosterone has poor oral bioavailability and undergoes extensive first-pass metabolism. Alkylated derivatives such as methyltestosterone and fluoxymesterone have been formulated, but this modification makes them considerably more hepatotoxic and therefore undesirable.

An alternative to the oral route is the buccal mucoadhesive system. This system adheres to the inside of the mouth and testosterone is absorbed through the oral mucosa and delivered to the systemic circulation with no first-pass effect. Side effects unique to this dosage form include oral irritation, bitter taste, and gum edema.

General side effects of testosterone include gynecomastia, dyslipidemia, polycythemia, and acne. Weight gain, hypertension, edema, and exacerbations of heart failure also occur due to sodium retention. Before initiating testosterone,

---

**Patient Encounter 2**

A 62-year-old man with a history of hypertension, prostatectomy 1 year ago, and recent diagnosis of ED. When in the office for a routine follow-up, he states the pill recently prescribed for his ED is not "doing the trick" so he has not been using it. He also complains that he is tired all the time, does not have much of a libido anymore, and is gaining weight.

**Meds:** losartan/hydrochlorothiazide 50/25 mg orally once daily, vardenafil 5 mg orally as needed

**ROS:** (–) Morning, nocturnal, or spontaneous erections suitable for intercourse; (–) nocturia, or urgency

**PE:**

**VS:** BP 132/74, P 82, Wt 214 lb (97 kg), Ht 75 in (191 cm)

**Labs:** Lipid panel, complete metabolic panel within normal limits

*Based on the information provided, what is your assessment of the patient's ED?*

*What should be recommended as the next step in treatment of his ED?*

## Patient Care Process

**Patient Assessment:**

- Assess the patient's specific symptoms to determine the type of dysfunction.
- Ask specific questions related to onset and frequency of dysfunction, and status of sexual relationships and assess severity with the IIEF-5 questionnaire.
- Perform complete histories, physical examination and laboratory tests (see Tables 51–1 and 51–2).
- Assess cardiovascular risk (see Table 51–5).

**Therapy Evaluation:**

- PDE inhibitors are first-line treatment unless contraindicated, not tolerated, or ineffective.
- If patient already receiving treatment, assess efficacy, safety, and patient adherence.

**Care Plan Development:**

- If possible, discontinue medications that may cause or worsen ED.

- Initiate PDE inhibitor or patient treatment of choice and provide education regarding:
  - ED
  - Lifestyle
  - Treatment of associated disease states
  - Drug therapy—mechanisms of action and adverse effects
  - Device technique

**Follow-up Evaluation:**

- Follow-up in 4 to 6 weeks or more frequently to assess effectiveness and safety of therapy including specific warning signs (eg, vision changes, fibrosis, pain, priapism, or hypotension).
- Reeducate on lifestyle, associated disease states, expectations, and methods for increasing efficacy with therapy.
- Increase dosage, switch to alternate therapy, or add alternate therapy if needed.

---

the patient should undergo evaluation for benign prostatic hypertrophy and prostate cancer. Routine follow-up includes yearly prostate-specific antigen, digital rectal examination, and hemoglobin and liver function, in addition to assessment of response.

## OUTCOME EVALUATION

Successful therapy for ED results in an increase in erections suitable for intercourse and, most importantly, in an improvement in the patient's quality of life. Ideally, the therapy chosen is free of significant adverse effects, discomfort, and inconvenience. Laboratory evaluation and a physical examination are not necessary for evaluation of effectiveness but may be necessary for adverse event monitoring.

Evaluate satisfaction and effectiveness after a 4-week trial. Some therapies will require multiple visits over the long term to determine the correct dose and to detect adverse effects. If the initial therapy is not effective, the patient must be further evaluated to determine whether the initial assessment of comorbid disease states, type of dysfunction, and patient goals were appropriate. After providing further education and determination of realistic goals, providers may then increase the dose of medication, switch to another therapy, or add a therapy if indicated.

## Abbreviations Introduced in This Chapter

| | |
|---|---|
| cAMP | Cyclic adenosine monophosphate |
| cGMP | Cyclic guanosine monophosphate |

# Benign Prostatic Hyperplasia

Mary Lee and Roohollah Sharifi

## LEARNING OBJECTIVES

● **Upon completion of the chapter, the reader will be able to:**

1. Explain the pathophysiologic mechanisms underlying the symptoms and signs of benign prostatic hyperplasia (BPH).

2. Recognize the symptoms and signs of BPH in individual patients.

3. List the desired treatment outcomes for a patient with BPH.

4. Identify factors that guide selection of a particular α-adrenergic antagonist for an individual patient.

5. Compare and contrast α-adrenergic antagonists versus 5α-reductase inhibitors in terms of mechanism of action, treatment outcomes, adverse effects, and interactions when used for management of BPH.

6. Describe the indications, advantages, and disadvantages of various combination drug regimens for BPH that include an α-adrenergic antagonist, 5α-reductase inhibitor, anticholinergic agent, tadalafil, or mirabegron.

7. Describe the indications for surgical intervention of BPH.

8. Formulate a monitoring plan for a patient on a given drug treatment regimen based on patient-specific information.

9. Formulate appropriate counseling information for patients receiving drug treatment for BPH.

## INTRODUCTION

The prostate is an organ, which is of the shape and size of a horse chestnut, that encircles the portion of the proximal posterior urethra that is located at the base of the urinary bladder. The prostate produces secretions, which are part of the ejaculate.

Benign prostatic hyperplasia (BPH) is the most common benign neoplasm in males who are at least 40 years of age. BPH can produce lower urinary tract symptoms (LUTS) that are consistent with impaired emptying of urine from and defective storage of urine in the bladder. Medications are a common mode of treatment to reduce symptoms and/or delay complications of BPH. For this reason, clinicians should be knowledgeable about the medical management of this disease.

## EPIDEMIOLOGY AND ETIOLOGY

BPH is present as histologic disease in many elderly males. The prevalence increases with advancing patient age. However, of patients with microscopic BPH disease, only about 50% of patients develop an enlarged prostate on digital palpation and 25% of patients exhibit clinical voiding symptoms.[1,2] It is estimated that 8% of males 40 years of age, increasing to 35% of men 60 to 69 years of age, have voiding symptoms consistent with BPH, and 20% to 30% of all male patients who live to the age of 80 years will require a **prostatectomy** for severe voiding symptoms of BPH.[2]

Two chief etiologic factors for BPH include advanced patient age and the stimulatory effect of androgens.

• Prior to 40 years of age, the prostate in the adult male stays the same size, approximately 15 to 20 g. However, in males who have reached 40 years of age, the prostate undergoes a growth spurt, which continues as the male advances in age. Enlargement of the prostate can result in clinically symptomatic BPH.

• The testes and adrenal glands produce 90% and 10%, respectively, of circulating testosterone. Testosterone enters prostate cells, where predominantly Type II 5α-reductase converts testosterone to dihydrotestosterone, which combines with a cytoplasmic receptor. The complex enters the nucleus and induces changes in protein synthesis that promote glandular tissue growth of the prostate. Thus 5α-reductase inhibitors (eg, finasteride and dutasteride) directly interfere with one of the major etiologic factors of BPH.

• The prostate is composed of two types of tissue: (a) glandular or epithelial tissue, which produces prostatic secretions, including prostate-specific antigen (PSA), and (b) muscle or stromal tissue, which can contract around the urethra and bladder outlet when stimulated. Whereas androgens stimulate glandular tissue growth, androgens have no direct effect on stromal tissue. Stromal tissue growth may be stimulated by estrogen. Because testosterone is converted to estrogen in peripheral tissues in males, testosterone may be

associated indirectly with stromal hyperplasia. Stromal tissue is innervated by $\alpha_{1A}$-receptors. When stimulated, prostatic stroma contracts around the urethra, narrowing the urethra and causing obstructive voiding symptoms.

## PATHOPHYSIOLOGY

**KEY CONCEPT** *LUTS and signs of BPH are due to static, dynamic, and/or detrusor factors.* The static factor refers to anatomic obstruction of the bladder neck caused by an enlarged prostate gland. As the gland grows around the urethra, the prostate occludes the urethral lumen. The dynamic factor refers to excessive stimulation of $\alpha_{1A}$-adrenergic receptors in the smooth muscle of the prostate, urethra, and bladder neck, which results in smooth muscle contraction. This reduces the caliber of the urethral lumen. The detrusor factor refers to bladder detrusor muscle hypertrophy in response to prolonged bladder outlet obstruction. To further explain, detrusor muscle fibers undergo hypertrophy so that the bladder can generate higher pressure to overcome bladder outlet obstruction and empty urine from the bladder. The hypertrophic detrusor muscle becomes irritable, contracting abnormally in response to small amounts of urine in the bladder. If obstruction is not treated, the bladder muscle will decompensate and be unable to empty completely; the postvoid residual urine volume (PVR) will increase.

In an enlarged gland, the epithelial/stromal tissue ratio is 1:5.[3] Androgens stimulate epithelial, but not stromal tissue hyperplasia. Hence, androgen antagonism does not induce a complete reduction in prostate size to normal. This explains one of the limitations of the clinical effect of 5$\alpha$-reductase inhibitors.

Stromal tissue is the primary locus of $\alpha_1$-adrenergic receptors in the prostate. An estimated 98% of the $\alpha$-adrenergic receptors in the prostate are found in prostatic stromal tissue. Of the $\alpha_1$-receptors found in the prostate, 70% of them are of the $\alpha_{1A}$-subtype and the remainder are of the $\alpha_{1B}$ and $\alpha_{1D}$ subtypes.[4] This explains why $\alpha$-adrenergic antagonists are effective for managing symptoms of BPH.

Symptoms of BPH are classified as obstructive or irritative. Obstructive symptoms result from failure of the urinary bladder to empty urine when the bladder is full. The patient will complain of a decreased force of the urinary stream, urinary hesitation, dribbling, intermittency, a sensation that the bladder is not empty even after voiding, and straining to empty the bladder. Irritative symptoms, including urinary frequency, nocturia, and urgency, result from the failure of the urinary bladder to store urine until the bladder is full.[1] The natural history of untreated BPH is unclear in patients with mild symptoms. It is estimated that up to 38% of untreated men with mild symptoms will have symptom improvement over a 2.5- to 5-year period.[5] It may be that such patients attribute their symptoms to aging, grow tolerant of their symptoms, or adopt behavioral changes in their lifestyle that minimize their voiding symptoms. On the other hand, a significant portion of patients with mild symptoms will likely experience disease progression. Patients with moderate to severe symptoms can experience a decreased quality of life as daily activities are adjusted because of lower urinary tract voiding symptoms. Also, such patients may develop complications of BPH, which include acute refractory urinary retention, renal failure, urinary tract infection, urinary incontinence, bladder stones, large bladder diverticuli, and recurrent gross hematuria. Predictors of disease progression include an enlarged prostate of at least 30 g (1.05 oz) or PSA of 1.4 ng/mL (1.4 mcg/L) or

---

### Patient Encounter 1

A 65-year-old man with an AUA Symptom Score of 7, urinary hesitancy, a slow urinary stream, urinary frequency, and nocturia present to clinic. He wakes up two times every night to void. A DRE reveals a prostate of 25 g (0.9 oz). His PSA is 1.4 ng/mL (1.4 mcg/L). A urinary flow rate is 10 mL/s and PVR is 0 mL.

*What stage of BPH does this patient have?*

*How should the patient be managed?*

---

greater.[6,7] Finally, erectile dysfunction commonly develops in patients with BPH. Effective treatment of BPH symptoms often improves sexual function without initiating specific treatment for erectile dysfunction.[8]

## TREATMENT

### Desired Outcomes[6,7]

- **KEY CONCEPT** *Reducing or eliminating obstructive and irritative voiding symptoms.* Drug treatment with an $\alpha$-adrenergic antagonist or 5$\alpha$-reductase inhibitor is expected to decrease the American Urological Association (AUA) Symptom Score by 30% to 50% (or at least by three or more points), improve peak and mean urinary flow rate by 1 to 3 mL/s, and decrease postvoid residual urine volume (PVR) to normal (less than 50 mL total) when compared with pretreatment baseline values. The AUA Symptom Score may not correlate with response to therapy.

- Slowing disease progression. When compared with baseline, symptoms and serum blood urea nitrogen (BUN) and creatinine should improve, stabilize, or decrease to the normal range with treatment.

- Preventing disease complications and reducing the need for surgical intervention.

- Avoiding or minimizing adverse treatment effects.

- Providing economical therapy.

- Maintaining or improving quality of life.

### General Approach to Treatment

Until recently, the principal approach to treatment focused on reducing BPH symptoms (**Figure 52–1**, **Tables 52–1**, **52–2**, and **52–3**). However, treatment should also slow disease progression and decrease complications of BPH.[9]

**KEY CONCEPT** *For patients with mild symptoms (AUA Symptom Score of 7 or less) that the patient does not consider to be bothersome, watchful waiting is a reasonable approach to treatment.* The patient is instructed to schedule return visits to the clinician every 6 to 12 months. At each visit, the patient's symptoms are reassessed using the AUA Symptom Scoring Index, and results are compared with baseline (see Table 52–1). In addition, the patient is educated about implementing nonpharmacologic measures to reduce voiding symptoms (see section on Nonpharmacologic Therapy) and avoiding factors that worsen obstructive and irritative voiding symptoms (**Table 52–4**). The digital rectal examination (DRE) is repeated annually. If the patient's symptoms are unchanged, then watchful waiting is continued. If the patient's symptoms worsen, then specific treatment is initiated.[7] Watchful waiting is effective in approximately 65% of patients after 5 years.[9]

## Clinical Presentation and Diagnosis of BPH

### General

Patients may or may not be in acute distress. In early stages of disease, the patient may complain of obstructive voiding symptoms. If untreated, the disease may progress and the patient may complain of irritative voiding symptoms or acute urinary retention, which is painful due to maximal distention of the urinary bladder. Also, the patient may be symptomatic of disease complications, including urosepsis, pyelonephritis, cystitis, or overflow urinary incontinence.

### Symptoms

Patients may complain of obstructive voiding symptoms (eg, urinary hesitancy, decreased force of urinary stream, straining to void, incomplete bladder emptying, dribbling, and intermittency) and/or irritative voiding symptoms (eg, urinary frequency, nocturia, and urgency). Severity of symptoms should be assessed by the patient using a standardized instrument (eg, the American Urological Association [AUA] Symptom Scoring Index; Table 52–1). However, it is important to recognize that a patient's perception of the bothersomeness of his voiding symptoms may not match with the AUA Symptom Score. In this case, after thorough evaluation of the signs and complications of BPH disease, if present, the physician and patient should discuss the bothersomeness of the patient's symptoms and decide together on the most appropriate course of treatment for the patient.[1,7] Lower urinary tract symptoms (LUTS) is a term that refers to the collection of obstructive and irritative voiding symptoms characteristic of, but not specific for, BPH. That is, other urologic diseases (eg, urinary tract infection, prostate cancer, prostatitis, or neurogenic bladder) can also cause LUTS.

### Signs

- Enlarged prostate on digital rectal examination (DRE); check for prostate nodules or induration, which would suggest prostate cancer instead of BPH as the cause of the patient's voiding symptoms
- Distended urinary bladder
- Rule out **meatal stenosis** or urethral stricture, which could cause voiding symptoms similar to LUTS
- Check anal sphincter tone as an indirect assessment of peripheral innervation to the detrusor muscle of the bladder

### Complications of Untreated BPH

Upper and lower urinary tract infection, urosepsis, urinary incontinence refractory urinary retention, chronic renal failure, bladder diverticula, bladder stones, or recurrent gross hematuria.

### Medical History

- Check the patient's general health, including previous surgery, presence of diabetes mellitus, or medications that may cause or worsen voiding symptoms.
- Have the patient provide a diary of his voiding pattern for the past week: date and time of each voiding, volume voided, and whether or not the patient had urinary leakage during the day.

### Laboratory Tests

- Serum PSA: The combination of PSA and DRE of the prostate can be used to screen for prostate cancer, which could also cause an enlarged prostate. Also, PSA is a surrogate marker for an enlarged prostate due to BPH. A PSA greater than 1.5 ng/mL (1.5 mcg/L) suggests that a patient has a prostate volume greater than 30 cm$^3$ (30 g or 1.05 oz).[7]
- Urinalysis to rule out infection as a cause of the patient's voiding symptoms; also check urinalysis for microscopic hematuria, which typically accompanies BPH.
- Plasma blood urea nitrogen (BUN) and serum creatinine may be increased as a result of long-standing bladder outlet obstruction. These tests are not routinely performed but rather are reserved for those patients in whom renal dysfunction is suspected.

### Other Diagnostic Tests (Table 52–2)

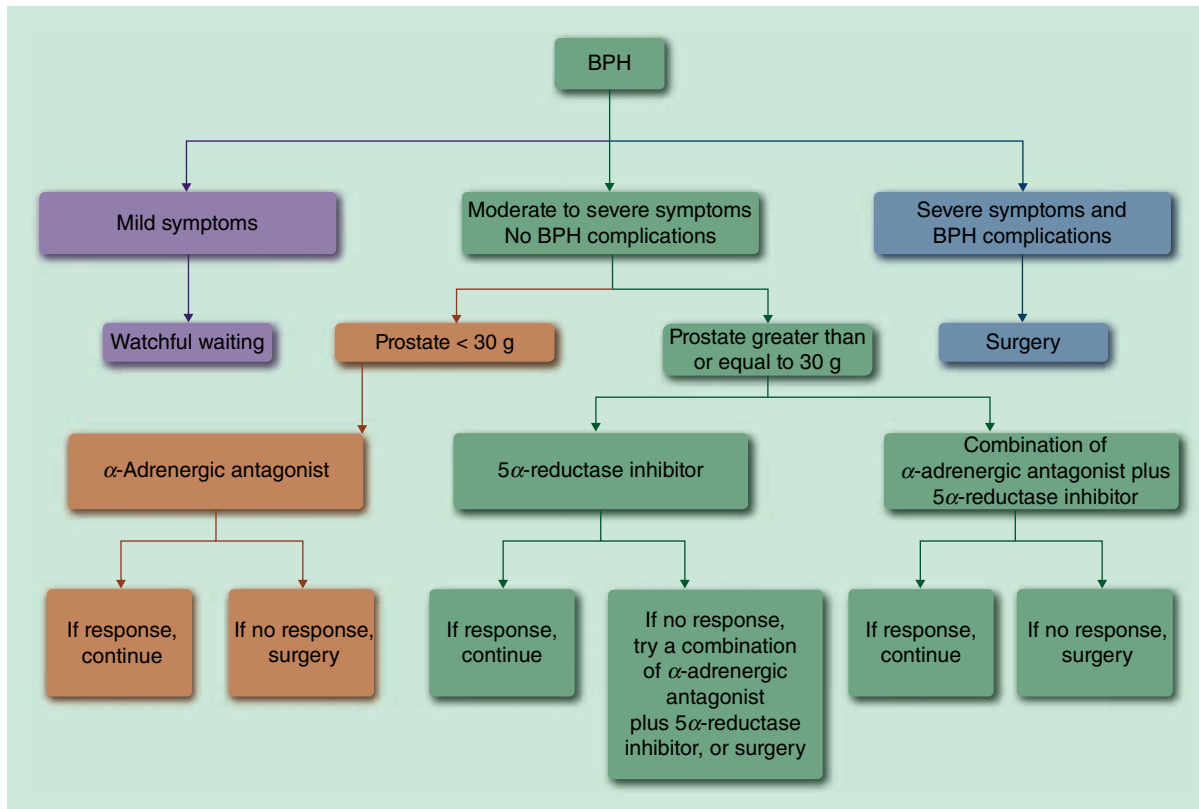
- Decreased peak and mean urinary flow rate (less than 10–15 mL/s) on uroflowmetry; decreased urinary flow rate is not specific for BPH; it can also be due to other urologic disorders (eg, urethral stricture, meatal stenosis, or **bladder hypotonicity**).
- Increased postvoid residual urine volume (PVR) (greater than 50 mL)
- DRE to check for an enlarged prostate (greater than 15–20 g [0.5–0.7 oz]).
- A focused neurological examination to check the integrity of innervation to the urinary bladder (that is responsible for bladder emptying).
- Transurethral cystoscopy reveals an enlarged prostate, which decreases urethral lumen caliber; information from this procedure helps the surgeon decide on the best surgical approach.
- Transrectal ultrasound of the prostate; a transrectal probe is inserted to evaluate prostate size and best surgical approach.
- Transrectal prostate needle biopsy to be done if the patient has areas of nodularity or induration on DRE; tissue biopsy can document the presence of prostate cancer, which can also cause enlargement of the prostate.
- IV pyelogram (IVP) will show retention of radiocontrast in the bladder if the patient has bladder outlet obstruction due to an enlarged prostate; this is only indicated in patients with recurrent hematuria, recurrent urinary tract infection, renal insufficiency, and urolithiasis.
- Filling cystometry provides information on bladder capacity, detrusor contractility, and the presence of uninhibited bladder contractions, which could also cause LUTS.


**FIGURE 52–1.** Algorithm for selection of treatment for BPH based on symptom severity and presence of disease complications.

---

**Table 52–1**

**Questions to Determine the AUA Symptom Score**

**Directions for the patient:** The patient should be asked to respond to each question based on the absence or presence of symptoms over the past month. For each question, the patient can respond using a 1–5 scale, where 0 = not at all or none; 1 = less than 1 time in 5; 2 = less than half of the time; 3 = about half of the time; 4 = more than half of the time; and 5 = almost always

**Directions for the clinician:** After the patient completes the questionnaire, the scores for individual items should be tallied for a final score. Scores of 0–7 = mild symptoms; scores of 8–19 = moderate symptoms; scores more than 20 = severe symptoms

**Questions to Assess Obstructive Voiding Symptoms**
1. How often have you had a sensation of not emptying your bladder completely after you finished urinating?
2. How often have you found you stopped and started again several times when you urinated?
3. How often have you had a weak urinary stream?
4. How often have you had to push or strain to begin urinating?

**Questions to Assess Irritative Voiding Symptoms**
5. How often have you found it difficult to postpone urination?
6. How often have you had to urinate again < 2 hours after you finished urinating?
7. How many times did you most typically get up to urinate from the time you went to bed at night until the time you got up in the morning?

Data from AUA Practice Guidelines Committee. AUA guideline on the management of benign prostatic hyperplasia (2010). www.auanet.org/content/guidelines-and-quality care/clinical-guidelines.cfm?sub=bph. Last accessed July 7, 2014.

---

**KEY CONCEPT** *For patients with moderate to severe symptoms and no complications of BPH, the patient is usually offered drug treatment first. α-Adrenergic antagonists are preferred over 5α-reductase inhibitors because the former have a faster onset of action (days to a few weeks) and improve symptoms independent of prostate size. α-Adrenergic antagonists are preferred for patients with lower urinary tract voiding symptoms, who also have small prostates (less than 30 cm³ [approximately 30 g or 1.05 oz]).*

5α-Reductase inhibitors have a delayed onset of action (ie, peak effect may be delayed for up to 6 months) and are most effective in patients with moderate LUTS and larger size prostate glands (greater than 30 g or 1.05 oz). Drug treatment must be continued as long as the patient responds (**Table 52–5**).[7,10]

**KEY CONCEPT** *Combinations of medications to treat moderate or severe symptoms of BPH are more expensive and can cause more adverse effects than single drug treatment. Therefore, combination medication regimens are reserved for patients who have specific symptoms that do not respond to an adequate trial of single drug treatment or patients who are at high risk of developing complications of BPH.* Refer to the section on Combination Therapy for a detailed description of various regimens and their advantages and disadvantages.

**KEY CONCEPT** *For patients who are at risk of disease progression (ie, those with large prostates [greater than 30 g or 1.05 oz]), have moderate-severe symptoms that are not responsive to drug treatment, or have complications of BPH disease, surgery is indicated.*[7] Although it is potentially curative, surgery can result in significant morbidity, including erectile dysfunction, **retrograde ejaculation, urethral stricture,** urinary incontinence, bleeding, or urinary tract infection. The gold standard is prostatectomy, which can be performed transurethrally using electrocautery or

## Table 52–2

**Objective Tests Used to Assess the Severity and Complications of BPH**

| Test | How the Test Is Performed | Normal Test Result | Test Result in Patients with BPH |
|---|---|---|---|
| DRE of the prostate | Prostate is palpated through the rectal mucosa; the physician inserts an index finger into the patient's rectum | Prostate is soft, symmetric, mobile; size is 15–20 g (0.5–0.7 oz) | Prostate is enlarged, > 20 g (0.7 oz); no areas of induration or nodularity |
| Peak and mean urinary flow rate | Patient drinks water until bladder is full; patient empties bladder; volume of urine output and time to empty the bladder are measured; the flow rate (mL/s) is calculated | Peak and mean urinary flow rate are at least 10 mL/s | Peak and mean urinary flow rates are < 10 mL/s |
| PVR | Measurement of urine left in the bladder after the patient has tried to empty out his bladder; assessed by urethral catheterization or ultrasonography | PVR should be 0 mL | PVR > 50 mL is a significant amount of retained urine; this is associated with recurrent urinary tract infection |
| Urinalysis | Midstream urine is analyzed microscopically for white blood cells and bacteria | Urine should have no white cells or bacteria in it | Urine with white blood cells and bacteria is suggestive of inflammation and infection; if positive, urine is sent for bacteriologic culture |
| Prostate needle biopsy | Transrectally, a biopsy needle is inserted into the prostate; tissue core is sent to a pathologist for analysis | A normal prostate should have no evidence of BPH or prostate cancer | The biopsy is consistent with BPH |
| PSA | Blood test for this chemical, which is secreted by the prostate | < 4 ng/mL (4 mcg/L) | A PSA > 1.5 ng/mL (1.5 mcg/L) is a surrogate marker for an enlarged prostate > 30 g (1.05 oz) |

DRE, digital rectal examination; PVR, postvoid residual urine volume; PSA, prostate-specific antigen.

as an open surgical procedure, which can be performed suprapubically or retropubically. A transurethral prostatectomy is typically reserved for prostates of intermediate size (30 g [1.05 oz] to 80 g [2.83 oz]), whereas an open prostatectomy is used for very large prostates (greater than 80 g [2.83 oz]) or when the patient has BPH and other associated urologic disorders, for example, large bladder stones or bladder diverticula, that can be surgically treated at the same time.[7] The newer bipolar technique for performing a TURP, which uses saline irrigating solution, has reduced the incidence of dilutional hyponatremia, a common adverse effect of the older monopolar technique, which uses glycine or sterile water irrigating solution. The outcomes of prostatectomy include an almost immediate improvement of LUTS, an increase of peak urinary flow rate by 6 to 15 mL/s, and a PVR decrease of 30 to 80 mL.

To minimize complications of prostatectomy or in patients who are taking anticoagulants, minimally invasive surgical procedures, such as transurethral incision of the prostate, transurethral needle ablation, transurethral microwave thermotherapy or transurethral laser ablation, are options.[12–14] A

## Table 52–3

**Staging the Severity of BPH Based on AUA Symptom Score and Example Signs of Disease**

| | AUA Symptom Score | Signs of Disease |
|---|---|---|
| Mild | ≤ 7 | Enlarged prostate on DRE, peak urinary flow rate ≤ 10 mL/s |
| Moderate | 8–19 | All of the above, PVR > 50 mL, irritative symptoms |
| Severe | ≥ 20 | All of the above plus one or more complications of BPH |

AUA, American Urological Association; BPH, benign prostatic hyperplasia; DRE, digital rectal examination; PVR, postvoid residual urine volume.

The AUA Symptom Score focuses on seven items (incomplete emptying, frequency, intermittency, urgency, weak stream, straining, and nocturia) and asks that the patient quantify the severity of each complaint on a scale of 0 to 5. Thus the score can range from 0 to 35. A decrease in score of 3 points or more is considered a clinically significant improvement.

## Table 52–4

**Drugs That Can Cause Irritative or Obstructive Voiding Symptoms**

| Pharmacologic Class | Example Drugs | Mechanism of Effect |
|---|---|---|
| Androgens | Testosterone | Stimulate prostate enlargement |
| α-Adrenergic agonists | Phenylephrine, pseudoephedrine | Stimulate contraction of prostatic and bladder neck smooth muscle |
| Anticholinergic agents | Antihistamines, phenothiazines, tricyclic antidepressants, antiparkinsonian agents | Block bladder detrusor muscle contraction, thereby impairing bladder emptying |
| Caffeine | Caffeine | Acts like a diuretic |
| Diuretics | Thiazides diuretics, loop diuretics | Produce polyuria |
| Sedatives | Benzodiazepines, ethanol | Can cause functional incontinence |

| Table 52–5 |

**Comparison of α-Adrenergic Antagonists, 5α-Reductase Inhibitors, Anticholinergic Agents, and Tadalafil for Treatment of BPH**

| Characteristic | α-Adrenergic Antagonists | 5α-Reductase Inhibitors | Anticholinergic Agents | Tadalafil |
| --- | --- | --- | --- | --- |
| Relaxes prostatic smooth muscle | Yes | No | No | Yes |
| Reduces size of enlarged prostate | No | Yes | No | No |
| Useful in patients with enlarged prostates | Yes (works independent of the size of the prostate) | Yes | Yes | Yes |
| Efficacy in relieving voiding symptoms and improving flow rate | ++ | + | +, irritative symptoms | + |
| Reduces the frequency of BPH-related complications | No | Yes | No | No |
| Reduces the frequency of BPH-related surgery | No | Yes | No | No |
| Frequency of daily dosing | Once or twice daily, depending on the agent and the dosage formulation | Once daily | Once or twice daily, depending on the agent | Once daily |
| Requirement for up-titration of dose | Yes (for terazosin and doxazosin immediate-release); no (for alfuzosin or silodosin; possibly for doxazosin extended-release and tamsulosin) | No | Yes, depending on the agent | No |
| Peak onset of action | Days to 6 weeks, depending on need for dose titration | 6 months | Days | Days |
| Decreases PSA | No | Yes | No | No |
| Cardiovascular adverse effects | Yes, hypotension | No | Yes, tachycardia | Yes, hypotension |
| Drug-induced sexual dysfunction | Ejaculation disorders | Decreased libido, erectile dysfunction, ejaculation disorders | Yes, erectile dysfunction | No |

PSA, prostate-specific antigen.

variety of ablative laser energy sources are used to vaporize tissue: holmium, potassium-titanyl-phosphate (KTP or green light), or diode. The choice of energy source is largely determined by the surgeon's level of training, the patient's anatomy, and potential risks for the patient.[11] The potential advantages of minimally invasive surgical procedures include less blood loss, shorter periods of catheterization postoperatively, and the ability to complete the procedure on an outpatient basis. However, minimally invasive surgical procedures are associated with a higher reoperation rate than a prostatectomy. Drug treatment is used in patients with severe disease when the patient refuses surgery or when the patient is not a surgical candidate because of concomitant diseases.

## Nonpharmacologic Therapy (Behavioral Modification)

To reduce nocturia, patients should be instructed to stop drinking fluids 3 or 4 hours before going to bed and then void before going to sleep. During the day, timed voidings every 2 to 3 hours and use of double voiding help to empty urine from the bladder. Patients should avoid excessive caffeine and alcohol intake, because these may cause urinary frequency. Patients should avoid taking nonprescription medications that can worsen obstructive voiding symptoms (eg, antihistamines or decongestants) (see Table 52–4). In addition, toilet mapping (knowing the location of toilets on the way to and from various destinations)

may help reassure the patient that he can still continue with many of his routine daily activities despite having LUTS. Patients are also advised to lose weight, if overweight. Because testosterone is converted to estrogen in adipose tissue, an alteration in the testosterone:estrogen ratio occurs in overweight men, similar to that which occurs in elderly males, which may contribute to the development of BPH.[17]

Although a variety of herbal agents are used for symptomatic management, including pygeum (African plum), secale cereale (rye pollen), serenoa repens, and hypoxis rooperi (South African star grass), objective evidence of efficacy is lacking.[15,16]

## Pharmacologic Therapy

### ▶ α-Adrenergic Antagonist Monotherapy[17]

**KEY CONCEPT** *α-Adrenergic antagonists reduce the dynamic factor causing BPH symptoms. These drugs competitively antagonize α-adrenergic receptors, thereby causing relaxation of the bladder neck, prostatic urethra, and prostate smooth muscle.*[7,17] A secondary mechanism of action may be that α-adrenergic antagonists induce prostatic apoptosis,[18] which suggests that these agents may cause some shrinkage of an enlarged prostate.

All α-adrenergic antagonists are considered equally effective in relieving symptoms.[7,17] See Table 52-6 In various clinical trials, 30% to 80% of patients experience improvement in AUA Symptom Score by 30% to 45%, and 20% to 40% of patients experience urinary flow rate increases of 2 to 3 mL/s. The onset of action is

**Table 52–6**

**Comparison of Pharmacologic Properties of *α*-Adrenergic Antagonists**

| | Terazosin | Doxazosin | Alfuzosin | Tamsulosin | Silodosin |
|---|---|---|---|---|---|
| Brand name | Hytrin | Cardura | Uroxatral | Flomax | Rapaflo |
| Generation | Second | Second | Second | Third | Third |
| Uroselective | No | No | Functionally (Clinically) | Pharmacologically | Pharmacologically |
| Need for up-titration | Yes | Yes (with immediate-release); possibly (with extended-release) | No | Minimal | No |
| Daily oral dose (mg) | 5–20 | 2–8, immediate-release; 4–8, extended-release | 10 | 0.4–0.8; (0.8 mg/day dose has not consistently produced clinical improvement over 0.4 mg/day) | 8 |
| Recommended dose reduction in patients with renal dysfunction | None needed | None needed | Manufacturer recommends caution in patients with severe renal insufficiency. No specific dosing recommendations provided | If creatinine clearance > 10 mL/min (0.17 mL/s), none needed. Tamsulosin has not been studied in patients with creatinine clearance < 10 mL/min (0.17 mL/s) | If creatinine clearance 30–50 mL/min (0.50–0.83 mL/s), use 4 mg/day. Contraindicated in patients with creatinine clearance < 30 mL/min (0.50 mL/s) |
| Recommended dose reduction in patients with hepatic dysfunction | Manufacturer provides no specific recommendation. Terazosin should be used cautiously as it undergoes extensive hepatic metabolism | Manufacturer provides no specific recommendation. Doxazosin should be used cautiously as it undergoes extensive hepatic metabolism | Contraindicated in patients with moderate/severe hepatic impairment. Alfuzosin should be used cautiously in patients with mild hepatic impairment | Patients with mild/moderate hepatic impairment require no dosage adjustment. Tamsulosin has not been studied in patients with severe hepatic impairment | Patients with mild/moderate hepatic impairment require no dosage adjustment. Contraindicated in patients with severe hepatic impairment |
| Best time to take doses | At bedtime | Immediate-release: anytime during the day; however, it is typically given at bedtime Extended-release: anytime during the day | After meals for best oral absorption | On an empty stomach for best oral absorption. If taken 30 minutes after a meal, as recommended by the manufacturer, extent of absorption is reduced, thereby further reducing the potential for hypotensive adverse effects | Take with a meal, which decreases extent of absorption. Theoretically, this would help decrease hypotensive adverse effects |
| Half-life (hours) | 12 | 22 | 5 | 10 | 13 |

| Rhinitis | + | + | + | + | + |
| Malaise | + | + | + | + | + |

+, minimal; ++ moderate.

days to weeks, depending on the need for titration of the dose from a subtherapeutic starting dose to a therapeutic maintenance dose. An adequate clinical trial is considered to be at least 1 to 2 weeks of continuous treatment at a full maintenance dose with any of these agents.[7] Durable responses have been demonstrated for up to 10 years with doxazosin.[19] However, some patients will develop disease progression despite treatment. α-Adrenergic antagonists are hepatically metabolized. Therefore, in patients with significant hepatic dysfunction, these drugs should be used in the lowest possible dose. With the exception of silodosin, these drugs do not require dosage modification in patients with renal dysfunction.

These agents can be differentiated by their adverse effect profile. The most common dose-limiting adverse effects are hypotension and syncope, which are more common with immediate-release terazosin and doxazosin, less frequent with extended-release doxazosin and alfuzosin, and least frequent with pharmacologically uroselective $\alpha_{1A}$-adrenergic antagonists—tamsulosin and silodosin.[20] Combined use with antihypertensives, diuretics, or phosphodiesterase type 5 inhibitors can lead to additive blood pressure–lowering effects; however, this appears to be less of a problem with tamsulosin and silodosin.[7,21]

α-Adrenergic antagonists can be distinguished by several characteristics:

- *Uroselectivity.* Pharmacologic uroselectivity refers to preferential inhibition of $\alpha_{1A}$-receptors, which predominate in the prostatic stroma, prostatic urethra, and bladder neck, and $\alpha_{1D}$-receptors, which predominate in the bladder detrusor muscle.[17] Pharmacologically uroselective $\alpha_{1A}$-adrenergic antagonists have the potential to produce less hypotension, because they have a lower propensity to antagonize $\alpha_{1B}$-adrenergic receptors in the peripheral vasculature. Tamsulosin and silodosin are the only commercially available $\alpha_{1A}$-adrenergic antagonists with pharmacologic uroselectivity.[21] In contrast, despite the potential of inhibiting α-adrenergic receptors in both the prostate and peripheral vasculature, functionally uroselective α-adrenergic antagonists in usually prescribed doses produce effective relaxation of prostatic smooth muscle with minimal vascular vasodilation. Thus blood pressure–lowering effects are mild or absent. The only functionally uroselective α-adrenergic antagonist is alfuzosin extended-release tablets.[22]

- **KEY CONCEPT** *Both pharmacologically and functionally uroselective agents appear to be clinically uroselective, in that they improve BPH symptoms with a low potential to cause cardiovascular adverse effects in humans.*[17] They are preferred in patients who usually have low blood pressure or those taking multiple antihypertensives.[22,23]

Pharmacologic and functional uroselectivity are dose-related phenomena. Large daily doses of tamsulosin, silodosin, or alfuzosin may cause loss of uroselectivity, with resultant hypotension and dizziness in some patients.[23]

Despite the blood-pressure lowering property of α-adrenergic antagonists, they are not recommended to be used alone to treat patients with both BPH and essential hypertension. In the ALLHAT study[24], where doxazosin was compared with other agents for treatment of essential hypertension, doxazosin was associated with a higher incidence of congestive heart failure. Therefore, in patients with both hypertension and moderate to severe LUTS, it is recommended that an appropriate antihypertensive be added to an α-adrenergic antagonist.

- *Need for up-titration of daily dose.* Up-titration is required for immediate-release terazosin and doxazosin. It is minimally required for extended-release doxazosin and tamsulosin. It is not required for extended-release alfuzosin or silodosin. The need for up-titration with a particular α-adrenergic antagonist delays its peak onset of action and the time when the patient can experience maximal clinical benefit.

- *Plasma half-life.* α-Adrenergic antagonists with short plasma half-lives (eg, prazosin) require multiple doses during the day. This is challenging for most patients, and thus prazosin is not recommended for BPH.[7]

- *Dosage formulation.* Immediate-release formulations of terazosin and doxazosin are quickly absorbed and produce high peak plasma levels. Modified- or extended-release formulations of doxazosin, alfuzosin, and tamsulosin produce lower peak levels, but more sustained therapeutic plasma levels, than immediate-release formulations and have less potential for producing hypotensive episodes. This allows for initiation of treatment with a therapeutic dose, a shorter time to peak onset of clinical effects, and once daily dosing.[17,22]

- *Adverse effects.* Hypotensive adverse effects of α-adrenergic antagonists can range from asymptomatic blood pressure reductions to dizziness and syncope. This adverse effect occurs in approximately 2% to 14% of treated patients and is most commonly associated with immediate-release terazosin and doxazosin; is less commonly associated with extended-release alfuzosin and extended-release doxazosin; and least commonly associated with tamsulosin and silodosin.[7,22] To minimize first-dose syncope from terazosin and doxazosin immediate-release, a slow up-titration from a subtherapeutic dose of 1 mg/day to a therapeutic dose is essential. The first dose should be given at bedtime so that the patient can sleep through the peak serum concentration of the drug when the adverse effect is most likely to occur. A 3- to 7-day interval between each dosage increase should be allowed, and the patient should be maintained on the lowest effective dose of an α-adrenergic antagonist. If the patient is noncompliant with his regimen or he skips or interrupts treatment, the α-adrenergic antagonist should be restarted using the usual starting dose and then retitrated up. He should not be instructed to simply double up on missed doses or resume treatment with his currently prescribed daily dose, as this can lead to significant hypotension or syncope.

Ejaculation disorders, including delayed, absent and retrograde ejaculation, occur with all adrenergic antagonists. This is largely thought to be due to pharmacologic blockade of peripheral α-adrenergic receptors at the bladder neck (ie, the bladder neck is unable to close during ejaculation in the presence of α-adrenergic blockade), however, a central nervous system mechanism of action cannot be discounted.[25] The incidence appears to be dose-related and highest with daily doses of tamsulosin 0.8 mg and silodosin 8 mg, occurring in up to 26% and 28% of treated patients, respectively. Ejaculation disorders generally do not necessitate discontinuation of treatment, except in younger patients. Although this adverse effect may decrease the patient's satisfaction with the quality of sexual intercourse, ejaculation disorders are not harmful to the patient.

Rhinitis and malaise occur with α-adrenergic antagonists and are an extension of the pharmacologic blockade of α-adrenergic receptors in the vasculature of the nasal mucosa and in the central nervous system, respectively. Tolerance often develops to these adverse effects and they rarely require discontinuation of

With regard to their use for the symptomatic treatment of BPH, finasteride and dutasteride are considered equally effective in relieving LUTS by 15% to 30% in 30% to 70% of patients and increasing the urinary flow rate by 1 to 2 mL/s, which is less improvement than that seen with $\alpha$-adrenergic antagonists.[7,30,31] A minimum of 6 months is required to evaluate the effectiveness of treatment. This is a disadvantage in patients with moderate to severe symptoms, as it will take that long to determine whether the drug is or is not effective. Durable responses have been demonstrated in responding patients treated up to 6 years with finasteride and 4 years with dutasteride.[32,33] Unlike α-adrenergic antagonists, 5α-reductase inhibitors are used to prevent BPH-related complications and disease progression. Finasteride has been shown to reduce both the incidence of acute urinary retention by 57% and the need for prostate surgery by 55% in patients with significantly enlarged prostate glands (greater than 40 g [1.4 oz]).[34,35] These agents are hepatically metabolized. No specific recommendations for dosage modification are currently available in patients with significant hepatic dysfunction; however, due to the drug's specificity for its enzyme target, it is unlikely that any dosage adjustment will be required. No dosage adjustment is needed in patients with renal impairment. Adverse effects include decreased libido, erectile dysfunction, and ejaculation disorders, which may persist after the drug is stopped, and gynecomastia and breast tenderness. When used to prevent prostate cancer, these agents reduce the incidence of prostate cancer by 25%, but are suspected to increase the risk of developing moderate to high grade cancer, if prostate cancer does develop.[36,37] Serum testosterone levels increase by 10% to 20% in treated patients; however, the clinical significance of this is not clear at this time.[7] Drug interactions are uncommon. These drugs decrease serum levels of PSA by approximately 50%. Therefore, to preserve the usefulness of this laboratory test as a diagnostic and monitoring tool, it is recommended that prescribers obtain a baseline PSA prior to the start of treatment and repeat it at least annually during treatment. A significantly elevated PSA in treated patients suggests that the patient is not compliant with his prescribed 5α-reductase inhibitor regimen or is an indicator for further diagnostic workup for prostate cancer. Exposure to 5α-reductase inhibitors is contraindicated in pregnant females, as the drugs may cause feminization of a male fetus. Pregnant females should not handle these drugs unless they are wearing gloves.

▶ *Combination Therapy*

`KEY CONCEPT`  *A combination of an α-adrenergic antagonist and 5α-reductase inhibitor may be considered in symptomatic patients who do not respond to an adequate trial of monotherapy or in those at high risk of BPH complications, that is, those with an*

*enlarged prostate of at least 30 g (1.05 oz).[7,11,30] In such patients, combination therapy will relieve voiding symptoms and also may reduce the risk of developing BPH-related complications and reduce the need for prostatectomy by 67% after 4 years.[34,35]* The Reduce Trial compared dutasteride, tamsulosin, and the combination of dutasteride and tamsulosin. Results showed that patients treated with the combination had greater symptom improvement after 9 months and less disease progression at 4 years than patients treated with single drug therapy.[38] Because combination therapy is more expensive and associated with the array of adverse effects associated with each drug in the combination, clinicians should discuss the advantages and disadvantages of such a treatment regimen with the patient before a final decision is made (see Table 52-5).[7,30] A commercially available combination formulation of dutasteride 0.5 mg and tamsulosin 0.4 mg may be convenient for some patients.

To streamline and reduce the cost of treatment regimens, it has been suggested that the α-adrenergic antagonist may be discontinued after the first 6 to 12 months of combination therapy in patients with moderate LUTS. However, in patients with severe LUTS and an enlarged prostate gland, the combination regimen should be continued as long as the patients are responding.[39]

Another enhancement to BPH symptom management is the addition of an anticholinergic agent (eg, tolterodine) to an α-adrenergic antagonist with or without a 5α-reductase inhibitor. The rationale for the anticholinergic agent is that irritative symptoms (eg, urinary urgency and frequency) are thought to be due to hyperreactive bladder detrusor muscle contraction, which can be ameliorated by blockade of $M_2$ and $M_3$ muscarinic receptors.[40–43] Also, $\alpha_{1D}$-adrenergic receptors in the detrusor muscle, which cause muscle contraction when stimulated, can be blocked by α-adrenergic antagonists. An α-adrenergic antagonist may decrease involuntary bladder muscle contraction and increase the bladder's compliance. Thus, the combination may have an additive pharmacologic effect on relieving irritative voiding symptoms.[43] A recent meta-analysis documenting the addition of an anticholinergic agent to an α-adrenergic antagonist produced significant irritative symptom improvement, more than what was observed with the α-adrenergic antagonist alone.[43] No cases of urinary retention were reported. If irritative symptoms do not improve after starting an anticholinergic agent, up-titrating the dose or switching to another anticholinergic agent may be helpful. Patients at the highest risk of anticholinergic agent-induced acute urinary retention include those with a high postvoid residual urine volume (250 mL or more). Thus anticholinergic agents should be used precautiously in these patients. Finally, the medication profile of patients should be checked for overall anticholinergic burden, which increases the likelihood of anticholinergic adverse effects, including dry mouth, tachycardia, constipation, confusion, and drowsiness.

Once daily dosing of tadalafil is approved for treatment of LUTS. It may be prescribed alone,[44] or along with an α-adrenergic antagonist[45] or 5α-reductase inhibitor.[46] Its mechanism may be due to relaxation of smooth muscle of the urethra, prostate, and bladder, which is mediated by inhibiting the Rho/Rhokinase pathway. This inhibits the proliferation and contraction of prostatic smooth muscle, or enhances the action of nitric oxide.[8,47] Tadalafil is comparable to α-adrenergic antagonists in relieving LUTS and decreasing the AUA Symptom Score by 3.8 points after 12 weeks; however, it does not increase urinary flow rate or reduce PVR.[48] Because tadalafil is expensive, the best candidates for treatment are those with BPH and erectile

## Patient Encounter 3

A 66-year-old man with severe obstructive voiding symptoms of BPH presents to the clinic. A DRE reveals a prostate of 45 g (1.6 oz) and a PSA of 1.8 ng/mL (1.8 mcg/L). He is started on dutasteride 0.5 mg daily by mouth. After 3 months, the patient complains that his symptoms have not significantly improved.

*Explain why the patient has not responded to treatment.*

*Identify an alternative treatment regimen for this patient.*

### Table 52–8

**Summary of Adverse Effects of *a*-Adrenergic Antagonists, 5*a*-Reductase Inhibitors, Anticholinergic Agents, and Tadalafil and Management Suggestions**

| Drug Class | Adverse Reaction | Management Suggestion |
|---|---|---|
| *a*-Adrenergic antagonist | Hypotension | Start with lowest effective dose, give doses at bedtime, and slowly up-titrate at 0.5- to 1-week intervals to a full therapeutic dose, if using immediate-release terazosin or doxazosin.<br>Use tamsulosin, silodosin, extended-release doxazosin, or alfuzosin, as alternatives to immediate-release products, particularly in patients taking other antihypertensives. |
| | Malaise | Educate the patient that this is a common adverse effect; tolerance may develop to malaise. Usually does not require discontinuation of treatment. |
| | Rhinitis | Educate the patient that this is a common adverse effect; tolerance may develop to rhinitis. Usually does not require discontinuation of treatment. |
| | Ejaculation disorders | Educate the patient that this is a common adverse effect and it is not harmful. |
| 5*a*-Reductase inhibitor | Gynecomastia | Educate the patient that this may be bothersome, but not harmful. |
| | Decreased libido | If the patient is sexually active, sexual counseling may be helpful. May be reversible despite continued use of the 5*a*-reductase inhibitor. |
| | Erectile dysfunction | The addition of sildenafil or another erectogenic drug may be helpful. May be reversible despite continued use of the 5*a*-reductase inhibitor. |
| | Ejaculation disorders | Educate the patient that this may occur but it is not harmful. May be reversible despite continued use of the 5*a*-reductase inhibitor. |
| Anticholinergic agent | Dry mouth | Educate the patient that this is a common adverse effect. If drinking fluids and sucking on sugarless hard candy are not effective, the physician may switch to another agent in the same class or possibly reduce the daily dose. |
| | Constipation | This is a common adverse effect. Educate the patient to drink plenty of fluids and eat a high fiber diet. |
| | Confusion, drowsiness | If this occurs, the physician may switch to another agent in the same class with less potential to cross the blood brain barrier, eg, trospium. |
| | Acute urinary retention | Do not use anticholinergic agents in patients with a PVR > 250 mL as they are high risk of developing this adverse effect, which is a urologic emergency. |
| | Increased risk of heat stroke | By decreasing perspiration, patients who are in hot climates and who do not have access to air conditioning, are at risk of heat stroke. Use of anticholinergic agents in elderly who are exposed to these conditions should be avoided. |
| Tadalafil | Headache | Educate the patient that this is a common adverse effect. It is usually mild, temporary, and does not require treatment. If necessary, a low dose of acetaminophen is usually effective. |
| | Dizziness | Educate the patient that this is a common adverse effect and does not require treatment. If the patient is taking other blood pressure lowering medications, stabilize blood pressure on these medications before starting tadalafil. |
| | Dyspepsia | Heartburn-like symptoms may occur. Usually, it is mild and does not require treatment. |
| | Back pain or myalgia | This occurs more often with tadalafil than with the other phosphodiesterase inhibitors. It usually resolves once the drug is stopped. If not severe, tadalafil may be continued as the adverse effect may resolve with continued tadalafil use. |

dysfunction, or those patients with LUTS that is not responsive to α-adrenergic agonists. The usual recommended dose is 5 mg by mouth daily; the dose should be reduced to 2.5 mg daily if the creatinine clearance is 30 to 50 mL/min (0.50–0.83 mL/s). Tadalafil should be avoided if the creatinine clearance is less than 30 mL/min (0.50 mL/s). Tadalafil is contraindicated in patients on nitrates by any route of administration; patients with unstable angina, uncontrolled or high-risk arrhythmias, persistent hypotension, poorly controlled hypertension, or New York Heart Association Classification IV congestive heart failure; or patients who have had a myocardial infarction within the past 2 weeks.[49] Common adverse effects include headache, dizziness, dyspepsia, back pain, and myalgia (Table 52–8).

Mirabegron is a $β_3$-adrenergic agonist. When it stimulates beta$_3$ adrenergic receptors in the urinary bladder detrusor muscle, mirabegron reduces irritative voiding symptoms and improves urine storage in the bladder.[11] Although not FDA approved for this indication, mirabegron is an alternative to an anticholinergic agent in patients who poorly tolerate anticholinergic adverse effects or whose irritative voiding symptoms

do not respond to an anticholinergic agent. Mirabegron is typically added to an α-adrenergic agonist.[50] The usual dose is 50 mg by mouth daily; reduce the dose to 25 mg daily if the creatinine clearance is 15 to 29 mL/min (0.25–0.49 mL/s).

### Patient Encounter 4

A 67-year-old man presents with severe LUTS. His prostate gland is estimated to be 40 cm³ (40 g or 1.4 oz) in size and his PSA is 3 ng/mL (3 mcg/L). The patient also suffers from recurrent urinary tract infection and persistent gross hematuria. The patient's peak urinary flow rate is 5 mL/s and PVR is 200 cm³ (200 mL). The patient's AUA Symptom Score is 25. The patient prefers medical management for his BPH. He asks if tadalafil would be a good choice for him.

*Is tadalafil a good choice? If not, what is the best treatment option for this patient?*

Mirabegron should be avoided if the creatinine clearance is less than 15 mL/min (0.25 mL/s). Common adverse effects of mirabegon include headache, hypertension, tachycardia, constipation, and nasopharyngitis.

## OUTCOME EVALUATION

**KEY CONCEPT** *Once the peak effects of drug treatment are expected to occur, monitor the drug for effectiveness. This is approximately 1 month after the start of an α-adrenergic antagonist and 3 and 6 months after the start of a 5α-reductase inhibitor.* Assess symptom improvement using the AUA Symptom Scoring Index. A reduction in symptom score by a minimum of 3 points is anticipated with symptom improvement. However, it should be noted that the AUA Symptom Score may not match the patient's perception of the bothersomeness of his voiding symptoms. If the patient perceives his symptoms as bothersome, independent of the AUA Symptom Score, consideration should be given to modifying the patient's treatment regimen. Similarly, a patient may regard his symptoms as not bothersome even though the AUA symptom score is high. In this case, the physician should objectively assess symptoms at baseline and during treatment by performing a repeat uroflowmetry, which can detect an improvement in peak and mean urinary flow rate, and checking for a reduction in PVR and the absence of complications of BPH. If the patient shows a response to treatment, instruct the patient to continue the drug regimen and have the patient return at 6-month intervals for monitoring. If the patient shows an inadequate response to treatment, the dose of α-adrenergic antagonist can be increased (except for extended-release alfuzosin and silodosin) until the patient's symptoms improve or until the patient experiences adverse drug effects.

For the α-adrenergic antagonists, the severity of hypotensive-related adverse effects, which may manifest as dizziness or syncope, may require a dosage reduction or a slower up-titration of immediate-release terazosin or doxazosin, or halting the up-titration of the α-adrenergic antagonist. If the patient develops adverse effects at this dose, the drug should be discontinued. Other adverse effects of α-adrenergic antagonists are nasal congestion, malaise, headache, and ejaculation disorders. None of

## The Patient Care Process

### Patient Assessment:

- Based on the patient's chief complaint and review of systems, determine whether the patient is experiencing LUTS.
- Review the medical history and physical examination. Does the patient have a history of BPH? Does he have an enlarged prostate? Does he have a history of complications of BPH, for example, recurrent urinary tract infection, gross hematuria, acute urinary retention, and so on. Have various tests been performed to establish the severity of BPH (Table 52–2)?
- Conduct a medication history (including prescription and over the counter medications, and dietary supplements) that could be contributing to his voiding symptoms (Table 52–4). Does the patient have any drug allergies? Is the patient receiving treatment for LUTS (Table 52–5)? If yes, when was the treatment started and has the patient completed an adequate clinical trial? Is the patient experiencing adverse effects from therapy (Table 52–8)?
- Review available laboratory tests, especially serum electrolytes, renal function, and urinalysis.
- Assess the severity of the patient's LUTS by having the patient complete the AUA Symptom Scoring Index (Table 52–3).

### Therapy Evaluation:

- If the patient is already receiving medications for LUTS, assess the efficacy, safety, and patient adherence. Are there any significant drug interactions?
- If the patient needs to be started on drug therapy, ensure that the patient has moderate or severe LUTS, check prostate size, and check patient for any contraindications or precautions for various treatments. Is the patient at risk of

BPH progression? Does the patient prefer medical or surgical treatment of BPH?

- Determine whether the patient has prescription coverage or whether recommended agents are included on the institution's formulary.

### Care Plan Development:

- Institute nonpharmacologic therapies to minimize LUTS.
- Institute appropriate medication treatment for moderate or severe LUTS.
- Determine whether drug dose is optimal (Table 52–6 and 52–7).
- Address any patient concerns about LUTS, BPH, and management.
- Discuss importance of medication adherence and nonpharmacologic therapies to control LUTS.

### Follow-Up Evaluation:

- After starting an α-adrenergic antagonist, assess effectiveness and safety of therapy in 1 month, and then at 6 months. At each visit, repeat AUA Symptoms Scoring Index, check for disease progression, repeat urinary flow rate and PVR and for adverse effects of treatment. As long as the patient continues to respond and tolerates the medication well, repeat all assessments at yearly intervals thereafter.
- After starting a 5α-reductase inhibitor, assess effectiveness and safety of therapy at the end of the third and sixth month.

At each visit, repeat AUA Symptoms Scoring Index, check for disease progression, repeat urinary flow rate and PVR and for adverse effects of treatment. As long as the patient continues to respond and tolerates the medication well, repeat all assessments at yearly intervals thereafter.

these generally require discontinuation of treatment, and these often improve as treatment continues. For the 5α-reductase inhibitors, the most bothersome adverse effects are decreased libido, erectile dysfunction, and ejaculation disorders. In sexually active males, erectile dysfunction may be improved with erectogenic drugs; however, this adverse effect may necessitate discontinuation of treatment.

During continuing treatment of BPH, the patient should undergo an annual repeat PSA and DRE. A rising PSA level suggests that the patient has worsening BPH, new-onset prostate cancer, or that the patient is noncompliant with his regimen of 5α-reductase inhibitor. An abnormal DRE suggestive of prostate cancer would reveal a nodule or area of induration on the prostate. In such a case, a prostate biopsy is required to rule out prostate cancer.
